This feature makes it possible to take alternative actions for various comparison results. A practical example is in address coding against a Geographic Base File where the records contain two address ranges, one for each side of the street. If a match occurred with a range on one side of the street, it is desirable to transfer the geographic codes relating to that side only. Other commands permit examination of the group weight and penalty scores providing for data transfer contingent upon a range of values. Character text can be moved into the data file record instead of information from the reference file record. The transfer of text can be conditional upon comparison results, weight and penalty values, etc. Simple arithmetic functions can be executed upon the weights and penalties, allowing for example, the placing of the odds favoring a match on each data file record. A memory feature allows the reformatting of fields on the data file, imputation of information on the data file, as well as computations on data file fields.

FIELD MANIPULATION AND FILE CONTROL FEATURES

The UNIMATCH system provides the capability of converting input field values to new values on the basis of conversion tables. For example, area codes may differ between both files, in which case a correspondence dictionary may be prepared to provide for conversion of the area codes. The capability of assigning default values to fields not coded is also provided. Selection of data file records for matching may be accomplished via SELECT statements. For example, it may be desired only to match records occurring in one city where a number of cities are present in the data file.

The file management system provides the capability of separating rejected output records from the accepted ones, or combining them as desired. In addition, it is possible to separate rejected records of different types, and to print listings of selected records in the output file. A post-processor feature allows the matcher to be used in non-record linkage applications where field conversion, record selection, and reject separation tasks can be performed on single data files.

STATISTICAL INFORMATION

UNIMATCH provides much statistical information regarding each run that is executed. The output data records contain twelve digit status codes prefixed to the body of the record which indicate the status of that output record. A code of "MT" indicates that the record was matched successfully, and the penalty scores of up to five high ranking groups are printed.

It is thereby possible to determine if a given data file record is an exact match, and if not, what the degree of uncertainty is. Critical field rejects are indicated by a code of "CR" followed by the name of the field that caused the mismatch. Group rejects produce a code of "GR" followed by the group name and the penalty score for that group. This gives the user an indication of how much he must "loosen the reins" to permit the record to be linked. Selection rejects and search field rejects are also flagged.

At the end of each run the number of rejects by type, field name and group name are printed. In addition, statistics are printed tabulating the number of exact matches, the number of input/output disk operations required, the number of different reference file domains used, the average domain, the effective domain (the average number of records for any domain), input and output record counts, etc. This information provides the user with a good picture of the effectiveness of the record linkage application.

CONCLUSION

This paper has attempted to present the operation of UNIMATCH by presenting both the theory underlying the development and the physical implementation of the system. All features and the exact details of the specifications could not be discussed in a paper of this scope. UNIMATCH will provide a generalized record linkage capability to IBM System/360 users, but more importantly will permit experimentation with varying linkage algorithms with resultant greater knowledge of the practical considerations of the record linkage problem. Since a large portion of the record linkage problem is record standardization, a Universal Standardizer (UNISTAND) is being written as a companion system for UNIMATCH. UNISTAND will scan free-form text under pattern recognition control in order to place recognizable components in fixed fields for matching. Procedures will be supplied to the user of both systems to process the most common problems (such as address coding, transportation coding, etc.). These procedures will allow the user to perform complex record linkage tasks without requiring the sophistication needed for weight and algorithm development. It is expected that these systems, along with supplied procedures, will provide the capability of solving most of the current record linkage problems.

New directions in legal information processing*

INTRODUCTION

Present areas of application of computers to the law fall into three broad categories: (1) those involving applications of business accounting techniques such as in tax preparation and client billing, (2) those involving data management techniques such as law enforcement, criminal justice, and keyword legal source material information systems, and (3) those involving on-line file manipulation in such areas as text-editing and drafting. These systems demonstrate that computers can work very well with problems that can be expressed in terms of numbers or information that can be handled on the basis of its external form.

During the coming decade, we foresee the continued expansion of the use of existing systems and also the development of some new systems based on conventional data processing techniques. Such new systems may be expected in automating the accession to index systems patterned on existing manual systems, processing land use documents, supervising paroled offenders, etc. However, ordinary data processing methods are by their very nature incapable of providing much-needed assistance in the central area of legal work, where the content of the material at hand (laws, contracts, depositions, etc.) must be understood and analyzed in terms of its meaning and logical relationships. It is impossible, using file management techniques to deal with, for example, a set of conflicting laws or regulations. Problems such as these must be attacked at a level where the interrelationships among the various words and phrases (as well as their individual meanings) are understood.

Comprehensive machine-readable data bases of legal materials are rapidly becoming available as a result of the economies they afford in such areas as typesetting and legislative drafting. However, the conversion of legal materials to machine-readable form has not made them significantly more accessible to those who must use them. Because of the great complexity and volume of legal materials their analysis now requires great investment of time by highly trained personnel. If computers could "understand" legal materials, their attractive assets (their large reliable memory, and their extraordinary capacity for rapid and accurate information processing) would make them ideal assistants in the field of law.

The ability to provide such an understanding is emerging in new techniques currently being developed in a computer area called "artificial intelligence" in dealing with such problems as automated logical deduction, problem solving, and natural language understanding. These techniques appear to be the key to solving many of the problems of legal automation.

In particular, we foresee the development of a number of computer based services in this new technology. These include:

1. Automated systems to provide quick and inexpensive assistance for many non-controversial, but not necessarily simple legal questions to aid lawyers, social and welfare workers, administrators, police, and of course the public itself;
2. Automated consistency-checking, and consequence-finding systems to aid in codification

* The work presented here was performed at the Coordinated Science Laboratory of the University of Illinois at Urbana-Champaign. It was supported by the Joint Services Electronics Program (U.S. Army, U.S. Navy, U.S. Air Force) under Contract No. DAAB-07-67-C-0199.

** On leave from the Coordinated Science Laboratory and the Department of Electrical Engineering at the University of Illinois at Urbana-Champaign.

and law reform for legislative and administrative bodies;

3. Automated systems to assist in teaching law and legal reasoning for those who need to know the law; and
4. Automated interviewing systems for initial client and witness screening.

In this paper we include a brief survey of recent applications of computers to the law, a discussion of the further types of automation that are needed in the law, an outline of current developments in artificial intelligence which could be applied to aid in the automation of the law, and finally a description of the new directions we envision for legal information processing during the 1970s.

A SURVEY OF RECENT APPLICATIONS OF COMPUTERS TO THE LAW

Automation has been applied to problems in criminal justice and law enforcement as well as a host of other applications including legal information retrieval, income tax preparation, and legislative drafting systems. In this section a brief description of these application areas is given. For a more thorough survey of this work see Robins;[47] Bigelow,[7] the May, 1971 issue of *Law Library Journal*, which is devoted to computers and law; and the individual references cited in this paper.

Criminal justice and law enforcement information systems

For our purposes, we can view criminal justice and law enforcement information systems as consisting of users, a computer, and an ever changing data base being used to collect, store, and update information in such a way so as to facilitate the retrieval and exchange of criminal justice and law enforcement information for governmental units. The most advanced of these systems include: Project SEARCH[61] (System for Electronic Analysis and Retrieval of Criminal Histories) developed jointly by LEAA (Law Enforcement Assistance Administration) of the Justice Department and a number of participating states, the NCIC[19,23] (National Criminal Information Center) computer network of the Federal Bureau of Investigation, and the NYSIIS[22] (New York State Identification and Intelligence System).

Legal information retrieval systems

The volume of jurisprudential reference material in the form of cases, statutes, and administrative rulings and regulations has prompted the development of automated law retrieval systems to aid the legal researcher. This work has been based in part upon research being carried out in the area of library automation and is specifically related to the problem of document retrieval.

Of the experimental projects that have been undertaken for performing automated legal information retrieval the basic assumptions have been that a person seeking technical legal information can be led to relevant information using a keyword type approach, and that technical legal information can be categorized in such a fashion as to be retrieved by a keyword type approach. Within this framework there are basically two approaches that have been taken: those systems which rely on prior manual abstracting of library material and those which operate on full natural text without abstracting.

Systems requiring manual abstracting

The first system for computer storage and retrieval of legal material developed by Morgan[42,58] was used for the retrieval of case law. It employed an approach where concepts were identified and assigned code numbers which were in turn linked back to the original case. Thus, having once determined the relevant concepts one could retrieve the citations to pertinent cases. This approach was very similar to the manual indices that have widespread use today such as the West Key Number System. Other attempts at automated legal research using this approach have been made by the Federal Trade Commission,[2] and the Antitrust Division of the Department of Justice.[47]

Systems operating on full natural text

A significant departure from the manual abstracting approach is the Key Word in Combination approach of John Horty.[28,29,31] Here, no abstracting or indexing of the material was done manually. Retrieval was done by finding combinations of keywords in the original text. A researcher could specify lists of words that must appear in the same sentence or statute as well as the desired word ordering. The LITE (Legal Information Through Electronics) Project developed by the Air Force Accounting and Finance Center[37] and the Root Index System developed by the Southwestern Legal Foundation[43,49,56] are two other systems that are similar in design with the Key Word in Combination approach. The OBAR System developed by the Ohio Bar Association[45] and Mead Data Central has added significant on-line interactive capabilities to this type of approach.

The ABF-IBM project

The ABF-IBM (American Bar Foundation and International Business Machines) Project[15–18] attempted to overcome the disadvantages of either of the other previous approaches by automatically generating frequencies for each word used in the original case. Deviations or "skewness" of certain words from a normal distribution were assumed to convey information about the contents of the case.

Other applications of computers to the law

There are many other applications within the legal area for which automation has been proposed, and in some cases even implemented.[6,34,35,39] Most of this work represents straightforward applications of current technology to the particular problems encountered in the legal area using methodology well established in other areas, such as office management and business accounting. Automated legislative drafting and revision, will drafting, as well as general law office document drafting are good examples of the extension of available hardware and software that has been made available in recent years. Automated court management, legislative reapportionment, law office management, income tax preparation, land title recording, and estate planning are examples of established data processing techniques that have been used for legal problems.

THE NEED FOR NEW DIRECTIONS

The quantity and complexity of legal materials is increasing at a rate that cannot be adequately handled by traditional means. In many areas the growing demands of modern society have been met by automation. However, modern computer techniques have had only a minor effect on the three major areas of legal work where they might seem applicable: legal research, legislation, and legal education. As mentioned above numerous attempts have been made to apply scientific and business data processing techniques to such legal problems, but all have fallen short of major impact because they have been by their nature unable to deal with the verbal and logical complexities of the law.

Most areas of legal work have remained relatively untouched by automation. The problem is not that the legal profession has neglected automation; rather it is that technology has failed to meet the demands of the law. What is lacking is the capacity to give legal personnel the same sort of assistance in their routine work with words and concepts that engineers get from the computer in their routine work with numbers and formulas. What is needed is the automation of the process involved in routine legal reasoning and research.

Modern statutes and administrative regulations are of such immense complexity as to be impossible to understand for the layman and difficult even for the lawyer. The problem is particularly acute in many areas where the task of interpreting and enforcing the law has traditionally been left to non-lawyers, for instance, welfare administration.

To give an example of the problem: At present when local administrative authorities receive an application for welfare benefits, the eligibility of the applicant and the benefits to which he is entitled are determined by a large and conflicting body of local, state, and federal welfare laws and regulations which may total hundreds, if not thousands, of pages in length. Typically an applicant may have to wait for weeks or even months while an overburdened administrator attempts to determine his legal status. As another example, a business transaction involving questions of tax laws, zoning regulations, and building codes may fall through because of the delays and expense involved in the drafting of the transaction to conform to the many, and possibly conflicting, requirements of the law.

The successful development of automated techniques for dealing with complex legal situations would help in these and many other areas by providing quick and inexpensive answers to many routine legal questions. Such techniques could also help employers and employees determine their rights under labor relations contracts. They could help both the taxpayer and the government in tax planning and administration. It would be possible to provide legal guidance for some small businessman's transactions which involve too little money to justify full scale analysis by a lawyer.

In many areas, where the law now consists of confusing and conflicting regulations at different levels—federal, state, and local, the first step toward law reform would be the unscrambling of a situation that has been caused by years of haphazard legislation so as to provide a clearer assignment of rights, duties, and administrative responsibilities. However, legislators have been unable to take even this first step, not merely because of the cost, but also because human ability to enact complex legislation appears to exceed human ability to reorganize, recodify and simplify that legislation.

The total length of the United States Code and the collected statutes of the various states has doubled in

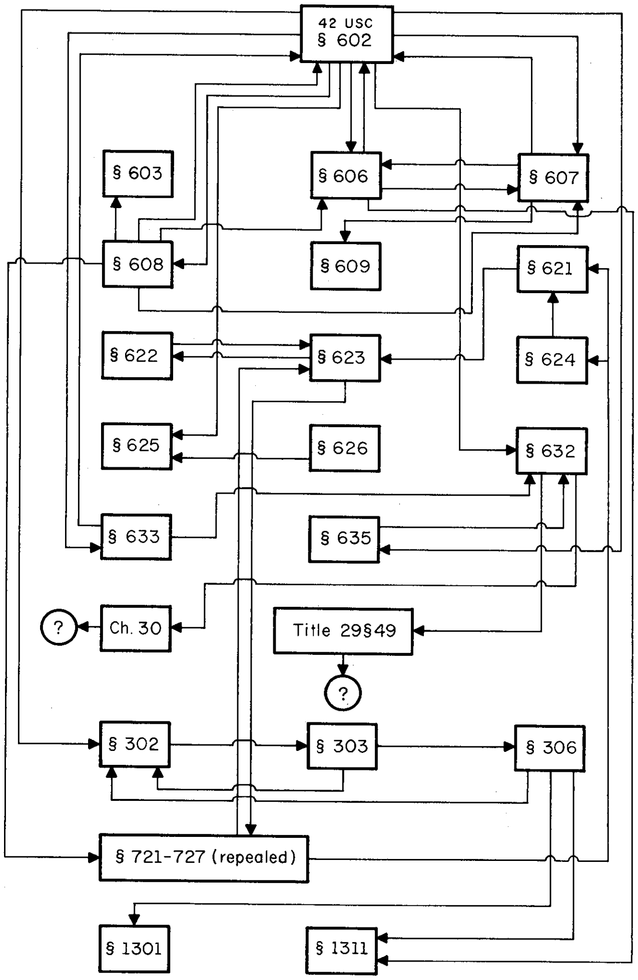

Figure 1—Network of References from 42 U.S.C. §602, "State Plans for Aid and Services to Needy Families with Children." References to the laws of the fifty states, implicit cross references, and references to federal and state administrative and judicial interpretation of the statute have been omitted for lack of space.

the past few years and promises to double again in this decade. In commercially important areas such as tax law, it is possible, at high cost, to find specialists who understand even the present incredibly complex legal picture. In many socially important areas, such as welfare law, pollution control law, environmental quality law, and urban planning law, it is almost impossible to find anyone who has a thorough working knowledge of the field. As a result, many important social programs are either slowed down or stifled.

To illustrate the complexity of the problems involved consider a single section of federal welfare legislation, for instance, that dealing with state plans for aid to needy families with children (42 U.S.C. §602). This single section refers to eight other sections, most of which in turn refer to still other sections creating an incredibly complex network (as illustrated in Figure 1). Even one of the shortest sections referred to by §602, namely §625, which defines "child welfare service" has an extraordinarily complicated internal logical structure (as illustrated in Figure 2).

There is a major unfilled demand for legal services in the United States. It is particularly acute for lower

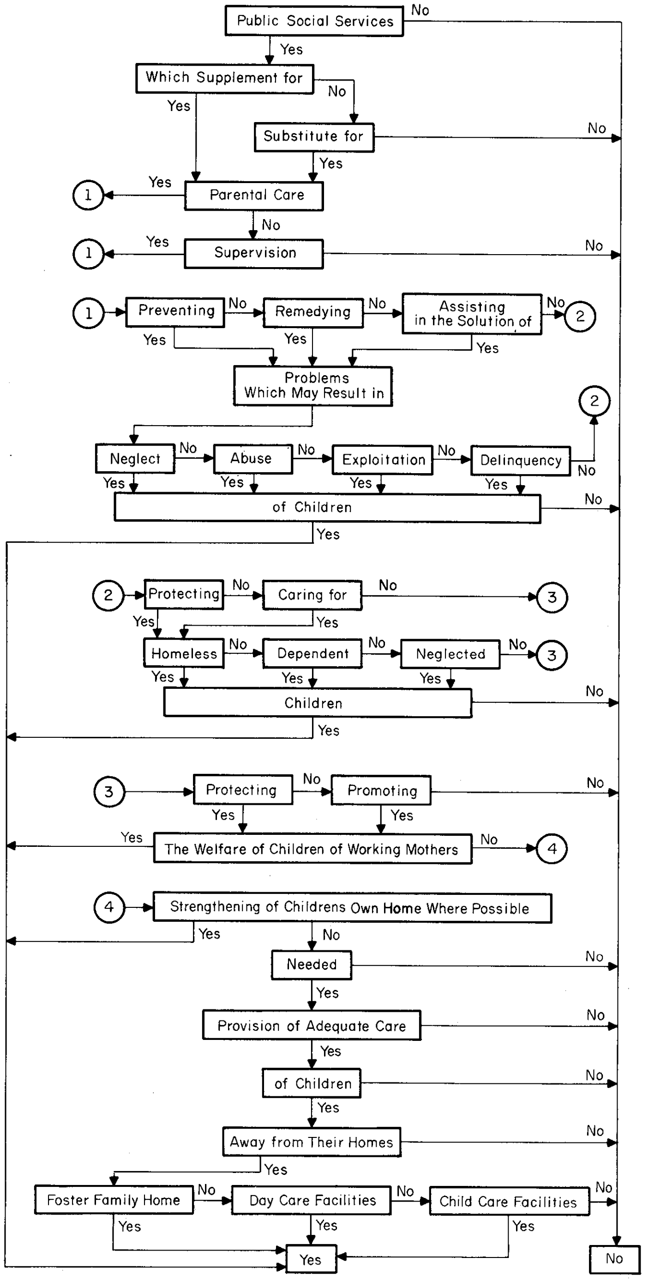

Figure 2—Logical structure of 42 U.S.C. §625 " 'Child-Welfare Services' Defined." One of the Simpler Sections. The appendix contains the text of this section

income groups, but legal services, like other unautomated services, are increasingly becoming priced out of the reach of larger and larger segments of the American public. At present large law firms provide excellent legal services for those able to pay their fees. Most of the lawyers in these firms spend most of their time in legal research and drafting legal documents.[55] The small businessman or average citizen, if he can afford legal service at all, typically employs a sole practitioner who cannot afford the library or the time necessary to do an adequate job of legal research on his client's problems.[11]

The experience of the medical profession in dealing with the problem of the cost of doctors' services suggests that two approaches be tried simultaneously. First, the rapid automation of those areas suitable for automation, and second the training of paraprofessionals to free the professional from routine tasks. However, the training of paraprofessionals in law—welfare administrators, social workers, lay magistrates, law clerks, etc., has been neglected by American education until very recently. Application of traditional methods of legal education to the problem would be possible, but it would be expensive, and would be difficult in view of the fact that all American law schools are filled to capacity.[5]

RECENT DEVELOPMENTS IN ARTIFICIAL INTELLIGENCE APPLICABLE TO LEGAL AUTOMATION

A significantly broad theoretical framework has been established for the application of computers to the law as the result of research and development in the area of artificial intelligence, in particular in question-answering systems where work has been carried on for over a decade. For information concerning such systems we refer the reader to Simmons.[52,53] Of the more advanced question-answering systems Green and Raphael[24,25] have developed a very powerful deductive procedure, and Simmons, Burger, and Schwarcz[51,54] introduced an extremely attractive representation scheme, while Biss, Chien and Stahl[8] have developed the R2 system which incorporates a number of advanced features not found in these other systems. These systems have attacked the problem of understanding facts and answering questions about them on an automatic basis. It is understood as a result of the development of these systems, how to, for example, resolve certain kinds of semantic and syntactic ambiguities. In addition, a number of sophisticated formal internal structures have been developed that allow much of the expressiveness found in natural English and yet can be manipulated by machines in a systematic fashion.

Transformation of natural English into a formal internal representation

Generally, natural language question-answering systems use some formal internal representation for information in order to facilitate deductive manipulations. In a number of earlier systems the representation was based upon some type of limited relational calculi, as for example Raphael's SIR,[64] and Black's SQA.[9] Green and Raphael[24,25] subsequently developed a system that offered the full expressiveness of the first-order predicate calculus for the representation of natural language information. Simmons, Burger, and Schwarcz[51,54] developed a system that used nested binary relations for the formal representation of natural language information. The R2 question-answering system developed by Biss, Chien, and Stahl[8] uses a high-order formal language for the internal representation of information. This system represents relations between relations and quantification of variables ranging over rather complex structures. The data base chosen to demonstrate the capabilities of this system is an informal description of the motor vechicle laws of Illinois.

Logical deduction as performed by computers

What types of "reasoning" or logical operations can be performed by a computer upon factual information expressed in a formal language? There has been significant progress in recent years in the research of deductive reasoning as performed by computers. Nevertheless the computer's ability to reason with formal concepts such as those as found in legal materials is still far from fully realized.

Automated deduction procedures have been developed for the propositional calculus, but the limitations of this calculus for most practical applications led to the search for automated procedures for the first-order predicate calculus. For the first-order predicate calculus, an effective deduction procedure based upon an automatic theorem-proving algorithm was first described by Robinson[48] and was improved upon by Wos, et al.[62–65] and others.[3,4,33] Currently work is being done by a number of researchers to find effective procedures for high-order logic where concepts that cannot be handled adequately in the first-order logic can be accommodated.

NEW DIRECTIONS

The use of computers as an aid to the legal process is already extensive as indicated by the work described above. There is, however, a vast difference between providing automated criminal justice and law enforcement information systems or legal information retrieval systems on the one hand, and improving the availability and quality of legal services on the other hand. In the first case the computer is used to accomplish well-defined but time-consuming routine tasks; the second case has been almost completely ignored with respect to the cognitive potential that computers can provide. Research in this country in this second area is virtually non-existent.

We envision the initiation of research programs within the near future to meet the need for automation in the law with the following objectives: first, to increase the ability of lawyers, administrators and the public to deal effectively with many of their legal problems; second, to aid legislative and administrative agencies in the reform and development of legislation and regulations concerning current social problems; third, to provide legal training on an automated basis for lawyers, social workers, police, and others who need to know the law for the performance of their duties; and fourth, to automate client and witness interviewing and screening.

As outlined above, the theoretical framework for such research must be drawn from the field of artificial intelligence and in particular from current investigations in automated natural language question-answering and logical deduction. Eventually the development of automated inductive logic may also offer significant aid in legal work. For an excellent discussion of this possibility see Reference 10. Numerous data bases of machine-readable legal materials already exist. The specific tasks that must be accomplished are:

1. The development of techniques for the transformation of natural language legal information into formal internal representations.
2. The development of techniques for automated logical deduction from legal materials in formal internal representations.
3. The development of practical automated legal question-answering systems based upon these logical deduction techniques.
4. The development of systems for machine assisted consistency-checking and consequence-finding to aid in the normalization, integration, and modification of legislation and administrative regulations.
5. The development of computer based legal education systems based upon the automation of the traditional Socratic method of legal instruction, using dynamic question-generating techniques rather than preprogrammed instruction; and
6. The development of conversational computer techniques for obtaining information from clients and witnesses.

The data base

A large quantity of federal and state legislation has already been converted to machine-readable form, and in a number of jurisdictions new legislation is being recorded initially in machine-readable form. The availability of legislation in this form has led to significant economies in the process of inserting amendments both at the original enactment of a statute and as a result of later legislative action, and has helped in the development of keyword document retrieval schemes. The Illinois Legislative Reference Bureau, for instance, has an advanced on-line system developed by Data Retrieval Corporation, with a dozen terminals for use in legislative drafting, law revision and keyword retrieval. While these techniques are not in the central area of legal work, their existence, and the benefits and economies they provide, guarantee the availability of data bases in machine readable form.

Existing machine-readable materials include all types of primary legal sources. These are: comprehensive codes such as the Uniform Commercial Code and the Internal Revenue Code; uncodified legislation such as state statute collections; and judicial and administrative decisions.

Selection of relevant materials from the data base

The selection of relevant materials from the data base may be based on a combination of four methods. The keyword method, despite the shortcomings which have prevented its widespread adoption in legal research, is very efficient for certain types of questions. The automation of the present manual system involving networks of case and statutory citations would present few technical problems.[36] The automation of the current system of abstracts and digests combined with new techniques of automated abstracting might save the current system from the strain of the legal information explosion. Finally, as computer time becomes cheaper and cheaper, the artificial intelligence techniques discussed below (which might be expected to bring significantly better results but to use substantially more computer time) might supplant the other methods.

Transformation of legal English into a formal internal representation

Lawyers have already developed a highly formalized language as a means of communication. Development of effective legal information systems will require investigation of the problems associated with transforming this subset of natural English into an internal representation suitable for use in legal question-answering, consistency-checking, consequence-finding, and instruction systems. This research can draw upon recent advances in automated syntactic and semantic analysis, e.g.[7,50,59]

Logical deduction

In order to automate the processes involved in legal reasoning an analysis of the logical structure of legal information is necessary. Knowledge of this structure will aid in the selection and development of effective automated legal reasoning techniques based upon theorem-proving techniques mentioned above. Within the framework provided by automated theorem-proving techniques it is necessary to find reasonable models for deductive legal reasoning. These procedures can be incorporated in the legal question-answering, consistency-checking, consequence-finding, and instruction systems described in the next few paragraphs.

Legal question-answering

Interactive legal question-answering systems with internal representation and logical deduction techniques adapted from prior research on general natural language question-answering systems to reflect the nature of legal materials should be developed, for only natural language question-answering systems allow the user to engage a machine in a meaningful dialogue in order to specify his needs and receive appropriate responses. Since almost no legal personnel have any knowledge of computer programming, communications between the user and the machine should be performed entirely in the natural language question-answering mode in English.

Consistency-checking and consequence-finding

In addition to the question-answering function of the future systems, the ability to find relevant consequences for given sets of facts with respect to specified rules, regulations, laws, statutes, contracts, etc., should be incorporated. They should be capable of determining the relative consistency of any body of legal information. At present these functions, as carried out by lawyers on a manual basis, are very time consuming and are subject to error.

These systems when completed will involve direct benefits for legislators and administrative rule-makers. They will be able to use their capabilities to help in the detection and elimination of contradictions and ambiguities in existing law. Legislators will also be able to examine more fully the implications of proposed additions to the existing body of legislations.

Automated legal instruction

Legal instruction now takes many forms.[5] Some of the methods which are and will be most important in the future lend themselves to automation using artificial intelligence techniques. These include basic instruction in legal doctrine and method designed to give the student basic skills in legal vocabulary and reasoning;[5, pp. 17–18] extensive instruction designed to expose the student to surveys of broad areas of the law,[5, pp. 21–22] and simulated clinical instruction designed to develop practical skills and awareness.[5, pp. 41–42]

The accepted method of teaching basic skills in legal vocabulary and reasoning in the United States has long involved the asking of specific questions and their answering by the students as a major if not the major component of the instructional process. However, because this procedure is effective only when applied by highly qualified instructors to relatively small groups, it has been expensive to use in law schools and it has found comparatively little use in programs of legal education for non-lawyers. An authoritative recent study places the cost per legal instructor in programs for non-lawyers at $55,000, a large figure, even though less than the $80,000 a year cost for each professor in regular law school instruction.[5, pp. 69] It is hoped that the automation of this process will reduce its cost and extend its availability.

A legal question-answering system may be modified to form a system where questions are generated automatically to aid in the instruction of the law. Such a system could supplement some of the instruction now being given in law schools, but perhaps a more important application would be in training administrative officials, police, social workers, and others whose job requires day-to-day legal interpretation and administration.

One approach to such a system would be as follows: A series of typical factual situations would be posed for each of the conditions of a given statute. In order to ask a question an appropriate selection of a number of conditions would be automatically made such that the conclusion under consideration would be true. A question could be made false by eliminating some necessary conditions, and could be made more difficult by adding some irrelevant condition. In either case the answer given would be checked for consistency against the given situation and pertinent statutes. The coverage and difficulty of the questions could be structured by a dynamic teaching strategy determined by the nature and quality of student response.

Survey courses for practitioners, advanced law students, and non-lawyers are now taught largely by a lecture method, a method adopted largely for reasons of speed and economy. Automation would allow the institution of more efficient interactive methods of this type of instruction.

Computer-simulated clinical instruction, even without natural language capability, has already proved to be of considerable significance in medical teaching. It could be of similar importance in law if artificial intelligence techniques capable of handling the highly verbal nature of the lawyer-client interview were developed. Prototypes of this approach already existing in the medical area suggest the direction simulated legal clinic instruction can take.[12,13,60]

Automated client and witness screening

An experimental program has already been put into use for automated client interviewing at a legal aid office. Because the program lacks natural language capabilities, it can only accept yes/no or multiple choice answers from the interviewee.[38] Addition of natural language interactive capability would greatly enhance the power of such computerized interviewing and allow a real dialogue between the interviewee and the system.

CONCLUSION

The American public is becoming increasingly dissatisfied with the expense, delay, and inefficiency of the legal system. Application of existing computer techniques can help with some of these problems. However, real progress during the next decade demands new directions. Recent success in the field of artificial intelligence points the way for the future of legal automation.

ACKNOWLEDGMENTS

The authors, while taking full responsibility for all errors and omissions, wish to thank Professor Stephen Marx of the School of Law of the State University of New York at Buffalo and Professor Layman Allen of the University of Michigan Law School for their many comments and suggestions related to the subject of this paper. In particular, we would like to acknowledge Stephen Marx for his suggestion on simulated clinical instruction and Layman Allen for his corrections to the logic of Figure 2.

Text of 42 U.S.C. §625—"Child-welfare services" defined

§625. "Child-welfare services" defined.

For pruposes of this subchapter, the term "child-welfare services" means public social services which supplement, or substitute for, parental care and supervision for the purpose of (1) preventing or remedying, or assisting in the solution of problems which may result in, the neglect, abuse, exploitation, or deliquency of children, (2) protecting and caring for homeless, dependent, or neglected children, (3) protecting and promoting the welfare of children of working mothers, and (4) otherwise protecting and promoting the welfare of children, *including* the strengthening of their own homes where possible or, where needed, the provision of adequate care of children away from their homes in foster family homes or day-care or other child-care facilities. (Aug. 14, 1935, ch. 531, title IV, §425, as added Jan. 2, 1968, Pub.L.90-248, title II, §250(c), 81 Stat.914.)

HOMLIST—A computerized real estate information retrieval system

by DONALD J. SIMON and BARRY L. BATEMAN

University of Southwestern Louisiana
Lafayette, Louisiana

INTRODUCTION

An automated information retrieval system for real estate dealers would be desirable when the number of business transactions is large and the file of available homes is also quite large. A manual search of such a large file may be tedious and, most important, may fail to retrieve the desired information when it is actually contained within the file.[1]

In designing such a retrieval system for high-volume dealers, the fact that many homes have quite similar specifications must be borne in mind. The designer of the system must strive for a workable balance between lack of specificity and too great a degree of specificity in creating records for such real estate files. Too great a degree of specificity will result in a very limited number of records from which to choose and too little specificity may result in an unwieldy list which could only confuse the customer. It is apparent that an information retrieval system designed for this purpose should allow for future modification so as to incorporate the optimum degree of specificity in record and file structure as determined through usage.

THE HOMLST SYSTEM

The HOMLST system is an information retrieval system designed for the recording, updating, and listing of homes for sale by a real estate dealer.

System requirements

The HOMLST system, written in the COBOL language, was designed to be implemented on the RCA Spectra 70/46-G TSOS. The M70-590 disk storage unit is required for file storage and file access is achieved through a remote terminal.

Outline of the system

The HOMLST system is designed to be operated from a remote terminal[2] and employs the indexed-sequential file processing facility[3] to add, delete, and retrieve records. These records each contain a unique record-key, part of which is constructed manually, and part by programming.

Two indexed-sequential disk files are used in the operation of the HOMLST system. One file, (HOMFIL), contains records of the homes for sale and the other, (KEYFIL), is a file of sequential numbers used to create part of the record-key for each record on HOMFIL.

The system consists of two main programs each having several routines which perform various functions. One of the main programs, HOMUP, performs updating functions and the other, HOMRET, is used for retrieval of records from HOMFIL.

Record descriptions

The record description for a record in HOMFIL is as follows:

> HOMFIL utilizes a variable length record which is accessed by a unique record-key containing 14 digits. The first 9 digit field is referred to as the HOME-RECORD-CODE and is constructed as shown below:

DIGITS	
1-2	determine price range of home—for example 15 would be entered for a home costing between $15,000 and $20,000; 20 for a home costing between $20,000 and $25,000, etc.

3	Location: North = 1, South = 2, East = 3, West = 4
4	Exterior: Brick = 1, Wood = 2, Frame = 3
5	Baths: 1 Bath = 1, 1½ Bath = 2, 2 Baths = 3
6	Carpet: None = 0, Carpeting = 1
7	Bedrooms: 1 Bedroom = 1, 2 Bedrooms = 2, 3 Bedrooms = 3
8	Carport: None = 0, Single = 1, Double = 2
9	Garage: None = 0, Single = 1, Double = 2

The remaining 5 digits are taken from KEYFIL which contains sequentially generated, unique numbers so as to make each record-key unique even in cases where the home's specifications are the same as another's and the first 9 digits are identical. The following example of a record-key illustrates how it was constructed:

15121322000150

This record-key represents a home costing between $15,000 and $20,000, located on the north side of the city, with brick exterior, having *two* bathrooms, carpeting, and *three* bedrooms with a double carport. This was the 150th home record added to the file.

The following record description, using COBOL field designators, shows the positions of the data fields within the record:

```
01  HOM-REC.
    02  DUM  PICTURE X.
    02  FIX-PRT.
        03  HOM-KEY   PICTURE X (14).
        03  ACT-PRC   PICTURE 9(6) v99.
        03  IRC      PICTURE S99
                         COMPUTATIONAL
        02  VAR-PRT  OCCURS 10 TIMES
                          DEPENDING ON
                          IRC.
        03  DETAL  PICTURE X (65).
```

DUM—this is a dummy character which, by its position in the record, is used for deletion of records. In COBOL, a READ followed by a move of HIGH-VALUE to this data field with a subsequent REWRITE will delete the desired record.

FIX-PRT—this part of the record consits of fixed length data fields.

HOM-KEY—this field contains the record-key.

ACT-PRC—this field contains the actual price of the home.

IRC—this field, depending on its value, will determine how many lines of descriptive data about the home are contained in the record.

VAR-PRT—this part of the record is variable in length.

DETAL—this field is used to enter descriptive data about the home. In the record description shown above, there may be as many as 10 lines of descriptive data each containing 65 characters.

The record description for a record in KEYFIL is as follows:

```
01  KEY-REC.
    02  DUM2   PICTURE X.
    02  KEY-NO   PICTURE X (5).
```

DUM2—this data field is used to delete the record from the file in the manner described above.

KEY-NO—this is the record-key and also the record itself. These records are 5 digit numbers, sequentially generated for subsequent use in the formation of a unique record-key for records on HOMFIL.

File construction and maintenance

The files comprising the HOMLST system are constructed as follows:

KEYFIL—this indexed-sequential file, containing only 5 digit unique numbers as records, is constructed using the PRIMARY LOAD MODE of the indexed-sequential file processing facility. A pre-determined number of records is placed on the file during this load routine.

HOMFIL—this indexed-sequential file containing the records of homes for sale is constructed by entering a previously determined HOME-RECORD-CODE on a remote terminal during the execution of the updating program, HOMUP. The program then obtains a 5 digit number from KEYFIL and deletes this number from the file in order that no other record on HOMFIL may contain this number. This 5 digit number is then appended to the 9 digit HOME-RECORD-CODE thereby comprising a 14 digit, unique record-key. The actual price is then entered and finally from 1 to 10 lines of descriptive data about the home is entered as part of the record.

The two above files are updated each time a home is added to or deleted from HOMFIL. Detailed descriptions of the updating routines are contained in the section on HOMUP's routines.

Homret's routines

Operating instructions for this program and for HOMUP are provided to an operator upon request. Both programs provide the operator of the system with simple and direct instructions in response to the message: DO YOU WISH INSTRUCTIONS (YES OR NO)?—

Other than providing operating instructions, HOMRET has essentially only one routine whose function is to retrieve records of homes upon request. In response to the message: ENTER HOME-RECORD-CODE, a previously constructed HOME-RECORD-CODE is entered from the terminal. The 14 digit FULL-RECORD-KEY is displayed as the first item in the home record followed by the actual price and the descriptive data for the home. If there are no homes matching the specifications denoted by the HOME-RECORD-CODE, a message is displayed stating this. After all homes fitting the desired specifications are listed, a message is displayed on the terminal indicating such. The operator is then asked if he wishes to enter other specifications or terminate the program.

HOMRET has an error recovery routine to provide for the entrance of a non-numeric HOME-RECORD-CODE wherein the operator is informed of this fact and asked to reenter the number.

Homup's routines

HOMUP contains a CONTROL ROUTINE from which the operator may branch to any one of three separate routines to perform various functions. These routines are as follows:

1. ADD ROUTINE—the functions of this routine were described under HOMFIL in the section on File Construction and Maintenance.
2. DELETE ROUTINE—this routine provides for the deletion of records from HOMFIL. The record-key is entered from the terminal in response to the message: ENTER FULL-RECORD-KEY. The record-key is obtained from the listing of the home record by HOMRET. It is the first item listed in the home record. When this record-key is entered and a READ to HOMFIL is issued, a move of HIGH-VALUE to the first character in the record (the dummy character) with a subsequent REWRITE, results in the deletion of the desired record from HOMFIL. As part of the delete operation, the 5 digit suffix of the record-key is replaced on KEYFIL for reuse at a later time.
3. UPDATE ROUTINE—if a change in the selling price of a home is required, this may be accomplished in this routine. The record-key is entered from the terminal and the record is retrieved indicating the old price. The new price is then entered and a REWRITE is issued thereby updating the record.

When the functions of the above routines are complete, a branch to the CONTROL ROUTINE may be executed by the operator or he may terminate the program.

There are several error recovery provisions in the above routines. If a non-numeric HOME-RECORD-CODE or FULL-RECORD-KEY is entered, the operator is notified of this and asked to reenter the number. If the actual price of the home entered is non-numeric the same messages are displayed. Also, when the price entered exceeds the range implied by the first two digits of the HOME-RECORD-CODE, a message is displayed stating this and the operator is asked to reenter the price.

PROPOSED EXTENSIONS

Since many home specifications are sometimes quite similar, a greater degree of specificity may be required in constructing the HOME-RECORD-CODE. This would require changing the length of this subfield from 9 digits to the desired length. This could be accomplished with little difficulty if the record-key length would be made greater by increasing the length of the suffix from 5 digits to possibly 10 digits. Hence, when a lengthening of the HOME-RECORD-CODE is desired, the suffix could be shortened thereby not affecting the record-key length and the total record length would also be unaffected.

EVALUATION

Retrieval of records using the HOMLST system is sufficiently fast and the record provision of descriptive data concerning the homes simulates the detailed description found in most home listings. This provides the customer with most of the detailed information he requires. This provision also imposes little format restriction when entering data for a record.

Organization of a natural resources data bank system

by ALVIN J. SURKAN

University of Nebraska
Lincoln, Nebraska

INTRODUCTION

The growing dependence on electronic computers for analysis of geophysical and other environmental data, brings an increasing awareness that the organization of these data in storage and retrieval systems is intimately connected with the acquisition systems and analytic transformations the data are to undergo. Current computer technology is almost totally dominated by serial storage and processing mechanisms. This peculiarity of available hardware dictates a design of data structures oriented toward the storage, retrieval and analysis of time series.

Nearly every acquisition system, whether it consists of automatic analog or digital recording instruments or humans manually keeping records, generates time series that are subsequently analyzed as continuous sequences. The subsequent analysis requires either internal comparisons within sequences or intercomparisons among other sequences collected in the same general area. Consequently, an appropriate organization for such sequenced data should readily allow a natural decomposition of the entire data base into time series-like sequences of elements which are the values of either time varying data at fixed locations or of data differing at various geographic locations and changing negligibly during the period in which observations over a set of locations are made.

The organization of the blocks of time series data generated by some acquisition system is relatively straightforward since the acquisition device dictates the sequencing. Attention must be given only to devising an indexing system that allows each such series to be located whenever its space and time coordinates fall inside a particular search window supplied to the retrieval system.

The procedure for casting the geophysical data specifying geographic variations into a time series form is not so straightforward. For example, it may be necessary to store as a time series such irregular entities as mapped areas of rock or soil type and land use variations or descriptions of river systems and the locations of natural boundaries of watersheds, lakes and coastlines or sometimes artificial administrative boundaries created by government agencies. After it is clear how such data might be cast into a time series form, it is possible to describe general algorithms for performing operations on the series to accomplish the transformation needed in analyzing the internal structure and interrelationships of such geographic entities.

If one is to accept that nearly all geophysical data can be stored and processed in time series form, it is necessary to show how a data bank system storing the various series can be related to the acquisition system and logically organized to now accommodate current types of data and ideally, other data arising in the future. The approach taken here for the design of such a data bank system is an evolutionary one as indicated in Figure 1. The results of this paper include a review of relateds ystems, a formulation of objectives and the identification of an approach to the decomposition of the data base.

CONSTRAINTS ON THE ORGANIZATION OF THE DATA BANK SYSTEM

The system must provide a data organization flexible enough to accommodate geophysical, environmental or administrative information that is now useful in connection with the natural resources of a state. Emphasis must be placed on preserving the natural groupings arising from proximity or other regional factors which influence the sequences of acquisition or use, such as the topologic connections within hydrologic networks, geographic location within basin boundaries or position with respect to a natural divide. The same

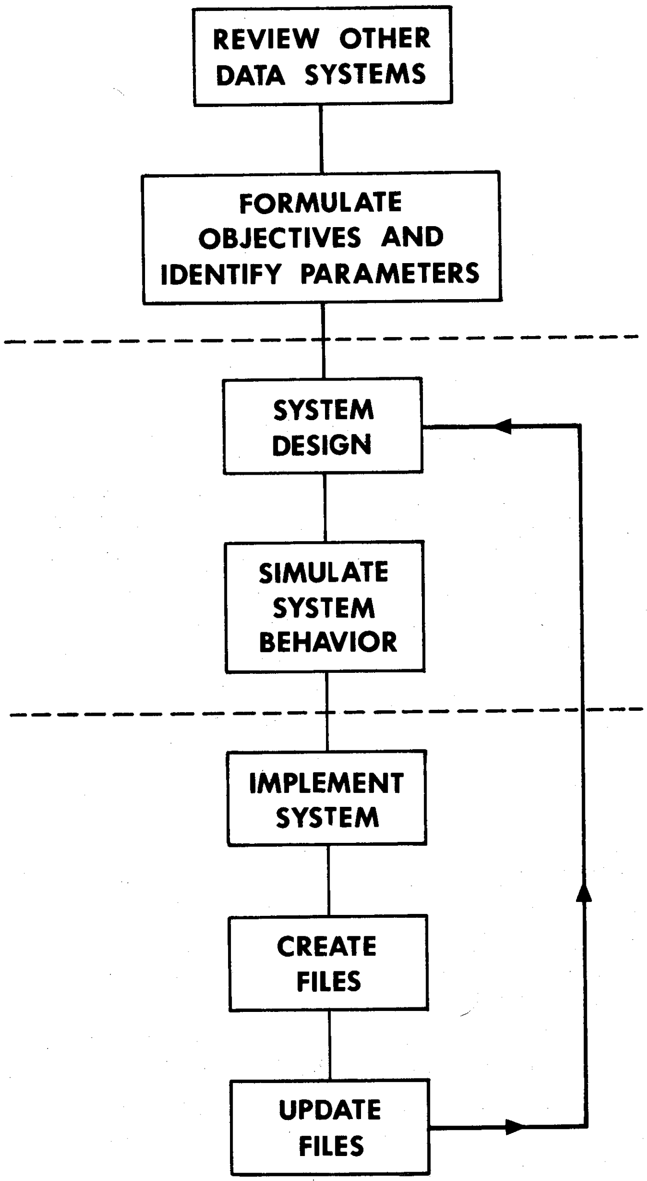

Figure 1

system should accommodate artificially grouped data within the same framework as those data with natural groupings. Artificially grouped data might, for example, be based on arbitrary and idealized administrative factors such as the positions of state or county boundaries or arbitrarily mapped survey grids, shorelines, stream limits and ridges.

Various networks such as the mathematical tree structure representations of drainage systems or administrative hierarchies, must be stored in some representation which can be easily retrieved, updated or analyzed. The analysis of such tree structures must provide the capability of identifying those subsets of structures modeled by mathematical trees which influence a particular point in the modeled system or those which are influenced by changes at a given point. For example, one might program the computer to indicate which points of a system are possibly responsible for pollution appearing at a specific point, or in the case of a known pollution source, it might be necessary to know what points could be influenced.

PARAMETERS CHARACTERIZING A DATA BANK

In describing a data bank system, it is convenient to separate the parameters into two classes. The first class characterizes the input and storage while the second characterizes the output functions and internal transformations that are associated with its operation. Parameters identified in each of these classes are summarized in Table I.

After identifying these parameters, one then seeks independent methods for finding what values apply to a data bank system needed for the geophysical data of a state. The data members will, in general, be labeled time series-like vectors. The amount of data in each consists of bit or character estimates for the size of the label plus the total number of bits or characters required for representing all the elements of the associated data vector. The total number of such vectors will, of course, depend on how finely divided, on the average, is the area of interest. For an area corresponding to an average sized state, one expects 10^5 square units of area could have varying data vectors of importance. The amount of data in each vector will typically be a few hundreds of characters or thousands of bits. Thus, the most conservative estimates of the amount of data that must be stored is 10^8 bits. In practice one must expect about 10^{10} bits and at most

TABLE I

CLASSES	DESCRIPTION OF PARAMETER	Estimate Range of Values
INPUT & STORAGE	Initial amounts of data	10^8-10^{12} bits
	Rate of adding data	10^7-10^{11} bits/yr
	Rate of data purging	0-10^7 bits/yr
	Rate of updating of data value	10^6-10^{10} bits/yr
	Levels of data categorization	6 levels
OUTPUT & DISPLAY	Rate of arrival of search requests	0.1-1.10 min
	Number of search priority categories	6 levels
	Documents retrieval rate	.01-.1 document/minute
	Number of types of document display	2-6 types

10^{12} bits after continued data accumulation concurrent with a maximum of purging of obsolete data.

The rate at which data will be added will increase with time and therefore might best be estimated for a particular time from the number of sources of data multiplied by the average number of bits or pages delivered by each. Again a conservative estimate might be 500 sources, each delivering 2×10^5 bits. These would yield 10^7 bits per year or a growth factor of 0.1 in static or permanent data. This growth factor is also reasonable for the continuously recorded time series data, if it is assumed that effectively such data would also have a ten year life and could be automatically purged to microfilm archives after that period of time.

The purge rate will then also be a function of time which is initially zero and then should grow to approach the addition rate. Such growth will require a period of time approximately of the order of the mean useful lifetime for all non-permanent information.

The rate of modification or updating of values for permanent data is estimated not to exceed 0.01 of the static component of the data base. Thus, a time of 100 years would have elapsed before the entire base would be renewed.

The number of levels of categorization of data could be kept small. The categorized data members would be vectors of typically 10^4 bits, the elements of each being addressable only by index. This would mean the number of logical routes or decision points leading to all data vectors or stored series would be between 10^4 and 10^6. Suppose there were on the average a 10-way branch or an organization tree having an average dispersion or bifurcation ratio of 10, only $\log_{10}10^4 = 4$ or at most $\log_{10}10^6 = 6$ levels of classification would suffice. An estimate of the number of levels of categorization needed is important because it is directly related to the ease with which time series information can be classified and retrieved. Classification is consciously or unconsciously imposed by the person presenting information to the data bank. Not more than six different qualifiers each chosen from an alphabet of ten or fewer letters or words need be specified to enter or retrieve a vector or time series. This estimate can serve as a realistic guideline in the structuring of the index for a properly organized, practical data bank system.

ESTIMATES OF VALUES OF PERFORMANCE PARAMETERS

The rate of arrival of requests for searches of the data bank is most important, and in fact, is a self-dependent parameter. Whenever the value of results of the search, measured in terms of its completeness and freedom from errors, compared with cost and time required is high, the arrival rate for requests will increase. This will in turn degrade the subsequent service of any system operated close to its ultimate capability. For planning purposes, one might arbitrarily select a request rate which is consistent with the economics of storage for the various data sequences in the data bank system. On the assumption there are between 10^4 and 10^6 documents or time series stored in the system when in operation and that such a system might cost \$1000 to \$10,000 per year to operate, it seems reasonable to expect a request rate of 1000 to 10,000 per year or $\approx$30-300/day or $\approx$0.1-1.0/minute.

Priority categories for search could allow for a range of search services and responses ranging from immediate with the system dedicated to a single user to delayed service permitting economization resulting from periods for the accumulation or batching of search arguments. Six appropriate priority categories might be (a) no waiting; (b) 1 minute; (c) 6 minutes; (d) 30 minutes; (e) half day; and (f) daily.

Document retrieval rate might be estimated as 0.1 to 0.5 times the search rate. The number of classes of document display will depend on what output terminal devices are available. These might include the printed page, magnetic tape, paper tape, cathode ray tube photographs, and incremental plotters. Thus, control signals or interfacing with at least six different output devices must be provided.

DESIGN GOALS OR OBJECTIVES FOR A FUNCTIONAL SYSTEM

The central reason for constructing a data bank system is the concentration or channeling of the output from a number of acquisition systems into a single channel that leads to unique storage and complete updating functions. The systems make nearly simultaneous modifications of what is stored and make it feasible to detect duplication of information by independent sources. It then becomes possible to determine if specific information has been previously introduced. These capabilities of a data bank system provide the information needed for generating reports on the current state or past changes in certain resources. The ability to determine which data are not present provides the information directly needed for planning data collection programs. Using the system to provide the amount and location of resources makes it possible for various strategies of resource management to be optimized with respect to certain objectives. In the case of exhaustible or unreplenished resources, the depletion rates of the remnants may be quantitatively monitored. This information can then be used for making policy with regard to the updating of records of licenses or other legal rights to resource utilization.

FUNCTIONS OF COMPUTER DATA BANK SYSTEM

Three broad classes of functions that the system must perform with the information handled by it are: (1) storage, (2) retrieval, and (3) reporting. The first function, storage, has two subdivisions, namely (a) the classification of a series and (b) the writing of its elements into machine addressable locations. The classification aspect of storage facilitates the retrieval and introduces local coherence into the storage system that will permit data with similar space and time coordinates to be obtained with a minimum of reaccessing of the storage medium. The writing aspect of storage is the production of a machine-readable change of state at the addressed locations of memory.

The retrieval of information proceeds in two phases. The first, which is referred to as a search, identifies the entries which satisfy the given search arguments according to some criterion and indicates some of the descriptive properties of each, such as the location, size and the nature of contents. The extraction or display phase of retrieval then copies the set or subset of desired entries to an output unit which may make an electronic record, a physical punched or printed record, or a temporary image such as a cathode ray tube display.

The third function, that of reporting, involves an automatic use of the retrieval function for the purpose of generating reports with statistical or other measures summarizing the data present or indicating what data are missing in a specified region and time interval.

FEATURES REQUIRED IN A PRACTICAL IMPLEMENTATION

The central feature of a data bank system that gives rise to its value is the provision for sharing single copies of data, programs and processing units. The system can remain useful and manageable if it can be insured that only one internal and one or more external backup copies of a specific set of data from any given source can be retained. Also, storage wastage must be minimized by the elimination of unallocated locations through the use of chaining vectors and list structures. The locations of a specific file entry or retrieval point should not be available without a protective password. A provision for enciphering and deciphering the data in sensitive files using pseudo-random number sequences should be available (Carrol 1970). The user should be provided with a facility for creating personal index files to be created for individual user's own applications. Data should be accepted by the system only if it is accompanied by an automatic purge date. All active system files should be backed up by external self-contained files with both table of contents directory and the data records.

OVERALL VIEW OF A DATA BANK SYSTEM

The key feature of a natural resources data bank system is the high degree of structuring derived from the geographic proximity in natural networks and environmental factors such as geologic composition, soil types and rainfall patterns. The total data bank system involves the three components (Figure 2); (1) personnel, (2) programs, and (3) hardware or equipment. The personnel constitute an interface between the acquisition system and the input devices. They also demand that the system stores, searches for, and retrieves data. The programs serve as a vehicle for instructing the hardware to accept instructions from the users. Additional functions that can be performed by the programs include directing further data acquisition, reducing data, and preparing summaries and reports (Figure 3).

It is expected that user's requirements can continue to be met by direct communication of data from the acquisition system and augmented increasingly by the computer-based data bank system. The latter should permit the generation of a central data depository making possible unique and complete updating as well as automation in search and retrieval functions.

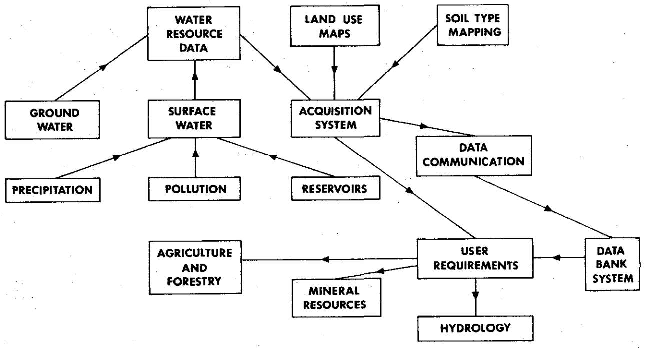

Figure 2

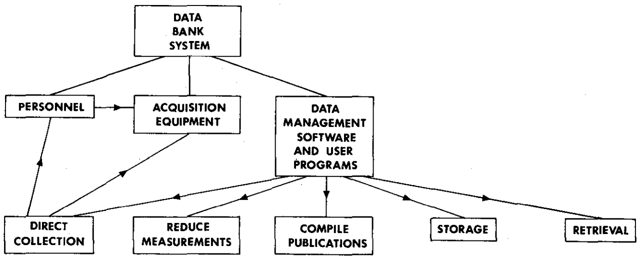

Figure 3

The creation of a data bank system, because of changes in needs and computing systems, must be evolutionary. It is proposed that effective steps are: (1) review of other viable systems, (2) design a system based on data acquisition and unmet needs, (3) simulation of the proposed system design, (4) implementation and use, and finally (5) a redesign or extension repeated recursively, followed by steps 3 through 5.

ENTITIES RECOGNIZED IN THE DATA BANK SYSTEM

One may recognize four distinct classes of natural resources or environmental data, namely: (1) observatory sequences, (2) labeled document-type objects, (3) graph or mathematical tree structures, and (4) area boundaries. Each entity upon undergoing appropriate transformations can be reduced to series to be stored by a computer. The observatory sequences are usually numeric and require little altering other than the affixing of appropriate labels. The sequencing of the elements or values constituting these entities remain, at least within each stored data member, as supplied by the acquisition system. Labeled objects refer to documents with two specified source dimensions. For storage purposes their representation must be decomposed into one-dimensional bit sequences which can be used to reconstruct a display of the source. The graph structures of most frequent interest in natural resources systems are the trees representing drainage networks. These may be decomposed into a binary vector specifying the topology of a particular network and auxiliary vectors corresponding with the types of data associated with each link of the network as shown in Figure 5(a). All such vectors have the same length. Consequently, storing of graphs this way reduces to storing matrices or families of regular sequences. Finally, the fourth distinct entity that arises in natural resources systems are area boundaries. Vectors of equal length may also be used for specifying these by choosing

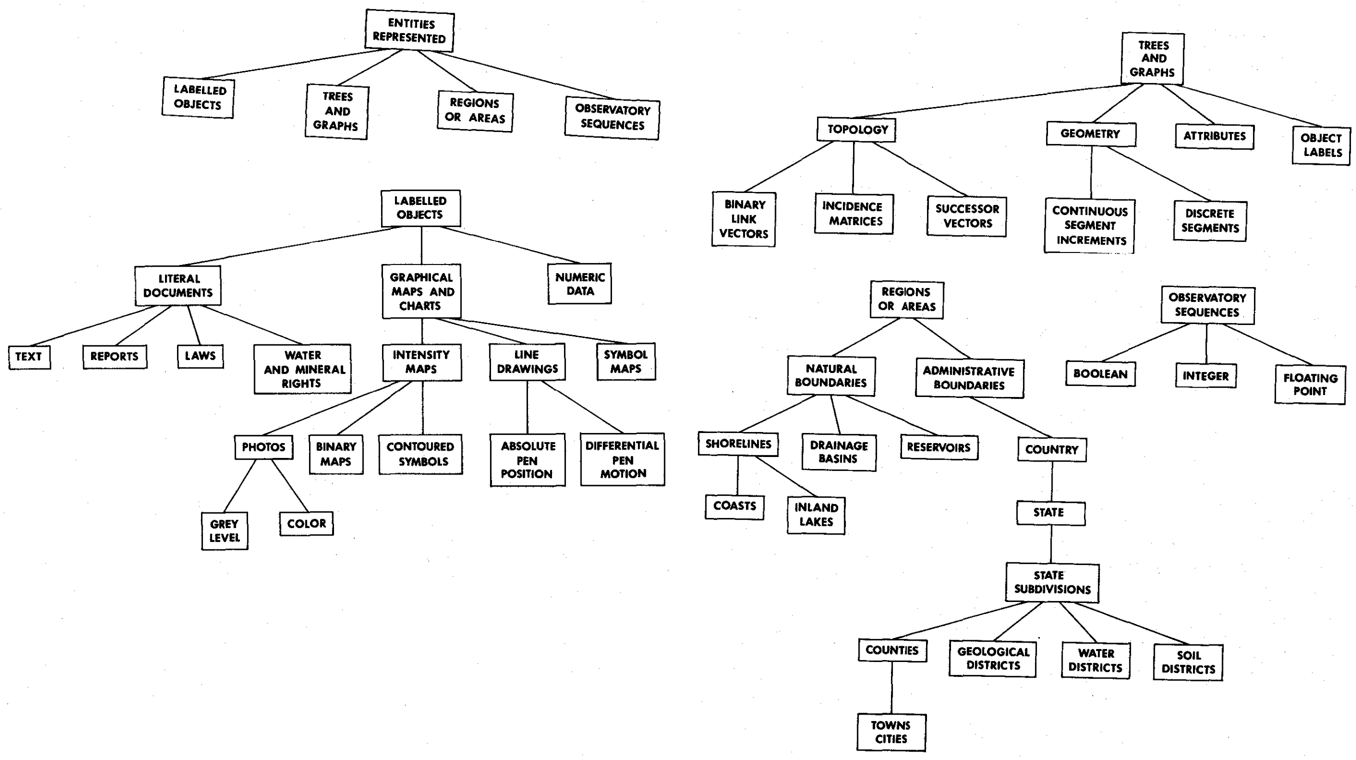

Figure 4

Figure 5a

to approximate a boundary of an area with a sequence of linear segments forming a closed polygon. A pair of vectors with length equal to the number of linear segments can provide the values of coordinate pairs at the terminus of each segment as shown in Figure 5(b). The current word size of computers allows adequate resolution for specifying the segments with all the precision of currently used survey data.

AN ORGANIZATIONAL TREE REDUCING DATA ENTITIES TO SERIES

Data, independent of the form in which it is presented to a computer-based system, must for purposes of computer manipulation be reduced to sequences of bits representing characters or numeric words. The effectiveness with which these data can be retrieved and manipulated depends on how well adapted to the applications is its reduction to the internal form stored within the computer. Economy and rapidity in the manipulation of data depend largely on the data structures chosen for representing the entities of interest.

A practical system should allow the naturally sequenced time series type of data such as observatory records to be stored in their numeric form as directly as possible. A data entity such as time series after being labeled need only have its file entry indexed with respect to geographic location, time, and appropriate documentation.

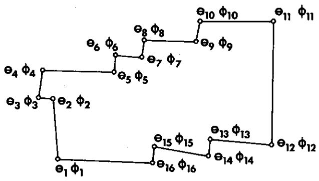
Another type of data entity, referred to here as labeled objects, may be utilized for storing such documentation. These labeled objects may also take on a number of different forms of literal, numeric or graphical information. The common feature of the members of this entity is their internal structure being essentially the sequences of markings and control information required to reconstruct charts or pages of symbols, print, tables, or line drawings. The possibility of the further decompositions of the labeled object type of entity is shown in Figure 4.

Natural resources are usually associated with locations or networks that are concentrated at points or along lines. The points are frequently linked to at least their nearest neighbors by some relationship described by mathematical graph representations which are very often tree structures. An example of a usually low area-density tree is the system of converging channels which make up drainage basins. It is necessary that in the acquisition and storage of the data associated with such systems there be recognized a graph or tree type of entity to provide a consistent and organized way of coding and storing their linked data in series form. It is then possible to formulate algorithms to perform operations defined with respect to the systems they constitute. For example, one might define operations which would correspond with the transport of pollutants from a point in a network to downstream points and identify the latter. Similar tree structures may be needed for storing administrative linkages important in organized data acquisition.

Finally, the fourth entity or data type recognized to be important in geophysical and natural resources information is that of the geographic area which is most economically delineated by describing the path of its boundary. These areas and the boundaries representing them may be natural such as those of watersheds and soil or rock types or artificial such as those representing administrative districts or land use patterns. In many cases the areas overlap or have important memberships in larger areas. Such relationships can be established using appropriate programs designed to operate on series representations of the areas. These representations may be formed out of vectors containing sequenced pairs of numbers corresponding to boundary segments.

CONCLUSIONS

The organization structure identifies a natural resources data bank system with flexibility to accom-



VERTEX COORDINATES θ_1 ϕ_1 θ_2 ϕ_2 . . . θ_n ϕ_n

Figure 5b

modate environmental data within a standardized framework designed to insure low redundancy and high accessibility for regionally distributed data. The central thesis for efficient storage and retrieval is a classification based on the type of format or medium available from the acquisition source and an indexing based on the geographic and time frames of the data. Four types of data entities are proposed, namely: (1) observatory records, (2) labeled objects, (3) tree structures, and (4) geographic areas. Each entity of this classification is decomposed to terminal members which point to the stored sequences or time series-like vectors. Such classification structure is aimed at ideally structured hardware independence to be exploited for the efficient distribution or selective dissemination of geophysical data.

The current acquisition methods and uses of environmental data require a computer based storage system that is organized to facilitate selective retrieval and mapping or data displays. Important features of the system include program controlled purging of obsolescent data and objective program-implemented measures that determine the potential value of particular data members. These two features are needed for the judicious release and allocation of computing resources. The actual implementation of such a system will always be some compromise among cost, access time, integrity of data, and the ease of use. Ease of use refers primarily to data and updating but it is also necessary that requesting a search or retrieval be simple. Search programs serve either to locate available data or indicate data not available. The retrieval function may be used for acquiring statistics on data values, for monitoring purposes, scientific studies, or administrative report generation.

THE COMMAND TERMINAL—A computerized law enforcement tool

by DAVID M. HUDAK

Automation Technology, Incorporated
Champaign, Illinois

INTRODUCTION

The most crucial problems being faced by local law enforcement agencies today are the collection, analysis, and utilization of police-oriented data. Information is the life blood of any law enforcement agency, and there exists a continuous requirement to collect and produce data which provide information useful to operation, planning, records maintenance, and management decision making.[1]

Police data may occur in many forms; i.e., contact reports, patrol observations, fingerprint files, arrest reports, warrant files, or other identification files. Government agencies at the federal and state level are currently collecting information and making it available to local law enforcement agencies via police teleprocessing techniques (see Figure 1). The NCIC (National Crime Information Center) operated by the Federal Bureau of Investigation in Washington, D.C. is an example of this type of system. It can best be described as a computerized index to documented police information concerning crime and criminals of nationwide interest.[2] Over 25 states now have their own computerized law enforcement systems modeled after the NCIC.

With information pertaining to criminals and criminal activity being maintained at the federal and some state levels, it is to the advantage of police officers to have access to that information whenever possible. If a patrol officer at the scene of an incident or investigation is able to query these data banks at the state and federal levels for the "wanted" status of vehicles or people, he will be able to use this information to make a better judgment of his situation. The timeliness of this inquiry and subsequent response is extremely important, and should be typically less than three to four minutes. Unfortunately, most of the systems currently in use do not accomplish this in an efficient manner, and thus the prime user, the patrol officer, is discouraged from using the system because he usually cannot obtain responses in the time frame that he requires.[1]

THE DISPATCH CENTER

The patrol officer's contact with supporting resources is through the radio or dispatch center. Almost all of his assignments and emergency directives come to him via radio communications and under the control of a radio dispatcher.

Radio dispatchers, monitoring the activities of a widely scattered fleet of vehicles, are the recipients of a vast amount of vital information which has to be sifted, organized, and made available for use in making operational and administrative decisions. The dispatcher's effectiveness depends critically upon the ability of his information handling systems to supply critical data as quickly as possible, with a minimum of wasted effort.

The functions of the dispatch center have changed tremendously in recent years. With the advent of modern communication techniques which can effectively place a two-way radio on every patrol officer, and with

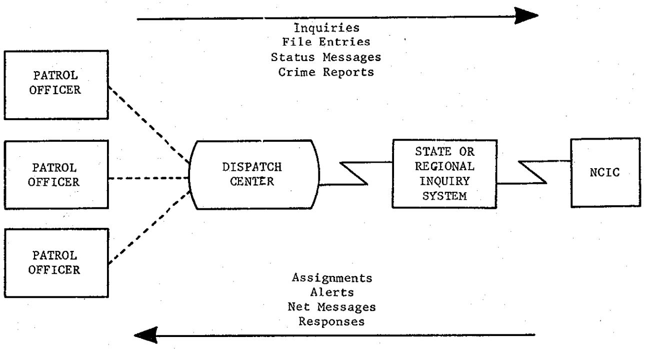

Figure 1—General information flow

the mobile capabilities of law enforcement forces such as patrol cars, motorcycles, scooters, and even helicopters, the dispatch center has become a scene of busy and sometimes frenzied activity, with a corresponding increase in paperwork.[4] Most radio rooms or dispatch centers are not prepared to handle the current volume of activity that exists in law enforcement agencies today. They are often overcrowded, understaffed, and are usually working under an antiquated system that has been "updated" only occasionally over the past years. Although the dispatcher is the field officer's link to other law enforcement resources, responses to their requests for information are frequently delayed minutes, and sometimes hours.

Another important function of the dispatcher accepting complaints or requests for service from citizens is assigning the proper personnel to those incidents from a list of available resources. Recent studies show that 65 percent of all crimes can be solved if the police respond within two minutes of an occurrence of the crime, but if they are delayed up to five minutes, this efficiency drops to 20 percent.[5] In making these assignments, the dispatcher usually makes use of policy and procedure guidelines, experience, and sometimes visual aids such as status boards. It is necessary that he have at his finger tips the status, location, and degree of availability of all of his forces, in order to assign the correct resource to each task.[6]

RADIO TICKETS

The flow of data through a dispatch center is usually controlled by paper forms called radio tickets (or dispatch tickets, complaint tickets, etc.). This is a data collection method that has been used in police departments throughout the country for a number of years. As much as they may vary from department to department, radio tickets are generally used to record some basic facts about each assignment, event, or incident that requires the use of the police departments' primary resource, manpower.[7] Some of the most common elements of the radio ticket include: time complaint was received, type of incident, location of incident, unit number assigned, time dispatched, time of arrival on scene, a document control number, time assignment was concluded, etc. These tickets may be completed entirely by the dispatcher as the incident progresses, or may be later filled in by the patrol officer when he returns to the station. In larger departments the radio tickets are initiated by complaint clerks who take the complaints from the public and pass them on to dispatchers, who assign the mobile units and complete the radio tickets.

Current manual radio tickets provide a very important collection device in the data management procedures of a law enforcement agency. However, there are some serious drawbacks to their use. For instance, if the data are going to be input to a law enforcement management information system, then the information on the radio ticket must be recorded twice, once by the dispatcher as it occurs, and again by a clerk who codes the information into machine-sensible form. In some cases the physical environment of the dispatch room requires that some mechanical method be used to transport the radio ticket from one position to another, thereby increasing the time from receipt of complaint to the time the unit is dispatched.

Should a patrol officer wish to make an inquiry on a wanted person or car, the request for information must be logged on a radio ticket, and the dispatcher must relay the request via a terminal to the state or regional data base inquiry system. The dispatcher must input the inquiry in a very rigorous format, because errors will cause it to be rejected and necessitate its reentry. Not only is this activity frustrating to the operator of the terminal, but in emergency situations it could endanger the patrol officer who has asked for this information NOW and is unable to get it.

It is readily apparent that there are many stumbling blocks between the information system and its user, the officer on patrol. The system often appears unresponsive to his needs, so he tends to use it only when absolutely necessary, and not as part of a normal operating sequence. To cope with these problems, the attack must be launched at the nucleus of the difficulty, the radio room itself, its operating personnel and procedures, and the operator-information system interface. The radio dispatcher must be provided with an integrated mechanism for handling his normal dispatching and data collection duties, and also for interfacing with the automated information system in an efficient manner. A system has been constructed which will solve many of these problems. This system is called the COMMAND TERMINAL.

FUNCTIONS OF THE COMMAND TERMINAL SYSTEM

The basic COMMAND TERMINAL System is composed of a minicomputer, a disk, a visual display device (CRT), a standard keyboard unit, a special function keyboard unit, a standard teletypewriter, and a set of operational computer programs. While the system is welded together logically into a total operating package, the dispatcher is physically confronted with only the visual display device, the two keyboards, and infrequently, the teletypewriter (see Figure 2).

In many cases the visual display device can be integrated into the radio console itself, so that it is immediately in front of the dispatcher when he is seated in his normal operating position. The two keyboards are placed on the console desk top in front of the dispatcher. The teletypewriter, which is used primarily for hard copy output, may be located in various places, depending upon the department's normal operational procedures. All other equipment may be located in a separate room with the communications equipment, or in any other suitable place. The system is designed to replace, on a plug-for-plug basis, the present real-time information system terminal. Since the COMMAND TERMINAL can emulate the previous type of terminal, no modification to the real-time system's programs is necessary.

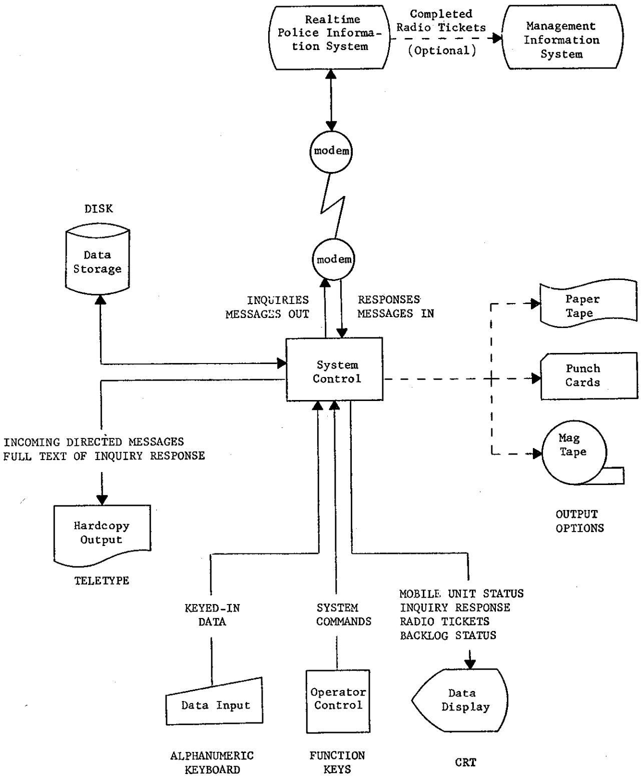

Figure 2—Information flow for COMMAND TERMINAL SYSTEM

With the COMMAND TERMINAL, radio tickets are no longer pieces of paper to be completed in handwriting, time stamped, filed in slots, and ultimately keypunched to permit further analysis by computer. Instead, the radio ticket is an electronic form appearing before the dispatcher on a display device. The dispatcher fills in some of the blanks by utilizing a keyboard, while the system assists him by filling in others automatically (see Figure 3). In some cases, when data fields have been filled in by the dispatcher, an auto-

Figure 4—Mobile unit status

matic edit is performed by the system to check the validity of the data.

Tickets may be temporarily filed away in the system's computer memory at any time to permit the dispatcher to process or initiate other tickets. These stored-away tickets may be recalled at will by the dispatcher until such time as the particular assignment has been concluded and the mobile unit is back in service.

A mobile unit status display is maintained on an up-to-the-minute basis by the system as a by-product of processing the radio tickets. Thus, the dispatcher can at any time press one function key and review the in- or out-of-service status of all cars under his command, along with some additional facts about various units (see Figure 4).

As the dispatcher records the particular beat or patrol area identifier for an incoming complaint, the system will automatically recommend a specific mobile unit to handle the incident. The recommendation is based on a priority structure established initially by the department and, naturally, also considers the present availability status of all units. On more sophisticated models of the system, it will be possible to automatically translate a street address into the appropriate beat number, thereby saving the dispatcher this task.

The dispatcher also has the option of placing a new incident on backlog status, instead of assigning it immediately to a unit. If he does, the system automatically assigns the ticket a priority based on the type of incident, and backlogs it for future reference. Subsequently, it will be brought to the attention of the dispatcher as a logical unit becomes available. A status report on the backlog can be viewed at any time by the dispatcher (see Figure 5).

As name and vehicle checks come in from the mobile unit handling a specific incident, the dispatcher need only fill in the necessary fields on that unit's radio ticket. The system then automatically formats this data into the proper inquiry language, and transmits the resultant inquiry to the real-time system.

As a safety feature for the man on the street, the system contains a "watchdog timer" which notifies the dispatcher if no contact has been made with a particular unit within some predetermined amount of time. The amount of time permitted before an alert message is displayed can vary, depending upon the type of incident being handled.

Complete radio tickets, being recorded originally in machine-sensible form, can be sent directly to the management information system computer if it is capable of accepting data this way, or it can be recorded on any type of output medium desired, such as paper tape, punched cards, or magnetic tape.

Directed or point-to-point messages coming to the agency through the real-time-information/message-switching system are automatically routed for output to the teletype by the COMMAND TERMINAL's small computer. This precludes interference with the dispatcher's normal operation. Outgoing directed messages can be sent from the dispatcher's visual display unit, or the teletype. In either event, the system will handle all necessary formatting and the insertion of fixed message header elements.

SYSTEM CONFIGURATION

As mentioned before, the basic system consists of a minicomputer, a disk, a CRT with a standard keyboard,

Figure 5—Backlog status

and a function keyboard. One of the design goals in the development of the COMMAND TERMINAL was to achieve a satisfactory price/performance relationship with a sound functional system. The Honeywell H316 computer was selected as the system CPU. The Engineered Data Peripherals 3032 disk was interfaced in-house, and the basic sector size set at 128 16-bit words. This sector size was defined so as to contain a single radio ticket with an average number of entries, and to minimize the number of sector transfers when executing program overlays. The CRT used is a TEC Model 400 with a complete set of edit functions and standard alphanumeric keyboard. The special function keyboard was built in house and merely converts the dispatcher's finger stroke into an 8-bit character. All of the system functions are implemented by programming.

All of the computer programs were coded in DAP, the machine assembly language of the Honeywell computer. A disk-based monitor was designed to control the disk-resident overlay processors and data storage. Almost all of the data being handled are maintained on the disk. This includes completed radio tickets, radio tickets in progress, unit status tables, patrol area status tables, input and output message queues, and other user-specified information that needs to be maintained in real-time.

Due to the variety of data base structures and the individuality of each law enforcement agency, a major design goal was modularity of function programs. It is now a minimal effort to design and implement a tailor-made system to any agency's specifications. Parameters such as radio ticket format, patrol area labels, response patterns, and even incident priorities can be specified during an installation by a short system generation procedure.

EXPANDABILITY

The basic system is easily expandable both in core and disk size. For larger installations that require more than one dispatcher station, additional CRTs and keyboards may be added to the system (see Figure 6). However, each additional dispatcher station approximately doubles the processing requirements of the system, and therefore usually requires additional core and disk space in order to guarantee acceptable interaction of the dispatcher with the system. "Acceptable Interaction" is defined as the system's response to data input or action by the dispatcher, and has a maximum time lapse of two seconds. The COMMAND TERMINAL interface to a police real-time information system is usually via a modem and requires only specific formatting of already developed character streams, and is, therefore, relatively easy to implement.

SUMMARY

We have described a system that has been designed to facilitate the flow of police information through the dispatch station of a typical law enforcement agency. Particular attention has been given to system modularity, flexibility, and ease of modification for varied installations. Use of a general purpose computer as the system controller guarantees ease of expandability when future "add-ons," such as mobile teleprinters and automatic vehicle monitoring devices, become available. These two items would serve to automatically close the loop for an integrated command-and-control system.[9]

The COMMAND TERMINAL has proved itself a capable tool in a real-time computer-oriented dispatch environment. It is valuable because any tool that collects and organizes data in a complicated and changing fact situation is a significant aid to judgment.[10] And that is the goal—to provide a tool for our law enforcement officers.

Experience gained in the development and use of TSS

by RICHARD E. SCHWEMM

IBM Corporation
White Plains, New York

INTRODUCTION

Six and a half years have elapsed since W. T. Comfort described TSS/360 to the 1965 Fall Joint Computer Conference.[1] Since that time, much has been learned by IBM and its customers about time-sharing, about TSS, and about large-scale, interactive systems in general. Scores of people have worked with the system; dozens of articles have been published; it would clearly be impossible to put in one paper a comprehensive answer to the question—what has been learned developing TSS? Yet, with the availability of Release 8.1, the major development work on the system has been completed, and this is an appropriate time to take stock of where we have been, where we are, and where we might go from here.

One summary paragraph of that 1965 paper says the following: "This report attempts to give an overall picture of the System/360 Model 67 Time-Sharing System, its system design, and major hardware and control program characteristics. The unique combination of hardware and software objectives makes a very complex problem, for which a simple and efficient solution is desired—a difficult task at best." Indeed, bringing TSS/360 to the marketplace and making it productive in customer installations has been a very difficult task, both technically and financially.

No attempt has been made in this paper to give detailed technical descriptions of programming systems problems and solutions. Instead problems have been described in a general way, their impact on the system discussed, and the strategy for solution outlined along with the results obtained. Four major areas will be discussed:

- Lessons Learned about System Structure
- Lessons Learned about System Performance Analysis
- Lessons Learned about Software Development Tools
- Lessons Learned about Management of Software Development

SYSTEM STRUCTURE

Version 1 of TSS/360 was released in October, 1967. Use for experimental, developmental, and instructional purposes was advised. By the fall of 1968, A. S. Lett and W. L. Konigsford were able to report[2] on a version which was more stable, performed better, and contained more function. Based on this progress made during the first year in the field, plus progress anticipated from items designed and then in development, a very positive view of the system was presented.

Several important lessons had emerged from the TSS experience by this time. It seems clear that the proper way to construct a system of this type is to build a small, hard-core base first, and add function later. As Lett and Konigsford put it—"The initial emphasis was on building a stable system, followed by extensive measurement—and—analysis efforts to identify potential system modifications."

The same paper reported that the design of the TSS Resident Supervisor had proved sound and remained essentially as described in 1965, a statement as valid today as it was in 1968. On the other hand, major portions of the original design had to be abandoned for the simple reason that they were unacceptable to the Users. One example of this was the replacement of the original rigid set of commands with Command System II.[3] Another was the replacement of the system's hard-coded scheduling algorithm with an extremely flexible Table Driven Scheduler.[4] The important thing here is not that the original design was unacceptable, but that a communication channel was open from the Users to TSS Development, and that the latter was responsive to the former's requirements.*

* In both cases cited as examples, Users made strong technical presentations. T. A. Dolotta of Princeton University and A. Irvine of System Development Corporation made a "Proposal for Time-Sharing Command Structure" at SHARE in August, 1966. The basic thinking behind table driven scheduling came from F. G. Livermore of General Motors Research.

The table below displays the functional buildup of TSS/360 by release:

TABLE I—Summary of Major Functions Added to TSS/360

Date	*Release*	*Major Functions Added*
2/1/68	1.1	(Incremental reliability improvements only)
4/15/68	1.2	(Incremental performance improvements only)
7/1/68	2.0	• *Support for Extended Address Translation (32 bit)* On Model 67 equipped with the special feature, users can address up to 4096 virtual memory segments. • *Multiple Sequential Access Method (MSAM)* This is a special access method for card equipment and printers which allows a single task (BULKIO) to process all spooling operations.
10/21/68	3.0	• *Command System II* This system provides a consistent command syntax, an extensive default and profile facility, a general editing capability, and allows users to define their own commands and call programs directly. • *Time Sharing Support System* (*TS*[3]) A Virtual Support Subsystem executes in parallel with other TSS operations, allowing system programmers to access and modify the privileged, shared Virtual Memory; a Resident Support Subsystem provides the same facility for the resident supervisor in a non time-shared mode.
1/20/69	4.0	• *Table Driven Scheduler* This technique provides installation control and dynamic regulation of scheduling parameters, for complete flexibility in obtaining optimum scheduling balance within and among tasks.
7/8/69	5.0	• *Support For Duplex Configurations* This was the first system release which was tested on and suitable for a multiprocessing configuration. • *Virtual Access Method II* This rewrite of VAM provides more efficient handling of physical devices, ability to create duplicate data sets, and an overall improvement to data set integrity.
10/15/69	5.1	(Incremental human factors improvements only)
3/31/70	6.0	• *Resident Terminal Access Method (RTAM)* Removing TAM from shared virtual memory reduces paging which significantly improves conversational task performance. • *Multiple Terminals per Task (MTT)* A large number of users can share the same task and the concomitant overhead. The effect is the addition of a generalized way to add subsystems.
5/15/70	6.1	(Maintenance only)
6/30/70	7.0	• *PL/I Compiler* A version of the OS/360 F-level compiler is modified to operate within TSS. • *Remote Job Entry* Non-conversational job streams can be introduced into TSS from a remotely located work station; spooling to/from the work station is also provided.
12/17/70	8.0	(Incremental improvements only)
10/1/71	8.1	• *Dynamic Catalog* The user portion of the master catalog is made a working catalog for the duration of the user's task, eliminating contention for the master catalog. • *Page Table Paging* Demand paging of page tables allows effective use of very large virtual memories.

This functional buildup was accompanied by a steady improvement in performance and reliability. The performance picture is discussed in detail in a subsequent section. To date, a total of 2442 program errors detected by Users have been corrected.

Figure 1 displays the system size as a function of release. It is worthy of note that only the addition of the PL/I Compiler caused a significant increase in system size.

SYSTEM PERFORMANCE ANALYSIS

The economic viability of any system is determined by a complex equation which combines price, performance, and the value of function.[5] Since a given set of hardware has a fixed price, and a given set of software functions appear to a User to have a constant value, performance is the critical factor in determining success or failure. A simple example will illustrate this:

> *Let us assume that an interactive system operates on a configuration that costs $1,000,000 per year. Let us further assume that users feel that each professional employee using this system will double his productive output and that an average employee of this type costs $30,000. Then the value of the system is a simple function of how many users it can support—if it supports 33 or fewer, it will be a loser, 34 or more a winner.*

During the development of TSS/360, a comprehensive scheme for treatment of system performance evolved. The elements of this scheme are:

- Establishment of Performance Objectives
- Creation of External Performance Measurement Tools
- Creation of Internal Recording Tools and Appropriate Data Reduction Facilities

Performance objectives

How well will the system perform the functions it provides? This simple question receives a complex answer. TSS/360 is designed for conversational use, batch use, and a mixture of the two. A performance objective was established for each type of use. The conversational objective is the most difficult to describe and of greatest interest here, so our discussion will be restricted to it.

Basically, conversational performance is defined as the maximum number of tasks which the system will support with acceptable response time. This very general definition is made more specific by creating a benchmark terminal session and dividing the interactions created by the session into three classes—trivial response, non-trivial response, and data-dependent response. Acceptable response to trivial commands (such as text entry) is defined as four seconds. Acceptable response to non-trivial commands (such as data set creation) is defined as 7.5 seconds. Data-dependent commands (such as compilation) have no specific acceptability criteria. With this definition of conversational performance, we have a constant, calibrated yardstick that answers the performance question.

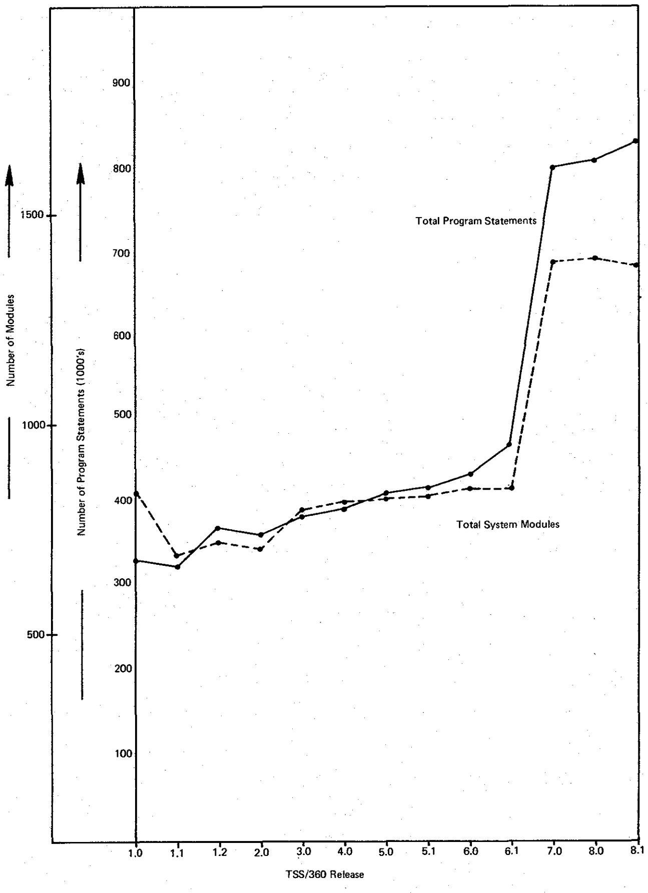

Figure 1—Size of TSS/360 as a function of release

Here we should point out that no User of TSS accepts our benchmark terminal session as typical of his conversational work load. Most have specified their own benchmarks. However, there is general agreement that the definition of performance is adequate. We have a yardstick; the users have metersticks; we are in fact measuring the same thing.

The initial conversational performance objective established for TSS/360 was to support 40 tasks running the benchmark terminal session on a configuration composed of 1 processing unit, 512K bytes of memory, 1 paging drum, and disk modules on 1 channel. Subsequently, objectives for larger configurations were established.

External performance measurement tools

TSS operates in an extremely dynamic environment, and the load imposed upon it by live users is characterized by peaks and valleys of activity and demands for services. Yet, for performance objectives to be useful, they must be measurable, and the measurements must be repeatable. To achieve this, a measurement driver was created to simulate the actual environment under controlled and reproducible conditions.

Shown schematically in Figure 2, the driver has the following characteristics:

- It interfaces with the system in the same manner as actual terminals and, to the system, appears indistinguishable from them.
- It is capable of bringing the system up to a stable load level and keeping it there during the measurement period in order to eliminate starting and stopping transients from a measurement.
- It is capable of recognizing the expected system response for each transmission and contains sufficient logic to take appropriate action for any response received.

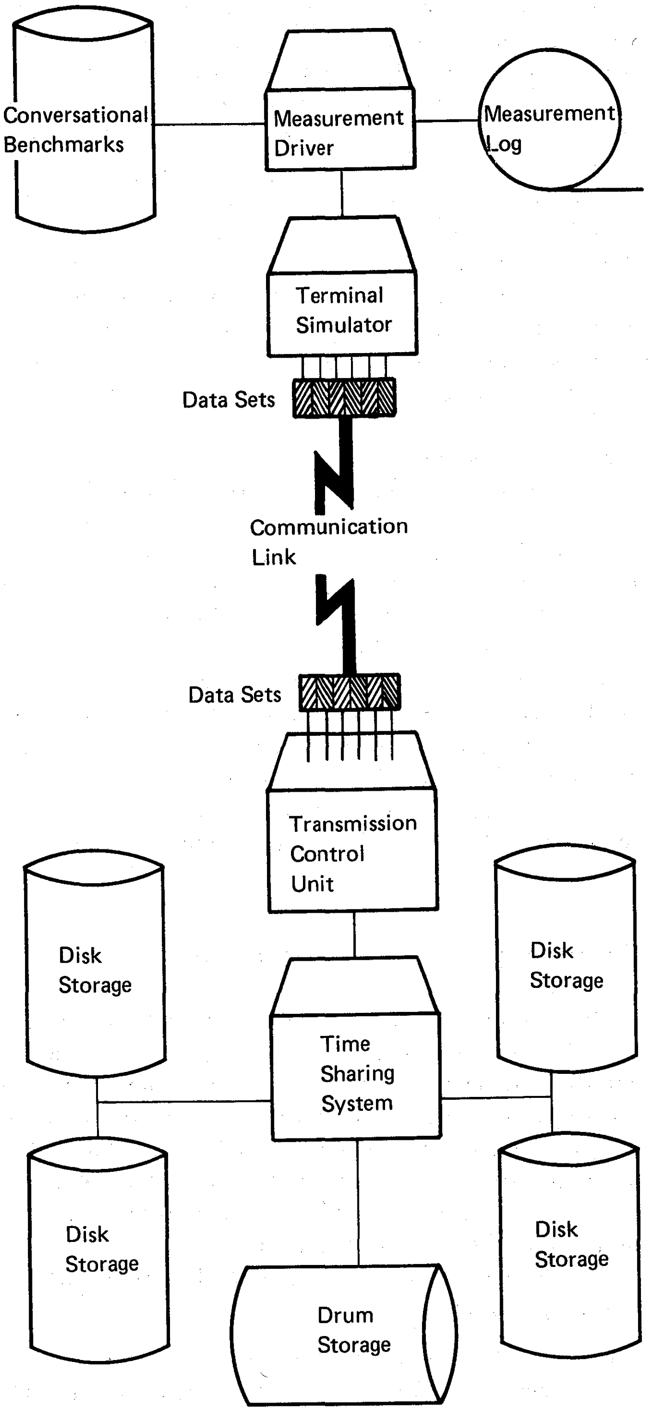

Figure 2—Schematic view of TSS/360 measurement driver

- It is capable of recovery from at least the "ordinary" kind of unexpected response, such as might result from transmission errors.
- It accepts as a parameter, a "human keying rate" for each "terminal" to adjust for the difference between machine-driven transmission rates and real keying rates.
- It records and time-stamps all transmissions in both directions on all lines, together with the control parameters and other such data, to allow data reduction and analysis at a later time.
- It is capable of terminating a run, based upon cut-off criteria specified for that run, to avoid wasteful use of machine time.
- It is data directed in its operation, so that not only the transaction to be transmitted but also the control of the individual delays between each interaction can be specified in the conversational benchmarks, in accordance with the measurement rules.

Conversational performance is measured by executing a series of driver runs varying the number of tasks for each run. A curve is then constructed which represents response time as a function of the number of tasks. Such a curve for TSS Release 6.0 is shown in Figure 3.

The measurement driver developed by IBM runs on a System/360 Model 40. Several Users of TSS have used this system to evaluate system performance on their own benchmarks. A second measurement driver has been developed by Carnegie-Mellon University. This driver has the advantage of running on the System/360 Model 67 with the version of TSS under study. Although compensation must be made for the system resources devoted to the driver function, the Carnegie-Mellon Simulator (SLIN) is compatible in script and timing characteristics with IBM's, and the output produced is comparable.

Internal recording tools

Answering the question "how well is the system performing?" from an external viewpoint provides little insight into the question "how can performance be improved?" For this task, internal recording tools must be used to obtain knowledge of the internal operation of the programming system and of how that system utilizes its hardware facilities. The basic measurement and recording tools used by TSS Development are **S**ystems **P**erformance **A**ctivity **R**ecorder (SPAR),[6] Systems **I**nternal **P**erformance **E**valuation (SIPE),[7] and **I**nstruction **T**race **M**onitor (ITM).

The System Performance Activity Recorder (SPAR) is a one-of-a-kind hardware recording system. It is hardwired to the system being monitored and does not cause any degradation in performance.* SPAR can

* Similar capability is provided by IBM's System Measurement Instrument Unit (SMI).

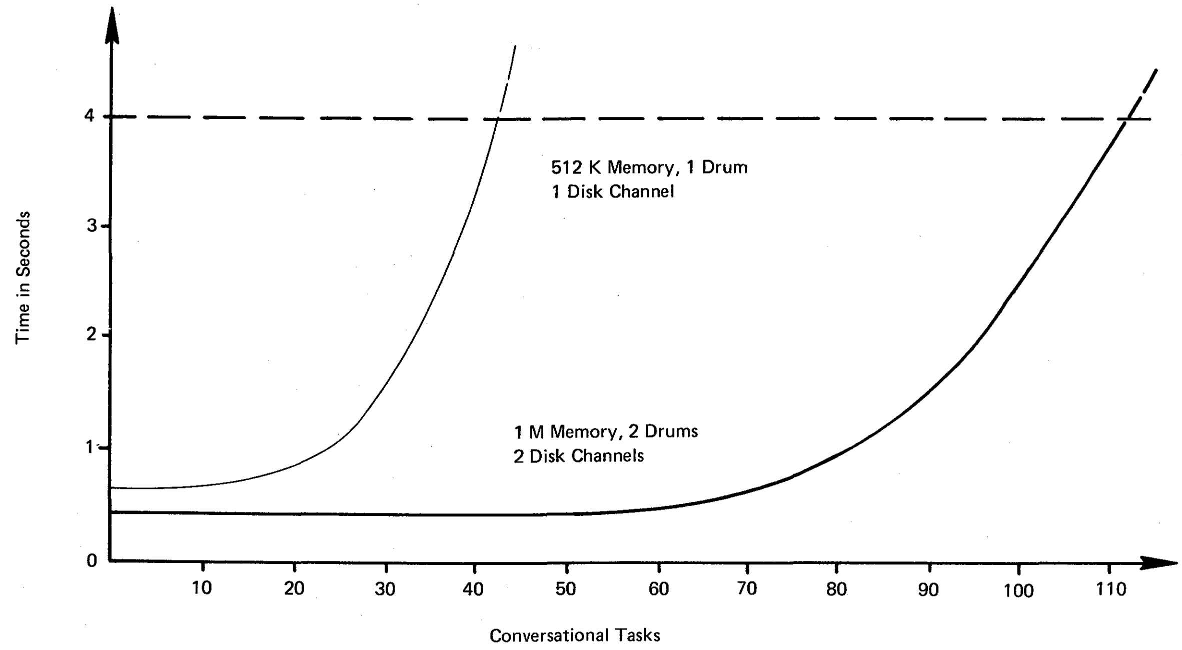

Figure 3—TSS/360 release 6.0 response to trivial commands as a function of number of tasks

provide accurate measurements of system facility utilization. The facilities monitored for TSS/360 include the CPU, processor storage, I/O channels, and direct access devices. SPAR is used to provide the following types of information:

- Time utilization of the system hardware facilities
- Counts and time relationship of indentifiable events such as:
  - Time-slice ends
  - Pages transferred between devices
  - Entries to a module

System Internal Performance Evaluation (SIPE) is a software recording system that produces a degradation of approximately five percent in system performance. Hooks in the resident supervisor cause information to be collected and written on tape. The internal actions of the supervisor are then available for later data reduction. SIPE is used to provide the following types of information:

- Time utilization of system hardware facilities
- Space utilization of processor storage, drum, disk storage
- Counts of system events
- Time relationship of important internal events in the supervisor

The Instruction Trace Monitor (ITM) is a hardware and software combination that causes every instruction executed to be written in sequence on tape. The instruction sequence in resident supervisor or virtual memory is thus available for later data reduction. It should be noted that ITM causes a relatively large degradation in system performance by increasing system running time. ITM is used to provide the following types of information:

- Time sequence of virtual memory modules executed and referenced
- Time spent in each module
- SVC's issued from each module

With these tools, and with an appropriate set of reduction programs, virtually any question dealing with the internal system performance can be answered. Access to information of this type, allows an intelligent, aggressive program of performance improvement to be carried out. The results of such a program are shown in Figure 4.

One final point should be made about internal recording tools—they have been as valuable to Users as they were to the development organization. As mentioned earlier, Users have their unique workloads, and TSS's completely flexible scheduling technique is most effectively used with detailed knowledge of how

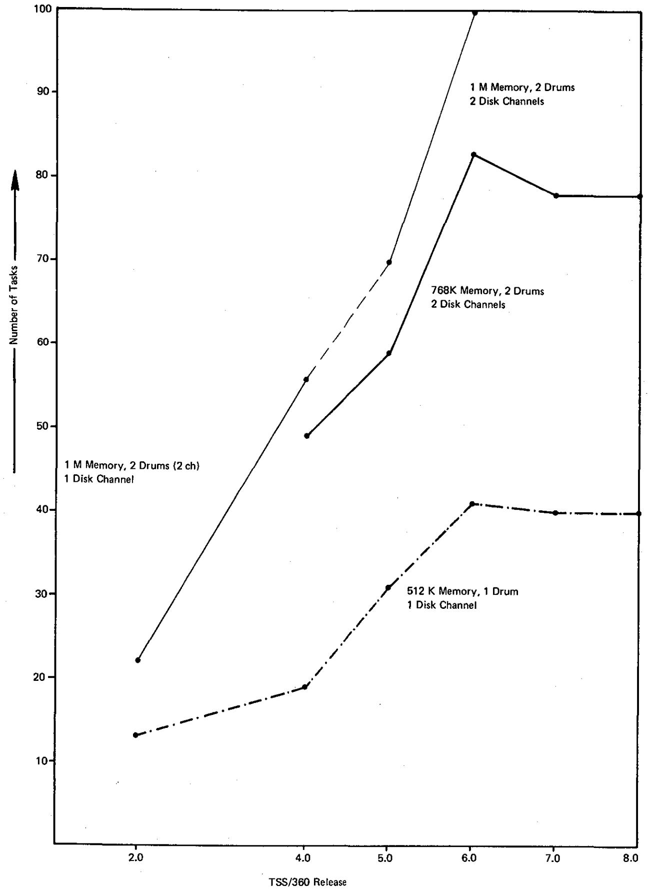

Figure 4—Number of tasks within response time objectives

the system is operating on that individual workload. SIPE is in use at most TSS installations, and several Users have developed their own measurement tools. Of particular interest in this category are DEMON—a real time software measurement monitor developed at Bell Telephone Laboratories, Naperville, Illinois and XDEMON—an expanded version developed jointly by Carnegie-Mellon University and IBM's Watson Research Center.

XDEMON is a time-driven measurement tool providing statistics on the usage of resources in TSS/360. XDEMON works as a shared facility under the system maintaining a set of public tables, whose information is updated automatically and made available to the users, who can display selected information concerning TSS usage accumulated since STARTUP time and for the period since the last update. There is a privileged user, called the 'MONITOR' who has the capability of issuing some selected commands, including the updating of the shared tables, the recording of statistics for later reduction, and the monitoring of tasks that are imposing an excessive load upon the system, with the possibility of changing priorities and scheduling parameters for such tasks.

SOFTWARE DEVELOPMENT TOOLS

"Give us the tools, and we will finish the job." Looking back over six years much can be said about the tools necessary to develop a system such as TSS, and that is the subject matter of this section.

The types of tools utilized can be broken into three general categories:

- Machinery
- Language Translator with appropriate utilities
- Debugging Aids

Little that is unique in the first two categories was done by TSS Development. As in the case of many total systems projects (hardware and software combinations) software development began well in advance of the availability of the System/360 Model 67 hardware. To overcome this situation, a Model 67 Simulator was created to operate on the standard System/360. The TSS system itself is written in Macro Assembler. Initial assemblies were accomplished on a version of the Basic Operating System/360 (BOS/360) Assembler modified to expand TSS macros. Additionally, a utility function was created which produced TSS object module format from the output of the BOS/360 Linkage Editor.

Debugging aids

The initial set of TSS debugging aids was provided by a system called Support for **T**est, **R**elease and **T**ime-Shared **O**perations (STRATO). STRATO was a major modification of BOS/360. It provided three major functions:

- An Interactive Console Command Language
- A Model 67 Simulator
- A Test Case Driver

The STRATO Command Language provided facilities to system programmers to load and unload programs, to start, stop, and dynamically interrupt programs, to display, alter and dump memory. The Test Case Driver would supply inputs to a version of TSS running under the Simulator and record outputs.

Early versions of the TSS Resident Supervisor were hand-built as BOS/360 Jobs and then run and tested under STRATO. Once the Supervisor was cycling, critical Virtual Memory Functions were integrated. Much of this work was completed on Model 40 systems before the first Model 67 was installed.

The second phase in the development of debugging aids consisted of removing the dependency upon STRATO. With the availability of the Model 67, the Simulator function was removed, and STRATO was moved to the Model 67. Integration and Test of the TSS Assembler and Dynamic Loader was the next milestone; the dependency upon the BOS Assembler was removed. STRATO itself was released with TSS, since it remained the only system programmer tool for manipulating the resident supervisor and shared virtual memory.

Figure 6—Schematic views of TSS/360 debugging aids

The Time-Sharing Support System (TS^3) which was delivered with Release 3.0 removed the final dependency upon STRATO. The Resident Support Subsystem (RSS) and Virtual Support Subsystem (VSS) are more general and easier to use than STRATO command language, but they have one significant weakness. RSS itself is dependent upon some resident supervisor facilities, e.g., interrupt stacker and supervisor core allocation. The effect is that RSS is not a valuable debugging aid for those parts of the resident supervisor.

One of the most valuable aids in TSS was a fortuitous invention—dynamic modification of the system through the use of Delta Data Sets. The system initialization program, STARTUP, builds both the resident supervisor and Initial Virtual Memory (IVM) from modules stored on the Initial Program Load (IPL) Control Volume. (This is in contrast to OS/360 in which the entire supervisor is link edited together during the System Generation procedure.) If dynamic modification of the resident supervisor or IVM is desired, the changes are prepared on a private disk and the operator informs STARTUP to search this disk for "deltas." The process is shown schematically in Figure 5. The modifications included in this manner stay in effect only until shutdown. The next time the system is started, they can be removed or altered at the user's option.

To understand the next phase in the development of debugging aids, let us summarize where we stood with Release 3.0. Figure 6 gives a schematic view of the system operation. At his individual terminal, each user had at his command a comprehensive set of debugging aids to work within his virtual memory. With the **P**rogram **C**ontrol **S**ubsystem (PCS) of Command System II, he could dynamically start, stop, or interrupt programs, and he could display or patch within them. The TSS Dynamic Loader allowed him to substitute an altered copy for any module within his virtual memory. This power and flexibility was replicated for each active user, i.e., debugging in non-shared virtual memory was time-shared.

The same was not true either for shared virtual memory or the resident supervisor. Exploratory debugging could be done with RSS and VSS but modules could only be replaced by going through STARTUP. What was desired beyond these aids were techniques to allow time-shared debugging work on both shared virtual memory and the resident supervisor.

Such a facility for modules within shared virtual memory is provided by HOOK. With HOOK a system programmer can cause a private (modified) copy of a shared virtual memory module to be used *for his task only*. Linkage to the private copy is established dynamically in response to a HK command. If testing shows an error in the module, the programmer can UNHOOK it, assemble further modifications, and HOOK that version for further testing. This activity goes on in parallel with other use of the system, including other users of HOOK. What was said previously about the value of measurement tools to users is probably more true of debugging aids. Recognizing this and realizing that users desire to modify shared as well as non-shared virtual memory, HOOK was made available to all TSS users late in 1971.

Achieving time-shared debugging for the resident supervisor is a more difficult challenge. To meet it, TSS Development looked outside its own domain to Virtual Machines. Such technology underlies the design of CP-67/CMS.[8] CP-67 creates a complete Virtual Machine for each user, so several users can work with virtual Model 67 machines and debug versions of CP. It is clearly feasible to provide Virtual Machines under TSS, and the addition of such a facility would complete a most powerful set of program debugging aids. With Virtual Machines, there would be little, if any, need for single-thread, restart-prone debugging. Figure 7 shows the debugging aids as they could be with Virtual Machine added.

MANAGING SOFTWARE DEVELOPMENT

Bringing any large system from concept to fruition is a difficult task. TSS Development had many problems, some not unlike those described recently by F. P. Brooks, Jr.[9] Probably the most valuable lesson learned in the process was how to manage a large software development project in the "steady state."

The TSS development organization was composed of three major functions: Design, Development, and Build and Test.[10] Ideally, these functions should be accomplished serially, for in this case, the same people could do the work, and no need would exist for communications mechanisms between functions. For practical purposes, the functions do overlap. The design cannot be complete or perfect. The development job must continue to correct program errors and implement new functions. Build and Test is required until the total system is stabilized. Further, the size of TSS both in concept and design precluded implementation by a small group.

Here I will insert an opinion on the merits of large versus small development groups. A small group has two distinct advantages. It is easy to manage (one

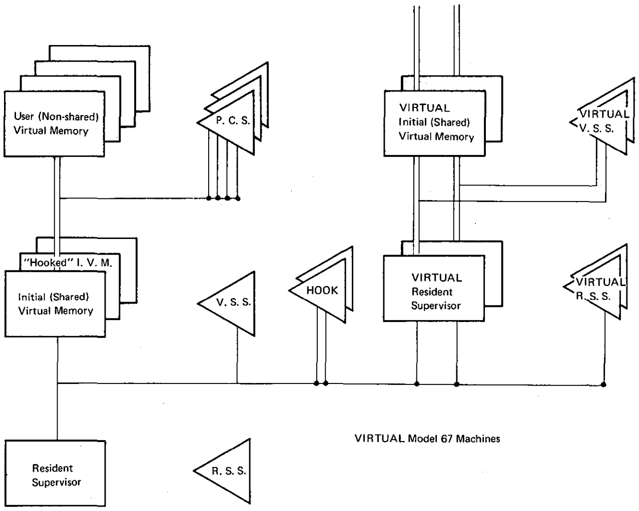

Figure 7—Schematic views of TSS/360 debugging aids

person can direct the efforts of 7-12 people); and a uniformly high standard of quality can be maintained in the selection of the group's members. Large groups suffer from the opposite problems. There is, however, nothing inherently bad about a large programming group. The critical requirement is for effective management.

The systems management technique employed in TSS was known as the New Scope Review Board (NSRB). Control was exercised in the following way. The design of TSS was considered complete at the Release 1.0 level so that the only source of new code would be fixes to identified programming errors (APAR's). Any other change that was identified was designed and presented to the NSRB for approval. The board was composed of representatives of all functional areas with the System Manager serving as chairman. Approval of a given item meant inclusion of its design into the system and hence implementation, test, and integration in a System Release. With this mechanism in place, sources of new code were restricted to error correction and approved NSRB items.

Each proposal to change TSS was described in an NSRB Technical Summary, composed of eight (8) parts.

1. Title of the item and sequence number
2. Four line abstract of the item
3. Reference to the design document
4. List of all external publications affected
5. A description of the character of the change, e.g., does the item affect performance, reliability, human factors, or function—positively or negatively—and how much?
6. List of other items upon which this item depends, i.e., other NSRB items, APAR's or hardware Engineering Changes
7. List of all parts of the system affected, e.g., what modules, DSECT's, Macros, or Data Sets are revised, added or deleted—and, if a revision, is the change small, medium, or large?
8. Signature of the designer and his manager

With all proposals for new programming before the Board and in a standard format, the system became manageable. For instance, a concentrated program to improve performance was instituted by selecting NSRB items whose character indicated large, performance plus while rejecting others. A control on resources was also possible since each NSRB item carried with it an estimate of the work required to complete it. The System Manager could either restrict the quantity of new scope to match his resource or he could add or substract resource to match the new scope desired.

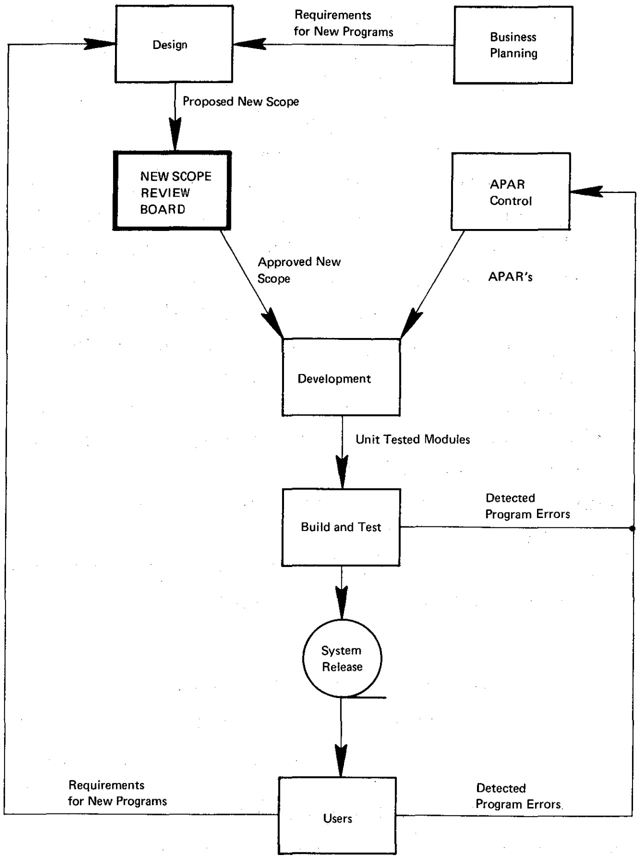

Figure 8—TSS/360 development cycle showing major functions and the flow of information

Figure 8 illustrates the interrelationships of the various functions and the flow of information between them.

The major sources for requirements input are the System Users and a Business Planning Group. Once a requirement is known, a design is prepared and the item is submitted to the NSRB. Those items which are approved form one of two sources of work for the development group.

Here a word should be said about the unique place occupied by the design function. We have mentioned that TSS had a sound basic design, and certainly this was essential to the success of its implementation. We also subscribe to the philosophy that designers must have control over the manner in which the system is developed. Yet, design must be responsive to a multitude of outside influences, including Systems Management. Several of the best features of TSS have resulted from corrections to short-sited design.

A philosophy used throughout TSS has been to deliver the best possible code. Therefore, all program errors detected by the build and test group are submitted to the same APAR Control group as User-detected errors. APAR control verifies the error, eliminates duplicates, and tracks the status of all errors. Errors to be fixed form the second source of work for Development. Here we have had success with the idea of module ownership. The development programmer responsible for a module does all the work necessary to implement NSRB changes and APAR corrections. (Having a separate maintenance group tends to remove an incentive for qualtity development work, i.e., ones bugs come back to haunt the maintenance programmer not the developer.) The resultant changed modules are the source of input to Build and Test.

The cycle is completed when Build and Test ships a system release.

The table below shows the activity of TSS Development from the three sources described.

TABLE II—System Content by Release

Release	Number of NSRB Items Included	Number of APARS Corrected	
		User-detected	Internal
1.1	9	91	—
1.2	32	136	7
2.0	49	181	72
3.0	56	190	255
4.0	42	111	201
5.0	80	321	534
5.1	32	192	471
6.0	84	226	538
6.1	—	40	85
7.0	64	174	466
8.0	50	206	442
8.1	70	574	1016
Subsequent	—	NA	NA
TOTAL	568	2442	4087

CONCLUSION

Where does TSS go from here? What is the prognosis for large-scale, interactive systems in general? The first question is easier to answer.

Work remains to be done to bring TSS up to a high degree of reliability. This task is receiving the highest priority. In addition, we are dedicated to improving the system's error recovery facilities. There is a high potential plateau for dependability and availability; we are working to reach it.

Impressive as the TSS performance story has been, we accept our users' contention that performance is not as good as it needs to be. The proper course now is to specify new benchmarks that more closely parallel the real customers workloads, and to use the powerful tools previously described to drive performance upward.

Last, but not least, is the fact that TSS users have been and are continuing to improve the system. Both the usability and the utility of TSS continue to grow.

The prognosis? I cannot provide that, but I can put forward two thoughts—both deeply rooted in the TSS/360 experience.

I have noted that where TSS/360 has succeeded people efficiency is held more important than machine efficiency, and that it is becoming broadly accepted that the availability of skilled people, not the availability of better hardware, is the limiting factor in the growth of our industry. From this I conclude that, if our industry is to thrive, systems which go to the user, which make people more efficient, in short, interactive systems like TSS must play a dominant role in the decade ahead.

Finally, I will express my belief that the single most important requirement before us is to modernize the program development process itself. Years ago, the application of computing to hardware design and manufacture removed bottlenecks which threatened to retard industry growth. Today, the bottlenecks are in software design and manufacture.

ACKNOWLEDGMENTS

The outlook of this paper is historical not journalistic. I hope that readers who have been more deeply involved in TSS development than I will agree with the sense of the paper even though they disagree with this or that detail.

I have cited some references, and I have made use of some unpublished information. For the latter, I would like to thank M. R. Babacci, D. R. Cease, K. M. Hilmar, A. Kamerman, O. R. LaMaire, and C. E. Seabold.

Finally, it must be said that TSS/360 would have been a very uninteresting subject were it not the creation of fine people. Each man and woman who worked on the system deserves a fair share of credit. My special thanks go to Bill Florac, Scott Locken, Nick Martellotto, and Ida Scott. These people more than any others gave me insight into the nature of TSS.

INTRODUCTION

In 1964, following implementation of the Compatible Time-Sharing System (CTSS)[1,2] serious planning began on the development of a new computer system specifically organized as a prototype of a computer utility. The plans and aspirations for this system, called Multics (for **Multi**plexed **I**nformation and **C**omputing **S**ervice), were described in a set of six papers presented at the 1965 Fall Joint Computer Conference.[3-8] The development of the system was undertaken as a cooperative effort involving the Bell Telephone Laboratories (from 1965 to 1969), the computer department of the General Electric Company,* and Project MAC of M.I.T.

Implicit in the 1965 papers was the expectation that there should be a later examination of the development effort. From the present vantage point, however, it is clear that a definitive examination cannot be presented in a single paper. As a result, the present paper discusses only some of the many possible topics. First we review the goals, history and current status of the Multics project. This review is followed by a brief description of the appearance of the Multics system to its various classes of users. Finally several topics are given which represent some of the research insights which have come out of the development activities. This organization has been chosen in order to emphasize those aspects of software systems having the goals of a computer utility which we feel to be of special interest. We do not attempt detailed discussion of the organization of Multics; that is the purpose of specialized technical books and papers.*

GOALS

The goals of the computer utility, although stated at length in the 1965 papers, deserve a brief review. By a computer utility it was meant that one had a community computer facility with:

(1) Convenient remote terminal access as the normal mode of system usage;
(2) A view of continuous operation analogous to that of the electric power and telephone companies;
(3) A wide range of capacity to allow growth or contraction without either system or user reorganization;
(4) An internal file system so reliable that users trust their only copy of programs and data to be stored in it;
(5) Sufficient control of access to allow selective sharing of information;
(6) The ability to structure hierarchically both the logical storage of information as well as the administration of the system;
(7) The capability of serving large and small users without inefficiency to either;
(8) The ability to support different programming environments and human interfaces within a single system;

* Subsequently acquired by Honeywell Information Systems Inc.

* For example, the essential mechanisms for much of the Multics system are given in books by Organick[9] and Watson.[10]

(9) The flexibility and generality of system organization required for evolution through successive waves of technological improvements and the inevitable growth of user expectations.

In an absolute sense the above goals are extremely difficult to achieve. Nevertheless, it is our belief that Multics, as it now exists, has made substantial progress toward achieving each of the nine goals.* Most importantly, none of these goals had to be compromised in any important way.

HISTORY OF THE DEVELOPMENT

As previously mentioned, the Multics project got under way in the Fall of 1964. The computer equipment to be used was a modified General Electric 635 which was later named the 645. The most significant changes made were in the processor addressing and access control logic where paging and segmentation were introduced. A completely new Generalized Input/Output Controller was designed and implemented to accommodate the varied needs of devices such as disks, tapes and teletypewriters without presenting an excessive interrupt burden to the processors. To handle the expected paging traffic, a 4-million word (36-bit) high-performance drum system with hardware queueing was developed. The design specifications for these items were completed by Fall 1965, and the equipment became available for software development in early 1967.

Software preparation underwent several phases. The first phase was the development and blocking out of major ideas, followed by the writing of detailed program module specifications. The resulting 3,000 typewritten pages formed the Multics System Programmers' Manual and served as the starting point for all programming. Furthermore, the software designers were expected to implement their own designs. As a general policy PL/I was used as the system programming language wherever possible to maximize lucidity and maintainability of the system.[14,15] This policy also increased the effectiveness of system programmers by allowing each one to keep more of the system within his grasp.

The second major phase of software development, well under way by early 1967, was that of module implementation and unit checkout followed by merging into larger aggregates for integrated testing. Up to then most software and hardware difficulties had been anticipated on the basis of previous experience. But what gradually became apparent as the module integration continued was that there were gross discrepancies between actual and expected performance of the various logical execution paths throughout the software. The result was that an unanticipated phase of design iterations was necessary. These design iterations did not mean that major portions of the system were scrapped without being used. On the contrary, until their replacements could be implemented, often months later, they were crucially necessary to allow the testing and evaluation of the other portions of the system. The cause of the required redesigns was rarely "bad coding" since most of the system programmers were well above average ability. Moreover the redesigns did not mean that the goals of the project were compromised. Rather three recurrent phenomena were observed: (1) typically, specifications representing less-important features were found to be introducing much of the complexity, (2) the initial choice of modularity and interfacing between modules was sometimes awkward and (3) it was rediscovered that the most important property of algorithms is simplicity rather than special mechanisms for unusual cases.*

The reason for bringing out in detail the above design iteration experience is that frequently the planning of large software projects still does not properly take the need for continuing iteration into account. And yet we believe that design iterations are a required activity on any large scale system which attempts to break new conceptual ground such that individual programmers cannot comprehend the entire system in detail. For when new ground is broken, it is usually impossible to deduce the consequent system behavior except by experimental operation. Simulation is not particularly effective when the system concepts and user behavior are new. Unfortunately, one does not understand the system well enough to simplify it correctly and thereby obtain a manageable model which requires less effort to implement than the system itself. Instead one must develop a different view:

(1) The initial program version of a module should be viewed only as the first complete specification of the module and should be subject to design review *before* being debugged or checked out.

(2) Module design and implementation should be based upon an assumption of periodic evaluation, redesign, and evolution.

In retrospect, the design iteration effect was apparent

* To the best of our knowledge, the only other attempt to comprehensively attack all of these goals simultaneously is the TSS/360 project at IBM.[11,12,13]

* "In anything at all, perfection is finally attained not when there is no longer anything to add, but when there is no longer anything to take away . . ."

—Antoine de Saint-Exupéry, *Wind, Sand and Stars* Quoted with permission of Harcourt Brace Jovanovich, Inc.

even in the development of the earlier Compatible Time-Sharing System (CTSS) when a second file system with many functional improvements turned out to have poor performance when initially installed. A hasty design iteration succeeded in rectifying the matter but the episode at the time was viewed as an anomaly perhaps due to inadequate technical review of individual programming efforts.

CURRENT STATUS

In spite of the unexpected design iteration phase, the Multics system became sufficiently effective by late 1968 to allow system programmers to use the system while still developing it. By October 1969, the system was made available for general use on a "cost-recovery" charging basis similar to that used for other major computation facilities at M.I.T. Multics is now the most widely used time-sharing system at M.I.T., supporting a user community of some 500 registered subscribers. The system is currently operated for users 22 hours per day, 7 days per week. For at least eight hours each day the system operates with two processors and three memory modules containing a total of 384k (k = 1024) 36-bit words. This configuration currently is rated at a capacity of about 55 fairly demanding users such that most trivial requests obtain response in one to five seconds. (Future design iterations are expected to increase the capacity rating.) Several times a day during the off-peak usage hours the system is dynamically reconfigured into two systems: a reduced capacity service system and an independent development system. The development system is used for testing those hardware and software changes which cannot be done under normal service operation.

The reliability of the round-the-clock system operation described above has been a matter of great concern, for in any on-line real-time system the impact of mishaps is usually far more severe than in batch processing systems. In an on-line system especially important considerations are:

(1) the time required before the system is usable again following a mishap,
(2) the extra precautions required for restoring possibly lost files, and
(3) the psychological stress of breaking the interactive dialogue with users who were counting on system availability.

Because of the importance of these considerations, careful logs are kept of all Multics "crashes" (i.e., system service disruption for all active users) at M.I.T. in order that analysis can reveal their causes. These analyses indicate currently an average of between one and two crashes per 24 hour day. These crashes have no single cause. Some are due to hardware failures, others to operator error and still others to software bugs introduced during the course of development. At the two other sites where Multics is operated, but where active system development does not take place, there have been almost no system failures traced to software.

TABLE I—A comparison of the system development and use periods of CTSS and Multics. The Multics development period is not significantly longer than that for CTSS despite the development of about 10 times as much code for Multics as for CTSS and a geographically distributed staff. Although reasons for this similarity in time span include the use of a higher-level programming language and a somewhat larger staff, the use of CTSS as a develoрment tool for Multics was of pivitol importance.

System	*Development Only*	*Development + Use*	*Use Only*
CTSS	1960-1963	1963-1965	1965-present
Multics	1964-1969	1969-present	

Currently the Multics system, including compilers, commands, and subroutine libraries, consists of about 1500 modules, averaging roughly 200 lines of PL/I apiece. These compile to produce some 1,000,000 words of procedure code. Another measure of the system is the size of the resident supervisor which is about 30k words of procedure and, for a 55 user load, about 36k words of data and buffer areas.

Because the system is so large, the most powerful maintenance tool available was chosen—the system itself. With all of the system modules stored on-line, it is easy to manipulate the many components of different versions of the system. Thus it has been possible to maintain steadily for the last year or so a pace of installing 5 or 10 new or modified system modules a day. Some three-quarters of these changes can be installed while the system is in operation. The remainder, pertaining to the central supervisor, are installed in batches once or twice a week. This on-line maintenance capability has proven indispensable to the rapid development and maintenance of Multics since it permits constant upgrading of the user interface without interrupting the service. We are just beginning to see instances of user-written applications which require this same capability so that the application users need not be interrupted while the software they are using is being modified.

The software effort which has been spent on Multics is difficult to est:mate. Approximately 150 man-years were applied directly to design and system programming during the "development-only" period of Table I.

Since then we estimate that another 50 man-years have been devoted to improving and extending the system. But the actual cost of a single successful system is misleading, for if one starts afresh to build a similar system, one must compensate for the non-zero probability of failure.

THE APPEARANCE OF MULTICS TO ITS USERS

Having reviewed the background of the project, we may now ask who are the users of the Multics system and what do the facilities that Multics provides mean to these users. Before answering, it is worth describing the generic user as "viewed" by Multics. Although from the system's point of view all users have the same general characteristics and interface with it uniformly, no single human interface represents the Multics machine. That machine is determined by each user's initial procedure coupled with those functions accessible to him. Thus there exists the potential to present each Multics user with a unique external interface.

However, Multics does provide a native internal program environment consisting of a stack-oriented, pure-procedure, collection of PL/I procedures imbedded in a segmented virtual memory containing all procedures and data stored on-line. The extent to which some, all, or none of this internal environment is visible to the various users is an administrative choice.

The implications of these two views—both the external interface and the internal programming environment—are discussed in terms of the following categories of users:

- System programmers and user application programmers responsible for writing system and user software.
- Administrative personnel responsible for the management of system resources and privileges.
- The ultimate users of applications systems.
- Operations and hardware maintenance personnel responsible, respectively, for running the machine room and maintaining the hardware.

Multics as viewed by system and subsystem programmers

The machine presented to both the Multics system programmer and the application system programmer is the one with which we have the most experience; it is the raw material from which one constructs other environments. It is worth reemphasizing that the only differentiation between Multics system programmers and user programmers is embodied in the access control mechanism which determines what on-line information can be referenced; therefore, what are apparently two groups of users can be discussed as one.

Major interfaces presented to programmers on the Multics system can be classified as the program preparation and documentation facilities and the program execution and debugging environment. They will be touched upon briefly, in the order used for program preparation.

Program preparation and documentation

The facilities for program preparation on Multics are typical of those found on other time-sharing systems, with some shifts in emphasis (see the Appendix). For example, programmers consider the file system sufficiently invulnerable to physical loss that it is used casually and routinely to save all information. Thus, the punched card has vanished from the work routine of Multics programmers and access to one's programs and the ability to work on them are provided by the closest terminal.

As another example, the full ASCII character set is employed in preparing programs, data, and documentation, thereby eliminating the need for multiple text editors, several varieties of text formatting and comparison programs, and multiple facilities for printing information both on-line and off-line. This generalization of user interfaces facilitates the learning and subsequent use of the system by reducing the number of conventions which must be mastered.

Finally, because the PL/I compiler is a large set of programs, considerable attention was given to shielding the user from the size of the compiler and to aiding him in mastering the complexities of the language. As in many other time-sharing systems, the compiler is invoked by issuing a simple command line from a terminal exactly as for the less ambitious commands. No knowledge is required of the user regarding the various phases of compilation, temporary files required, and optional capabilities for the specialist; explanatory "sermons" diagnosing syntactic errors are delivered to the terminal to effect a self-teaching session during each compilation. To the programmer, the PL/I compiler is just another command.

Program execution environment

Another set of interfaces is embodied in the implementation environment seen by PL/I programmers. This environment consists of a directly addressable virtual memory containing the entire hierarchy of on-line information, a dynamic linking facility which searches this hierarchy to bind procedure references, a device-independent input/output[16] system,* and program debugging and metering facilities. These facilities enjoy a symbiotic relationship with the PL/I procedure environment used both to implement them and to implement user facilities co-existing with them. Of major significance is that the natural internal environment provided and required by the system is exactly that environment expected by PL/I procedures. For example, PL/I pointer variables, call and return statements, conditions, and static and automatic storage all correspond directly to mechanisms provided in the internal environment. Consequently, the system supports PL/I code as a matter of course.

The main effect of the combination of these features is to permit the implementer to spend his time concentrating on the logic of his problem; for the most part he is freed from the usual mechanical problems of storage management and overlays, input/output device quirks, and machine-dependent features.

Some implementation experience

The Multics team began to be much more productive once the Multics system became useful for software development. A few cases are worth citing to illustrate the effectiveness of the implementation environment. A good example is the current PL/I compiler, which is the third one to be implemented for the project, and which consists of some 250 procedures and about 125k words of object code. Four people implemented this compiler in two years, from start to first general use. The first version of the Multics program debugging system, composed of over 3,000 lines of source code, was usable after one person spent some six months of nights and weekends "bootlegging" its implementation. As a last example, a facility consisting of 50 procedures with a total of nearly 4,000 PL/I statements permitting execution of Honeywell 635 programs under Multics became operational after one person spent eight months learning about the GCOS operating system for the 635, PL/I, and Multics, and then implemented the environment. In each of these examples the implementation was accomplished from remote terminals using PL/I.

Multics users have discovered that it is possible to get their programs running very quickly in this environment. They frequently prepare "rough drafts" of programs, execute them, and then improve their overall design and operating strategy using the results of experience obtained during actual operation. As an example, again drawn from the implementation of Multics, the early designs and implementations of the programs supporting the virtual memory[18] made overoptimistic use of variable-sized storage allocation techniques. The result was a functionally correct but inadequately performing set of programs. Nevertheless, these modules were used as the foundation for subsequent work for many months. When they were finally replaced with modules using simplified fixed-size storage techniques, performance improvements of over an order of magnitude were realized. This technique emphasizes two points: first, it is frequently possible to provide a practical, usable facility containing temporary versions of programs; second, often the insight required to significantly improve the behavior of a program comes only after it is studied in operation. As implied in the earlier discussion of design iteration, our experience has been that structural and strategic changes rather than "polishing" (or recoding in assembly language) produce the most significant performance improvements.

In general, we have noticed a significant "amplifier" or "leverage" effect with the use of an effective on-line environment as a system programming facility. Major implementation projects on the Multics system seldom involve more than a few programmers, thereby easing the management and communications problems usually entailed by complex system implementations. As would be expected, the amplification effect is most apparent with the best project personnel.

Administration of Multics facilities and resources

The problem of managing the capabilities of a computer utility with geographically dispersed subscribers leads to a requirement of decentralized administration. At the apex of an administrative pyramid resides a system administrator with the ability to register new users, confer resource quotas, and generate periodic bills for services rendered. The system administrator deals with user groups called projects. Each group can in turn designate a project administrator who is delegated the authority to manage a budget of system resources on behalf of the project. The project administrator is then free to deal directly with project members without further intervention from the system administrator, thereby greatly reducing the bottlenecks inherent in a completely centralized administrative structure.

Environment shaping

In addition to having immediate control of such resources as secondary storage, port access, and rate of processor usage, the project administrator is also able to define or shape the environment seen by the members

* The Michigan Terminal System[17] has a similar device-independent input/output system.

of his project when they log into the system. He does this by defining those procedures that can be accessed by members of his project and by specifying the initial procedure executed by each member of his project when he logs in. This environment shaping facility has led to the notion of a private project subsystem on Multics. It combines the administrative and programming facilities of Multics so that a project administrator and a few project implementers can build, maintain, and evolve environments entirely on their own. Thus, some subsystems bear no internal resemblance to the standard Multics procedure environment.

For example, the Dartmouth BASIC[19] compiler executes in a closed subsystem implemented by an M.I.T. student group for use by undergraduate students. The compiler, its object code, and all support routines execute in a simulation of the native environment provided at Dartmouth. The users of this subsystem need little, if any, knowledge of Multics and are able to behave as if logged into the Dartmouth system proper. Other examples of controlled environment subsystems include one to permit many programs which normally run under the GCOS operating system to also run unmodified in Multics. Finally, an APL[20] subsystem allows the user to behave for the most part as if he were logged into an APL machine. The significance of these subsystems is that their implementers did not need to interact with the system administrator or to modify already existing Multics capabilities. The administrative facilities permit each such subsystem to be offered by its supporters as a private service with its own group of users, each effectively having its own private computer system.

Other Multics users

Finally, we observe that the roles of the application user, the system operators and the hardware maintainers as seen by the system are simply those of ordinary Multics users with specialized access to the on-line procedures and data. The effect of this uniformity of treatment is to reduce greatly the maintenance burden of the system control software. One example, of great practical importance, has been the ease with which system performance measurement tools have been prepared for use by the operating staff.

INSIGHTS

So far, we have discussed the status and appearance of the Multics system. A further question is what has been learned in the construction of Multics which is of use to the designers of other systems. Having a bright idea which clearly solves a problem is not sufficient cause to claim a contribution if the idea is to be part of a complex system. In order to establish the real feasibility of an idea, all of its implications and consequences must be followed out. Much of the work on Multics since 1965 has involved following out implications and consequences of the many ideas then proposed for the prototype computer utility. That following out is an essential part of proof of ideas is attested by the difficulties which have been encountered in other engineering efforts such as the development of nuclear fusion power plants and the electric automobile. Not all proposals work out; for example, extended attempts to engineer an atomic powered airplane suggest infeasibility.

Perhaps Multics' most significant single contribution to the state of the art of computer system construction is the demonstration of a large set of fully implemented ideas in a working system. Further, most of these ideas have been integrated without straining the overall design; most additional proposals would not topple the structure. Ideas such as virtual memory access to online storage, parallel process organization, routine but controlled information sharing, dynamic linking of procedures, and high-level language implementa-

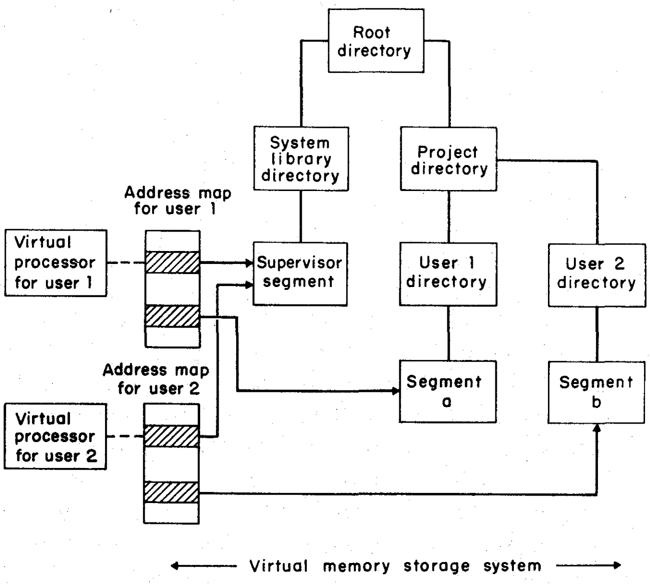

Figure 1—The entire storage hierarchy may be mapped into individual user process address spaces (see arrows) as if contained in primary memory. Illustrated are the sharing of a supervisor segment by user 1 and user 2 and private access to segment a and segment b. The necessary primary storage is simulated by a demand paging technique which moves information between the real primary memory and secondary storage

tion have proven remarkably compatible and complementary.

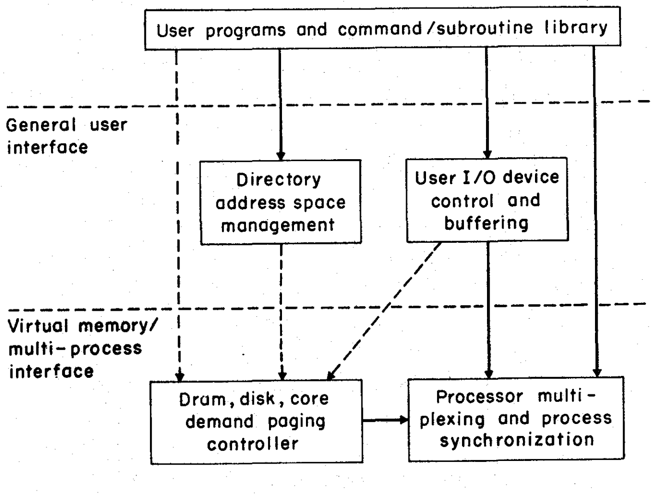
To illustrate some of the areas of progress in understanding of system organization and construction which have been achieved in Multics, we consider here the following five topics:

1. Modular division of responsibility
2. Dynamic reconfiguration
3. Automatically managed multilevel memory
4. Protection of programs and data
5. System programming language

Modular division of responsibility

Early in the design of Multics a decision had to be made whether or not to treat the segmented virtual memory as a separately usable "feature," independent of a traditionally organized read/write type file system. The alternative, to use the segmented virtual memory as the file system itself, providing the illusion of direct "in-core" access to all on-line storage, was certainly the less conservative approach (see Figure 1). The second approach, which was the one chosen, led to a strong test of the ability of a computing system to support an apparent one-level memory for an arbitrarily large information base. It is interesting that the resulting almost total decoupling between physical storage allocation and data movement on the one hand and directory structure, naming, and file organization on the other led to a remarkably simple and functionally modular structure for that part of the system[18] (see Figure 2).

Another area of Multics in which a high degree of functional modularity was achieved was in the area of scheduling, multiprogramming, and processor management. Because harnessing of multiple processors was an objective from the beginning, a careful and methodical approach to multiplexing processors, handling interrupts, and providing interprocess synchronizing primitives was developed. The resulting design, known as the Multics traffic controller, absorbed into a single, simple module a set of responsibilities often diffused among a scheduling algorithm, the input/output controlling system, the on-line file management system, and special purpose inter-user communication mechanisms.[21]



User programs and command/subroutine library
General user interface
Directory address space management
User I/O device control and buffering
Virtual memory/ multi-process interface
Drum, disk, core demand paging controller
Processor multiplexing and process synchronization

Figure 2—Major lines of modular division in Multics. Solid lines indicate calls for services. Dotted lines indicate implicit use of the virtual memory

Finally, with processor management and on-line storage management uncoupled into well-isolated modules, the Multics input/output system was left with the similarly isolatable function of managing streams of data flowing from and to source and sink type devices.[16] Thus, this section of the system concentrates only on switching of the streams, allocation of data buffering areas, and device control strategies.

Each of the divisions of labor described above represents an interesting result primarily because it is so difficult to discover appropriate divisions of complex systems.* Establishing that a certain proposed division results in simplicity, creates an uncluttered interface, and does not interfere with performance, is generally cause for a minor celebration.

Dynamic reconfiguration

If the computer utility is ever to become as much a reality as the electric power utility or the telephone communication service, its continued operation must not be dependent upon any single physical component, since individual components will eventually require maintenance. This observation leads an electric power utility to provide procedures whereby an idle generator may be dynamically added to the utility's generating capacity, while another is removed for maintenance, all without any disruption of service to customers. A similar scenario has long been proposed for multiprocessor, multimemory computer systems, in which one would dynamically switch processsors and memory boxes in and out of the operating configuration as needed. Unfortunately, though there have been demonstrated a few "special purpose" designs,* it has not been apparent how to provide for such operations in a general purpose system. A recent thesis[24] proposed a general model for the dynamic binding and unbinding of computation and memory structures to and from ongoing computa-

* See Dijkstra[22] for a further discussion of this point.

* An outstanding example is the American Airlines SABRE system.[23]

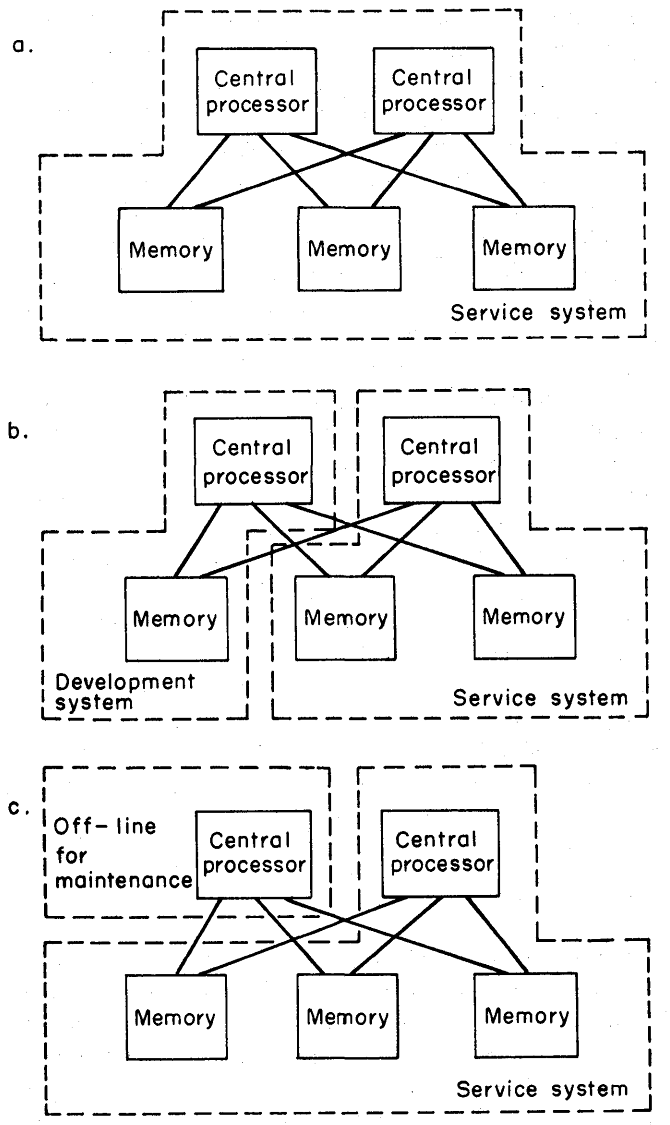


Figure 3—Dynamic reconfiguration permits switching among the three typical operating configurations shown here, without currently logged-in users being aware that a change has taken place

tions. Using this model as a basis, the thesis also proposed a specific implementation for a typical multiprocessor, multimemory computing system. One of the results of this work was the addition to the operating Multics system of the capability of dynamically adding and removing central processors and memory modules as in Figure 3. The usefulness of the idea may be gauged by observing that at M.I.T. five to ten such reconfigurations are performed in a typical 24-hour operating day. Most of the reconfigurations are used to provide a secondary system for Multics development.

Automatically managed multilevel memory

By now it has become accepted lore in the computer system field that the use of automatic management algorithms for memory systems constructed of several levels with different access times can provide a significant reduction of user programming effort. Examples of such automatic management strategies include the buffer memories of the IBM system 370 models 155, 165, and 195[25] and the demand paging virtual memories of Multics, IBM's CP-67[26] and the Michigan Terminal System.[17] Unfortunately, behind the mask of acceptance hides a worrisome lack of knowledge about how to engineer a multilevel memory system with appropriate strategy algorithms which are matched to the load and hardware characteristics. One of the goals of the Multics project has been to instrument and experiment with the multilevel memory system of Multics, in order to learn better how to predict in advance the performance of proposed new automatically managed multilevel memory systems. Several specific aspects of this goal have been explored:

- A strategy to treat core memory, drum, and disk as a three-level system has been proposed, including a "least-recently-used" algorithm for moving information from drum to disk. Such an algorithm has been used for some time to determine which pages should be removed from core memory.[27] The dynamics of interaction among two such algorithms operating at different levels are weakly understood, and some experimental work should provide much insight. The proposed strategy will be implemented, and then compared with the simpler present strategy which never moves things from drum to disk, but instead makes educated "guesses" as to which device is most appropriate for the permanent residence of a given page. If the automatic algorithm is at least as good as the older, static one, it would represent an improvement in overall design by itself, since it would automatically track changes in user behavior, while the static algorithm requires attention to the validity of its guesses.
- A scheme to permit experimentation with predictive paging algorithms was devised. The scheme provides for each process a list of pages to be preloaded whenever the process is run, and a second list to be immediately purged whenever the process stops. The updating of these lists is controlled by a decision table exercised every time the process stops running. Since every page of the Multics virtual memory is potentially shared, the decision table represents a set of heuristics designed to separate out those which are probably not being shared at the moment.

- A series of measurements was made to establish the effectiveness of a small hardware associative memory used to hold recently accessed page descriptors. These measurements established a profile of hit ratio (probability of finding a page descriptor in the associative memory) versus associative memory size which should be useful to the designers of virtual memory systems.[28]
- A set of models, both analytic and simulation, was constructed to try to understand program behavior in a virtual memory. So far, two results have been obtained. One is the finding that a single program characteristic (the mean execution time before encountering a "missing" page in the virtual memory as a function of memory size) suffices to provide a quite accurate prediction of paging and idle overheads. The second is direct calculation of the distribution of response times under multiprogramming. Having available the entire response time distribution, rather than just averages, permits estimation of the variance and 90-percentile points of the distribution, which may be more meaningful than just the average. A doctoral thesis is in progress on this topic.

Although the immediate effect of each of these investigations is to improve the understanding or performance of the current version of Multics, the long-range payoff in methodical engineering using better-understood memory structures is also evident.

Protection of programs and data

A long-standing objective of the public computer utility has been to provide facilities for the protection of executing programs from one another, so that users may with confidence place appropriate control on the release of their private information. In 1967, a mechanism was proposed[29] and implemented in software which generalized the usual supervisor-user protection relationship. This mechanism, named "rings of protection," provides user-written subsystems with the same protection from other users that the supervisor has, yet does not require that the user-written subsystem be incorporated into the supervisor. Recently, this approach was brought under intense review, with two results:

- A hardware architecture which implements the mechanism was proposed.[30] One of the chief features of the proposed architecture is that subroutine calls from one protection ring to another use exactly the same mechanisms as do subroutine calls among procedures within a protection area. The proposal appears sufficiently promising that it is included in the specifications for the next genera tion of hardware to be used for Multics.
- As an experiment in the feasibility of a multilayered supervisor, several supervisor procedures which required protection, but not all supervisor privileges, were moved into a ring of protection intermediate between the users and the main supervisor. The success of this experiment established that such layering is a practical way to reduce the quantity of supervisor code which must be given all privileges.

Both of these results are viewed as steps toward first, a more complete exploitation and understanding of rings of protection, and later, a less constrained organization of the type suggested by Evans and LeClerc[31] and by Lampson.[32] But more importantly, rings of protection appear applicable to any computer system using a segmented virtual memory. Two doctoral theses are under way in this area.

System programming language

Another technique of system engineering methodology being explored within the Multics project is that of higher level programming language for system implementation. The initial step in this direction (which proved to be a very big step) was the choice of the PL/I language for the implementation of Multics. By now, Multics offers an extensive case study in the viability of this strategy. Not only has the cost of using a higher level language been acceptable, but increased maintainability of the software has permitted more rapid evolution of the system in response to development ideas as well as user needs. Three specific aspects of this experience have now been completed:

- The transition from an early PL/I subset compiler[14] to a newer compiler which handles almost the entire language was completed. This transition was carried out with performance improvement in practically every module converted in spite of the larger language involved. The significance of the transition is the demonstration that it is not necessary to narrow one's sights to a "simple" subset language for system programming. If the language is thoroughly understood, even a language as complex as the full PL/I can be effectively used. As a result, the same language and compiler provided for users can also be used for system implementation, thereby minimizing maintenance, confusion, and specialization.
- Notwithstanding the observation just made, the time required to implement a full PL/I compiler is still too great for many situations in which the

compiler implementation cannot be started far enough in advance of system coding. For this reason, there is considerable interest in defining a smaller language which is easily compilable, yet retains the features most important for system implementation. On the basis of the experience of programming Multics in a subset of PL/I, such a language was defined but not implemented, since it was not needed.[33]

- A census of Multics system modules reveals how much of the system was actually coded in PL/I, and reasons for use of other languages. Roughly, of the 1500 system modules, about 250 were written in machine language. Most of the machine language modules represent data bases or small subroutines which execute a single privileged instruction. (No attempt was made to provide either a data base compiler or PL/I built-in functions for specialized hardware needs.) Significantly, only a half dozen areas (primarily in the traffic controller, the central page fault path, and interrupt handlers) which were originally written in PL/I have been recoded in machine language for reasons of squeezing out the utmost in performance. Several programs, originally in machine language, have been recoded in PL/I to increase their maintainability.

As with the earlier topics, the implications of this work with PL/I should be felt far beyond the Multics system. Most implementers, when faced with the economic uncertainties of a higher-level language, have chosen machine language for their central operating systems. The experience of PL/I in Multics when added to the expanding collection of experience elsewhere[34] should help reduce the uncertainty.

In a research project as large, long, and complex as Multics, any paper such as this must necessarily omit many equally significant ideas, and touch only a few which may happen to have wide current interest. It is the purpose of individual and detailed technical papers to explain these and other ideas more fully. The bibliography found in Reference 35 contains over twenty such technical papers.

Immediate future plans

The Multics software is continuing to evolve in response to user needs and improved understanding of its organization. In 1972 a new hardware base for Multics will be installed by the Information Processing Center at M.I.T. for use by the M.I.T. computing community. This program compatible hardware base contains small but significant architectural extensions to the current hardware. The circuit technology used will be that of the Honeywell 6080 computer. The substantial changes include:

(1) replacement of the high-performance paging drum initially with bulk core and, when available, LSI memory, and
(2) implementation of rings of protection as part of the paging and segmentation hardware.

Wherever possible the strategy of using off-the-shelf standard equipment rather than specially engineered units for Multics has been followed. This strategy is intended to simplify maintenance.

CONCLUSIONS

There are many conclusions which could possibly be drawn from the experience of the Multics project. Of these, we consider four to be major and worthy of note. First, we feel it is clear that it is possible to achieve the goals of a prototype computer utility. The current implementation of Multics provides a measure of the mechanisms required. Moreover, the specific implementation of the system, because it has been written in PL/I, forms a model for other system designers to draw upon when constructing similar systems.

Second, the question of whether or not the specific software features and mechanisms which were postulated for effective computer utility operation are desirable has now been tested with specific user experience. Although the specific mechanisms implemented subsequently may be superseded by better ones, it is certainly clear that the improvement of the user environment which was wanted has been achieved.

Third, systems of the computer utility class must evolve indefinitely since the cost of starting over is usually prohibitive and the many-year lead time required may be equally unacceptable. The requirement of evolvability places stringent demands on design, maintainability, and implementation techniques.

Fourth and finally, the very act of creating a system which solves many of the problems posed in 1965 has opened up many new directions of research and development. It would appear almost a certainty that increased user aspirations will continue to require intensive work in the areas of computer system principles and techniques.

In closing, perhaps we should take note that in the seven years since Multics was proposed, a great many other systems have also been proposed and constructed;

many of these have developed similar ideas.* In most cases, their designers have developed effective implementations which are directed to a different interpretation of the goals, or to a smaller set of goals than those required for the complete computer utility. This diversity is valuable, and probably necessary, to accomplish a thorough exploration of many individually complex ideas, and thereby to meet a future which holds increasing demand for systems which embrace the totality of computer utility requirements.

ACKNOWLEDGMENT

It is impossible to acknowledge accurately the contributions of all the individuals or even the several organizations which have given various forms of support to the development of Multics over the past seven years. As would be expected of any multi-organization project spanning several years there has been a turnover in the personnel involved. As the individual contributors now number in the hundreds, proper recognition cannot be given here. Instead, since the development of significant features and designs of Multics has occurred in specific areas and disciplines such as input/output, virtual memory design, languages, and resource multiplexing, a more accurate delineation of achievements should be made in specialized papers. So in the end we must defer to the authors of individual papers, past and future, to acknowledge the efforts of some of the many contributors who have made the evolution of Multics possible.

APPENDIX: A CHECKLIST OF MULTICS FEATURES

Following is a checklist of currently available features and facilities of Multics. Although many of the features are described in cryptic and untranslated local jargon, one can at least obtain a feel for the range of facilities now provided. Further information on most of these features may be found in the Multics Programmers' Manual.[35]

Interactive Time-Sharing Facilities
- file editors
- file manipulation (rename/move/delete)
- personal command abbreviations
- recursive command language
- source language debugging with breakpoints
- subroutine call tracer
- can stop any running command or program

Programming Languages
- PL/I
- FORTRAN
- BASIC*
- APL
- LISP
- BCPL
- ALM (assembly language/Multics)

Information Storage System
- configuration independent
- accessed through virtual memory (segments)
- access control lists by user and project
- links to segments of other users
- hierarchical directory (catalog) arrangement
- public library facilities
- sharing at all levels
- multiple segment names (synonyms)
- separate control of read, write, and execute

Programming Environment
- segmented virtual memory
- dynamic linking of procedures and data, or prelinking
- interprocess communication
- independent of configuration
- uniform error handling mechanism
- user definable protection rings
- microsecond calendar clock with interrupt
- program interrupt signal from console

Input and Output
- standard typewriter interface for device independence
- ASCII character set used throughout
- input characters converted to canonical form
- erase and kill editing on typed input

- I/O streams switchable during execution
- magnetic tape, printer, card punch, card reader
- typewriter terminals: IBM 2741, 1050
  Teletype 37, 33, 35
  Dura, Datel, Execuport,
  Terminet-300
- graphic support library (devices: ARDS, IMLAC, DEC 338)
- ARPA network
- interfaces at three levels:
  - formatted data conversion
  - bit stream control
  - full device control

Management Facilities
- passwords required for login
- project may interpose authentication procedure
- decentralized projects
- accounting, billing, and quotas
- on-line probing and account adjustment
- operator or system initiated logout of users
- unlisted and anonymous users
- limited service system
- dynamic reconfiguration of memories and processors
- system performance metering for parameter adjustment
- project-imposed starting procedure

Communication Facilities
- interuser mail
- help command; help files
- message of the day
- on-line error reporting and consultation service
- on-line user graffiti board
- operations message broadcast to logged-in users

Absentee Facilities
- priority/defer queues for printer, card punch
- queued translator facility
- general absentee job facility

Reliability Measures
- weekly file copies onto tape
- daily disk/drum copy onto tape
- incremental file copies onto tape, ½ hour behind use
- salvager to clean up files after system crash
- emergency shutdown entry to system

Maintenance Features
- on-line library change, no disruption of current users
- entire system source on-line, maintenance tools
- system checkout on small hardware configuration
- on-line performance monitoring of
  - multiprogramming
  - paging traffic
  - drum/disk usage
  - typewriter traffic
- user performance feedback:
  - cpu time and paging load on each command
  - page trace always operating
  - subroutine call counters

Private Project Subsystems
- project providable command interface
- Dartmouth environment*
- student environment

Miscellaneous Facilities
- desk calculators
- sort command
- memorandum formatting and typing subsystem
- user-provided list of programs to be automatically executed when user logs in
- GCOS environment

* The BASIC system and the Dartmouth environment were developed at Dartmouth College. They are used at M.I.T. by permission of Dartmouth College.

Organization and features of the Michigan terminal system

by MICHAEL T. ALEXANDER

University of Michigan
Ann Arbor, Michigan

INTRODUCTION

This paper will explore some aspects of the Michigan Terminal System (MTS) developed at the University of Michigan. MTS is the operating system used on the IBM 360/67 at the University of Michigan Computing Center, as well as at several other installations. It supports a large variety of uses ranging from very small student-type jobs to large jobs requiring several million bytes of storage and hours of processor time. Currently at the University of Michigan there are about 13,000 users running as many as 86,000 jobs per month.

MTS was developed almost entirely by the staff of the University of Michigan Computing Center, although some components were developed by other installations using it, and many compilers and subsystems were borrowed from other systems. Fewer man-years have been spent developing and maintaining MTS than most comparable systems (about 50 man-years total for both development and maintenance), and some of the organizational aspects that allow this will be explored here. A few of the more unusual aspects of the system will be considered, along with an attempt to evaluate their effectiveness.

HISTORY

It will be useful to consider the history of the development of MTS in order to provide the proper perspective for later discussions. The course of its development was rather unusual and influenced some of the features to be mentioned later.

In 1965 the University of Michigan Computing Center made plans to install an IBM 360/67[4] in late 1966. It was planned to use the standard IBM operating system (Time-Sharing System/360[6]) for this machine rather than to develop an operating system for it. Since the model 67 includes special features to simplify time-sharing, a special operating system was required for it. The Computing Center acquired an IBM 360/50 for use both in performing peripheral operations for the IBM 7090 then in use and in checking out 360/67 programs to be used with TSS. In May 1966 development of a very small operating system for this machine was initiated by two members of the Computing Center staff. This system had very modest goals: to allow one or two Computing Center staff members to run certain 360 programs, and to handle at the same time the peripheral operations for the 7090. These goals were reached within a few months, and the system was in use by Computing Center staff by the first part of 1966.

When the 360/67 was delivered in early 1967 the plan was still to run TSS as soon as it reached an acceptable level of reliability. In the meantime, the 360/50 software system was moved over to the 360/67, but it still did not use any of the special hardware on the 360/67.

At this point MTS was a rather primitive system which would allow the simultaneous use of the machine by one or two batch jobs and three or four conversational users. The facilities available included most of the essentials but very few frills, and the system was used almost exclusively by Computing Center staff members. However, from the very beginning the system had been designed to be open ended, so that more facilities could be easily added.

By the spring of 1967, it was decided to make MTS available to a limited number of persons not on the Computing Center staff who were most interested in conversational computing. This required a number of changes, the most important of which was the addition of accounting procedures to charge for machine usage, and the decision also provided an impetus to further augment the system. Although the system was far from complete at this time, it had already been in daily use for several months.

The first of several major changes in the system

TABLE I—Summary of MTS Usage for One Year

	Number Jobs	CPU Time (Hours)	Lines Printed	Pages Printed	Cards Punched	Cards Read
DEC. 1970	68040	400	28520413	835019	387423	6785972
JAN. 1971	48909	304	20564780	597105	274767	4050356
FEB. 1971	64734	388	25029078	740910	259886	5323226
MAR. 1971	81894	481	32936379	982605	318247	7623300
APR. 1971	57558	356	24968176	754722	455143	6100019
MAY 1971	35141	232	16487547	449463	216799	3741426

JULY 1971	57927	415	27112847	765186	422543	4970674
AUG. 1971	55996	379	25756018	734292	453018	4743966
SEP. 1971	56302	301	20030212	567504	325344	3659216
OCT. 1971	86107	380	27795205	830841	404359	5773416
NOV. 1971	90243	394	29264425	879604	381753	6268137

occured in November 1967 when it was modified to use both the special relocation hardware of the 360/67 and the paging drum. This required replacing one component and adding two components to the system, and was done without any changes to user programs or procedures. In fact it was so transparent to users of the system that for several weeks after it was put into use people were still asking when it would be installed. More importantly, the change was transparent to the rest of the system, most of which was not even reassembled. The most notable external sign of the change was a sudden eightfold jump in system capacity.

Other changes of similar magnitude have been made since then with equal success. For example, the supervisor was changed in September 1968 to support hardware configurations with more than one central processing unit. This change was made with modifications to only two components. Another example was the addition of remote job entry to the batch monitor, which was done without significant changes to other modules.

The resulting system is capable of serving the needs of a large and sophisticated user population. On a typical day there will be about 70 people using the system from terminals with any remaining processor time being used by up to 5 or 6 batch jobs. This load runs with response times of about a second on a two processor machine with 1.5 million bytes of storage. Table I gives some information concerning the usage of the system in the last year and Table II gives more details concerning November 1971.

In summary, MTS has grown from a very small, simple system to a sophisticated one that supports a wide variety of applications for over 20,000 users at five installations. This growth has been achieved without requiring reprogramming or control language changes by users of the system. This evolutionary approach to system development contrasts with the more usual approach in which most of the system is designed on paper before any of it is in regular use. The evolutionary approach has a number of advantages and perhaps should be more frequently considered. It allows the designers of the system to use it and become aware of its advantages and disadvantages while it is still possible to change parts of the design with relative ease. It also allows the best people to work on the whole system since they can move from component to component as the system develops. On the other hand, it requires that the designers be able to foresee possible

TABLE II—MTS usage during November, 1971

TOTAL NUMBER OF JOBS RUN	90243
TOTAL NUMBER OF BATCH JOBS RUN	52903
TOTAL NUMBER OF TERMINAL SESSIONS	37340

TOTAL CONNECT TIME: 10735 HOURS
TOTAL CPU TIME: 394 HOURS
MAXIMUM NUMBER OF TERMINAL USERS SIGNED ON AT ONE TIME: 72

		Total	Batch	Terminal
Number of Jobs Run per Day,	AVERAGE:	3008	1763	1245
	MAXIMUM:	4825	3079	2076
	MINIMUM:	171	94	44
Number of Jobs Run 8 TO 12,	AVERAGE:	2790	1606	1185
	MAXIMUM:	4363	2691	1901
	MINIMUM:	9	1	8
Number of Jobs Run 9 TO 5,	AVERAGE:	1492	718	774
	MAXIMUM:	2311	1311	1215
	MINIMUM:	0	0	0

	MAXIMUM:	377	295	205
	MINIMUM:	0	0	0

directions for change and to allow for them when designing parts of the system.

ORGANIZATION AND IMPLEMENTATION OF MTS

In order to be able to extend and modify the system easily, it was organized as a set of independent components with well-defined interfaces between them. This idea is, of course, neither new nor unique; but there are differences in this respect between MTS and other systems. For one thing the term "component" as used here refers to a rather large fragment of the system, for example the entire supervisor. Also the interfaces between components are much more rigid than in many systems. The result is that components are independent of one another to the extent that it is quite easy to replace almost any one of them without affecting any other. Quite major changes can be introduced this way with relatively little work or trouble.

The dependence of components on one another is reduced by the fact that most components communicate with only a few others. Almost all components communicate with the supervisor, and with at most one or two other components. The interface with the supervisor is the same for all components and is the most important in the system. Dependency is further reduced by allowing very few special cases in interfaces; for example, all input/output operations are done using the same supervisor facilities whether the input/output is for a card reader, a paging drum, or anything else.

It is very important that any tables or control blocks maintained by the system should be directly referenced by as few programs as possible. For example, the control blocks relating to the file system should be accessed only by the subroutines comprising the file system. Other programs that wish to access a table or control block should call a subroutine that is part of the component that "owns" it. It is not enough to simply parameterize the format of the table or control block, since even finding all components that refer to it and reassembling them can be a very difficult and time consuming project. MTS is superior in this respect, and this is one major reason the system has developed smoothly. It is often necessary to reformat some system control block and it must be possible to do so easily.

One interface that must be well-designed is the one between the system and the application program. This must be the cleanest of all since there is no hope of changing the application programs when the system changes. In particular, no user program should ever refer directly to any system control block. If the information is needed it should be made available through a subroutine in the system. If the hardware allows it at a reasonable price, all system control blocks should be protected from user programs for both reference and change.

Since most large programs written for the IBM/360 are written to run under IBM's OS/360 system, it was desirable to make it easy to convert programs written for OS/360 to run in MTS. For this reason MTS provides many of the same services as OS/360. It also provides many other services and most of the similar ones are different in detail, requiring some modification to OS/360 programs. However, programs written in Fortran or PL/I can normally be run without modification since all dependency on OS/360 is in the run time library which has been converted to run in MTS. Furthermore, there is a program that allows some OS/360 object programs, such as the COBOL compiler and its object programs, to run in MTS by simulating exactly the services that are provided by OS/360.

With large components and well-defined interfaces it has been possible to divide the programming effort for MTS vertically rather than horizontally. By this it is meant that one or two individuals are assigned responsibility for a component and then follow it from design through implementation and even maintenance. The person responsible for a component is given considerable freedom to design the internal structure of the component so long as the interfaces are maintained unchanged. The fact that he also must implement and maintain the component means both that the design will be realistic and that it will be conformed to. This organization avoids part of the trouble many systems have had in trying to translate the design into code, since the people writing the code are not novices and thoroughly understand the design of the component.

Most components of the system can be debugged and many can be installed while the system is running without affecting the reliability of operation. It is possible to substitute a private copy of all components except the supervisor, the batch monitor, parts of the command language, and certain other similar things. It is also possible to replace a module without shutting down in most cases. Those modules that cannot be debugged in this way can be debugged by running the system in a "virtual machine" under the production system. The virtual machine program allows any system designed to run on a 360/67, including OS/360, MTS, or any other "stand alone" program, to be run. This type of operation does not greatly affect reliability. Indeed the software reliability of MTS is good. Between September 1970 and September 1971 there were 38 software caused system crashes. This is only 9 percent of the total crashes in this period, 85 percent of which were caused by hardware failure. During this time many parts of the system were debugged online.

FILE AND DEVICE MANAGEMENT

Perhaps the most interesting technical innovation in MTS is found in the methods used to support different types of input/output devices and files. These methods also provide a good example of how a well-defined interface can solve many problems.

A major problem in the implementation of any operating system is providing software support for the many different types of input/output devices to be used with it. This can consume a very large amount of time and energy. Furthermore, if the system does not provide truly device-independent input/output it will be much more difficult to debug and run programs under it. The approach taken toward I/O in MTS solves these problems better than in most commonly used systems.

The first and most important consideration concerning the I/O structure in MTS is that all input/output, whether by MTS itself or by a program running under MTS, is done by the same set of subroutine calls. These calls are independent of what program is doing the I/O and of the type of file or device being used. This means that any program including any part of MTS can read or write from any type of file or device with no code changes. This extends to all devices including typewriter and graphic terminals, unit record devices, files, magnetic and paper tape, etc. Of course a program may be designed to take advantage of special characteristics of a particular device type—for example, it might use the vector generating capabilities of a graphics terminal—and if it does so it loses some of its device independence.

Any call to the input/output routines in MTS specifies, either implicitly or explicitly, a quantity known as a File or Device name (FDname). The call may specify a Logical Unit Name to which an FDname has been attached, or it may specify the internal representation of a specific FDname returned by a subroutine for the purpose. An understanding of the concept of an FDname is crucial to an understanding of MTS input/output processing.

The simplest form of an FDname is simply the name of some file or device known to the system. For example,

SOURCEFILE

An FDname can also specify a subset of a file by appending a line number range to the simple name:

SOURCEFILE (10,20)

specifies lines 10 though 20 of the file SOURCEFILE. It is also possible to specify "modifiers" that determine special processing to be done for I/O on this FDname. For example, to convert all data read or written to upper case one could use

SOURCEFILE@UC

This will not affect the contents of the file on read operations, but only the data read or written using this FDname. More complicated FDnames can be constructed by concatenating the simple ones described so far. For example,

SOURCEFILE1(10,20)+SOURCEFILE2(−23,32)
+(100.75,123)

specifies lines 10 through 20 from SOURCEFILE1 followed by lines −23 through 32 and lines 100.75 through 123 from SOURCEFILE2. This type of concatenation is called explicit concatenation; it is also possible to specify concatenation implicitly by the data read. If a line read from any FDname is of the form "$CONTINUE WITH FDname [RETURN]" then the contents of the FDname given in this line will be used for further input, followed by the remaining lines from the current FDname if RETURN is specified. This action can of course be turned off to allow such records to be read directly. This generality in specification of FDnames is the single most useful feature of MTS and allows great flexibility in the use of commands and files.

It is difficult to design a set of input/output subroutines that will be suitable for all different types of input/output devices, and inevitably certain compromises must be made. It was decided to treat input/output as a transmission of a series of logical records, not as an unbroken stream of characters. It seemed that too many input/output devices had "natural" record boundaries that are hard to ignore. Hence the basic subroutines are subroutines to read or write a single record to or from an input/output device or file. In general the approach has been to make the various different files and devices look as much as possible like line files, which consist of a sequence of records associated with line numbers.

It was intended to develop an input/output system designed so that it would be easy to add support for any type of device that would fit into the structure described above. It was necessary that it be possible to debug support routines, and to install new ones, without disrupting normal operation of the system. It was also necessary that all code peculiar to a particular type of device be located in a single component of the system. To meet these and other goals the concept of a Device Support Routine (DSR) was created. There is a DSR for each type of device supported by MTS (some 20 in all) and each one supports one class of devices, for example low speed telephone lines, line files, magnetic tape drives, or some similar category of file or device.

The interface between a DSR and MTS is completely independent of the type of file or device. Every DSR has the same eight entry points and when MTS calls one of them it is completely unaware of the nature of the device. When a DSR is called at one of its entries it is responsible for interpreting the parameters properly for the device in question and for initiating, via calls on the supervisor, any actual input/output operations. The communication between MTS and the DSR is on a record level, while the communication between the DSR and the supervisor or the device is on a channel program level.

A DSR may be either private to a single task or shared among some or all tasks using the appropriate type of device. Furthermore any task may use a private copy of a shared DSR, for example to allow a DSR to be debugged. Using this technique it was possible to completely rewrite and install the DSR for magnetic tapes without any time on a dedicated machine; all development was done under regular production MTS without any adverse effects on the rest of the system. This was possible largely because the interface between MTS and the DSR is extremely clean and each side is independent of the other. This interface is described in reference 8 on pages 353 and following.

VIRTUAL MEMORY AND MULTI-PROCESSING

Two of the aspects of the system that attract the most attention are its use of virtual memory[2] with demand paging and the fact that it supports multiple central processors. The most interesting thing about these is that both were added to the system after it was already operational. This provided a good opportunity to observe both the implementation difficulty and the effect on performance of paging and multi-processor support.

Adding virtual memory to the system required about six man-months of work and improved performance at least tenfold. The performance comparison should not be taken too seriously since the pre-paging version of MTS did not make use of any swapping techniques, but rather kept all programs in main storage at all times they were in use. A more meaningful comparison is currently being attempted at the University of Newcastle upon Tyne in England where a version of MTS that runs on a standard 360 and uses swapping has been prepared. It is planned to perform some comparisons between this system and the model 67 version of MTS.

Modifying the system to support multiple processors required only about four man-months of work. About half of this was spent writing code to handle the more complex input/output hardware configurations possible with larger versions of the model 67, and the rest was spent adding code to the supervisor to avoid simultaneous destructive access to data by more than one processor. To do this required a great deal less work than most people would think, with quite effective results.

Measurements have been made of the amount of degradation due to interference between processors in a two processor configuration. There are two major sources of interference in such a machine: one processor may have to wait to gain access to data the other is modifying, and the increased load on main storage may cause both processors to run slower. The first source of interference was measured directly in MTS and turned out to result in a performance degradation of 1.5 percent when the system was operating under a very heavy load. It is interesting to note that the average time that a processor had to wait for access to data was only 7.6 microseconds. The second source of interference was measured indirectly by running the same job stream on different configurations and results indicate that a degradation of about 3.6 percent occurs for this job stream and that it is highly variable.

FILE SYSTEM

In any modern operating system the file system that allows users to store and retrieve data in the system is most important. This is even more true of systems such as MTS that encourage conversational use. Unfortunately this is not one of the strong points of MTS and perhaps it would be instructive to look at some of the advantages and disadvantages of the MTS file system.

The MTS file system supports two types of files. "Line files" consist of a set of lines, or records, each of which is associated with a line number which is not part of the record. Lines may be read, written, inserted, or deleted by line number or sequentially. Because of the implementation no line may be longer than 255 characters and no file may be larger than about 300,000 characters. The ability to write by line number without knowing whether the line already exists in the file, and the ability to read and write sequentially, ignoring the line numbers, make line files very useful and easy to use, but the restrictions noted above are severe limitations.

The second type of file, "sequential files," consist of a set of lines or records which normally are read or written sequentially, and which do not have line numbers. This type of file was invented later both because of the above restrictions and in order to reduce the number of accesses to the direct access devices, particularly the IBM 2321 Data Cell Drives. If line files had been better designed, sequential files would not have been necessary.

The file system in MTS gives the user no opportunity or need to worry about the actual format of the information on the direct access devices. This means that the use of these devices can be optimized by using a good format and efficient input/output techniques. On the other hand, very sophisticated users with specialized file requirements could in some cases improve performance by specifying some of this information if it were possible. However, very few people have the inclination or ability to do this; more importantly, a good operating system should not require them to do so to get good performance. Furthermore, any single user may degrade total system performance by optimizing his own performance, for example by using too much channel time and thereby locking other users out of their files.

In the opinion of the implementors of MTS one major disadvantage of the file system is that it is independent of the paging system. It would be much better to treat file I/O in the same way as paging I/O, as is done in Multics.[1] This would allow much better optimization of direct access device operations and it would allow users to treat files as extensions of their virtual memory. It is hoped that someday such a virtual memory file system may be installed in MTS.

Another major disadvantage that we see in the MTS file system is that it uses a direct access volume format compatible with that of OS/360.[5] This format is very restrictive and slow with respect to allocation and deallocation of space. It would be much better to use a format similar to that of TSS/360,[7] in which the concept of an "extent" of contiguous space does not exist.

BATCH VERSUS TERMINAL USAGE

When development of MTS was started it was anticipated that it would be primarily a terminal system with batch or nonconversational usage playing a much more limited role. This prediction turned out to be completely wrong. In fact, the use of terminals started out on a much smaller scale than the use of batch, and only recently have the two modes become about equally popular. There are probably several reasons for this, not the least of which is habit. From the beginning MTS has made batch and terminal usage as nearly compatible as possible and equally convenient, and many people simply continued to use the computer in the way they were used to. Other reasons are that in the early days there were relatively few terminals available and they were rather expensive to use. Both of these problems have been largely corrected, but those who were burned are reluctant to try again.

It is important that a system provide compatible batch and terminal modes of operation with the same command language and facilities. Most uses of the system will require both modes of operation to some extent and switching back and forth is difficult if the modes are not compatible. In particular it must be possible to run any program in either mode.

FUTURE TIME-SHARING SYSTEMS

It is difficult, even foolhardy, to make specific predictions for the future in computing, but some trends seem clear at this time. For example, there are more and more terminals available and they are becoming more and more sophisticated.

There is a current trend toward computer networking which is approaching the point where practical networks will soon be operational. Most work in this area so far has focused on the technical problems of connecting dissimilar isolated systems, while the difficult problem of what is to be transmitted has been largely ignored. When networks become truly operational, there will be very difficult problems with standards for data formats, data description languages, programming languages, etc. These problem of course already exist, but the closer connection between systems resulting from networking will greatly aggravate them.

Another problem which must be overcome before networking is really practical is the administrative problem. When networks include nodes that must bill for all services rendered it becomes difficult to integrate these nodes into the network unless some convenient way can be found to bill for services provided to other nodes in the network. This may seem like a trivial problem; but since a very large number of end users may be involved, making it difficult for each node to bill them directly, and since nodes in the network will vary widely in accounting standards and practices, it is not trivial at all.

The term "computer utility" is used so frequently these days that is has almost lost any meaning. It does not accurately describe any existing system although some systems such as MTS include some aspects of it. However, we are approaching the time when we will see the first true computer utilities, and it is worthwhile to look at some of the problems that may be encountered.

One thing that seems obvious at this point is that most customers of the computer utility of the future will have little programming knowledge. Most programming will be done by organizations and individuals that wish to sell a problem-solving service to people who know little or nothing about programming. Some of these services will be provided by those who provide the computer; many or most, however, will be provided by third parties.

The computer utility of the future must somehow separate the customer from many of the details of the computing system he is using. There is no reason the customer needs to know, or should know, about such things as the characteristics of the direct access devices he is using. To involve the end user in this sort of thing is both a waste of his time and unduly restrictive to those operating the computer.

Closely related is the same old problem of compatibility and standardization. The users of the computer must be able to switch from one system to another with a minimum of necessary changes. Those who are developing programs for use by nonprogrammers will not be able or willing to rewrite them for the peculiarities of every computing system. To do so would be like having every TV station using its own video transmission techniques.

To allow problem solving services to be sold by third parties will require facilities which are not available in most current systems. The programs and data which comprise such a service will be stored in files in the system which must of course be protected from unauthorized access. In addition there must be facilities to allow for proper accounting by those providing the service. Implementation of this will require much better protection of different levels of code within the system. The main limitation to this presently is the lack of suitable hardware on most machines available today. The IBM 360 series, including the model 67, is particularly bad in this respect, since it does nothing to help implement levels of protection within a task as is done on the Honeywell 645.[3]

Better protection of this sort is also required in order to be able to solve some of the problems that are becoming acute concerning privacy and data bases. These problems, however, require more than technical innovation to solve. In general they are problems that have been around for a long time, but which had not been acute when the harmful information was so widely distributed as to be almost inaccessible. The role of the computer industry in the solution of these problems would seem to be to provide the technical tools and advice that will allow those outside the industry who must find solutions to do so.

There seems to be a trend away from the type of multiprocessor organization found in the 360/67 in which all processors and input/output equipment is connected symmetrically, and this is disturbing. The symmetric type of organization found in the 360/67 is much easier to support in software since no part of the system need ever be aware of which processor it is executing on, as is necessary in machines such as 360 M65MP in which certain input/output equipment is accessible from only one processor. Furthermore the 360/67 organization is very flexible in that almost any single hardware component can be removed from the system and the system can still run. This has been very valuable at the University of Michigan, where this capability has resulted in about 10 percent more "up time" for the system as a whole.

On the other hand, there seems to be growing acceptance of address translation hardware such as appears on the 360/67. This hardware is very valuable for a variety of reasons and should be on all machines in the future. It has rarely been exploited to its fullest but even in present systems it more than pays for itself.

In summary, it is clear that computing is still in its adolescence and that we are just beginning to involve the nonprofessional in it. This change will be both exciting and painful as we face the technical and ethical problems of the future.

Regulatory developments in data communications—The past five years

by PHILIP M. WALKER

Georgetown University Law Center
Washington, D.C.

INTRODUCTION

Since its creation in 1934, the Federal Communications Commission has exercised regulatory jurisdiction over all interstate common carrier communications service in the U.S. The Commission has broad powers to review rates and tariffs, determine investment and operating practices, approve new plant installations, and literally shape the entire communications carrier industry, but historically the Commission has failed to exercise these powers vigorously. Instead it, like most government regulatory agencies, has tended to become dominated by the industry it supposedly regulates, and has come to place the status quo high on its list of values to be protected; until recently, that is.

Communications carrier services in the U.S. are today provided on a monopoly, or at best, duopoly basis. Each telephone company has a monopoly in providing dial telephone service in its geographic operating area, and although Western Union provides private line services "competitive" with those of the telephone companies, WU's service offerings and rates are identical to those established by the Bell System and copied by all independent (non-Bell) telephone companies as well. Bell's mammoth size (serving over 83 percent of all U.S. telephones) as compared with WU and the independent telephone companies has made the terms "Bell" and "communications carrier industry" virtually synonymous, with effective competition within the industry nonexistent. Thus, decisions regarding introduction of new services and equipment, rates, and tariff regulations have been made by a single firm, with minimal federal and state regulatory control in most cases. The result with respect to data communications has been a sluggish response to user demand for new and improved services (especially felt by data users during the early and mid-60s), restrictive tariffs which impeded the user's ability to obtain maximum benefit from the communications network, and higher costs than might prevail in a competitive atmosphere.

Fortunately for the communications user, the past five years have seen tremendous changes in this picture. Some of these changes are the result of the rapid growth of computing and data communications, and the carrier's natural response to that growth, but the most fundamental changes are in the regulatory and policy environment. After decades of apparent satisfaction with regulated monopoly as the *modus operandi* of the communications industry, the FCC seems to have done a turn-about and embraced competition as a means of stimulating innovation and efficiency in this industry. For example, in its landmark *Carterfone* decision in 1968,[15] the Commission broke the carriers' monopoly on the supply of terminal equipment and systems to be attached to or interconnected with the telephone network. The following year, in its equally precedent-setting *MCI* decision,[8] the Commission authorized the first specialized private-line carrier to enter the market and compete with Bell and Western Union. A year later the FCC, urged by the White House,[16] reversed its previous attitude toward the establishment of domestic communications satellite systems and invited applications for competitive systems from all interested parties.[6]

More recently the Commission has somewhat relaxed its attitude toward the competitive offering of hybrid data processing-message switching services,[12] and has opened the way for cable television (CATV) systems to enter the major metropolitan markets and supply a wide variety of new communications services.[7] During this same five-year time period, President Johnson's Task Force on Communications Policy issued a comprehensive report[27] endorsing the wider use of competition in the communications carrier industry, and several years later President Nixon's new Office of Telecommunications Policy also began to advocate increased reliance upon the forces of competition to achieve our national communications goals. This paper attempts to provide an overview of these developments, and to assess their importance for the future.

THE FCC COMPUTER INQUIRY

In late 1966, the Federal Communications Commission began what has since become a widely-discussed public Inquiry into the "Regulatory and Policy Problems Presented by the Interdependence of Computer and Communication Services and Facilities."[9,21] Rapid developments in digital technology, and corresponding growth of the computer equipment manufacturing and computer services industry had been on what some have termed a collision course with telecommunications and the communications common carriers. Several controversies in recent years brought this home to the FCC and pointed out the need for policy guidance.[17,18] The FCC's reaction was to publish a list of broad and interrelated questions and to invite comments from all interested parties, hoping thereby to develop the framework for such policy formulation. Over sixty responses to this Notice of Inquiry, totaling over 3,000 pages, were received by the Commission before its deadline in March, 1968.

To assist in evaluation of this material, the Commission then engaged Stanford Research Institute, which submitted its report in early 1969—summarizing the responses and analyzing the issues, but raising more questions than it answered.[29] Soon thereafter, the Commission issued a Report and Further Notice of Inquiry,[10] asking for comments on the SRI report. A year later, after receiving additional comments from some of the parties to the Inquiry, the Commission issued its Tentative Decision.[11] Finally, after receiving another round of written comments from, and hearing oral argument by, the parties, the Commission in March, 1971 issued its Final Decision and Order.[12] As might be expected during the course of a five-year proceeding, some of the issues originally addressed in the Inquiry were overtaken by the course of events and became moot by the time of the Commission's final decision; unfortunately, certain other issues were not adequately resolved in the final decision, and at the time of this writing they remain a source of uncertainty.

Regulation of computer services

Let us now consider the issues addressed by the FCC in this Inquiry. First was the question of whether, and under what circumstances, computer-based data processing or information services—remote-access services employing communication lines, and also perhaps stand-alone services—should be deemed subject to FCC regulation under the Communications Act of 1934.

The anticipated growth of the "computer utility" concept, much-discussed during the mid-60s, had suggested to some observers the possible need for some sort of government regulation of that utility. On many issues in the FCC Inquiry there developed a dichotomy of opinion, with the communications common carriers on one side and the computer firms and users on the other; but regarding this first question there was general agreement that no need for government regulation of computer services exists or is likely to exist in the future.

There are a number of factors which may indicate the need for regulation of an industry, such as the existence of natural monopoly characteristics which make effective competition impossible in the industry (e.g., the electric utility industry), or compelling requirements that the quality and integrity of the industry's product be insured (e.g., the pharmaceutical and banking industries). Comprehensive rate and profit regulation is imposed upon the common carrier communications industry because of its natural monopoly characteristics (continually increasing economies to scale) and the public interest requirement that the service be offered on a regular, well neigh universal basis. The data services industry exhibits none of these qualities; on the contrary, it is thriving in an atmosphere approaching the pure competitive model. Concern for the protection of the consuming public has led to certain types of regulatory controls in other industries such as insurance and banking. On this score, also, data and information services do not appear to warrant regulatory attention. Significant abuses have not arisen yet, and there is no reason to believe that they will occur in the future. The FCC therefore concluded that "In view of all the foregoing evidence of an effective competitive situation, we see no need to assert regulatory authority over data processing services whether or not such services employ communications facilities in order to link the terminals of subscribers to centralized computers."[11]

The protection of privacy

A second question asked by the FCC concerned the need for legislative or other government action to protect the privacy and security of data stored in computers that are interconnected with common carrier communication lines. The respondents discussed a number of protection measures available to users and system operators, and generally felt that FCC intervention or regulatory control was not needed at this time.

The Commission, noting that the privacy and security issues extended well beyond the scope of its jurisdiction to regulate communications, and observing other efforts taking place in Congress and elsewhere in government concerning this problem, elected to follow the advice of the respondents and refrain from taking any action pending further developments or abuses. While this was probably the best course for the Commission to follow for the present, it seems clear that the multitude of privacy and security problems associated with widespread usage of the computer, and especially the large multiple-access system, in all areas of our society is growing as fast as—or perhaps faster than—the use of such systems.[20,22] Government controls of some sort thus appear inevitable, and the FCC will probably play a role in future years in attacking that part of the problem which falls within its regulatory jurisdiction. Proposals have been made for the creation of a new federal agency to provide regulatory control of the computer-privacy area,[22] and such an approach, if adopted, might reduce or eliminate the FCC's role in this area. But it seems at least equally likely that Congress may choose instead to provide for the protection of computer data-bank privacy and security through expansion of the regulatory jurisdiction of the FCC and other relevant federal agencies rather than through creation of a new agency.

Adequacy of facilities for data transmission

The third topic in the Inquiry which the FCC disposed of without taking any action concerned the adequacy of common carrier services and facilities for data transmission. Many of the computer-industry firms and users who participated in the Inquiry identified serious deficiencies in the service offerings of the telephone companies and Western Union, circa 1968, and urged certain modifications and improvements.[21] These included the provision of additional channel bandwidths, the development of a widespread switched broadband service, a reduction in the three-minute minimum charging period on the dial network, a reduction of error rates in data transmission generally, more rapid introduction of digital transmission systems such as T-carrier and digital microwave, and lower costs.

The FCC recognized these needs of the computer community, but concluded that several other events which had occurred during the pendency of the Inquiry obviated the need for any Commission action in the Inquiry docket. These external events included the FCC's approval in 1969 of the first specialized carrier, MCI, to compete with the established carriers[8,21,30,31] (discussed below); the Commission's landmark *Carterfone* decision in 1968 which permitted competitive supply of subscriber terminal equipment for use on the telephone network[15,21] (discussed below); and the advent of a number of new and improved data transmission services being planned and phased in by the existing carriers—partly in response to the new competition created by *MCI* and *Carterfone*.[30] In effect, the Commission opted to rely upon this new competition to achieve its goals of improved common carrier service for data transmission, rather than taking direct action itself to attempt to improve the carriers' performance.

While these competitive developments certainly have had a beneficial effect upon the quality and adequacy of the carriers' data transmission service, it is unfortunately not clear that all of the user's problems have been solved—or that they will be in the future. The telephone industry, as with most regulated quasi-monopoly public utilities (for the vast majority of the telephone carriers' revenues are safe from competitive inroads), continues to respond to customer demand rather sluggishly when measured by a competitive-industry yardstick. Telephone company performance is on the uptrend, but so are rates in many cases, and careful regulatory agency attention will be needed in the coming years—at both the federal and state levels—to insure that the user obtains maximum value for his data communications dollar. In the author's view, it is unfortunate that the FCC chose to sweep this problem under the rug in its final order in the computer inquiry.

Common carrier tariff restrictions

One additional issue in the Inquiry, very important when it was posed in 1966, was later found by the FCC to have been also largely mooted by ensuing events. This concerned the reasonableness of the carriers' traditional tariff prohibitions of (1) customer-owned "foreign" attachments on the telephone network, (2) interconnection to the network of customer-owned communications systems, and (3) customer sharing or resale of carrier lines. The Commission's 1968 *Carterfone* decision forbade unreasonable carrier restrictions upon the user's freedom to attach or interconnect harmless terminal equipment or communications systems, and the carriers subsequently made certain changes in their tariffs to comply with this ruling.[21] As discussed below, considerable disagreement remained as to whether the carriers went far enough in compliance with *Carterfone*, but the Commission had instituted procedures for continued discussion and study of this question, and felt that no additional action was required in the computer inquiry itself.

Concerning sharing and resale of private line channels released from the carriers, several things occurred during the pendency of the computer inquiry. First, MCI had previously proposed to offer sharing in its new private line service pending before the Commission. Sensing the likelihood of FCC approval of MCI's license applications (which in fact occurred in August, 1969), and perhaps also influenced by the numerous users' requests for sharing voiced in the computer inquiry, the Bell System in February, 1969 relaxed its tariffs to permit sharing ("joint use") of its voice-grade and telegraph-grade private lines.[21]

This relaxation of the prohibition against sharing did not apply to channels of greater than voice bandwidth, for most broadband channels are leased under the Telpak tariff at greatly reduced bulk rates, and sharing of such channels raises complex economic questions. Telpak has been in litigation during much of its ten-year history, most recently concerning the reasonableness of the carriers' permitting certain classes of customers to share, while barring others from doing likewise. In 1970 the FCC found that this restricted sharing was unreasonably discriminatory, and ordered unlimited Telpak sharing; after partial reversal by the Court of Appeals, the Commission modified its order to require only that the unlawful discrimination be removed—leaving the carriers free to permit unlimited Telpak sharing, abolish sharing altogether, or change the whole nature of the Telpak service.[14] At this writing the outcome is unclear, but it seems likely that even though Telpak as we have known it may cease to exist, competitive pressures will dictate that a bulk-rate private line offering of some sort remain.

Provision of data processing services by communications carriers

The most significant results of the FCC Inquiry were with respect to the very controversial issues of market entry and industry structure in the computer services and communications fields. This has two aspects. First, as communications common carriers began to enter the computer and information services field in the mid-60s, the FCC realized that it must face questions of possible unfair competition. Should the carriers be permitted to engage in data processing service activities; and if so, under what ground rules? On the other side of the fence, unregulated firms in the computer services industry had expressed their desire to offer computer-based store-and-forward message switching services, both on a stand-alone "pure" basis and also as a "hybrid" system combined with various data processing functions. All such attempts were rebuffed by the carriers—to whom message switching is merely another form of communication service, long regarded as an exclusive common carrier activity. Perhaps, the Commission speculated, this policy should be modified in light of today's changing technology.

There are several frameworks within which one might consider common carrier participation in the data processing services area. The first of these, and perhaps the most obvious, is simply that they be permitted to enter without restriction of any sort. This assumes that data processing services will remain an unregulated activity—which, as discussed above, is the way the FCC has left the matter. The common carriers would then be (1) offering both a regulated monopoly communication service and an unregulated highly-competitive data processing service, and (2) using common plant and personnel, at least to some degree, because of the economies that would be realized in that way.* Both factors would lead to problems of cost separation and allocation.

The FCC and the state public utility commissions in the U.S. establish rate and profit ceilings for common carrier services. This is done by setting rates for communications services at a level which will permit the carrier to recover his operating costs for the service, and earn a profit equal to a fixed percentage or percentage range (established by the regulatory commission) of his plant investment, or "rate base," associated with the service. This approach, called "rate base regulation," encourages the carrier to capitalize as many of his costs as possible, so as to increase the size of the rate base.

For the competitive (unregulated) data processing service, on the other hand, the carrier's incentive is to minimize the cost charged to that service. One then sees the immediate possibility for an intentional or covert type of cross-subsidization in which certain costs properly attributable to the data processing service would, in fact, be charged to the communications service—forcing the communications user, who has no choice in the matter, to bear a portion of the carrier's cost of entry into the data services market. The avoidance of this problem would require stringent cost separation techniques, and would require allocation of joint costs in the case of common use of facilities or personnel. These might be possible to accomplish, but only with some difficulty and with certain questions remaining.

* There is disagreement as to the importance of any economies which might be achieved by using common facilities for both communications and data processing services.[29] Western Union has urged that it be permitted to utilize off-peak capacity in its switching computers for data processing services, but some observers have estimated that any savings from such a practice would have a negligible effect upon WU's overall costs.[3]

One possible solution which had been proposed[21] would be to require that a common carrier offering data processing services do so under the framework of a separate corporate subsidiary which would not share resources with the carrier, thereby avoiding many of the cost separation problems. To avoid cross-subsidization from one service to another, the data processing subsidiary would be charged full price for the communication lines that it might require for a multi-access service, the same as any other user would pay. This would eliminate some of the potential problems of cross-subsidization. However, an additional form of cross-subsidization could occur if the parent corporation were buying data processing services (either machine time rental, or programming and consulting services) from the subsidiary. Intentional over-charging of the common carrier for these services would be just another way of the subsidiary's receiving undeserved revenue from the carrier's communications customers. To prevent this from occurring, the carrier could be barred from obtaining data processing service from its affiliate.

In its final decision in the computer inquiry, the FCC accepted these proposals, and adopted rules providing that "common carriers desiring to provide data processing services [can] do so only through affiliates utilizing separate books of account, separate officers, separate operating personnel, and separate equipment and facilities devoted exclusively to the rendition of data processing services." The Commission also prohibited the data processing affiliate from using the carrier's name and barred the carrier from obtaining any data processing services from the affiliate.[12] (Small carriers with annual revenues of less than one million dollars were exempted from these prohibitions.) Several independent telephone companies appealed this decision to the courts, and other parties petitioned the FCC for reconsideration. Pending disposition of these matters, the U.S. Court of Appeals stayed the effectiveness of the FCC's order. At the time of this writing, no further action has been taken, so the outcome remains unclear. The Commission has shown no inclination to substantially change its order, however, and it appears doubtful that the carriers will be able to convince the court that the Commission acted in an "arbitrary and capricious" manner—which would be necessary in order for their appeal to succeed. The likelihood thus is that the thrust of the 1971 order requiring complete separation of common carrier communications and data processing activities will remain.

Hybrid message-switching services

The second aspect of the market entry question studied in the FCC Inquiry regarding computer and communication services concerns those services which combine both data processing and communications (message-switching) functions in a single "hybrid" package. Should the provision of such computer-based services be treated as a common carrier undertaking and regulated accordingly, or would regulatory forbearance be more appropriate?

Message-switching is a relatively old communications concept. Most readers are familiar with the old punched paper tape reperforator systems sold by AT&T and Western Union. Western Union's Public Message Service (the common telegram) also uses a paper tape reperforator network. The only thing new in the message-switching concept is the fact that we are now using general-purpose digital computers to perform the switching function, and these same computers may also perform data processing functions—yielding a hybrid remote-access system which offers both communications and data processing services to its users. Since the FCC decided in the Inquiry that data processing services would not be regulated, whether using communications lines or not, and since the Commission considered and rejected the possibility that it might "de-regulate" pure message-switching services, how should the in-between hybrid service be treated?

One possibility was that the entire hybrid service could be exempted from regulation, even where it is oriented essentially to satisfying communications (message-switching) requirements of the subscriber. Some of the parties in the Inquiry suggested this course on the grounds that to do otherwise might retard the development of valuable hybrid services—which the carriers might not choose to offer, if given an exclusive monopoly in this area—and also that such computer-based services had few, if any, of the characteristics of traditional common carrier undertakings requiring government regulation (natural monopoly, need to make service widely available to the public, etc.). Rather, the argument ran, the hybrid service would flourish best in an unregulated competitive environment, regardless of the mix of data processing and communications features it might exhibit. The FCC rejected this argument, for two reasons: (1) it felt that there was a real question whether it had the authority under the Communications Act to decline to regulate a public communications service after Congress has decided that all such services are subject to regulation, and (2) it concluded that, based on the record in the Inquiry, those hybrid services which are "essentially communications" in nature "warrant appropriate regulatory treatment as common carrier services under the Act."[12] The Commission did not explain how it reached this latter conclusion, but one might assume that it did so merely because the proponents of change failed to convince it that the traditional regulatory treatment of communications services was inappropriate in this case.

On the other extreme, some of the common carrier respondents in the Inquiry urged that the Commission is obligated by law to regulate the hybrid service insofar as it contains a communication component. This view was rejected as well, for the Commission felt that the imposition of regulatory constraints on what is essentially a data processing service, just because it contained some incidental communications elements, would inhibit flexibility in the development of such services and would be contrary to the public interest. Furthermore, the Commission held that it has discretionary latitude "to refrain from subjecting a marginal activity to [its] regulatory process where it is clear that the public interest will be served by such a course."[12]

Having rejected both extremes—to regulate or to decline to regulate all hybrid services, regardless of their primary orientation or purpose—the FCC adopted a middle position calling for regulation of only those hybrid services which are essentially communications-oriented and in which data processing plays just an incidental part. This approach is unfortunately much more difficult to administer, and requires a case-by-case examination of each service to determine on which side of the line it falls. Perhaps even more important, the dividing line itself must be clearly defined by the Commission, in order to provide advance guidance to the entrepreneur and system designer and to avoid endless litigation.

The Commission made an attempt to define a clear line between regulated and unregulated hybrid systems, but it is questionable whether this guidance will suffice. First it said that,

> "*where message-switching is offered as an* integral *part of and as an* incidental *feature of a package offering that is primarily data processing, there will be total regulatory forbearance with respect to the entire service whether offered by a common carrier or non-common carrier, except to the extent that common carriers offering such a hybrid service will do so through* [*separate*] *affiliates. . . . If, on the other hand, the package offering is* oriented essentially *to satisfy the communications or message-switching requirements of the subscriber, and the data processing feature or function is an* integral part of and incidental to *message-switching, the entire service will be treated as a communications service for hire, whether offered by a common carrier or a non-common carrier and will be subject to regulation under the Communications Act.*"[11] (*emphasis added.*)

Two tests were given to help apply this criterion:

> (1) Does the service, by virtue of its message-switching capability, have the attributes of the point-to-point services offered by conventional communications carriers, and is it basically a substitute therefor? It so, this suggests that regulation may be applicable.
>
> (2) Does the message-switching feature of the service facilitate or relate to the data processing component, or are the two components essentially independent?

In order to avoid regulation, the message-switching feature must be not only secondary in importance as compared with the data processing aspect of the service, but also the two must be closely related to one another. If the two components are functionally independent of one another (although perhaps performed on the same computer), the FCC's staff has indicated that it would regulate the entire service—regardless of the preponderance of the data processing element.

Considering this second test, it is interesting to note a certain circularity in the Commission's reasoning. If a firm desires to offer the public a hybrid service having essentially unrelated data processing and message-switching components, this test would require that the service be offered only on a regulated common-carrier basis. The firm *could* perhaps convince the FCC to grant it a certificate of public convenience, interest, and necessity so that it could do business as a common carrier, but then it would encounter another snag. As a common carrier, the firm (if it or its corporate affiliates had annual revenues of $1 million or more) would be barred from offering data processing services except through a wholly separate affiliate. Therefore, the proposed hybrid service could never be offered—the new carrier could not provide data processing, its unregulated affiliate could not provide communications service, and the two could not collaborate in a joint "package" offering. If this is the result the Commission really intended, it would have been better for it simply to have stated that a hybrid service can be offered *only* when the two components are closely related and integral to one another—and that the service will then be regulated or not depending upon which component is preponderant.

We should also note, however, that the FCC will undoubtedly apply a *de minimis* rule, which will as a practical matter exempt from regulatory control those systems having a non-integrally-related communications element which theoretically makes them subject to regulation, but which is just too small or insignificant for the Commission to worry about. The chances of such a system escaping the regulatory net are probably greater where the system operator attaches little importance to the communications-for-communications'-sake capability of his system, in his promotional literature, advertising, and so forth. Thus, a remote-access computer service in which the central processor spent 99 percent of its useful time doing data processing and 1 percent of its time doing unrelated message-switching for system subscribers could probably be offered to the public by a private firm without FCC objection, but if the supplier placed a promotional emphasis on the communications aspect of the system it would become more likely that the common carrier providing communication circuits for the system would object and the FCC would be forced to rule on the case.

The FCC has emphasized that it considers the whole field of hybrid systems as being in its infancy, and that it (the Commission) will not hesitate to modify its rules regarding such systems as they mature and perhaps require different treatment. For this reason, we should not regard the above-stated guidelines as forever frozen in concrete, but it is still appropriate to consider whether their effect will be beneficial or detrimental in the near future.

Perhaps the most serious shortcoming of these rules is their vagueness. Just what is "integral" and "incidental," and what is not? How does one determine which component is the dog and which the tail in a hybrid system containing large doses of both data processing and message switching? As a procedural matter, can a system designer obtain a definite FCC ruling in advance (or, indeed, would he want to disclose his plans and thus forewarn his competitors?), or must he risk his capital by building the system and hoping that he does not encounter regulatory difficulties at a later date?

The above guidelines regarding hybrid systems were tentatively established by the FCC in 1970 and finalized in 1971. Since then there have been no formal FCC proceedings involving hybrid systems, and few, if any, informal requests to the Commission's staff for advice or opinion concerning a specific proposed system or service. Yet the author is personally aware of at least two instances since 1970 in which data processing-oriented firms have contemplated implementing hybrid computer-communications services and have backed away because of the regulatory uncertainty involved. One can only wonder how many other innovative new hybrid services have been stopped before they began by the same uncertainity. Since the investment required to implement a sophisticated remote-access system is high, and the time delay and cost involved in an adjudicatory proceeding at the FCC is substantial (often consuming several years and several hundred thousand dollars), it is easy to see why the entrepreneur is hesitant to go ahead without knowing what lies in store for him. And this hesitation is especially true with respect to the smaller firms in the computer services industry, from whom might otherwise come some of the most innovative and socially-desirable computer communication services.

In summary, the FCC has addressed a broad set of issues in its Inquiry into the interrelationship of computers and communications. Its initiation of this Inquiry was a very farsighted approach to policy determination in an era of new and rapidly changing technology, and the outcome was in general quite beneficial to the computer communications community. The Commission could have taken some positive steps in the Inquiry to help insure the availability of adequate data transmission services and facilities, but this failure to act seems less serious than the inadequate "resolution" of the question of the regulatory status of hybrid computer-communications services. Hopefully, additional steps will be taken in the coming years to remove the uncertainty presently surrounding such services and to encourage the development in a competitive market of creative new services of this kind.

INTERCONNECTION

One of the regulatory policy issues which has generated considerable discussion in the past half-decade concerns the interconnection to the telephone network of privately-owned terminal devices and communication systems. Historically, the telephone companies have generally prohibited such interconnection by their subscribers, which might jeopardize the telephone network if uncontrolled and almost certainly would cut into carrier equipment-rental revenues. Until recent years the carriers' well-developed arguments of potential harm have been accepted without question by the FCC and the various state utility commissions, which permitted the carriers to build a seemingly-impregnable wall around the telephone network; but starting in 1956 the wall began to crumble.

A decade before the famous *Carterfone* ruling, the legality of the carriers' blanket foreign attachment/interconnection prohibition was tested before the U.S. Court of Appeals, in *Hush-a-Phone Corporation* v. *United States*, 238 F.2d 266 (D.C. Cir. 1956). This case concerned a cuplike rubber device designed to be attached to the microphone portion of the telephone handset to provide privacy in conversation; its use on the dial network had been barred by the foreign attachments rule. Reviewing the tariff in question, a prior version of the AT&T interstate toll telephone tariff, the court found it illegal and held specifically that this ban was ". . . an unwarranted interference with the telephone subscriber's right to use his telephone in ways which are privately beneficial without being publicly detrimental." AT&T was ordered to revise its tariff to permit use of the Hush-a-Phone device, and did so—but retained the *general* foreign attachment prohibition in the tariff. Three years later the Carterfone struggle began.

The Carterfone case

The Carterfone is an acoustic/inductive device for interconnection of the base station of a mobile radio system (or other private communication system) with the dial telephone network. The Carter Electronics Corporation of Dallas, Texas, which developed the Carterfone, sold approximately 3,500 of these devices in the United States and overseas between 1959 and 1966. The Bell System and the General Telephone System warned Carter's customers that their tariffs prohibited devices such as the Carterfone on the telephone network, and that customers who violated these tariff provisions risked having their telephone service terminated. Finally, in 1966, Carter brought an antitrust suit against the Bell System and the General Telephone Company of the Southwest. The U.S. District Court in Texas referred the case to the Federal Communications Commission because the Commission has primary jurisdiction in interstate communications matters.

AT&T and GTE argued before the FCC that use of the Carterfone violated their tariffs, and presented several technical arguments to support their position that the integrity of the telephone system necessitated the use of only carrier-supplied attachments, whether acoustically coupled or directly wired to the telephone network.[21] The FCC was unpersuaded by the telephone companies' arguments and, in a unanimous opinion issued in June, 1968, found that the tariff restrictions "are, and have since their inception been, unreasonable, unlawful, and unreasonably discriminatory under the Communications Act of 1934." The Commission further concluded:

> "*. . . a customer desiring to use an interconnecting device to improve the utility to him of both the telephone system and a private radio system should be able to do so, so long as the interconnection does not adversely affect the telephone company's operations or the telephone system's utility for others. A tariff which prevents this is unreasonable; it is also unduly discriminatory where, as here, the telephone company's own interconnecting equipment is approved for use. The vice of the present tariff . . . is that it prohibits the use of harmless, as well as harmful devices.*"
>
> * * *
>
> "*In view of the unlawfulness of the tariff, there would be no point in declaring it invalid as applied to the Carterfone and permitting it to continue in operation as to other interconnection devices. This would also put a clearly improper burden upon the manufacturers and users of other devices. The appropriate remedy is to strike the tariff and permit the carriers, if they so desire, to propose new tariffs which will protect the telephone system against harmful devices, and they may specify technical standards if they wish.*"[15]

The carriers initially responded to *Carterfone* by seeking FCC reconsideration; however, this was not granted. AT&T and GTE then filed for judicial review but, realizing this was fruitless, shortly withdrew their appeals and began to revise their interstate tariffs to conform with the FCC's decision.

Tariff revisions following Carterfone

The revised tariffs permitted the attachment of customer-provided devices, such as data modems, to the dial telephone network; they also permitted the interconnection of customer-provided communication systems, such as private branch exchange (PBX) switchboards, to both the dial telephone network and to "private line" channels leased from the carriers. Three new restrictions were imposed, however:

(1) The tariffs require that the power and spectral energy distribution of signals entering the switched network from interconnected customer equipment stay within prescribed limits. These criteria are intended to protect network services from excessive noise, intelligible crosstalk, and other forms of interference as well as to minimize circuit interruption, disconnections, improper billing, and voltages which might be hazardous to line maintenance personnel.

(2) A "protective connecting arrangement" supplied by the telephone company, for several dollars per month, is required where customer-provided devices or systems are interconnected to the dial telephone network. This coupler, called a data access arrangement (DAA) or voice access arrangement (VAA), effectively isolates the line from hazardous voltages potentially generated by customer attachments, and ensures that proper signal levels are not exceeded.

(3) The tariffs require that telephone-company-sup-

plied equipment perform all "network control signaling" functions on the dial telephone network, such as dialing and hook switch connect/disconnect. An exception to this rule became effective in 1971, to permit the use of customer-owned Touch-Tone dialing units (but not conventional rotary dials). This requirement is intended to prevent improper network signaling which may result in frequent wrong numbers, improper billing, and wasted maintenance and administrative effort.

The NAS report

Many users and potential suppliers of telephone equipment objected to the new tariffs filed by AT&T, on the grounds that they are still too restrictive by requiring both telephone company-supplied protective couplers and rotary dial equipment, and did not reflect the spirit of the *Carterfone* decision. In response to these objections, the FCC initiated informal engineering and technical conferences to assist in resolving questions raised by the tariff revisions and to ascertain the desirability and feasibility of further tariff changes. The informal conferences were conducted under the impartial auspices of a panel appointed by the Computer Sciences and Engineering Board of the National Academy of Sciences. The panel reported its findings in mid-1970.[26]

The National Academy of Sciences (NAS) panel reached the following conclusions:

(1) Uncontrolled interconnection can cause harm to personnel, network performance, and property.

(2) The use of protective couplers and signal level criteria is an acceptable way of assuring network protection; however, the added equipment reduces overall reliability while increasing costs.

(3) A program of standards and enforced certification of equipment would be another acceptable way of assuring network protection. This would increase the opportunities for innovation by users, without significantly impeding innovation by carriers. According to the panel, an equipment manufacturer could not be relied upon to certify its own equipment, thus requiring certification by an independent organization or government agency. The panel further concluded that equipment certification alone is inadequate; licensing of installation and maintenance personnel would also be required.

In essence, the NAS panel concluded that either of two approaches could assure a satisfactory degree of network protection:

(1) The use of protective connecting devices supplied by the telephone companies; or

(2) A program of standardization and properly enforced certification of equipment, plus licensing of installation and maintenance personnel.

A subsequent report to the FCC, prepared by Dittberner Associates, a Washington-based firm of data communications consultants, concluded that manufacturers of data modems and other sorts of interconnected customer equipment could easily build into their equipment the necessary circuitry to protect the telephone network.[4] It further found that the carriers need not have the exclusive right to provide network protective couplers. The report also concluded that a program of standards and certification of installation and maintenance *organizations* (rather than licensing of individual persons) would be an inexpensive way to extend interconnection privileges without harm to the common carrier network.

Recent interconnection developments

Both the NAS and Dittberner reports to the FCC concluded that safe and reliable interconnection of subscriber equipment could be accomplished without need for the onerous carrier-supplied access arrangement or coupler. The FCC had received many complaints from users and equipment manufacturers that the access arrangement represented a serious burden upon them—long delays were often encountered in obtaining a unit, once installed it sometimes degraded the signals passing through it, Bell kept changing its interface specifications, the device was grossly overpriced, etc.—and the Commission was eager to begin to implement an alternative program of equipment standards and certification. To get its feet wet, the Commission chose the private branch exchange (PBX) area for initial consideration, with the hope that experience gained there could soon be transferred to other interconnection areas (such as data communications) as well.

In March, 1971 the Commission established a PBX industry advisory committee with some thirty members representing carriers, equipment manufacturers, and users, and charged it with making recommendations concerning standards applicable to customer-provided PBX equipment. The PBX advisory committee intially proposed that the FCC establish a permanent Interconnect Board to oversee standards-making, equipment testing and certification, and other administrative aspects of an expanded interconnection program. This plan was criticized as being overly complex and bureaucratically cumbersome, and also several of the state utility commissions objected to Federal control of standards for installation, maintenance, or inspection of customer-owned equipment, or the licensing of inspectors for such equipment—feeling these to be matters of primarily local concern. NARUC, the national association of state regulatory commissioners, proposed the establishment of a federal-state joint board to provide policy guidance in interconnection matters; the FCC agreed to this proposal and promised to refer to the joint board for its consideration the final recommendations of the PBX advisory committee. Meanwhile, the PBX committee continued to explore feasible technical standards and less complex procedural machinery which might be established, and set April 1, 1972 as a target date for completion of the first phase of its final report.

At the time of this writing there is optimism that the FCC's PBX industry advisory committee will make significant headway in developing a workable interconnection program which will give maximum freedom to the PBX manufacturer and user without compromising the security of the telephone network. Such a program, if successful, can then serve as a model for other types of interconnection, such as data communications equipment. Unfortunately, the state commissions appear to represent a potentially significant obstacle to the liberalization of interconnection regulations. Commenting on the PBX advisory committee's equipment certification concept, NARUC expressed its traditional populist bias and said, "The liberalized interconnection of customer-provided PBX equipment will benefit a very affluent class of users by reducing their communication costs and, further, will benefit unregulated manufacturers of PBX equipment by increasing their profits." Perhaps NARUC should consider that communications represents a major part of the cost of doing business today, and when that cost is reduced, everyone benefits—the consumer as well as the corporation which sells to him. Also worth noting are AT&T's own admissions that the increased competition in communications—primarily through interconnection and the advent of specialized common carriers—has been good for Bell and good for the public.[28]

The changes brought on by *Carterfone* have been truly revolutionary, both in terms of creation of a new "interconnect" equipment industry and stimulation of innovation and lower costs in data communications hardware. It is estimated that nearly 200 firms have entered the data modem market since the FCC decision, bringing with them in many cases technology developed for defense and aerospace applications which previously had no commercial outlet. A wide variety of new, improved, and less expensive products have been introduced. Data terminal and multiplex manufacturers can now reduce overall system costs by incorporating modems (which they can manufacture themselves or obtain in the OEM market) directly into their equipment.[21]

The carriers have responded to this new competition by developing new products and cutting prices—much to the benefit of data communications users. For example, the "standard" low-speed modem has been Bell's series 103 data set, which has originate/answer capability (although many users operate in an originate-only mode) and rents for approximately $25 per month. When independent suppliers began to offer originate-only units for a small fraction of that price, Bell responded by introducing the 113 data set—originate-only, for roughly half the 103 price. Interestingly, 103 units in the field were then "converted" to 113s by merely snipping a lead to disable the unneeded "answer" capability. In the same vein, Bell in late 1971 announced plans to cut rental rates by 35 percent on its medium-speed series 200 data sets.

In spite of this vigorous competitive response by the telephone company, there is every indication that the interconnect industry is just beginning to take off. In the first 33 months since January, 1969 when Bell's new interconnection tariffs went into effect, Bell installed 8,100 data access arrangements for customer-owned modems—with almost 3,600, or 44 percent, of them put into service in the last six months of the period alone. The further regulatory changes which will hopefully be forthcoming soon through efforts such as those of the FCC's PBX advisory committee can only spur this growth and make available to more users the benefits of competition in the communications equipment industry.

SPECIALIZED COMMON CARRIERS

When one mentions "introduction of new competition" in the common carrier communications arena, probably the first thing which comes to mind is *Carterfone*, which introduced competition into the terminal equipment portion of the telephone network. But equally important for the future of data communications is a decision by the FCC the year after *Carterfone*, authorizing the first new "specialized carrier" to compete with the backbone intercity telephone network itself. This new carrier was Microwave Communications, Inc. (MCI), which had applied to the FCC in 1963 for permission to construct a microwave radio relay system between Chicago and St. Louis in order to offer the public a variety of dedicated private-line communications services in direct competition with Bell and Western Union.

MCI argued persuasively before the FCC that the established carriers were not adequately meeting all the specialized needs of business and data communications users and that its proposed services, tailored to these needs, would be in the public interest. On the other hand, the established carriers contended that FCC approval of a competing long-haul carrier would result in a wasteful duplication of facilities and would impair their ability to achieve maximum economies of scale. Furthermore, they said, MCI was just a "cream skimmer" trying to reap the profits of a dense high-traffic route while leaving the established carriers to serve the boondocks; if this were permitted it would destroy the traditional average-cost pricing system for telephone service and force the rates on less dense routes to rise. After almost six years of delay, hearings, legal briefs, and more delay, the FCC rejected the established carriers' arguments and approved the new entrant.[8] MCI was given construction permits for its 263-mile microwave system, and after some further procedural delays the company finally constructed its system and went on the air as a full-fledged carrier on January 1, 1972.

If this were all that happened, there would be little cause for more than academic interest among most data communications users. But the FCC's approval of MCI triggered a flood of over 1900 new microwave-station applications by several dozen firms proposing to build more than 40,000 miles of new specialized carrier communications facilities throughout the country. All but one of the applicants (16 of whom are affiliated with MCI) proposed MCI-like analog microwave facilities which would offer a variety of business-oriented private-line communication channels as well as channels specifically designed for data transmission. The exception was the Data Transmission Company, or Datran (a subsidiary of University Computing Co.), which proposed to build a nationwide all-digital switched network to offer exclusively data transmission services on both a switched and private-line basis.

These applications presented the FCC with a major policy problem, for the Commission was not sure that its *MCI* precedent should be extended on a nationwide basis without further analysis of the effects of such widespread competition among carriers. So the Commission in July, 1970 instituted a public inquiry into the merits of the specialized carrier concept. As might have been anticipated from previous experience in the computer inquiry, in which numerous respondents complained about the inadequacy of existing carrier services for data transmission, the specialized carrier inquiry elicited strong support for the MCI and Datran concepts from all sectors of the computer industry and from data communications users. The established carriers, of course, continued to bitterly oppose the new competition. The same issues concerning public need, effects upon telephone rate-averaging, and duplication of facilities were debated and resolved by the FCC in the same manner as it had done in the original *MCI* case. In May, 1971 the Commission issued its decision,[13] permitting virtually free entry of all financially and technically qualified applicants for specialized carrier service (many of whom had filed for the same routes and thus would compete with each other as well as with Bell and Western Union), subject only to resolution of any radio-frequency interference with existing microwave systems.

At the time of this writing a second specialized carrier has been granted construction permits by the FCC, for private-line service between New York City and Washington, D.C., and other systems will be cleared shortly. By the end of 1973 MCI-type specialized carrier systems could be operational throughout the country, and by the end of 1974 Datran could have its digital network on the air. It is inevitable that as the various specialized carriers construct their regional microwave systems they will interconnect with each other in order to offer through service between different parts of the country, and thus a nationwide "second network" will come into being to compete with the telephone network. In addition to the microwave relay facilities which will form the backbone of this new network (just as microwave is the backbone of today's long distance telephone network), other types of communications facilities may also be used; domestic satellites may provide economical long-haul trunk circuits (note that two specialized carriers, MCI and Western Tele-Communications, Inc., have applied for permission to operate domestic satellite systems) and two-way CATV systems may be used for local distribution to subscribers in urban areas.

In terms of impact upon data communications, the advent of the specialized carrier will bring with it a number of important and generally beneficial results:

- New data communication services (many different channel sizes, rapid-connect switched service, etc.).
- Lower error rates in data transmission.
- Specialized carrier rates considerably lower than today's telephone rates for equivalent service.
- Modification of certain telephone rate structures, as a response to the new competition.
- More rapid introduction of new technology (e.g., advanced digital microwave and solid-state switching) by the new and old carriers alike.
- More responsiveness by the telephone companies to the needs of data communications users.

- Ability of the FCC to use the new carriers as a yardstick to measure the performance of Bell and the other telephone companies.

The degree to which the individual user will be affected by or able to take advantage of these results will obviously vary widely depending upon individual circumstances, but it is safe to predict that the overall impact of the specialized carriers will be substantial.

Due to limitations of space this has been a necessarily brief and superficial overview of a rather involved subject. The reader interested in a comprehensive discussion of the specialized carrier concept, specific features of the MCI and Datran systems, policy considerations, and outlook for the future is referred to recent papers by the author in References 30 and 31.

DOMESTIC SATELLITES AND CABLE TELEVISION

During the past several years the FCC has taken action to open the communications market to the entrance of new competitors and to make available new services to the public in two important areas: domestic communications satellites and cable television (CATV). Both of these developments hold great potential significance for data communications.

Domestic communications satellites

The world's first satellite, Sputnik I, was launched fifteen years ago. Congress formed the Communications Satellite Corporation (COMSAT) ten years ago, to serve as the U.S. agent in establishing and operating an international communications satellite network. The first operational satellite in this international network was launched seven years ago, and in the same year the first of many proposals was made to establish a *domestic* communications satellite network for the U.S. Today. Russia has such a network (albeit with random-orbiting rather than synchronous satellites). Canada will launch its first domestic satellite later this year and other nations are also moving toward a similar goal. Still the U.S. does not have a domestic satellite system or even approved plans to build one. At last, however, it appears that one or more firms will be given FCC approval to establish such a system or systems in this country.

The economic benefits of a domestic communications satellite system were appreciated years ago,* and the technology to implement such a system has also been available for five years or more—for a domestic system would use essentially the same sort of geostationary synchronous satellite which INTELSAT has been using in its international network since 1965 (quantum improvements in system performance, cost, and channel capacity have been made since 1965, and several new generations of satellites have appeared, but the concept has remained unchanged). The stumbling block which has kept the U.S. from taking advantage of this technology has been a series of unresolved fundamental policy questions such as whether there should be only one or more than one domestic system, who should be permitted to operate such system(s), whether the satellite operator should sell service directly to the public or through the established terrestrial carriers (such as COMSAT does in the international arena), and other issues.

After the American Broadcasting Company submitted to the FCC in 1965 a semi-serious proposal to build a domestic satellite system for low-cost television distribution, the Commission opened an inquiry on this subject and invited comments and counter-proposals. Several alternative satellite proposals were promptly submitted by other organizations, and considerable public interest was generated. The FCC began its deliberations and for a while it looked as if we would have a satellite system in operation by 1970 or 1971. But then the Commission's decision-making process ground to a halt for more than a year while President Johnson's Task Force on Communications Policy studied the issues in late 1967 and 1968. The Task Force eventually recommended approval of a single "pilot" program to be run by COMSAT,[27] much as COMSAT had proposed in 1967 (see Figure 1), and the FCC—predisposed in this direction anyway—began to move once more toward a decision along these lines.

But President Nixon took office a few weeks after the Task Force report was received, and before the FCC had time to act the White House requested another delay so that the President's staff could study the issues anew. This study was directed by Dr. Clay T. ("Tom") Whitehead—a White House staff assistant who was

* For the data communications user, these benefits include a distance-independent cost structure, with circuit costs only a fraction of corresponding terrestrial microwave or cable costs for long-haul circuits—those over a thousand or so miles in length; a potential wide variety of channel bandwidths and data transmission capacities; lower error rates than frequently experienced on long terrestrial circuits; and relatively easy and economical access to remote areas of the country which may lack adequate terrestrial transmission facilities.

	1957	Sputnik I launched by USSR—the world's first satellite.
	1962	Congress passes Communications Satellite Act, providing for establishment of a new privately-owned corporation, Communications Satellite Corporation (COMSAT), to serve as the U.S. entity in *international* satellite communications.
	1963	Syncom launched by NASA—the first geostationary synchronous satellite.
	1964	International Telecommunications Satellite Consortium (INTELSAT) formed to create international satellite communications network.
	1965	Early Bird launched—the first commercial communications satellite and the beginning of the INTELSAT network.
	1965	American Broadcasting Co. submits proposal to FCC for a domestic TV-distribution satellite.
	1966	FCC opens inquiry on domestic satellites, and asks broad policy questions regarding establishment of systems by non-government entities.
	1966	Ford Foundation submits counter-proposal for a multi-purpose domestic satellite, with profits to be used to support educational television.
	1966	COMSAT proposes a multi-purpose domestic satellite, to be operated by COMSAT as a "direct-to-end-user" carrier (*not* a "carrier's carrier," as COMSAT operates internationally). Four other organizations also propose satellite systems.
March	1967	COMSAT proposes "pilot demonstration program," with two satellites to be operated by COMSAT as trustee until FCC decides ownership issue.
August	1967	President Johnson appoints Task Force on Communications Policy to study domestic satellites and other issues; FCC suspends action in its domestic satellite inquiry pending receipt of Task Force recommendations.
December	1968	President's Task Force submits report recommending approval of a single "pilot" domestic satellite program, with COMSAT having primary responsibility.
February	1969	General Electric Co. proposes domestic satellite concept using time-division multiple access (TDMA) techniques to provide new and expanded services.
July	1969	As FCC prepares to approve a pilot domestic system substantially as recommended by President Johnson's Task Force, the White House requests a delay until President Nixon's staff can study the matter and submit recommendations.
January	1970	White House sends memo to FCC urging approval of all financially and technically qualified applicants for common carrier or private domestic satellite systems—instead of single pilot system as contemplated by FCC.
March	1970	FCC issues Report and Order in domestic satellite inquiry, adopting White House recommendation and inviting all interested parties to submit domestic satellite proposals.
March	1971	Before its deadline, FCC receives eight applications for satellite systems.
May & July	1971	FCC receives comments and reply comments from the applicants and other interested parties regarding the eight applications.
Fall	1971	NASA performs technical evaluation of the applications for FCC.
Early	1972	FCC decision expected.

Figure 1—Domestic satellite chronology

later to become the first director of the new Office of Telecommunications Policy (OTP) in the Executive Office of the President—and came to conclusions quite different from those of President Johnson's Task Force and the FCC. Rather than supporting the concept of a single pilot system to test and demonstrate the workability of domestic satellite communications, which would create at least a temporary and perhaps a permanent monopoly structure in this new field, the White House in January, 1970 recommended to the FCC a policy of immediate open entry and free competition. In summary, it was urged,

> *"Subject to appropriate conditions to preclude harmful interference and anti-competitive practices, any financially qualified public or private entity, including Government corporations, should be permitted to establish and operate domestic satellite facilities for its own needs; join with related entities in common-user, cooperative facilities; establish facilities for lease to prospective users; or establish facilities to be used in providing specialized carrier services on a competitive basis."*[16]

Although theoretically the FCC is an independent regulatory agency, and need answer only to Congress for its policies, in practice it is difficult to ignore such direct pressure from the White House. Therefore, within three months after receiving these recommendations the Commission changed course and issued a report and order adopting the concept of open entry and free competition in domestic satellites.[6] Since the satellite applications submitted back in 1965-67 were technically out-of-date by 1970, the Commission invited the submission of new applications by all organizations interested in building either common carrier or private domestic satellite systems. Before its deadline in early 1971 the Commission received eight applications for satellite systems, all to be used to provide various types

Applicant	Operational satellites	In-orbit spares	Transponders per satellite[1]	Total no. of transponders[1]	Transmit-receive earth stations	Receive-only earth stations

Figure 2—Proposed domestic satellite systems

[1] Each transponder has a capacity of some 900 one-way telephone channels, or one color television channel, or some 35 megabits/sec. of time-division multiplexed (TDM) data.

[2] Plans include numerous additional earth stations of this type in the future.

[3] Initial system only. An additional satellite is proposed for later launch, when the first one approaches saturation.

of common carrier services. Figure 2 lists the applicants and gives a rough idea of the size of their proposed systems—number of satellites, transponders (the broadband microwave communications repeaters aboard the satellite), and earth stations. The different applicants proposed to offer a wide variety of communications services with their systems, including the following:[5]

- Augmentation of existing common carrier (AT&T, WU, GTE) trunk-capacity, for traditional switched and private-line services (voice telephone, data, teletype, facsimile, etc.).
- High-speed data channels at speeds well above the maximum available from the carriers today.
- Multi-destination one-way data channels for the distribution of news, educational material, financial, medical and scientific data.
- Video channels for studio-to-studio program distribution for the three commercial television networks and for CATV operators throughout the nation.
- Cost reductions of 50 percent and more for conventional voice, data, and video private line (leased) service.
- Public interest services such as free or reduced-rate video channels for educational television; free service to the medical community for improvement of health care; and full service to remote areas such as the Alaskan bush and the Panama Canal Zone.
- Intercity Picturephone service.
- Motion picture distribution service.
- Electronic mail service, in conjunction with the U.S. Postal Service.
- Lease of circuits or entire transponders to other carriers.

It is anticipated that the FCC will act on these applications in 1972, and will almost certainly approve several—if not all—of them. Two to three years thereafter, the U.S. will finally have an operational domestic satellite network, probably composed of a number of firms in hot competition with one another. Based on our national experience with industrial performance in a wide variety of competitive and non-competitive industries, it is reasonable to expect this competition to yield significant benefits. In the first place, it is unlikely that any single firm which might have been chosen to provide domestic satellite service on a monopoly basis would offer the wide range of services listed above, for several reasons—lack of competitive pressures, desire to protect existing terrestrial communications revenues (if the satellite firm were an established carrier), unwillingness to face the risks of introducing so many untried new services, lack of capacity of a single satellite system, etc. With multiple competing suppliers in the marketplace, the rate of innovation will be higher and the cost savings due to the new technology will be passed on to the user to a greater degree. Of course, if the market for domestic satellite service is inadequate to support all the competitors, ill effects of "ruinous competition" could occur; but it is expected that the would-be satellite operators will evaluate this risk carefully before undertaking actual system construction (and for this reason not all of the systems which the FCC might authorize may actually be built—just as with the specialized carriers, some of the weaker applicants may fall by the wayside).

In conclusion, it is unfortunate that this country, which was responsible for the development of most of today's impressive communications satellite technology, has had to wait so long to take advantage of it at home.

However, the changes in national communications policy thinking—from a monopoly environment to free competition in domestic satellites—which began to occur in 1969 should make our experience with the domestic satellite much more meaningful and beneficial. So perhaps it is worth waiting for after all.

Cable television service

When the data communications user or the designer of remote-access computer systems thinks about the communications resources at his disposal, he generally limits his universe to the various services offered by the traditional common carriers—the telephone company and Western Union. As we have seen, the new capabilities of specialized carrier systems and of domestic communications satellites have come onto the horizon in the last several years, and will have a large impact in the near future. Many users are at least vaguely aware of these developments and eager to begin to reap the benefits they hold in store. But few people in the computer community have given serious attention to yet another new technology and new communications sub-industry which has been evolving around us and which may eventually have an even larger impact in making the power of the computer widely and economically available throughout our society. This is the field of cable television, or CATV (sometimes referred to as community antenna television), which began in 1949 in the hills of eastern Pennsylvania and Oregon and has since spread to over 4000 cities and towns throughout the country.

The early CATV systems were located in isolated rural communities and consisted simply of a tall antenna (perhaps mounted atop a nearby hill) to pick up broadcast television signals from cities some distance away, amplifiers to boost the weak signals, and a coaxial cable network to distribute the signals to subscribing households in the community. Later, microwave radio began to be used to enhance the value of many CATV systems, by piping in signals from TV stations so distant that they could not be received by even the cable system's master antenna. In some isolated communities CATV provided the only means of television reception; and in other areas it enabled viewers to receive many more TV channels than they could by using a home antenna. The new medium thus offered a real benefit to the consumer and was also beneficial to the broadcaster, for it enlarged the size of his audience and thus his advertising revenues. But it was not long before cable outgrew its small-town beginnings and began to look toward the cities where the most dense and lucrative concentrations of viewers are located.

Sometimes a big-city cable system could (and can) attract subscribers by merely providing clear ghost-free reception of the local TV stations (e.g., in New York City, where ghosts are a serious problem for many viewers); but generally the cable operators found that success in the metropolitan areas depended upon their ability to "import" distant signals from other cities—for otherwise why would a viewer who already has several local channels pay $5.00 or so per month to connect to the cable? And, of course, the local over-the-air broadcasters were afraid that their previously captive audience would be fragmented if the cable system were permitted to import attractive distant signals. The stage was thus set for a regulatory battle of major proportions.

After previously declining to regulate cable television on the grounds that it was unsure of its jurisdiction under the Communications Act of 1934, the FCC changed course in 1965 and asserted jurisdiction over microwave-fed cable systems. Then in 1966, acting under pressure from the broadcasters, the Commission asserted jurisdiction over all CATV systems and imposed severe restrictions upon the carriage of distant signals in the top-100 television markets [which range from New York City (No. 1) to places like Fargo-Grand Forks-Valley City, N.D. (No. 98) and Monroe, La.-El Dorado, Ark. (No. 99)]. In 1968 the Supreme Court affirmed the FCC's assertion of regulatory jurisdiction over CATV, and soon thereafter the Commission imposed a virtual freeze on new CATV systems in the top markets—until the issues could be sorted out and a workable means found to open up cable's potential to serve the public without at the same time undermining the foundation of the existing over-the-air broadcast structure.

The Commission saw in CATV a threefold potential contribution toward improving the nation's communications system: "providing additional diversity of programming, serving as a communications outlet for many who previously have had little or no chance of ownership of or access to the television broadcast system, and creating the potential for a host of new communications services."[7] This third characteristic of cable is, of course, the important one for the data processing and data communications community and it is also the aspect of cable which has caused the most speculation about the future nature of the industry. The literature is replete with discussions of the "wired city" concept, which is based upon the broadband communications capability of the CATV cable.[25] Not only can cable provide 20, 40, or more channels of commercial, educational, and special-purpose (e.g., weather, stock ticker, news wire) television, but also it can provide a great variety of computer-oriented services such as information distribution and retrieval, interactive computing, remote shopping, computer-assisted instruction, opinion polling, and many others. In order to provide most of these services, CATV systems must have two-way transmission capability (for at least low-speed data input from the user in his home or office) rather than the one-way cable system designs which are almost universally used today. Considerable development work on two-way cable has been undertaken, and several experimental systems are presently in operation[1,19,24]—so the most critical problems today are regulatory and economic rather than technical in nature.

After freezing the growth of cable in the major metropolitan centers, and thus gaining a little breathing room, the FCC began to explore the policy problems in depth. In the fall of 1969 the Commission took an important step to further the growth and economic viability of cable, and permitted CATV systems to originate programming and to sell advertising. The key issue of distant signal importation, and a related question of compensation for program copyright owners, were the subjects of several attempted compromises between cable and broadcast interests during the period 1969-71. Finally in 1971 the FCC announced its intention to issue a comprehensive set of rules which would permit limited importation of distant signals into the major markets, would at the same time provide a measure of protection for affected broadcasters, and would require that cable systems include substantial non-broadcast features—mandatory two-way capability, free channels for public access, government and educational use, and excess channel capacity to be sold on a common carrier basis to all comers.[2,7] In late 1971 the FCC and OTP engineered a cable/broadcasting compromise agreement essentially along these lines, and at the time of this writing new FCC rules were expected momentarily.

Some observers feel that the expected FCC rules are still overly protective of broadcasters in the top-50 markets (the rules are less protective in markets 51-100), and will slow the development of cable in those cities. Thus, the Commission may need to liberalize its rules in the future after more experience is gained. In the meanwhile, at least the 1968 freeze is broken and cable can begin to enter the large cities and hopefully to fulfill the many promises which have been made about its potential.

The long-range implications of CATV for data communications and remote-access computer services are enormous. Once high-capacity two-way cable systems are operational in the major urban areas they will provide cost/effective access to the homes and offices of the customers of many of the remote-access computer services now on the drawing boards; they will provide broadband point-to-point transmission capacity for data communications users in the urban area; they will provide an additional alternative means of connecting specialized intercity microwave carriers with their customers in the city; and very likely many of the urban CATV systems will eventually be interconnected with one another through domestic satellite facilities, making possible a nationwide broadband network of enormous potential. The cable system already finds itself in ever-increasing competition with the broadcaster; soon it will also compete with the telephone company and perhaps with other sorts of communications entities as well, in providing a wide range of new communications services. Having set the stage by permitting CATV to compete, the FCC must now face the problems of regulating the new competition—setting detailed standards for common carrier services on the cable, etc.—so that CATV technology will most effectively serve the public. Questions of state regulation[33] and of possible new federal legislation will also be important in the coming years as cable matures.

SUMMARY

The past five years have witnessed a number of regulatory developments which will have a major impact upon the future of data communications. The FCC has introduced competition into the "interconnect" equipment market and into the long-haul communications carrier market, it has invited proposals for competitive domestic communications satellite systems from all interested parties, and it has cleared the way for cable television to enter the large urban areas and to provide a variety of new competitive communication services. Meanwhile, in its computer inquiry the Commission has studied several important computer-communications policy issues and has taken action regarding some of them, such as attempting to establish a regulatory framework for the public offering of hybrid message-switching services. Each of these developments is important in its own right for the benefits it brings to data communications; but viewed together they take on a larger importance, signaling the beginning of a new competitive era in the communications industry—a change in regulatory thinking which should benefit all members of the computer-communications community.

Data communications in 1980—A capital market view

by ROBERT E. LA BLANC and W. E. HIMSWORTH

Salomon Brothers
New York, New York

INTRODUCTION

Communications industry revenues presently represent approximately 2 percent of the GNP and are growing substantially faster than the GNP. The important question thus arises as to what capital resources will be available to support continued growth in the Seventies—a question of particular interest to the data communication user, whose needs are projected to expand at an explosive rate. By 1980, this growth could occur in any of the following areas:

- Continued use of the existing analog telephone network as well as new data services on the Picturephone network;
- New digital private line facilities offered by the existing carriers;
- Expansion of Western Union facilities and service offerings;
- Domestic satellite systems;
- Private line and switched facilities of the special service common carriers;
- Possible joint use of data on CATV systems.

This paper examines the capital resource needs of each of the major communications industry segments, and then, in the light of the likely expansion of the GNP and the consequent expansion of funds available from the capital markets, projects what data communication facilities are likely to be available by 1980.

While it is obviously difficult, if not impossible, to accurately project ten years into the future, we hope that the estimates made in this paper will provide a basic understanding of the problems and opportunities confronting the industry in the coming decade.

CAPITAL REQUIREMENTS TO 1980

The capital requirements of the communications industry for 1971-1980 are developed in this section for each of six market segments. Projections of operating revenue and gross plant, based primarily on industry expectations, are shown in Table I. Plant investment provides an indication of total financial requirements which, in turn, leads to our estimates of capital market demands shown in Table II.

Telephone

In terms of revenue and capital requirements, the telephone companies, and the Bell System in particular, have dominated and will continue to dominate the communications industry. The present telephone network, including the independents, serves a total of about 125 million telephones, which is up from 74 million in 1960 and 94 million in 1965. Interstate messages handled per year have increased from 1.0 billion in 1960 to 1.6 in 1965 to 2.7 billion by the end of last year. Gross plant investment has increased 134 percent in the decade of the Sixties, and today stands at over $66 billion. Annual revenues during the same period grew from $7.8 billion to $16.8 billion, or an increase of 215 percent.

In looking ahead to 1980, several factors should be kept in mind. AT&T has shown that local telephone service growth correlates closely with the growth in new family formations, and that demographic statistics indicate that with those entering the 18-to-25-year marriageable age category in the coming ten years, local telephone growth is expected to average 8 percent yearly. Toll service revenue, which grew an average of 11.5 percent yearly in the 1960s, finished the decade with growth of 15.2 percent in 1969. In 1970, during the economic downturn, network long distance revenues grew close to 8 percent for Bell. Interstate telephone message volume, excluding WATS, is expected to increase to about 10 billion messages per year by 1980 and Bell expects the number of private line circuits to more than double. We thus believe that total revenue growth

TABLE I—Revenue and Plant Projections (Billions of Dollars)

	1960	*1965*	*1970*	*1975E*	*1980E*
Operating Revenue					
Bell System	$8.1	$11.3	$17.0	$28.0	$40.0
Independent Telephone	1.0	1.7	2.9	4.7	7.3
CATV	0.0	0.1	0.4	1.0	3.1
Special Service Common Carriers	—	—	—	0.1	0.8
Western Union	0.3	0.3	0.4	0.8	1.5
Domestic Satellite	—	—	—	0.2	0.4

Western Union	0.3	0.5	0.7	1.5	3.0
Domestic Satellite	—	—	—	0.6	1.2

Source: Salomon Brothers' estimates.

from the telephone sector of communications can be reasonably expected to grow at an 8.5 percent to 10 percent compound rate through 1980.

Certainly, additional revenues generated by such growth areas as data communications and the Picturephone network will augment this growth. Bell has forecast growth in data transmission revenues from $500 million in 1970 to $5 billion in 1980. A Picturephone network of from 500,000 to one million terminals can be safely assumed for 1980, with data usage estimated at 25 percent of total network usage.

The telephone industry has conservatively estimated annual revenues approaching $50 billion by 1980. This would imply gross plant investment of over $160 billion in the industry by 1980. Based on our models of the industry, we estimate a need for about $63 billion in outside financing to fund this telephone plant investment. This includes roughly $5 billion in 1971, which accounted for almost all of the communication industry's capital demand.

CATV

CATV today serves over 6 million homes in over 4500 communities. Growth from 650,000 homes in 1960 and 1.3 million in 1965 has been at an annual rate of about 25 percent. With the projected implementation of the recent FCC proposals, growth to 25–30 million subscribers by 1980 is indicated. Revenues, up from an estimated $39 million in 1960 and about $80 million in 1965, reached $360 million in 1970. We believe revenues can reasonably be on the order of $1 billion by 1975 and $3.1 billion by 1980, reflecting greater channel usage and two-way services. Gross plant investment from a $900 million level in 1970 should be at about the $2.6 billion level in 1975 and $7.8 billion in 1980. This will require an estimated $5.7 billion in outside financing.

Special service common carriers

The special service common carriers, both DATRAN and the MCI types, are obviously starting from scratch. Construction permits are being issued by the FCC in accordance with the broad general policy laid out in the final order in Docket 18920. Estimates vary as to the impact these carriers will have on the industry. Forecasts of 1980 revenues range from $750 million (Arthur D. Little) to $2 billion (Frost and Sullivan). Taking a conservative approach, an estimated gross plant investment of at least $1.5 billion by 1980 and an external financing requirement of $1.2 billion is indicated.

Western Union

Western Union is rapidly moving to become the major provider of computer-enhanced record com-

TABLE II—External Financing Projections (Billions of Dollars)

munication in the United States. The concept of providing a fully integrated family of common user and private line message switching services took a giant step forward with the cutover in January of this year of the first of its Phase II ISCS Centers at Middletown, Virginia. This center, with a capacity of over one million prime time business messages per year, is currently being used to provide a wide variety of data communications services. Based on projections of growth for these varied services, revenues are likely to grow from the current $400 million level to over $1.5 billion by 1980. Since Western Union's computer-enhanced communications services provide an inherently efficient utilization of transmission and message switching facilities, this revenue level can be supported with a gross plant investment of only an estimated $3 billion, with $1.1 billion of external financing required.

Domestic satellites

Domestic satellites represent another exciting potential source of facilities for the data communications user in 1980. Here, however, it is necessary to realize the type of data communications which lend themselves feasibly to Domsat carriage. Due to the inherent time delay involved in an approximately 45,000-mile earth station-to-earth station path, these facilities are not really suitable for interactive types of data communications. Bulk transfer of one-way information, similar to the type of electronic mail currently being offered by the joint Postal Service/Western Union Mailgram service, is ideal, and certainly must be viewed as technically and economically feasible. Based on a projection of three operational systems carrying a variety of communications services by 1980, potential revenues of $400 million with a gross plant investment in both satellite and earth station facilities of about $1.2 billion seems reasonable. Taking into account the high depreciation rates on the satellites, we estimate that $0.8 billion will have to be raised from the capital markets.

Total requirements

The sum total of our projections shows a demand for new external capital of over $71 billion which must be raised in the ten-year period from 1971 to 1980. Additionally, over $5 billion must be raised to refinance telephone company bonds that will be maturing in the same period. The total capital requirements of the communications industry, therefore, exceeds $76 billion.

TABLE III—Capital Market Overview
(Billions of Dollars)

	1960	*1965*	*1970*	*1975E*	*1980E*
GNP	$504	$632	$977	$1300-1450	$1800-2200
Total Credit & Equity Market Supply	35	68	92	120-140	150-200

Source: Salomon Brothers' estimates.

This amounts to an annual rate of approximately $7 billion a year in 1975 and $10 billion in 1980. As shown on Table II, the telephone companies will use about 90 percent of this capital.

CAPITAL MARKETS THROUGH 1980

To fully understand the significance of these demands by the communications industry on the capital market, it is necessary to examine trends in both total money supply and demand in competing sectors of the economy.

GNP and net new capital

The GNP in current dollar terms stood at $504 billion in 1960, $632 billion in 1965, and $977 billion in 1970. This represents a growth in current dollar terms of over 6.8 percent per year. Looking out to 1975 and 1980 real growth in constant dollar terms of between 3.5 percent to 4.0 percent is estimated, with inflation of 3.0 percent to 4.5 percent yearly, yielding a growth in current dollar terms of 6.5 percent to 8.5 percent. It is estimated that the 1975 GNP will fall in a range of $1300 billion to $1450 billion, and the 1980 GNP will be between $1800 billion and $2200 billion (Table III).

In the late 1960s the average percent of the GNP saved and invested by government, business, and individuals ranged between 8.1 percent and 9.9 percent, with 9.0 percent as an average. Using the late 1960s as a representative model of what is likely to be encountered in the 1971-1980 time period, the total supply of debt and equity available for funding growth in the U.S. economy will likely be between $120 billion and $140 billion in 1975, and between $150 billion and $200 billion in 1980.

TABLE IV—Selected Demands Segments

	Percent		
	1961-65	*1966-70*	*1971E*
Private Mortgages	41.6	26.3	32.3
Total Corporate	12.4	22.7	23.5
State & Local	10.8	14.1	16.5
Federal Agencies	2.5	7.7	2.6
Sub-total	67.3	70.8	74.9
All Others	32.7	29.2	25.1

Source: Salomon Brothers' estimates.

Market demand

The total demand for funds can be categorized as follows:

A. Debt

1. Privately held mortgages
2. Corporate bonds
3. State and local securities
4. Foreign bonds
5. Business, consumer, and bank loans
6. Open market paper
7. Privately held Treasury and Federal Agency Securities

B. Corporate Equity

1. New cash offerings
2. Sale of stock options
3. Conversions of bonds

Of these categories, total corporate demand, mortgages, and certain governmental segments are of particular interest. The historic trends for these selected demand segments are shown in Table IV.

In the early 1960s corporations were relatively modest demanders of capital. In the 1961-65 period, corporate demand represented $35 billion, or 12 percent of the total demand for capital. By contrast, privately held mortgages consumed $117 billion, or 42 percent, of the total available funds. In the 1966-70 timeframe a number of factors caused significant changes. The credit crunch of 1966 coupled with the many statutory limitations on allowable interest that could be charged for mortgages caused the mortgage markets to tighten, and this sector declined to $105 billion, or 26 percent of total available funds. Corporate demands, on the other hand, more than doubled to a total of $91 billion, or 23 percent of total funds available. In 1971, with the "Federalization" of the mortgage market through such Federal agencies as FNMA, GNMA, and the Farm Home Loan Agency, mortgage demand is estimated at $40 billion, or 32 percent of totally available funds. Corporate demands, used largely to fund short-term liabilities, increased during the recent downturn in the economy, remaining relatively high at $29 billion or 23 percent.

State and local governments, responding to increasing pressure to meet the needs of society, have almost doubled their requirements for funds. In the 1961-65 period demand from this sector totaled $30 billion or 11 percent of total supply, while in the 1966-70 timeframe the comparable figures were $56 billion and 14 percent. For 1971, state and local governments required about $20 billion, or 16 percent, and demand from this sector is expected to continue to increase.

Another factor to consider is the growth in Federal Agency financing. In the 1961-65 timeframe these agencies funded $7 billion of debt—only 3 percent of the funds available. By the 1966-70 period total Agency demand had increased over four times to $31 billion or almost 8 percent of the total. The 1971 Agency demand is estimated at only $3 billion, or 3 percent.

CONCLUSIONS

Financial competition

Based on the above analysis, projected communications demands can now be placed in perspective, comparing them to the rising demand for corporate funds as a whole. In the 1961-65 period the communications industry required $7 billion in outside financing or some 20 percent of all corporate demand. Comparable figures for the 1966-70 timeframe were $13 billion and 14 percent. In both 1970 and 1971, however, annual requirements exceeded $5 billion and accounted for 17 -18 percent.

TABLE V—Communications Financing Demand
(Billions of Dollars)

	1961-65	*1966-70*	*1971*	*1971-75*	*1976-80*
Total Communications	$7.0	$12.7	$5.4	$31.2	$45.4
Percent Total Corporate	20	14	18	15-18	15-20

Source: Salomon Brothers' estimates.

As shown in Table V, it is estimated that the communications industry will continue to require 15-20 percent of the total corporate needs for external financing. In the coming decade, with increasing demands from all sectors of the economy, the industry will have to make itself relatively more attractive than its competitors in the capital markets in order to continue to attract this large a share. This means good balance sheets, "clean" accounting practices, attractive rates of return on both total capital and equity, and, of course, growth in earnings per share.

Very obviously, these requirements may be very difficult to achieve for the new entrants in the communications industry. In the more competitive, less sheltered atmosphere envisioned by both the FCC and the President's Office of Telecommunications Policy, a license to get into the business may not necessarily be a guarantee for making a profit, nor adequate collateral for obtaining capital funds. We feel very strongly, therefore, that communications in this decade will be shaped more decisively by financial constraints than by any other factor.

Data communications in 1980

In light of our view of the future of the communications industry as a whole, the following predictions can be made about the availability of data communications facilities in 1980.

A. The Bell System, with its continuing strong financial position, will continue to dominate the data communications business. Now that Bell has recognized that there will be a $5 billion data communications market in 1980, and that competition is increasing, we think you will see many more services geared to the data user. It is important to note that these services can be provided as an adjunct to voice (and, eventually, Picturephone services) with a relatively small incremental investment. Last year's announcement of future digital services, based on a "Data Under Voice" technique, is an indication of this approach. We also believe that, with the possible congestion of microwave frequencies for use in urban distribution of data communications signals, Bell will open up its cable distribution plant to low level, direct current type signals, eliminating the need for costly modems for limited distance use.

B. CATV will not have achieved its potential as a major provider of local data interchange services by 1980. The CATV business is a particularly capital-intensive one, whose growth will be financially limited. It is our opinion that the primary industry thrust in this decade will be to use its available financial resources to expand its subscriber base in the residential entertainment market. While certain token two-way services may be offered to serve specific markets or meet FCC regulations, full-scale development in this area will be postponed until the late Seventies or early Eighties.

C. The competitive response of the established common carriers to the MCI-type carriers will sufficiently limit the financial attractiveness of new point-to-point services, and keep them from becoming a major communications factor. DATRAN's nationwide, switched, digital system, on the other hand, is both technically unique and inherently more economical than either private line or switched analog facilit'es, or private line digital facilities. We feel DATRAN can be providing about 10 percent of the data communications traffic by 1980, assuming that its initially high capital requirements can be met.

D. We believe Western Union's centralized thrust—that of providing a fully integrated computer-centered message switching and transmission system to serve the record communications needs of business, government, and the general public—is an extremely viable one. Western Union's overbuild of its existing microwave network with full digital transmission capability very obviously allows them to make the most efficient use of their plant, with minimal capital investment. It is our feeling that Western Union will continue to aggressively market new communications services, as they have done with DATACOM, and that with the availability of their new Electronic Data Switch Network the company can be providing a whole range of switched and private line digital data services by 1975.

E. The use of satellite systems, except those provided by Bell and Western Union as fully integrated parts of their already existing and currently planned network operations, will be far too costly and far too limited for broad applicability to data communications.

The growth of data communications services and, in a broader sense, of the entire communications industry, is governed by the technological, marketing, and financial capabilities of the competing companies. Too often, discussions on the future of data communications concentrate on its exciting technological developments and potential applications demands while neglecting the very obvious fact that facility growth must be financed. As shown by the projections made in this paper, financing communications growth in the Seventies is a non-trivial problem with broad implications for users and providers alike.

Allocation of copies of a file in an information network

by R. G. CASEY

IBM Research Laboratory
San Jose, California

INTRODUCTION

We consider a mathematical model of an information network of n nodes, some of which contain copies of a given data file. Within this network, every node is able to communicate with every other node over communication links (a process which may entail routing through intermediate nodes). In particular, we are concerned with transactions with the multiply-located file. Such transactions fall into one of two classes: (1) query traffic between a node and the file, and (2) update traffic. An update message is assumed to be transmitted to every copy of the file, whereas a query is communicated only to a single copy.

We proceed to demonstrate, within a simple linear cost model for the network, several properties of the optimal assignment of files to nodes. One set of results expresses bounds on the number of copies of the file that should be included in the network, as a function of the relative volume of query and update traffic. Secondly, a test useful in determining the optimum configuration is derived.

The problem of allocating resources in a network first arose within the context of determining the most economical location for manufacturing plants and warehouses.[1,2,3] In some studies, the model of the network is made in such a way that an efficient algorithm yielding the optimal allocation is not readily obtainable, and heuristic or approximate techniques are tried instead. Frazer,[4] for example, has developed a method for allocating production facilities when the cost of deploying a resource at a given node consists of a fixed overhead expenditure plus an amount proportional to the total demand on the facility.

These manufacturing models are conceptually different from the file allocation problem, when updating traffic is considered in the latter. Since all copies of a file are modified by each update message, the total volume of data transmitted in the network is not independent of the allocation policy, as is the total volume of goods shipped in a manufacturing environment, but rather increases with the number of file copies allocated. Yet, as will be shown, the models are mathematically equivalent to the file model analyzed here.

Chu[5] has investigated a linear programming solution to the file allocation problem. His model includes storage costs and queuing delays, but the number of copies of each file in the system is assumed to be known. Whitney[6] has formulated a similar model, and applied it to the task of designing network topology, as well as that of allocating copies of the file.

THE MODEL

The fixed cost (mainly for storage) of locating a copy of the file at the kth node ($k=1, 2, \ldots, n$) will be denoted by an amount σ_k, measured in, say, dollars per month. The symbols λ_j and ψ_j will be used to represent the volume of query traffic and of update traffic, respectively, emanating from node j ($j=1, 2, \ldots, n$). The quantities d_{jk} and d_{jk}' are the costs of a unit of communication from node j to node k for a query and an update transaction, respectively. Thus, d_{jk} and d_{jk}' might be measured in dollars per megabit transmitted, and λ_j and ψ_j expressed in megabits per month. The possibility of a difference in cost rates is included in the model on the premise that in many applications updates can be accumulated and transmitted either via a cheaper medium (e.g., by mailing magnetic tapes), or at a time when communications rates are lower (e.g., at night using switched lines).* Queries are assumed to be entered on-line, at a higher communication rate. If the kth node contains a copy of the file, then communications from the jth node produce a cost term of $\lambda_j d_{jk}$ for query transactions and an amount $\psi_j d_{jk}'$ for update

* The author is indebted to Dr. W. D. Frazer of IBM Research for pointing out this generalization.

transactions. Actually, in much of the discussion that follows, and in the experiments carried out, we assume equal cost rates for inquiry and update.

In practice, the cost of shipping information may not be linear with the amount sent; the assumption is nonetheless of theoretical interest in order to obtain a first-order approximation to a rather complex monotonically increasing function.

We are concerned with the problem of determining at which nodes of the network copies of the file shall reside. We shall assume that this allocation is to be done in such a way as to minimize the total cost of communication between users and files. In general, the cost of querying is reduced as we increase the number of file nodes in the network (users near a new file node find their querying more economical; the other users are no worse off). On the other hand, storage costs and the cost of updating go up as new copies of the file are introduced, since every copy must be updated. In the limiting cases, if no updating is done, and if storage costs are low, a copy of the file should be kept at every node (and network communication not used), whereas if only updating is done, and no querying, a single copy of the file should be maintained at some optimal node of the network.

By an assignment of the file we shall mean a choice of nodes at which to locate the file. Let I denote a set of node indexes representing a given assignment. The total communication cost resulting from this choice of file locations is a sum over individual user nodes. In the case of query traffic, we assume that the user accesses that copy of the file which minimizes his communication cost. His updates, of course, must be transmitted to all the file nodes. The general expression for total cost is therefore:

$$C(I)=\sum_{j=1}^{n}\left[\sum_{k\epsilon I}\psi_j d_{jk}'+\lambda_j \min_{k\epsilon I} d_{jk}\right]+\sum_{k\epsilon I}\sigma_k$$

The problem of file allocation in this context is to choose the index set, I, so as to minimize $C(I)$.

This cost function can be written in the form

$$C(I)=\sum_{k\epsilon I} U_k+\sum_{j=1}^{n} G_j(I)$$

where

$$U_k=\sigma_k+\sum_{j=1}^{n}\psi_j d_{jk}'$$

$$G_j(I)=\lambda_j \min_{k\epsilon I} d_{jk}$$

With $C(I)$ expressed in this form the problem of minimizing cost is seen to be exactly the problem investigated by Efroymson and Ray,[1] Feldman, et al.,[2] Frazer,[4] and others. The update costs of the file model are analogous to the fixed costs of the plant location model, while query costs are analogous to the transportation costs. Previous researchers tried mixed integer-linear programming techniques for obtaining solutions to the minimization problem. Generally, the true minimum of $C(I)$ is computationally very expensive to obtain by such methods, and heuristics are developed that sacrifice optimality in order to arrive at "good" solutions quickly.

Here, we take an alternative approach. We shall first exhibit several mathematical properties of the cost function. We shall use these to construct a search procedure which is guaranteed to produce the minimum of $C(I)$. Finally, we suggest heuristic modifications to the general agorithm for use in cases where it is too expensive to be applied. Thus, both attempts to solve the problem, by means of integer programming and by exploiting the properties of the cost function, turn to *ad hoc* adjustments in order to obtain relief from the expense of guaranteeing an optimum solution. It would be of interest to compare the performance of the two approaches on the same problems.

The initial examination of the properties of $C(I)$ yields bounds on the number of elements in the optimal file node set I, when storage costs do not vary. This will be shown by means of the following theorem.

Let the cost of update communication be equal to the cost of query communication ($d_{jk}=d_{jk}'$).

Theorem 1:

If for some integer $r\leq n$ $\psi_j>\lambda_j/(r-1)$ for each $j=1, 2, \ldots, n$ then any r-node file assignment is more costly than the optimal one-node assignment.

We prove the theorem by means of the following lemma:

Lemma:

If $\psi_j=\rho\lambda_j$ for $j=1, 2, \ldots, n$ then, an r-node assignment cannot be less costly than the optimal one-node assignment if $\rho\geq 1/(r-1)$.

Proof of Lemma:

Consider an arbitrary assignment $I=\{1, 2, \ldots, r\}$. Let the elements of I be ordered such that node 1 is the lowest cost single-node assignment.

We have

$$C(I)=\rho\sum_{k=1}^{r}\sum_{j=1}^{n}\lambda_j d_{jk}+\sum_{j=1}^{n}\min_{k\epsilon I}\lambda_j d_{jk}+\sum_{k=1}^{r}\sigma_k$$

and

$$C(\{k\})=(1+\rho)\sum_{j=1}^{n}\lambda_j d_{jk}+\sigma_k \qquad k=1,2,\ldots,r$$

By the optimality of node 1 there are nonnegative numbers $\alpha_2,\ldots,\alpha_r$ such that

$$\sum_{j=1}^{n}\lambda_j d_{jk}=\sum_{j=1}^{n}\lambda_j d_{j1}+\alpha_k+\frac{\sigma_1-\sigma_k}{1+\rho} \qquad k=2,3,\ldots,r.$$

Substituting the above, we can write

$$C(I)-C(\{1\})=[\rho r-\rho-1]\sum_{j=1}^{n}\lambda_j d_{j1}+\sum_{k=2}^{r}\rho\alpha_k$$
$$+\sum_{j=1}^{n}\min_{k}\lambda_j d_{jk}+\frac{\rho(r-1)\sigma_1}{1+\rho}$$
$$+\frac{1}{1+\rho}\sum_{k=2}^{r}\sigma_k$$

which is certainly nonnegative if $(\rho r-\rho-1)$ is nonnegative. That is, $\rho\geq 1/(r-1)$ implies that $C(I)\geq C(\{1\})$.

If the optimal single node assignment is in I, then it is node 1 and the lemma is proved. If the optimal node, say k', is not in I, then we have $\rho\geq 1/(r-1)$ implies $C(I)\geq C(\{1\})>C(\{k'\})$ and so the lemma is true in this case as well.

Proof of Theorem 1

The lemma concerns the case where each user generates the same proportion of update traffic to query traffic. Suppose now that the proportions vary from node to node, but always exceed a given amount ρ. Then, there are nonnegative quantities ϵ_j such that

$$\psi_j=(\rho+\epsilon_j)\lambda_j \qquad j=1,2,\ldots,n$$

The cost functions can now be written:

$$C'(\{1\})=\sum_{j=1}^{n}(1+\rho+\epsilon_j)\lambda_j d_{j1}+\sigma=C(\{1\})+\sum_{j=1}^{n}\epsilon_j\lambda_j d_{j1}$$

$$C'(I)=\sum_{j=1}^{n}(\rho+\epsilon_j)\lambda_j\sum_{k=1}^{r}d_{jk}$$
$$+\sum_{j=1}^{n}\min_{k}(\rho+\epsilon_j)\,d_{jk}+r\cdot\sigma$$
$$=C(I)+\sum_{j=1}^{n}\epsilon_j\lambda_j\sum_{k=1}^{r}d_{jk}+\sum_{j=1}^{n}\epsilon_j\min_{k}d_{jk}$$

where the unprimed costs are those given in the lemma.

But clearly $C'(I)\geq C'(\{1\})$ whenever $C(I)\geq C(\{1\})$. Then applying the lemma, the condition $\rho\geq 1/(r-1)$ is sufficient to ensure that the r-node assignment is not optimal. In addition, if at least one of the ϵ_j's is greater than zero, we must have the strict inequality $C(I)>C(\{1\})$.

Corollary 1

If the update/query traffic ratio satisfies $\rho\geq 1/(r-1)$ (r an integer) then the optimal allocation consists of no more than r nodes.

Proof

If $\psi_j\geq\lambda_j/(r-1)$ for each j then certainly for any integer l

$$\psi_j>\lambda_j/(r+l-1)$$

and so theorem 1 rules out the optimality of an $(r+l)$-node assignment.

Corollary 2

If each user generates at least 50 percent of his traffic in the form of updates, then the optimal assignment policy is to locate only a single copy of the file in the network.

The corollary follows directly from the theorem by setting $r=2$, but is worth stating separately since it sets a bound beyond which multiple copies of the file should not be considered. Furthermore, it is easy to show that for equal proportions of update and query traffic the two-node assignment is no more costly than a one-node assignment of the file only if storage costs are neglected, and the rows and columns of the cost matrix can be permuted to yield the form:

$$\begin{bmatrix} 0 & 0\ldots 0 & a_1 & a_2\ldots a_m & 0 & 0\ldots 0 \\ b_1 & b_2\ldots b_l & 0 & 0\ldots 0 & 0 & 0\ldots 0 \\ \multicolumn{6}{c}{\text{(rest of matrix)}} \end{bmatrix}$$

where

$$\sum_{i=1}^{m}a_i\lambda_a=\sum_{i=1}^{m}b_i\lambda_b,$$

λ_a and λ_b being the respective traffic volumes for the first two rows (query or update).

A PROPERTY OF THE OPTIMAL FILE ALLOCATION

In this section, we examine the behavior of the cost function as additional file nodes are added. In particular, we consider a graph such as Figure 1, where each vertex is identified with a file assignment (denoted by a binary vector having 1's in those positions corresponding to file nodes, 0's elsewhere). Associated with each vertex is the corresponding value of the cost function (not shown in Figure 1). For mathematical convenience the null vertex is assigned infinite cost. The edges of the graph are directed paths corresponding to the addition of a single file node to the previous assignment. The graph is conveniently arranged in levels where the vertices at the kth level represent all k-node file assignments.

We demonstrate the significant property of this graph (which we shall call the "cost" graph) that if a given vertex has a cost less than the cost of any vertex along the paths leading to it, then the sequence of costs encountered along any one of these paths decreases monotonically. Thus, in order to find the optimal allocation policy, it is sufficient to follow every path of the cost graph until the cost increases, and no further. Because of this property, only a small subset of the possible assignments need be tested, compared with the exhaustive search procedure in which 2^n different file allocations must be evaluated.

The monotonicity will be exhibited in two stages: first, for the case of two steps through the graph, and then for the general case.

Let $I\sim X$, where $X\subset I$, denote the index set I with the elements of set X removed.

Consider an arbitrary file assignment corresponding to index set I, and assume the nodes are so numbered that $I=[1, 2, \ldots, r]$. We proceed to show:

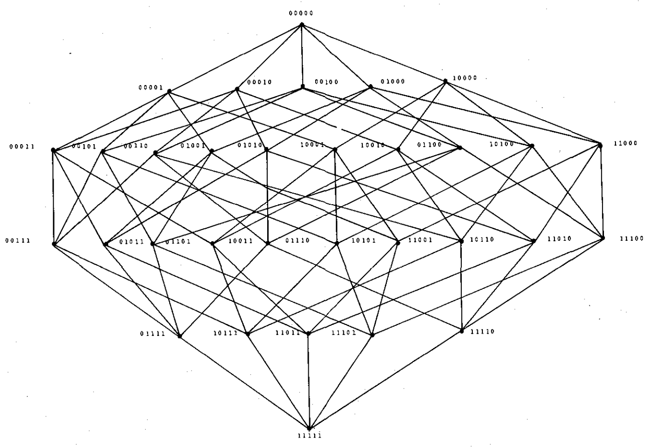

Figure 1—Graph of the allocation process

Lemma:

If $C(I)\leq C(\mathrm{I}\sim\{k\})$ for $k=1, 2$, then $C(I\sim\{k\}\leq C(I\sim\{1, 2\})$ for $k=1, 2$.

Proof of Lemma:

The cost function can be written, in general,

$$C(I\sim X)=\sum_{k\epsilon I\sim X} U_k+\sum_{j=1}^{n}\lambda_j \min_{k\epsilon I\sim X} d_{jk}$$

Thus

$$C(I)-C(I\sim\{1\})=U_1-\sum_{j=1}^{n}\lambda_j\Delta_j$$

where

$$\Delta_j=\min_{k\epsilon I\sim\{1\}} d_{jk}-\min_{k\epsilon I} d_{jk}$$

Also

$$C(I\sim\{2\})-C(I\sim\{1, 2\})=U_1-\sum_{j=1}^{n}\lambda_j\Delta_j'$$

where

$$\Delta_j'=\min_{k\epsilon I\sim\{1,2\}} d_{jk}-\min_{k\epsilon I\sim\{2\}} d_{jk}$$

Consider the difference

$$\Delta_j'-\Delta_j=\min_{k\epsilon I\sim\{1,2\}} d_{jk}+\min_{k\epsilon I} d_{jk}-\min_{k\epsilon I\sim\{2\}} d_{jk}-\min_{k\epsilon I\sim\{1\}} d_{jk}$$

We have

$$\min_{k\epsilon I} d_{jk}=\min(\min_{k\epsilon I\sim\{1\}} d_{jk}, \min_{k\epsilon I\sim\{2\}} d_{jk})$$

$$\min_{k\epsilon I\sim\{1,2\}} d_{jk}\geq\max(\min_{k\epsilon I\sim\{1\}} d_{jk}, \min_{k\epsilon I\sim\{2\}} d_{jk})$$

Therefore

$$\Delta_j'-\Delta_j\geq 0, \text{ that is } \Delta_j'\geq\Delta_j,$$

and so

$$C(I\sim\{2\})-C(I\sim\{1, 2\})\leq C(I)-C(I\sim\{1\})$$

thus,

$$C(I)\leq C(I\sim\{1\})$$

implies that

$$C(I\sim\{2\})\leq C(I\sim\{1, 2\})$$

By a mere permutation of indexes we may likewise prove that

$$C(I)\leq C(I\sim\{2\})$$

implies that

$$C(I\sim\{1\})\leq C(I\sim\{1,2\})$$

and so the lemma is true.

By means of this lemma, we can now prove the general theorem:

Theorem 2:

Given an index set $X\subseteq I$ containing r elements, and having the property

$$C(I)\leq C(I\sim\{x\}) \text{ for each } x\epsilon X$$

then for every sequence $R^{(1)}, R^{(2)}, \ldots, R^{(r)}$ of subsets of X such that $R^{(k)}$ has k elements, and $R^{(k)}\subset \mathrm{R}^{(k+1)}$ it is true that

$$C(I)\leq C(I\sim R^{(1)})\leq C(I\sim R^{(2)})$$
$$\leq C(I\sim R^{(3)})\leq \cdots \leq C(I\sim R^{(r)})$$

Proof: (by induction)

The first inequality above is given in the hypothesis. Since $R^{(2)}$ has two elements the second inequality follows from the lemma. It may thus be taken as hypothesis to prove the third, and so on. Each inequality proved can be used together with the lemma to prove the inequality to its right.

Observations:

If we take $X=\mathrm{I}$ in the theorem, then it states that along any path in the cost graph from the null vertex (which we have assigned infinite cost) to the vertex corresponding to I, cost decreases monotonically from one vertex to the next, providing of course that index set I satisfies the hypothesis of the theorem. The monotonic decreasing property can also be shown to hold in the reverse direction; i.e., for paths from the vertex $\{1, 2, \ldots, n\}$ to the optimum.*

APPLICATION TO FILE ALLOCATION

The theorem just proved provides a test that is useful in determining the minimum cost allocation of file copies to nodes of the network. Referring to the cost graph (Figure 1), let us define an "antecedent" of an arbitrary vertex v as a vertex which has a connection to v from the next lower level, and a "successor" of v as a vertex connected to v at the next higher level. An antecedent contains the file nodes of v less one node, while each successor contains the nodes of v plus one additional node. A vertex at the rth level of the graph has r antecedents, and $(n-r)$ successors, where n is the number of nodes in the network. (Note that, for clarity, we use the term "node" in referring to the computer network, and the term "vertex" with respect to the cost graph.)

We shall also define a "local optimum" of the cost graph as a vertex which is less costly than all of its antecedents and successors. Clearly, the global optimum we seek belongs to the set of local optima of the graph.

The theorem permits us to discover all the local optima without computing the cost of every vertex, for each path leading from the 0 level to a local optimum must give rise to a monotonically decreasing sequence cf costs. Whenever an increase is encountered in a step forward through the graph, that path can be abandoned since it cannot lead to a local (or global) optimum. A "path-tracing" routine which evaluates each possible sequence of node additions in this way is certain to produce the minimum value of $C(I)$. The amount of computation needed to extract the minimum will increase with the number of local optima, and with the number of nodes in the optimal configuration.

A computer algorithm can be implemented in several different ways to select file nodes one at a time up to the optimum configuration. One approach is to follow all paths in parallel through the cost graph, stepping

* A reviewer pointed out this generalization.

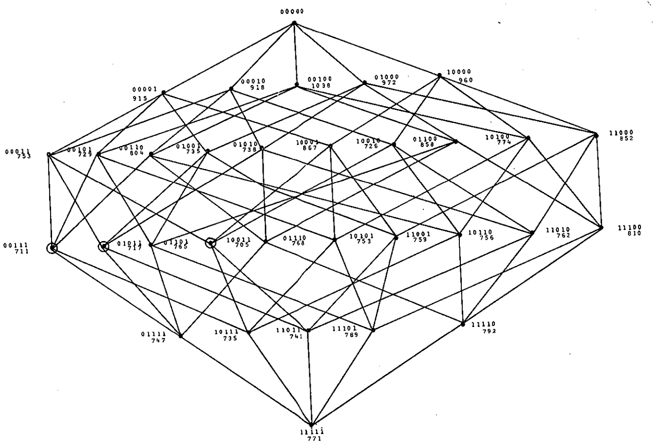

Figure 3—The cost graph for the example. Local optima are circled

one level per iteration. This method is computationally efficient, but may require a great deal of storage in a large problem. Alternatively, a program can be written to trace systematically one path at a time. Such a technique uses less storage, but may require redundant calculations since many different paths intersect each vertex.

EXAMPLES

We consider a five-node network with query and update parameters, and cost matrix as in Figure 2. Figure 3 shows the file node cost graph, and indicates the optimal allocations. This small-scale example illustrates the monotonicity of the cost function along paths leading to a local optimum.

Note that the matrix $\{d_{jk}\}$ is symmetric and has zero elements along the main diagonal. This is a plausible condition in a practical case, but is not required in any way by the theorems proven here.

As a second example, we postulate the ARPA computer network and its traffic matrix as given by Kleinrock.[7] In order to treat this case, which is not initially posed as a centralized data base configuration, we make the following rather arbitrary assumptions:

(1) All the resources of the network represented in the traffic matrix are gathered into one large file, copies of which are to be allocated to a subset of the nodes.

(2) The query traffic (Figure 4) from each user to the file is as given under the "node output" column in Kleinrock's table. If the user is accessing a program, we may think of this "query" traffic as comprising the command messages he must send in order to run the program, plus the program output sent back to him. (Note: Kleinrock does not give figures for each node's use of its own facilities.)

(3) "Update" traffic, which causes modification of programs and data in all copies of the file, is a fixed percentage of the query traffic defined in (2). The update/query ratio is the same for each user, and is varied as a parameter in the computer runs described below.

(4) The "cost" of communicating between two network nodes is as shown in Figure 4. The quantities given here are roughly the straight-line distances between nodes. Thus, the cost function to be minimized is the total amount of "flow" in the network, i.e., the product of message length in bits, multiplied by the distance through which the message must travel on a direct path to its destination, summed over all messages. In this view an update message is assumed to be sent separately to each file location, rather than relayed.

Assumptions (1)-(4) ignore the network communication links as configured by Kleinrock. Ordinarily these would determine the cost matrix. Substituting "distance" for "cost," as done here, might be expedient in a preliminary analysis to allocate resources prior to a topological design of the network. We employ the ARPA data primarily because it tests our model on a problem involving many nodes. In addition, we should like to encourage speculation on the concept of multiple copies of a resource (data or programs), and whether such a facility is attractive in future ARPA-like networks.

Figure 5 summarizes the file allocation experiments conducted using this data, in which the proportion of update traffic to query traffic was varied from 100 percent to 10 percent in steps. As expected, only single node allocations are indicated when the two types of traffic are equal. As a smaller volume of update traffic is generated, multiple node solutions begin to appear. The copies of the file are widely distributed geographically, and the single node solution is centrally located. However, such features result from the particular traffic distribution assumed, and are not generalizations valid for every case.

It is interesting to note the large number of local optima generated (see Figure 5). Because certain ARPA sites, e.g., MIT, BBN, Harvard, and Lincoln Laboratories, are very near one another, if one occurs in a local optimum one of its neighbors may be substituted for it to produce a second configuration that

Figure 4—The ARPA example. The locations of the nodes (from Kleinrock[7]) are: (1) Hanover, N.H., (2)-(5) Boston Area, (6) Murray Hill, N.J., (7) Washington, D.C., (8) Pittsburgh, Pa., (9) Ann Arbor, Michigan, (10) Urbana, Illinois, (11) St. Louis, Mo., (12) Salt Lake City, Utah, (13)-(15) San Francisco Bay Area, (16) Santa Barbara, California, (17)-(19) Los Angeles Area

is also locally optimum. Most of the local optima are due to this phenomenom, suggesting that greater computational efficiency would have resulted from lumping neighboring sites into a single network node for an initial application of the algorithm, followed by a stage of finer calculations. Such artifices are hardly necessary in problems of this size, however. The sequence of six runs depicted in Figure 5 was carried out on an IBM 360/91 in less than ten seconds, including Fortran compilation.

EXTENSIONS

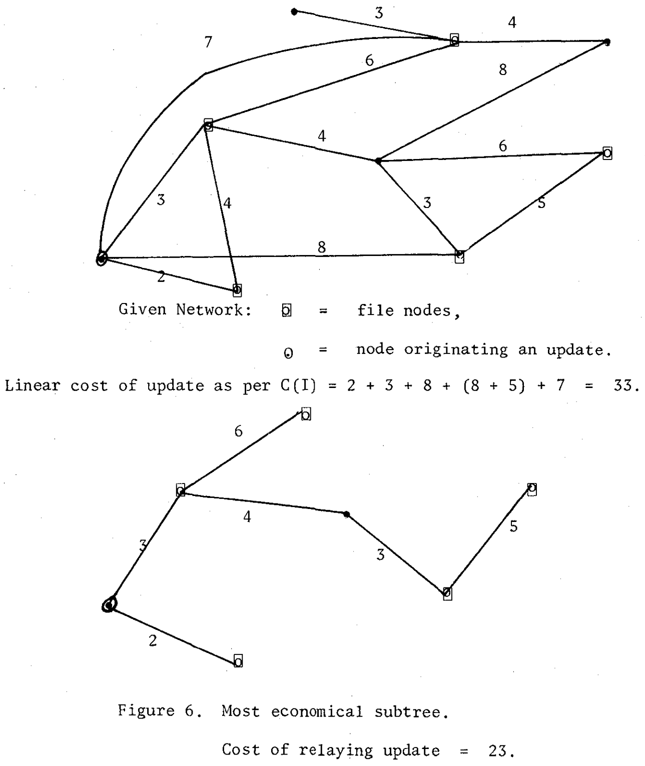
Path tracing on a related problem

One feature of the path-tracing technique is its versatility. It can be applied to problems that do not fit the linear programming framework. As one example consider the following modification of the file allocation model. The cost function as defined in the text assumes that the expense of transmitting an update message to all copies of the file is the sum of the costs of communicating with each copy separately, as if a distinct message had to be sent from the updater to every file node.

Update/Query Percent	Optimal Allocation	Cost	#Local Minima
10	2, 10, 14	117, 544	140
20	9, 14	188, 738	88
30	10, 14	242, 546	88
40	10, 12	291, 754	77
100	10	427, 460	19

Figure 5—Results for the ARPA example

Actually, the preferred mode of operation would be to relay the message through the network in the most economical manner. The resulting cost is less than that incurred by sending duplicate messages. It is the cost associated with the most economical subtree of the network that contains the originating node and the file nodes (see Figure 6). This new cost function defined when update costs are calculated in this way is nonlinear in a very complex way. Yet the path-tracing algorithm can still be applied to the allocation problem. We nò longer have the assurance provided by Theorem 2, which guarantees that the method will generate the optimal allocation. However, the cost function behaves in much the same manner as before. It still consists of two parts: an update (and fixed cost) term that increases as additional file copies are allocated, and a query term that decreases with additional copies. The algorithm may be heuristic in the new framework, but with only slight modification it can be programmed to determine at least allocations of the type we have called "local optima," of which the true optimum is one.



Given Network: ⊡ = file nodes,

⊙ = node originating an update.

Linear cost of update as per C(I) = 2 + 3 + 8 + (8 + 5) + 7 = 33.

Figure 6. Most economical subtree.

Cost of relaying update = 23.

Figure 6—Most economical subtree for relaying an update message

Heuristic modification of the path-tracing routine

If the optimal solution to the allocation problem consists of many network nodes then the general rule of following every monotonically decreasing path in the cost graph may be computationally too expensive. For example, if the optimum contains 40 nodes then at least $2^{40} \doteq 10^{12}$ values of the cost function must be evaluated. In order to decrease the amount of computation, it is necessary to sacrifice optimality for speed. We suggest several methods by which this may be done in a reasonable manner.

Assume that the cost graph is being searched level-by-level (i.e., in parallel). At each level, the vertices which are lower in cost than their antecedents are recorded. We call these vertices "admissible" and denote them by the set A_k at the kth level. We wish to carry only a limited number of the members of A_k into the $(k+1)$th stage. One plausible selection rule is to keep the vertices having the lowest cost. Alternatively, we may reason that if two assignments are similar (i.e., differ in only a few file nodes) then probably their union will also lie on a monotonic cost path, and it would be redundant to trace paths through both. In this view, we want to select the most "dissimilar" vertices from A_k. Several techniques are available to do this selection. One method, previously used in pattern recognition, is the following. Order the members of A_k arbitrarily, specify a threshold τ (a parameter), and examine the members of A_k in order. Denote by A_k' the subset being formed. The first member of A_k' is the first member of A_k, say a_1. The next member of A_k' (denoted a_2) is the first member of A_k which differs from a_1 by at least τ units. Next, test for an a_3 which differs from both a_1 and a_2 by at least τ and so on. If A_k' has too many members, or too few, the routine may be repeated with τ larger, or smaller, respectively. The set A_k' is used to generate A_{k+1}, which is in turn thinned down to A_{k+1}'.

A third method has actually been programmed and compared with the general search technique. The procedure is to do complete path-tracing (applying Theorem 2) up to a level of the cost graph at which set A_k begins to get too large. From this level on, only the most "promising" paths are followed. For example, as programmed the cost graph is completely evaluated through the second level (2-file nodes per vertex). From each admissible second level vertex only a single path is followed; namely, that path which gives minimal cost at each succeeding level. Since this program only has one-step look ahead, the optimum may be missed. In sample runs on the ARPA problem, the optimum was always found (for each value of the update/query parameter), although local optima were sometimes overlooked.

This heuristic program was also tested on the ARPA configuration using the revised cost function described above, i.e., a function which assumes that updates are relayed between file notes in the most economical manner. Use of a simplified program is called for in this case; the heuristic program required 12 minutes to repeat the five runs of Figure 5, which were performed in under ten seconds using the linear cost relationship. Figure 7 shows the allocations produced by this experiment. These assignments may not be global optima. They do satisfy our definition of a local optimum. Note that, as expected, for the same traffic more copies of the

Update/Query Percent	Optimal Allocation (Nodes)	Cost
10	2, 6, 8, 9, 10, 12, 13, 14, 16, 18	38, 285
20	2, 8, 10, 12, 14	105, 800
30	2, 8, 10, 12, 14	171, 225
40	8, 10, 12	227, 340
100	10	427, 460

Figure 7—Allocation results using the nonlinear cost model (ARPA network)

file are assigned if updates are relayed. In addition, total cost is reduced markedly under conditions of low update traffic, indicating the importance of including the more complex cost relations in the model.

CONCLUSION

The analytical properties of a linear-cost model of an information network have been investigated. The proportions of update traffic to query traffic generated by the users of a given file in the network were shown to determine an upper bound on the number of copies of the file present in the least-cost network. In addition, a basic property of the cost function was demonstrated and shown to justify a path-tracing procedure for determining the optimal assignment of copies of the file to nodes of the network.

The model, while simple, expresses relevant features of the tradeoff between the costs of querying and updating in the network. Presumably, the general properties derived apply at least approximately when more complex models are considered.

ACKNOWLEDGMENT

Dr. M. E. Senko first pointed out to the author the need for an allocation model which would distinguish between the query and update activity in a network. The work reported here owes additional debts to the encouragement and commentary of Drs. C. P. Wang, H. Ling and V. Lum.

Production and utilization of computer manpower in U.S. higher education*

by JOHN W. HAMBLEN

Southern Regional Education Board
Atlanta, Georgia

SURVEYS

During the past five years the Computer Science Project of the Southern Regional Education Board (SREB) has conducted three surveys on Computers in U.S. Higher Education including their utilization and related educational programs. These studies have resulted in three publications[1,2,3] the first by the SREB and the latter two by the National Science Foundation.

The first survey was a stratified random sample of 739 institutions, from a population of 2219, selected by systematic random sampling within strata by the U.S. Office of Education. Six hundred sixty nine or 92 percent of the institutions in the sample responded.

The base year for data collection was 1964-65 and projections were requested from the institutions for 1968-69. The data collection instrument was designed by the Mathematical Sciences Section of NSF to meet their existing program needs for planning. Consequently, emphasis was placed upon the financial aspects of college and university computer center operations and only limited information was gathered with regard to manpower training and utilization.

The second survey was much more comprehensive and was sent to all institutions of higher education listed in the U.S. Office of Education's Higher Education General Information Survey (HEGIS) file. Nineteen hundred sixty five or 79 percent of the 2477 institutions responded. The data collection forms were designed with the advice and counsel of thirty or more national professional and institutional associations and government agencies. The base year for reporting data was 1966-67.

Extensive modifications were made in the data collection forms for the third survey. The base year was 1969-70.

Problems resulting from lack of standardization in the computer industry are well-known. Unfortunately the educational and occupational nomenclature also suffers this malady. The shifting of terms and definitions over the years can inject disastrous consequences on estimates and, particularly, projections. Attempts to make comparisons with other studies become even more hazardous. In the following only estimates and projections based upon the three surveys described above will be presented. Two other papers in these proceedings[4,5] by Gilchrist and Weber will treat comparisons and incorporate higher education's role in manpower production and utilization to give a total picture of the supply and demand for computer personnel in the U.S.

MANPOWER PRODUCTION

Educational programs in Computer Science, Data Processing, Information Science, etc., exist in institutions of higher education at all levels. Two year programs terminate with an associate degree and four year programs with a bachelor's degree. Master's and doctorate programs exist at many institutions. Although computer science and data processing are by far the most popular program names (see Table I) there appears still to be far too many different names used for educational programs in institutions of higher education. Further consolidation is necessary to ensure a healthy and unified development of the disciplines. The efforts of the ACM Curriculum Committee on Computer Science[6] and the ACM Committee on Computer Education for Management[8] have and will continue to have a unifying influence on academic programs in computer and information science. The work of these

* The data upon which this paper is based was collected and processed through partial support from the National Science Foundation under contracts C465, C508 and C604. The SREB Computer Sciences Project is also supported by grants from the Esso Education Foundation and the IBM Corporation.

committees was supported by National Science Foundation.

Since 1966-67 the numbers of degree programs have doubled with the highest increase nearly threefold at the bachelor's level. Three out of five of the latter programs are called Computer Science and the next largest group (26) are designated as Data Processing. Twenty (20) new programs in Computer Science at the bachelor's level were expected to be started during 1971-72 and the next highest increase was expected to be at the master's level in Computer Science with sixteen new programs.

After the report[8] of the ACM Curriculum Committee for Computer Education for Management has had a chance to be circulated, I expect to see a surge in the master's level programs in Information Systems (Analysis and Design).

The numbers of majors enrolled in undergraduate programs have nearly tripled and the numbers of graduates per year have increased fourfold between 1966-67 and 1969-70 (see Table II). Figure 1 shows the growth trends at present. I do not expect significant changes in these trends for the next three to five years. After 1975 I believe that we can expect to see some

leveling off at all levels. Table III shows my estimates of degrees to be awarded during the year 1974-75.

When these figures of supply are compared with estimates[4] of demand we see that there is no longer a need to encourage a crash effort to start new degree programs at any level. However, if we examine the course offerings of the associate and bachelor's degree programs, in particular, as I have had occasion to do in the two NSF Inventories,[7] there is definitely a need to strengthen these programs both in facilities available and course offerings. During 1966-67 about one out of every two programs at the associate and bachelor's degree levels were judged (by me) to be lacking in either course offerings or computer facilities.[7] Preliminary investigation of data reported for 1969-70 indicate that percentagewise there has been little, if any, improvement when advances in technology are considered.

is the personnel of academic departments offering degree programs. For this category we have good estimates of the numbers of persons employed for 1966-67 and 1969-70 (see Tables IV and V and Figure 2). It is of interest to note that only about one out of every two faculty persons hold a doctorate and of those who do

only about one of four have a doctorate in computer science, information science, etc. This is not surprising because the supply of doctorates in this area has been too small to fill the need. However, as the supply increases, replacements will be made from their ranks rather than from other fields.

The second category of computer manpower utilization is that of personnel required to man the computer facilities of the institutions. This includes facilities for all types of uses—research, administration and instruction. Since similar data was collected for both 1966-67 and 1969-70 some comparisons can be made or trends noticed. Table VI and Figure 3 present these data for 1966-67.

Table VII shows estimated manpower utilization for 1969-70 in the computer facilities of institutions of higher education.

The third category of computer manpower is very difficult to estimate. These are mostly applications programmers, some operators and maintenance personnel who are scattered among the various departments (both academic and administrative) and are not on a computer center payroll. My estimates of such personnel are shown in Table VIII.

SUMMARY

The numbers of degree programs, majors and degrees awarded will be of some surprise to many who are proposing to begin new programs. Of course good, solid offerings will always be desirable. However, in terms of national emphasis it is apparent that we do not need to have a national effort to create new programs. On the other hand, there is a definite need to encourage and assist with the improvement of existing programs at all levels. As a starting point the AFIPS Education Committee sponsored a meeting at the 1971 Fall Joint Computer Conference on "Accreditation: What it is, Who does it, and How it is done," for leaders of the various curriculum committees, special interest groups, and others involved with curriculum planning for Computer Science, Data Processing, Information Science, etc. This was done with the belief that we can work with the various accreditation associations to help bring about the improvements needed in these programs. Government agencies such as the Office of Computing Activities of the National Science Foundation can offer invaluable assistance by providing some of the resources required for the improvement of these programs.

INTRODUCTION

The economic recession of the past two years has emphasized the need for better overall manpower planning in the computer field. However, such planning can only be accomplished if there are reasonably reliable data on both the sources of trained personnel and the industry needs for such personnel. The purpose of this paper is to summarize our current state of knowledge of the primary sources of personnel. A companion paper in these proceedings discusses the requirements aspects.[1] It is clear from these two papers that our knowledge of both aspects is limited as to accuracy as well as coverage. For the present this lack of knowledge makes it impossible to construct a manpower model suitable for prognostication. However, the growing interest of the various groups involved in data collection gives rise to optimism that a usable manpower model can be constructed in the foreseeable future.

No attempt is made in this paper to distinguish between the people who will be employed by computer users and those who will be employed by the computer, peripherals and software suppliers. This is due to the lack of data giving specific employments. There is good evidence, however, that the vast majority will be employed by the users of computers. It should also be emphasized that only the primary sources of trained personnel are considered. Promotions from within and movement between companies are important components of any manpower model but here again the lack of data prevents the inclusion of this level of detail at the present time.

In the following sections we review on a type by type basis the available quantitative data on the various sources of trained computer personnel. It should be kept in mind throughout that there are difficulties with regard to definitions. In the absence of generally accepted industry standards, there are many different uses of the titles "programmer" and "systems" analyst and many different assumptions as to what knowledge is required by holders of such titles. The same is true of expressions such as "computer science" and "data processing" as well as of the training or education needed to be eligible to enter one of the computing jobs as a trainee. These definitional problems make comparisons between various reports difficult, if not impossible. We believe, however, that by summarizing in one place all available data, we will point up the estimation, definitional and other problems and thereby encourage improved collection and standardization. This should in turn result in future compilations of data being more internally compatible. Meanwhile we believe that these figures give an idea of the order of magnitude of the output of the various training institutions.

SOURCES OF TRAINING

Public secondary schools

The only comprehensive study at this level is one by the American Institutes for Research under a grant from the National Science Foundation.[2] This study for the school year 1969-70 included a combination mail and interview survey of 23,030 public secondary schools; 12,396 (53.8 percent) of the schools responded in some form.

While the report contains a wealth of information, the question "how many students in each school were receiving instruction in the use of computers" was not specifically asked. Some interesting conclusions can, however, be drawn from the report.

Excluding guidance applications, 464 (or 12.3 per-

Total	.62		104,100

* Since this is a count of course enrollments, it does not represent individual pupils who may be enrolled in two or more courses simultaneously.
Data based on Office of Education pretest sample

cent) of the 3,770 schools responding to the main questionnaire reported that they gave instruction in EDP skills. (If guidance and administrative users are included this usage increases to 34.4 percent of all respondents.) While there were wide variations among schools in the number of students involved in each instructional application, the median was 50 students, each of whom participated on the average about ten hours per month. Assuming that the mean number per school is equal to this median, extrapolation to the total of 23,030 schools gives

$$\frac{464}{3770}\times 23{,}030\times 50=142{,}000$$

students receiving *some* instruction in EDP skills during the school year 1969-70.

Furthermore, the report indicates that 3 percent of schools not then offering computer instruction were planning to do so and 22 percent of those giving instruction expected to expand their instructional activities. It is probable, therefore, that enrollment for training in EDP skills in 1970-71 could have reached or exceeded 200,000 students. Based on interviews at some schools, one of the authors of the report estimates that 10 percent or 20,000 of these get sufficient instruction to be hired directly upon graduation as programmer trainees. From the employment viewpoint, we are mostly concerned with this 20,000. Of course, many of them will not look for such jobs but instead go on with their education or go into other fields.

The numbers given above all relate to student enrollments. To obtain an estimate of how many 1971 high school *graduates* had received computer instruction we use the New Jersey statistic that 21.5 percent of students in grades 9-12 graduate each year.[3] This results in an estimate that, of the students graduating from high school in June 1971, 43,000 had some computer training and of these 4,300 had significant programmer training.

Additional information on the number of the graduates will be forthcoming from the U.S. Office of Education. They are planning a sample mail survey of public schools having at least one of grades 7-12 in order to gather course and curriculum information as well as enrollments for the 1972-73 school year. In preparation for the main survey, a pretest of the questionnaire to be used was sent to a sample of 290 out of the 25,128 public schools on their 1968-69 list. The schools were arranged by size and then randomly sampled *within* each state with a minimum of 3 schools per state as the beginning point for each state.

Table I is a summary of some results from this test.[4]

The Office of Education figures are about half those inferred from the American Institutes for Research report. Each survey has its advantages and drawbacks so, for lack of further data, we average the two results to obtain an estimated 1971 graduating class of 33,000 with *some* computer training of which 3,300 have *significant* programmer training.

In order to arrive at job entry estimates we use New Jersey data to obtain percentage distributions of what happens to high school students after they graduate. Applied to the above figures, this results in Table II which indicates that about 7,600 entered the labor force in June 1971. The big assumption made here is that students with *some* computer training will follow the same post high school pattern as the average student.

TABLE II—Estimate of Destination of Students with *Some* Computer Training Graduating from Public Secondary Schools in June 1971

Destination	N.J. percent distribution	Number
Technical School	8	2,600
Junior College	15	5,000
College	41	13,500
Other	13	4,300
Employment	23	7,600
Totals	100	33,000

TABLE III—Students Enrolled in Computer Occupational Courses in Public Vocational Schools for the Years 1966-70

Type of Training	1966	1967	1968	1969	1970
Business Data Processing	42,764	85,063	109,769	134,723	165,977
Scientific Data Processing	—	26,367	26,374	35,914	18,162*
Total	42,764	111,430	136,143	170,637	184,159*

* Beginning in 1970, States with less than 5 percent of their enrollments in a particular category were permitted to include this number in a general category. This threw many of enrollments previously reported under scientific data processing into the general category. The 1970 figure is therefore not comparable with previous years nor necessarily indicative of the true picture.

It should be emphasized that the foregoing estimate considers only public secondary schools. In addition to these, there are approximately 4,000 private and parochial secondary schools with enrollments of about 1.4 million students.[5] If the same proportion of these students as of students in public secondary schools receive computer instruction, their inclusion would increase the numbers in Table II by about 8 percent.

Public vocational schools

Under the ongoing vocational education program the U.S. Office of Education requires each state to make annual reports of their enrollments in vocational programs. This data is then summarized and published by the Office of Education. Table III gives their latest data.[6]

Table III, excluding the incompatible 1970 figure, shows a fairly consistent annual growth rate. Linear extrapolation is therefore used to project the enrollments for 1971. Using these estimates and information from follow-up records provided by the U.S. Office of Education, Table IV has been prepared to show estimates of the numbers graduating from public vocational programs in June 1971 and of those entering the labor force and higher education.

Although it is impossible to give the exact numbers entering each occupation, it has been observed that the Business Data Processing program is intended to prepare students for entry into employment as computer programmers, computer operators or keypunch operators; whereas the Scientific Data Processing program prepares students for jobs as systems analysts and computer programmers.

It should be noted that these vocational programs are offered in comprehensive high schools, community colleges and four-year colleges, as well as specialized vocational schools. Thus, it is possible that there is some duplicate counting between this section and other parts of this report. It is believed that this duplication is minimal.

TABLE IV—Estimate of Students Enrolled in and Completing Vocational Programs and Number Placed in 1971

				Destination		
					Entering Labor Force	
Training and Level	Total Enrollment	In Preparatory Programs	Total Graduates	Entering Higher Education	Total	Field For Which Trained

Post Secondary		22,751	6,825	680	4,368	3,713
Total	242,300	161,534	45,427	6,790*	26,975*	21,805

* In addition to these two groups there were 11,662 that went into the armed services, married, became ill, etc., and were thus unavailable

TABLE V—Summary of Responses from 41 Private EDP Schools

Type of Course	Number of Courses	Median Course Length (Hrs.)	Expected 1969 Graduates
Programming	44	500	7,994
Computer Operations	17	180	1,446
Keypunching	14	78	4,359
Other	5	—	1,200
Totals	80	—	14,999

Private vocational schools

Due to the general shortage of programmers in the 1960's, a large number of so-called private EDP schools were begun. These schools advertised heavily and appealed to non-college graduates. Such schools are part of a larger set of private trade and technical schools.

Some of these schools are accredited by organizations such as the National Association of Trade and Technical Schools (NATTS) and in some states there are regulations governing various aspects of their operations. However, there are no nation-wide standards with respect to course length or content and no reporting scheme for enrollment and graduation data.

In 1969 Gilchrist made a mail survey of 207 private EDP schools located in 10 major U.S. cities.[7] The questionnaire asked for the number, type and length of courses offered together with the estimated number of graduates from such courses in 1969. The 41 schools which responded reported that they expected to graduate nearly 15,000 students that year as shown in Table V.

Using the sample data, Gilchrist then extrapolated linearly to the total population of private EDP schools which he estimated to be between 500 and 1,000. This resulted in the figures summarized in Table VI.

TABLE VI—Estimated Numbers of Private EDP School Graduates for 1969

Type of Course	Sample (41)	Low Estimate (500)	High Estimate (1000)
Programming	7,994	97,500	195,000
Computer Operations	1,446	17,600	35,000
Keypunching	4,359	53,200	106,000
Other	1,200	14,600	29,000
Totals	14,999	182,900	365,000

Belitsky, using 1966 data, found that there were then 3,000 private trade and technical schools with an average enrollment of 280 students and that data processing courses represented 22 percent of all vocational courses.[8] He also found that there were over 500 correspondence schools for vocational training. These results indicate that the correct number of graduates probably does lie between Gilchrist's high and low estimates.

Since 1969 private EDP schools appear to have contracted both in number of schools and in number of students per school. This is due to the slowing of the economy, the difficulties their graduates, especially in programming, are encountering finding jobs and the public disclosure of poor practices in some of these schools. While no survey results are available, limited data from New Jersey indicate that there could have been a 50 percent contraction since 1969. In New Jersey the number of private data processing schools for the years 1968 through 1971 were 52, 52, 40 and 28, respectively.[3] Allowing for some contraction Table VII uses 350 schools each having 225 graduates to estimate the 1971 output of the private EDP schools.

TABLE VII—Estimated Numbers of Private EDP School Graduates for 1971

Type of Course	Estimated Number of 1971 Graduates
Programming	43,000
Computer Operations	7,400
Keypunching	22,000
Others	6,600
Total	79,000

The nature of the courses given in private EDP schools and the whole flavor of their promotional advertising indicates that *all* their graduates enter the labor market rather than going on to higher education.

Higher education

In the area of higher education the U.S. Office of Education publishes annual reports on the number of graduates by discipline and by degree level.[9–10] These reports include a number of classifications relating to the computer field. In addition, the National Science Foundation has sponsored an information gathering project at the Southern Regional Education Board. This project has included surveys of the uses of computers in higher education during the school years 1964-65, 1966-67 and 1969-70. Full reports are available

TABLE VIII—Comparison between U.S. Office of Education and Southern Regional Education Board Classifications for Computer Related College Programs

Office of Education Classification	SREB Classification
Systems Analysis	Systems Analysis Information Systems Information Processing Systems Engineering
Computer Science	Computer Science Information Science Management Science Option in Electrical Engineering Option in Mathematics Option in Engineering Option in Industrial Engineering
Data Processing	Data Processing Computer Technology Computer Programming Option in Business Administration
Other	Classifications not listed above

for the first two surveys[11,12] and a preliminary report on the most recent one is included in these proceedings.[13]

Unfortunately, the Office of Education reports and the Southern Regional Education Board reports of 1966-67 and 1969-70 use somewhat different classifications. In order to compare data from the three sources we have grouped the various SREB classifications into four major groups which we believe to be sufficiently comparable to the Office of Education classifications. This grouping is shown in Table VIII.

Table IX was prepared by grouping the SREB results according to Table VIII and extrapolating to the total population of institutions for each year surveyed.

The very low ratio of graduates to majors for 1966-67 shown in Table IX indicates that in that year many programs were still in their early stages of operation. By 1970-71 this ratio had become more normal indicating that most programs were then in full operation. Even so, without an increase in enrollments, the number of graduates can still be expected to increase somewhat for the early 1970's. The increasing number of degrees awarded in computer related courses is confirmed by the U.S. Office of Education reports which are summarized in Table X.

The U.S. Office of Education also publishes data on the number of students enrolled for advanced degrees.[14] For the computer related disciplines, these data are summarized in Table XI. The 1967 numbers for "Systems Analysis" and "Other" categories look strange and suggest that definitional problems resulted in "Systems Analysis" students being put into the "Other" category.

The growth rates are remarkably consistent. They also indicate that the level of graduations at the bachelors and masters levels appear sufficient to continue the respective master and doctoral enrollments growing at substantial rates.

As a result of the aforementioned classification differences, comparisons from Tables IX, X, and XI leave something to be desired. However, considerable growth is implicit in Table IX and quite obvious in Tables X and XI. Regression analysis of the data from Tables X and XI reveals that the growth rates for nearly all categories were approximately constant. The mean growth rates are given in in Table XII.

The question now arises as to how many of these 1971 graduates entered the labor force in contrast to continuing their education. There appear to be no data upon which to base an answer to this question. A very rough approximation might be that a third of those receiving lower degrees continued their education

TABLE IX—Summary Results Derived from 1966-67 and 1969-70 Southern Regional Education Board Surveys

	Undergraduates						Graduates

and that two thirds of those receiving PhD's have gone into teaching. Applying these approximations to Table IX we get the estimate of the numbers entering the labor force in June 1971. These are given in Table XIII.

Summary of formal education programs

The data from the previous four sections are summarized in Table XIV.

With the exception of the Private Vocational Schools each program is producing a steadily increasing number of graduates and entrants to the labor force. There is, unfortunately, insufficient data to break down the 1971 entrants to the labor force into job skills. However, one can roughly say that the first three categories in Table XIV will primarily enter data-entry, electrical accounting machine and computer operations while the last three categories will primarily enter programming and systems analysis. The holders of Associate degrees will divide—the top students going into programming and the others into machine operations.

Other sources

In addition to the estimated 122,000 entrants to the labor force from the formal computer related programs discussed above, a significant number of people are trained by other sources. These include manufacturers of computing equipment and software as well as large

BA/BS	2,300
MA/MS	1,400
PhD	110

users. For example, in 1970 the U.S. Defense Department trained about 2,000 of their own personnel. Also, several insurance companies are known to have obtained state licenses to give courses for computer user personnel.

Little information exists with regard to the output of such sources of trained pesonnel. The importance of these training programs is illustrated by Table XV which is derived from the *1971 AFIPS Personnel Survey* which sampled the members of the AFIPS constituent societies.[15]

Most of the people trained by these other sources have probably had some prior training, perhaps in the secondary or vocational schools or Associate degree programs. Since we are here concerned mainly with primary sources, it is unclear just how to treat these other training sources. Our investigations suggest that in past years between 20,000 and 30,000 people were trained in this way, but that the figure for 1971 will be from 10,000 to 20,000. It is to be expected that as the level of training offered by the public schools and two year colleges is increased, training by manufacturers and users will become numerically less important insofar as primary sources are concerned.

The computer manufacturers' courses and in-house use training courses are also very important from the viewpoint of continuing education. In a rapidly developing field such as computing there will continue to be a great need for short refresher courses and courses on new developments. Some of these will be given by colleges, universities and companies devoted to training, but we suspect that the majority will continue to be provided by manufacturers and users.

TABLE XIV—Estimates of Number of Entrants into the Labor Force from Various Formal Computer Educational Programs in 1971

Educational Program	1971 Graduates	Entering Labor Force
High School	33,000	7,600
Public Vocational School	45,400	27,000
Private Vocational School	79,000	79,000
Associate	7,495	5,000
BA/BS	3,350	2,300
MA/MS	2,070	1,400
PhD	335	110
Totals	170,650	122,410

TABLE XV—Sources of Information Processing Training Reported by Respondents to the 1971 AFIPS Personnel Survey

Source	Percentage*
Computer Manufacturers	47.1
In-House	44.5

High School/Vocational School	1.5
Other	9.2

* Percentages add up to more than 100 due to multiple responses.

SUMMARY

The available data, supplemented by personal interviews, indicate that at least 170,000 people were trained by primary sources for the computer user labor market in 1971. The level of training is clearly heavily weighted toward the low end. It also appears that there is a trend toward higher level education together with a move toward general rather than specific training. It is further noted that there is a decided shift toward education in publicly supported institutions as opposed to private vocational and manufacturer's schools.

The estimated number of trained people entering the labor force does not appear proportionate to the requirements suggested by an employment figure for their occupational categories of the order of slightly over a half million. With the reduced growth rate being experienced by the computer industry an implied new hire ratio of nearly 30 percent seems entirely unlikely. Furthermore, preliminary indications are that the numbers of people trained for various levels are not commensurate with the needs of the industry at the respective levels.

In view of these conclusions, it is clear that a strong need exists for improved data collection followed by public release of accurate findings as to potential training outputs and job requirements at the various skill and educational levels. To this end measures should be taken by all concerned parties to initiate such projects. Thereby we may eliminate future imbalances and thus improve labor conditions in the computer field.

ACKNOWLEDGMENTS

The authors are very appreciative of the many individuals, both in industry and government who have helped them track down sources of data and who commented upon a working paper which formed the basis of this report.

Montvale, New Jersey

INTRODUCTION

After several years of chronic shortages of trained personnel, the economic recession of the past two years has resulted in some unemployment within the computer field. This unemployment has emphasized the long existing need for better overall manpower planning. Such planning can only be carried on successfully if reasonably reliable data and projections are available. The information collected and the resulting projections must include both the employment needs and the sources of trained personnel. The purpose of this paper is to summarize the current employment picture especially as it relates to the users of computers. A companion paper in these proceedings discusses the primary sources of such trained personnel.[1]

In the past, a number of general statements have been made about the employment of computer personnel. For example, the Bureau of Labor Statistics regularly publishes occupational outlook data for several computer related occupations,[2] and industry leaders are prone to making generalized comments. However, as was pointed out by Gilchrist in 1969, these numbers appear, upon inspection, to be based on relatively little firm data.[3]

AVAILABLE DATA SOURCES

The 1970 decennial census included, for a 20 percent sample of the population, a question on occupation. The encoders of these responses had available to them a number of classifications relating to computing. The summarized results should give an interesting picture of employment in the computer field. Unfortunately, the summaries will not be current when published since they will not be available until late 1972 at the earliest.

In the meantime, a number of groups have ongoing activities or are commencing new ones which should improve our knowledge of the employment picture.

AFIPS with partial support from the National Science Foundation is assembling available data and encouraging trade associations to obtain additional data from their individual member firms.

The Federal Government has for a number of years reported their EDP related employment figures. Now various states and cities are beginning to produce similar reports on their own or in conjunction with the Bureau of Labor Statistics (BLS) of the U.S. Department of Labor.

The BLS has recently included several computer related occupations in its regular *Area Wage Surveys*.[4] Although these data are collected primarily to determine wage patterns, they do provide estimates of employment in each occupation. With financial support from the National Science Foundation, BLS has recently commenced a major study of computer related employment. In addition, it has made a number of relevant studies of employment in individual cities and industries.

On a monthly basis, BLS publishes employment and earnings data covering every industry in the country. The difficulty in using this data to learn about computer related occupations is that the SIC classifications reflect the products of a company and not the type of employees. For example, programmers employed by a chemical company will be reported under the SIC code for the particular chemical products. Plants whose prime output is computer equipment are identified separately and employment data on these are available.

* This paper was prepared as part of the AFIPS Statistical Research Program which is partially funded by the National Science Foundation under Study Grant GJ 996.

TABLE I—Man-years Utilized in Federal Government ADP Operations

Fiscal Year	ADP Man-years
1960	48,700
1961	54,400
1962	58,800
1963	67,400
1964	72,300
1965	76,200
1966	89,600
1967	105,900
1968	118,800
1969	118,900
1970	127,500

SUMMARY OF DATA

Despite these varied activities, we can still paint only a hazy and incomplete picture of the employment situation in computer related occupations. In the following sections we summarize, source by source, the currently available data. It must be recognized throughout that there are problems arising from the lack of widely accepted standard definitions for occupations such as programmer, systems analyst, computer operator, etc. This makes exact comparisons between data from different sources very difficult. In addition, there are a growing number of individuals who spend part of their time programming and part of their time performing other tasks such as engineering or accounting. How these people are classified in the various surveys is unknown. This problem will undoubtedly get worse with the increasing use of terminals which make computers available to many more people who would not normally regard themselves as computer programmers or computer operators.

TABLE II—Distribution of Man-years Utilized in Federal Government ADP Operations

Occupation	1967	1968	1969	1970

Services and Support*	23,475	28,573	29,743	33,229
Total	105,934	118,813	118,869	127,491

* In a few agencies a large number of people are engaged in the handling of source documents.

Federal government

As the result of a directive from the Office of Management and Budget, the federal agencies are required to make annual reports on their use of automatic data processing (ADP) equipment.[5] These reports include cost, manpower and utilization data for all computers except those used for control purposes or installed in classified locations. A summary of all the agency reports is published annually. Tables I and II are taken from the report for fiscal year 1970.[6]

Although the numbers are subject to some uncertainty because of a lack of complete conformity in job descriptions the two tables present an interesting and quite detailed picture of Federal Government employment.

State governments

The most comprehensive source of data on employment in state governments is a survey made in 1970 by The Research and Education Committee of the National Association for State Information Systems (NASIS).[7] While the data is by no means complete the majority of the states, including the larger ones, did report computer related personnel figures. These are summarized in Table III which covers employment by 36 states and includes an extrapolation to the complete 50 states. This extrapolation is based on a report that the 36-included states account for 83.8 percent of all full-time equivalent employment by all 50 states.[8]

TABLE III—Employment of Computer Personnel by State Governments for FY 1970

Occupation	36 States*	50 State Extrapolation
Systems Analysis & Design	2,100	2,506
Programming	4,199	5,011
Computer Operations (incl. EAM)	5,832	6,959
Data Entry (Keypunching)	9,565	11,414
Supervision and Administration	1,633	1,949
Total	23,329	27,839

* In a few cases totals were prorated among the various job categories on the basis of overall percentages.

Local governments

A representative picture of computer related employment in city governments can be obtained from studies made between May and October of 1970 by BLS in cooperation with several cities.[9–15] The eight cities covered by these reports account for approximately 9 percent of all local government employees. Table IV summarizes these data and extrapolates them to all local governments.

In addition, New York City has prepared a detailed report on their EDP operations.[16] Table V, which gives the 1969 employment situation in more detail for New York City, is taken from this report and illustrates the importance of their computer operations. (This is far more comprehensive than a recent BLS survey of municipal government workers in New York City.[17])

TABLE IV—Employment of Computer Personnel by Cities for 1970

Occupation	8 Cities	All Local Governments
Systems Analyst	123	1,353
Programmer	276	3,036
Machine Operator (incl. EAM)	359	3,949
Keypunch Operator	846	9,306

Establishments in metropolitan areas

Data from the individual *Area Wage Surveys*[4] for the 90 Standard Metropolitan Statistical Areas (SMSA) have been consolidated and are presented in Table VI. The surveys were conducted at various times from late 1969 through early 1971 and cover about 24,000,000 employees in manufacturing and non-manufacturing. The latter group includes the transportation, communications, public utilities, wholesale and retail trade, finance, insurance, real estate and service industries. Data by industry group is summarized in Table VII. There is a great deal of additional detail in these surveys. For example, employment is broken down by level and by sex.

The twenty-four million employees covered by the surveys are about 42 percent of those on non-agricultural/non-government payrolls.[19] Using this percentage as a basis for extrapolation we obtain Table VIII which gives an estimate of employment in all non-agricultural/non-government establishments.

Definitional problems preclude direct comparison of data in Tables VI and VII with that in the earlier tables. A major problem is that the *Area Wage Surveys* clearly do not include *scientific* and *engineering* programmers and systems analysts whereas these categories are included in the various government figures.

TABLE V—City of New York Employees Performing DP Functions in 1969

Function	Number of Employees
DP Management	31

Manufacturers of electronic computing equipment

There are two sources of data on total employment by the manufacturers of computing equipment. The first is the Bureau of the Census' *Annual Survey of Manufacturers* which surveys one out of every five known computer firms. Results from this survey are included in Department of Commerce reports on the economy.[18] The second is the Bureau of Labor Statistics' monthly publication *Employment and Earnings*[19] which is based on a sample survey of firms derived from the Social Security Administration's corporate returns. Unfortunately the two sources do not agree, the Census estimates being lower than those of the Department of

TABLE VI—Employment of Computer Personnel in Covered SMSA by Size of Establishment

Occupation	Establishment		
	Large	Small	All
Business Systems Analyst	13,078	20,606	33,684

Number of Covered Employees	11,398,143	12,715,909	—	—	—	—	—

* The sum of the subdivisions do not equal these figures. In many cases the BLS criteria for publication do not permit full subdivision of totals within an SMSA. Clearly, the total figure is the most accurate. Likewise, manufacturing and non-manufacturing do not total to the "all establishment" figure on Table VI and in this case the "all establishment" figure is the more accurate.

** T.C.P.—Transportation, Communications and Public Utilities
R.I.F.—Real Estate, Insurance and Finance

Labor. A further difficulty arises from the fact that data from prior years is frequently corrected by both agencies and these corrections are only reported when new summaries covering past years are published. Moreover, neither of these surveys gives the data broken down by occupational specialty.

Local offices of the Bureau of Labor Statistics will, upon request, give out their latest figures. The figures given in Table IX were obtained from the New York office of the Bureau of Labor Statistics in December 1971.

In late 1970 AFIPS made a survey of the principal manufacturers of CPU's to determine the number of programmers and systems analysts employed by such firms. Data was obtained from five of the manufacturers including the three companies reputed to have the largest share of the CPU market. These companies reported a total of 14,800 programmers and systems analysts as of mid-1970 with academic training as given in Table X.

COMPARISON OF THE DATA

Before trying to make estimates of total employment in the various categories we first look at some averages derived from the foregoing tables. In Table XI we give the average number of employees in each occupation per one thousand employees in the group specified. It should be noted that federal, state and local figures include both *scientific* and *business* systems analysts and programmers while the other groups do not.

Examination of this table reveals both similarities and differences. For example, the total per thousand employment by Federal Government (15.9) is nearly equal to that of the large establishments (13.2). Likewise, the systems analyst and programmer figures for these two groups are nearly equal. Any differences can be rationalized by recalling the omission of scientific personnel from the establishment counts. The large establishment figures need only to be inflated by 33 percent to obtain the federal total for these two occupa-

TABLE VIII—Estimated 1970 Employment of Computer Personnel by Private Non-agricultural/Non-government Establishments

Occupation	Employment
Business Systems Analyst	80,000
Business Programmer	110,000
Computer Operator	125,000
Keypunch Operator	340,000
Total	655,000

TABLE IX—Total Employment by Companies in SIC 3573 (Electronic Computing Equipment) as Reported by BLS

Date	Employment
1967 Average	145,100
1968 Average	160,600
1969 Average	182,700
1970 Average	190,300
Jan 1971	175,800
April 1971	172,800
July 1971	171,500
Sept. 1971	169,500

TABLE X—Educational Background of Programmers and System Analysts Employed by Five Manufacturers of CPU's as of Mid-1970

Level	Percent of programmers and system analysts
PhD	0.5
MA/MS	10.8
BS/BA	58.3
Less than BS/BA	30.4
Total	100.0

tions (i.e., add 1.4 scientific programmers and analysts to the present 4.1 business programmers and analysts). One striking difference to be noted is the high figure for computer operators in the federal as compared to other groups. This may be the result of the job definition problem mentioned earlier. Another difference is that non-manufacturing industries employ more computer personnel on the average than manufacturing industries. We suspect that the finance and insurance segments account for much of this difference. Also to be noted, is that federal, state and local ratios for all occupations are in descending order of magnitude from federal through local with the latter two considerably below the federal levels. This last comparison also holds in absolute numbers as is evident from Tables II, III and IV.

We next examine the ratios of the various occupations to the number of systems analysts. Table XII presents these ratios.

There is a similarity between state and local government in their relative usage of all occupational categories with the possible exception of keypunch operators. One noticeable difference is that small establishments use relatively fewer systems analysts and considerably more keypunch operators than do large establishments. Another is that the Federal Government uses considerably fewer keypunch operators per systems analyst than any other employing group. In this connection it is interesting to note that Table II indicates that the Federal Government is employing a smaller percentage of keypunch operators each year. Table XII further shows that the use of computer personnel by wholesale and retail industries is weighted considerably more toward keypunch operators than other groups; the wholesale industry uses proportionately fewer systems analysts; and the retail group is the only one which employs more systems analysts than programmers.

A final useful comparison can be made between these staffing ratios and similar ratios based on staffing needs per computer. Table XIII presents two such sets of ratios. One is adapted from a British report[20] and a second from information provided in an interview with personnel of a large computer manufacturer.

As can be noted, with the possible exception of computer operators for large CPU's, these ratios are similar to those presented in Table XII. There is also considerable similarity with ratios derived from the 1971 *Business Automation* "EDP Salary Survey."[21] This survey reports on the three categories "Systems Analyst," "Analyst/Programmer" and "Programmer." Ignoring the middle category (or alternatively, assuming that it divides in the same ratio), the ratio of programmers to systems analysts is 1.66. In the 1970 reports this ratio was 1.5.

FINAL ESTIMATE

In order to estimate total U.S. employment in the four occupations, we first accumulate in Table XIV the data for federal, state, local and non-agricultural establishment groups from the preceding sections.

TABLE XI—Average Computer Personnel Per Thousand Covered Employees in SMSA Surveys

	Government*			Establishment			Industry	
Occupation	Federal	State	Local	Large	Small	All	Manu-facturing	Non-Manu-facturing
Business Systems Analyst	2.3	0.9	0.2	1.9	1.2	1.4	1.2	1.4
Business Programmer	3.2	1.8	0.5	2.2	1.8	1.9	1.4	2.3
Computer Operator	6.4	2.5	0.6	2.6	2.0	2.2	1.6	2.6
Keypunch Operator	4.0	4.2	1.5	6.5	5.7	5.9	4.2	7.5
Total	15.9	9.4	2.8	13.2	10.7	11.4	8.4	13.7

* Government figures also include *scientific* and *engineering* systems analysts and programmers

TABLE XII—Ratio of Computer Personnel in Various Occupations to Those in Systems Analysis as Shown in Table XI

Occupation	Government*			Establishment			Industry						
	Federal	State	Local	Large	Small	All	Manufacturing	Non-Manufacturing					
								Total	T.C.P.**	Wholesale	Retail	R.I.F.**	Service
Business Systems Analyst	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
Business Programmer	1.4	2.0	2.2	1.1	1.5	1.4	1.1	1.6	1.9	2.4	.96	1.7	2.0
Computer Operator	2.8	2.8	2.9	1.3	1.7	1.6	1.4	1.7	1.8	5.4	3.9	1.9	2.5
Keypunch Operator	1.8	4.6	6.9	3.3	4.8	4.2	3.5	5.3	7.8	26.7	43.1	3.1	5.0

* Government figures also include scientific and engineering systems analysts and programmers
** T.C.P.—Transportation, Communications and Public Utilities
R.I.F.—Real Estate, Insurance and Finance

The numbers in this table are undoubtedly low due to the failure to include at least four major groups. These are the employees of educational institutions which were only partially included in the state government data as well as scientific systems analysts and programmers, agricultural employees and the self-employed, all of which are excluded from the *Area Wage Surveys.*

A crude correction for the non-inclusion of some of the scientific and engineering related personnel might be to increase the systems analyst and programmer categories by 33 percent. This adjustment is based on our earlier discussion of the difference between the "Federal Government" and the "Large Establishment" group on Table XI. In addition, we might, somewhat arbitrarily, increase all occupations by 15 percent to correct for the other omissions. Our justifications for this last correction are that at least 10 percent of the labor force is self-employed or engaged in agriculture and that the universities and colleges are known to employ many computer people. Using these corrections we obtain Table XV which represents our best estimate of total U.S. employment in the four categories.

TABLE XIII—Estimated Staffing Ratios by CPU Size

Occupation	British	Manufacturer		
		Small CPU	Medium CPU	Large CPU
System Analyst	1.0	1.0	1.0	1.0
Programmer	1.5	2.0	1.3	1.6
Computer Operator	1.3	3.0	1.3	.5

A comparison for this estimate can be derived from the 1971 EDP salary survey of *Business Automation* which reports that there are 13.4 systems analysts and programmers per installation in the U.S. Combining this with an International Data Corporation report that there are 34,700 installations in the U.S.[22] yields an estimate that there are 465,000 systems analysts and programmers as compared with our estimate of 360,000.

TABLE XIV—Estimate of Total Computer Personnel Employed by Federal, State and Local Governments and Non-agricultural Establishments

Occupation	Employed*	Per 1000 covered employees	Ratio to systems analyst
Business Systems Analyst	97,000	1.4	1.0
Business Programmer	137,000	1.9	1.4
Computer Operator	173,000	2.5	1.8
Keypunch Operator	384,000	5.4	4.0
Total of Above	791,000	11.2	8.0

* Includes *scientific* and *engineering* personnel employed by government.

TABLE XV—Final Estimate of Total U.S. Employment of Four Categories of Computer Personnel for 1970

Occupation	Employed
Systems Analyst	150,000
Programmer	210,000
Computer Operator	200,000
Keypunch Operator	440,000
Grand Total	1,000,000

Since criticisms can be levelled against both estimating procedures, the discrepancy is probably not surprising.

Our estimates are remarkably close to those made by the BLS in their *Occupational Outlook Handbook*. Their estimates are based on the average staffing per particular size of CPU, the numbers of the various size CPU's in use, and correction factors for productivity changes. This approach which is entirely different from ours yielded estimates of 150,000 systems analysts, 175,000 programmers and 175,000 computer operators for 1968.

CONCLUSION

Despite the collection and publication of much information by various private and governmental agencies, it is still impossible to make an accurate estimate of the number of computer personnel as defined in this paper (or by any other definition for that matter). Certainly, it is in excess of the 800,000 indicated on Table XIV. Most likely it exceeds one million. Due to the lack of use of standard occupational classifications, any attempt at disagregation into occupational specialities may really be more a matter of speculation than enumeration.

Since the major objective of collection and publication of these data is to provide information for manpower planning (i.e., the matching of the numbers of persons trained to those needed for a particular occupation), the lack of detailed estimates is a serious problem. The result so far has been a period of serious manpower shortages from about 1960 to 1969 followed by the present condition of moderate oversupply. Further, present and future prospects are for large oversupplies in some occupational specialties while at the same time there are critical shortages in others.

It is clear that total employment of computer operators, programmers and systems analysts is not significantly greater than 560,000. In our companion paper we found that the current annual production of people trained for these jobs is over 170,000. To employ these would require a new entry rate of about 30 percent which is much higher than the estimates of relative openings given by BLS of about 11 percent for computer operators, 13 percent for programmers, and 18 percent for systems analysts.[23] Thus, current production trends are not commensurate with current employment needs.

Our major conclusion is that a serious potential imbalance exists and that much additional effort is needed in gathering and publishing reliable statistics in order to prevent future such imbalances.

ACKNOWLEDGMENTS

The authors are very appreciative of the many individuals, both in industry and government, who have helped them track down sources of data.

Sociological analysis of public attitudes toward computers and information files*

by RONALD E. ANDERSON

University of Minnesota
Minneapolis, Minnesota

As individuals increasingly experience a variety of contacts with computers, it becomes important to know something about the impact of these contacts and how different sectors of society feel about computerization. Such knowledge would (not only) give us insight into the source of public attitudes toward computers but would provide some basis upon which to anticipate public acceptance or rejection of computerization. These considerations should be taken into account in planning future computer applications, particularly social information systems.

Data on public perceptions of computers has been surprisingly slow in appearing. Our knowledge of such perceptions is sketchy and incomplete and measurement techniques need evaluation and refinement. The pioneering work on public attitudes toward computers was done in 1963 by Robert S. Lee with a national survey supported by IBM. The results of this study were not reported for several years. Yet until this year no one attempted another large survey devoted to public opinion and computerization.

Lee reported that the public in 1963 viewed computers from two distinct perspectives: (1) beneficial tools providing a better life for man, and (2) awesome thinking machines that threaten individuality. Lee suggests that the lack of correlation between these two views of the computer implies that a simple pro-con opinion assessment strategy would be misleading.[5,p.59]

Several small scale, exploratory research efforts have been reported during the last few years. Armor and Feinhandler conducted a study for the Harvard Program on Technology and Society investigating public perceptions of technology. Included in their survey of several communities in the Boston area were a number of questions specifically on the topic of computers. They found a pronounced social view of computers as beneficial and useful tools; yet persons simultaneously expressed fear and reservations concerning some aspects of computerization, such as data banks. This study is likely to provide important information concerning the social significance of the distinction between technology and computers.

Other miscellaneous studies have focused upon differences in belief structures among different social groups. Rosenberg and his associates at a psychiatric hospital compared attitudes of patients and hospital staff toward computers. Certain differences were found but their significance is difficult to assess because controls were lacking on crucial variables.

The scant literature on public opinion toward computerization suggests that public reaction to computer technology is best characterized as diverse, complex, and indicative of individuals' prior experiences, as well as their general orientations toward life. Public perceptions of computers are probably more analogous to attitudes on public affairs issues rather than attitudes toward specific objects like typewriters. Thus it seems particularly important to explore the interrelationship of computer conceptions with numerous other variables representing various social processes and social characteristics. To pursue this end it would be useful to begin by outlining a framework for analysis.

CONCEPTUAL FRAMEWORK

The goal of this analysis is to arrive at an improved understanding of the process of the emergence of

* The research reported herein is based in part upon survey data gathered by the Minnesota poll of the Minneapolis Tribune. I which especially to thank Mr. Robert Coursen, manager of the News Research Department, for his assistance in providing data and information.
This paper was prepared prior to the release of the AFIPS/Time Inc. Report on a national survey of attitudes towards computerization. Their findings are impressively consistent with the conclusions reported here.

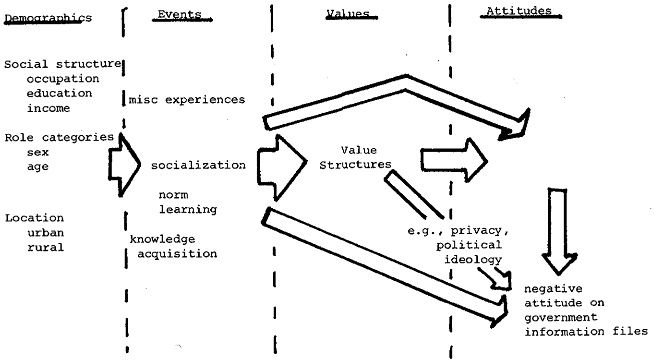

Figure 1—Conceptual scheme

particular conceptions of computer-relevant objects. Such understanding will make it possible to account for individual variation on feelings about computers and computer information files.

The orientation of our conceptual scheme is more sociological than psychological in that value orientation and experiences are stressed rather than personality factors. Furthermore, ecological-demographic characteristics are integrated with experiences and values to account for differences occurring in attitude toward computerization. Figure 1 outlines the general flow of effects generated by the combination of numerous, complexly organized variables. Demographic categories are seen to significantly determine chances of obtaining various experiences and values that in turn are crucial to an individual's cognitive process by which he arrives at particular beliefs and feelings about computerization.

Working in reverse order across the chart, each of the four sets of variables will be considered individually.

Attitudes

Two areas of affective orientation receive the focus of this investigation: attitudes about computers and attitudes about government information files. These two phenomena embody the processes defined by the other variables in the conceptual scheme. Attitude toward computers and attitude toward government information files are not entirely independent. If one has negative feelings about computers, then one is also likely to have negative feelings about government information files; these files are generally thought to be computer-based. Access to government information files typically requires computers, so if computers do not elicit good feelings, neither should the files "guarded" by them. On the other hand, computers may be negatively evaluated in part because they allow large, threatening files to survive.

While there may be a reciprocal causal relationship between attitudes toward computers and attitudes toward information files, computers chronologically preceded computer-based information systems. Thus we will assume a causal direction of computer attitude to information file attitude. Large government files existed long before computers were invented; never-the-less, widespread concern is a recent trend resulting primarily from the computer's potential for centralizing information. Attitudes toward both computers and government information files are assumed to result from a combination of (1) value orientations, (2) previous events and experiences, and (3) other attitudes.

Values

Although the conventional distinction between attitudes and values is not entirely precise, general usage restricts values to mental constructs with terminal (end-state) attributes and moral (highly desirable or ethical) implications. Attitudes are typically directed toward specific objects which are historically dependent. Given these definitions, cognitive orientations directed toward computers will be termed attitudes whereas orientations toward technological progress will be considered values. Likewise feelings about man-computer relationships are termed attitudes but feelings and beliefs on friendship, sharing, love, respect, harmony, expressiveness, and communication are thought of as values.

Not only has the values concept persisted through the history of social thought, but discussions of technology have generally been preoccupied with value issues. Recent protest movements and numerous writers have expounded anti-technological points of view. Their statements inevitably are based upon value preferences such as personal expressiveness, creativity, spontaneity, friendship, etc. On the other hand pro-technological statements are based upon value preferences such as economic prosperity, orderliness, control, etc.

The level and structure of one's values largely determines how one views the significance of technology. But technology in general is not typically an issue with which individuals are personally involved. Individuals are involved with specific technologies, specific machines. Complex value structures may not be as closely tied to specific objects as to technology in general; however, there is evidence that computers and technology are closely associated in most persons' conceptualizations. Because of its tremendous power and awesomeness, the computer has become a symbol of super-technology. The folklore, as illustrated in cartoons, science fiction, and popular science, presents this image. Computers simultaneously represent the best and the worst in technology.

Value systems other than technology-oriented value structures are likely to determine attitudes relevant to computers. The importance one places upon privacy relative to governmental or organizational needs will automatically affect one's feelings about whether or not databanks are threatening. Valuing privacy might result in the opinion that computers should not be used in an information system because computers would allow for cross-referencing of information. Political ideology also affects attitudes toward databanks. An ideology directed against strong governmental control would be wary of databank systems because of their implications for increased centralized control.

Events

The emergence of personal values and value systems is based upon a sequence of events which provide knowledge and experience to the social actor. This event series is commonly called socialization or cultural learning. It is this process that allows group norms and other social conditions to generate an impact upon individuals. Some events, tremendously more significant than others, cause immediate impact upon attitudes and values. It is this possibility that accounts for the arrows in Figure 1 going directly from "events" to "attitudes" bypassing "values." A single traumatic encounter such as a major foulup in computer dating or a computerized billing hangup might be sufficient to cause change in feelings about the desirability of computerization.

Demographics

Demographic variables such as occupation, sex, and age serve as gates opening or closing certain event sequences. The end result is a variety of life styles, role patterns and values. Lee reports a regression analysis using demographic and personality variables to predict position on his "awesome machine" attitude factor. He found that although there were correlations between education, sex, and the attitude factor, their contribution was negligible in predicting attitude on the "awesome machine" dimension. While this is superficially consistent with our conceptual scheme, ignoring the indirect effects of demographic variables is misleading. Demographic-ecological factors provide the foundation for crucial experiences which in turn create different attitudes and values. Neglecting the relationships between demographic variables and attitudes toward computers because such variables are, on the surface, weak is conceptually misguided and ignores interesting relationships that will be investigated in the following sections.

DATA COLLECTION

The Minnesota Poll interviewed a randomly selected cross-section of Minnesotans age eighteen and older during July 1971. This was one of *Minneapolis Tribune*'s periodic surveys of 600 persons; included in the July 1971 survey were several questions pertaining to computerization. One of the first questions relevant to computers was the following:

Question 1. Some people say that the relationship between businesses and their customers has become too impersonal because of the computer. Are you inclined to agree or disagree?

Two-thirds (66 percent) of the interviewees agreed with this statement linking impersonal business with the computer; 28 percent disagreed; and 6 percent gave no opinion. Respondents were next asked the following question:

Question 2. Have you ever had a mistake made in a transaction that was hard to get cleared up because billing was handled by a computer?

Only about one-third answered this question affirmatively. In actuality some persons who said they had the computer-based problem may not have known for certain that a computer was involved, but the key point is that these persons *perceived* the computer responsible for the difficulty.

Whenever a respondent admitted they had experienced computer billing problems, interviewers probed into the details of the dispute. Later on the interviewers launched into questions pertaining to databanks and privacy. The first question in this series was:

Question 3. Some people say that American society is threatened by the increase in information that the government collects about individuals from the census, tax returns, social security, and so on. Are you inclined to agree or disagree?

The key element of this question is the notion of increased collection of information by the government.

Centralization of information and links between information files are implicit but not explicit; the question suggests an environment that lacks controls over access to and centralization of information. With the term "threat" the statement expresses a rather strong statement against government information collection, so it is startling that 41 percent of all respondents agreed with this statement; 53 percent disagreed; and 5 percent gave no opinion. The next question asked was:

Question 4. Which do you think is more important for society to function properly—the government's right to know about its citizens, or the individual's right to privacy?

An overwhelming two-thirds (66 percent) indicated that privacy was more important for society; 28 percent selected the government's "right to know" over privacy; and 6 percent did not choose one or the other.

In addition to these data collected from a representative sample of voting-age residents of Minnesota (the state of Minnesota is in many ways typical of the United States population as a whole [although certain minority groups such as blacks and chicanoes are not well represented)], a questionnaire survey was carried out on a convenience sample of students at the University of Minnesota. Students in several undergraduate sociology classes were asked to fill out a questionnaire which included questions mostly concerning attitudes toward computers. A total of 100 questionnaires were received and processed during the early Fall of 1971. Included among the many questions on attitudes toward computerization were the above four Minnesota Poll questions mentioned above with identical wording in identical order. The distribution of responses from the student sample are remarkably similar to the Minnesota Poll results. Of the students, 64 percent agreed with the first question (impersonal business and computers), compared with the statewide results of 66 percent. Forty-two percent of the students had encountered a computer billing problem, compared with 35 percent statewide. On the statement concerning threat from government information collection, 50 percent of the student sample agreed, contrasted with only 41 percent agreement statewide. And 83 percent of the students chose privacy over the government's right to know; 66 percent made the same choice statewide. This difference between the results of these two studies concerning this privacy issue is not as significant as might be expected; in the statewide Minnesota Poll, 72 percent in the 18-29 age bracket and 75 percent with some college experience selected privacy over the government's right to know. In summary the response distributions from the two studies are very similar on the questions pertaining to computerization and information privacy.

CONTRASTS AMONG DEMOGRAPHIC GROUPINGS

The previously mentioned four questions dip into an important array of issues: the link between computers and impersonal business, the discomforting experiences of computer consumers, the perceived threat of government information collection and the value of privacy. Each of the questions is presented in Table A with breakdowns contrasting groupings on sex, age, location (urban/rural), and education. Income is not included because in most cases income trends were nearly identical to differences in education levels.

Question 1—*Impersonal business because of computers*

Looking first at question #1, by reading down the column of Table A it is possible to readily note that differences exist between men and women and also

TABLE A—Computerization Responses With Demographic Breakdowns—Minnesota Poll Statewide Sample, July 1971

		Quest 1	*Quest 2*	*Quest 3*	*Quest 4*
	No. of Persons	Imper-sonal	Billing	Gov't Threat	Privacy
Total	600	66*	35	41	66
Sex					
Male	292	60	37	47	70
Female	308	70	33	36	63
Age					
18-29	153	59	34	41	72
30-59	293	71	42	42	65
60+	154	64	27	38	61
Location					
Urban	425	66	40	42	67
Rural	175	63	25	42	66
Education (highest level)					
Grade (some)	119	61	19	43	64
High School (some)	297	68	33	37	62
College (some)	184	65	50	47	75

* All numbers in columns under question numbers 1, 2, 3, 4 are percentages answering the question in the indicated way.

between the younger (18-29) age group and the middle (30-59) age group. Sixty percent of the men and 60 percent of those individuals aged 18-29 agreed with the statement that linked computers with impersonal business: a greater percentage (70 percent) of the women and those respondents in the middle age group agreed with that statement. Very slight differences are found in other areas: the urban percentage exceeds the rural figure, and the high school and college educated are slightly more likely to agree with the statement than those with only a grade school education. These contrasts are based upon such small differences that they are unreliable; that is, the differences may be due to sampling variation alone. Furthermore, the difference among education levels are largely artifactual. There are many more persons in the lower education levels that did not answer the question; both agreement and disagreement are less frequent at the lowest (some grade school) education level. (This same pattern of response occurs for the income groupings as well, although the income group percentages are not included in the Table.)

To interpret the significance of these response patterns we should explore the meaning of the question. One might guess that the notion of impersonal businesses predominates and "computer" is a trivial element in the statement. This, of course, might be true with some respondents, but there is clear evidence from the student sample that the interviewees are reacting primarily to the idea of computers causing impersonality. Responses to this question were correlated with many other variables the highest correlation was found to occur with agreement to the statement, "Computerization tends to dehumanize people." In the various factor analytic investigations that we have performed on items concerned with attitudes toward computers, the negative idea of dehumanization and over-dependency have consistently turned up together in a dominant pattern. These findings suggest that agreement with the statement on impersonal business caused by computers is a fairly adequate indicator of *negative feelings toward computers.*

Given that question #1 is an adequate device to assess negative attitude toward computers, we can expand our interpretation of the data. Women are substantially more likely to have negative attitudes toward computers as are those in the middle-range (age 30-59) age groups. It would seem that in our society the different age and sex roles result in different experiences or lack of experiences such that different views of computers are acquired. Perhaps one of these experiences is frustrating encounters with computerized bills.

TABLE B

Question 1. (Impersonal . . . computer) by question 2 (billing problem) for statewide sample

Question 2. Computer billing problem ever encountered?

Question 1 Impersonal because of computer	Yes	No	Total
Agree	83	56	66
Disagree	16	35	27
NA	1	9	7
	100	100	100
	(212)	(388)	(600)*

* Total number of respondents are given in parentheses. All other numbers are percentages.

Question 2—Computer billing problem ever encountered?

Returning again to Table A, the 2nd column reveals substantial differences in susceptibility to billing problems due to computers. One is much more likely to experience a computer-based billing difficulty if one is in the 30-59 age bracket, if one lives in an urban location, and if one has a relatively high education and income level. All of these factors appear to be economic or social structural in character. That is, persons falling into the middle age, urban, and high socio-economic levels are the most likely to have money to spend; they also have greater preferences for credit systems, which automatically involve credit-users in additional billing systems. It is to be expected then that high money/credit users have an unusually high chance of encountering billing problems, especially problems due to computers.

ANALYSIS OF RELATIONSHIPS

It might be expected that persons facing frustrating experiences in clearing up computer-based bills come to view computer systems as unresponsive and rigid. This conception of unresponsive computer systems in businesses might actually grow into a long-term negative feeling about computers. To explore this possibility we examine the relationship between question #1 and question #2 (see Tables B and C). These tables show a strikingly strong association or correlation between computer-based billing difficulty experiences and tendency to agree with the notion of impersonal business resulting from computers.

TABLE C

Question 1. (Impersonal . . . computer) by question 2 (billing problem) for student sample

Question 2. Computer billing problem ever encountered?

Question 1 Impersonal because of computer	Yes	No	Total
Agree	74	57	64
Disagree	26	43	36
NA	—	—	—
	—	—	—
	100	100	100
	(42)	(58)	(101)

In both the statewide and the student samples there exists a strong tendency for those individuals who have faced a computer-based billing problem to express negative feelings toward computers. Those who have not experienced the frustration of a computer billing difficulty are much less likely to express negative feelings toward computers.

If negative experiences result in negative feelings, positive experiences may result in positive feelings. To explore this question as regards computer attitudes there must be a clarification of the kind of experiences involving exposure to computers which suggest that computers are important in creating a better life, what kind of experiences show computers as useful tools generally provide desired benefits. As yet there is insufficient data to determine whether or not class experience or job experience in computing is associated with a change in the level of negative attitude toward computers. The evidence thus far is ambiguous, which could mean that in many instances actual class or job exposure to computers is quite frustrating. There is evidence, however, that *anticipated* exposure to computers as a useful tool is correlated with a more positive attitude toward computers.

The following question was included in the student questionnaire: Do you expect to use computers in your future occupation? There were three alternatives: yes, maybe, and no. The responses, when crosstabulated with question 1 (indicating negative feeling toward computers) appear in Table D.

Although the association indicated in Table D is not unusually strong, students expecting to make occupational use of computers were less likely to agree with Question 1, then were those that did not foresee using computers in their future occupations.

Occupational use of computers is most likely to occur in the professions or highly skilled technical jobs. These occupational groups are more likely to occur in urban than in rural areas, and they are also associated with persons of higher education and income. Assuming that occupational experiences with computers are more favorable than unfavorable, we conclude that being urban, aged 30-59, having a college education, and having a high income predispose one to have positive computer experiences. This connection is graphically illustrated in Figure 2. This diagram vividly portrays the ironical fact that the same demographic characteristics pointing to positive experiences with computers also increases the chances of negative computer experiences, e.g., computer billing problems. The total effect of these opposite forces is to wash out the effects of certain demographic factors upon negative attitudes toward computers.

Those demographic variables whose effect is not largely cancelled are sex and age categories. Men and the younger age group both tend toward more positive attitudes; this is probably due to a link between these characteristics and positive occupational or educational experiences with computers. Being a woman or being over age 60 increases one's chances of having negative computer attitudes, but not having computer billing problems. In Figure 2 these two demographic groups are routed separately because these groups are probably characterized by lack of contact with computers. Since computers are culturally defined as "awesome thinking machines", it would not be surprising to discover that lack of contact and knowledge generates fear and distrust of computers, which in turn tends to lead one toward negative attitudes.

TABLE D

Question 1 (impersonal ... computer) by Anticipated occupational use of computers.

Do you expect to use computers in your future occupation?

Question 1.	YES	MAYBE	NO	TOTAL
AGREE	61	57	75	64
DISAGREE	39	43	25	36
	—	—	—	—
	100	100	100	100
	(18)	(47)	(34)	(100)

Question 3—Governmental information files and privacy

The question of whether or not a threat exists from governmental collection of information from "the census, tax returns, social security, and so on," follows the demographic patterns of Question 4 (privacy) more closely than Question 1 (negative attitude about computer). Contrasts between demographic categories are interesting only for the sex and socio-economic status (education and income) variables. Men are substantially more likely to perceive a threat from governmental information systems than are women. This difference parallels the differences between the sexes on Question 4 (privacy), while it reverses the direction of contrast on Question 1. There appears to be a distinct aspect of the female sex role that results in more negative feelings about computers; but males are more negative about information files and more likely to value privacy.

One possible interpretation of emphasis upon privacy among men is their wider variety of interpersonal and instrumental activities. The complexity and conflict of these varied activities can sometimes be reduced by isolation and privacy. Women in our culture are not generally allowed as much privacy as men. The sex role differences on attitude toward computers may be largely a result of early socialization patterns which direct girls to dolls and boys to mechanical toys. Girls are also discouraged from pursuing mathematical and technical skills and thus have more justification for viewing the computer as an "awesome thinking machine."

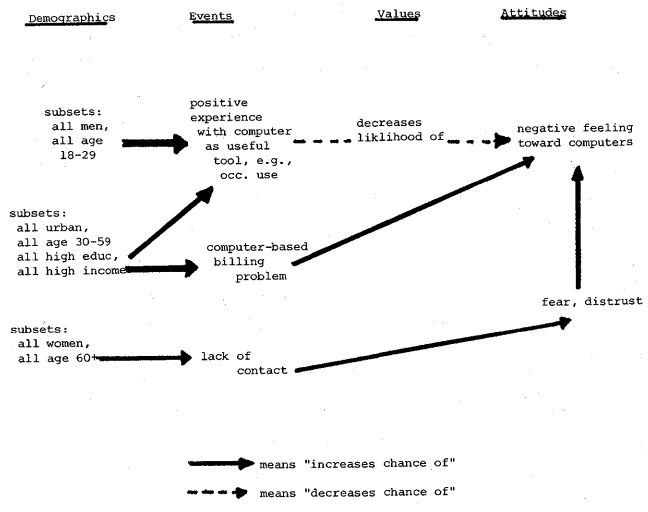

Figure 2—Interrelationships among variables pertaining to attitudes toward computers

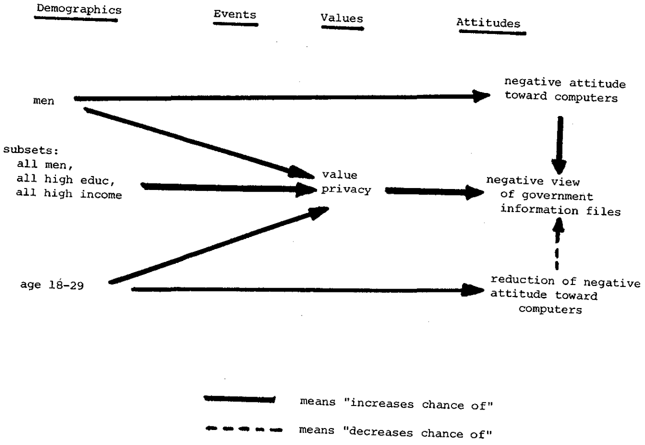

Figure 3—Interrelationships among variables pertaining to attitude toward government information files

Question 4—Value privacy or government?

The tendency to value privacy is greater among men, the 18-29 age group, the college educated, the high income groups, and the political independents. Except for the age trend, all these demographic patterns are identical to responses to Question 3.

In regard to socio-economic status, those with at least some college education and those with higher incomes are more likely to view government information collection as threatening and to value privacy.

Looking at the question from an alternative perspective, the contrast can be interpreted to result from political ideology differences or other value system differences. In this instance negative attitudes do not seem to result from events so much as values. Actually the lower income and education classes are more likely to experience negative events in connection with government information files. Databanks, especially at the local level, increasingly incorporate welfare records, arrest records, and other information more likely to involve persons of low social class. Ironically, persons in these lower socio-economic levels are the least likely to value privacy, yet they are the most likely victims of privacy invasions.

Analysis of relationships

Figure 3 presents the proposed causal relationships given the demographic findings. Again demographics are viewed as shaping the nature of values (privacy in particular) which in turn determine the nature of the attitudes toward government information files. Com-

TABLE E—Negative Attitude Toward Computer By Perceived Government Information Threat For Student Sample

Question 3. Government Information Threat

Question 1		Yes	No	Total
Impersonal Computer	Yes	74	54	65
	No	26	46	35
	Total	100 (50)	100 (50)	100 (100)

plexity in these relationships is seen to arise from the inter-relationship between attitude toward computers and attitude toward government information files. Tables E and F present the data from the Minnesota student sample for the correlation of Question 1 with Questions 3 and 4. These findings show a sizable association between responses to these questions. As Figure 3 illustrates, age and sex may indirectly affect attitude toward government information files: the 18-29 age group tends to lead into reduced negative attitudes toward computers, and men are more likely to have negative attitudes toward computers. The resulting effect of these two conditions may be to cancel out some of the variation in attitude toward information files that is due to attitudes toward computers.

IMPLICATIONS FOR CHANGE AND THE FUTURE

Cross-sectional survey data gathered at one point in time provides very little basis for generalizing to trends occurring over time. In addition, the survey approach provides little understanding of processes involving event sequences. Consequently it is imperative for future research to move toward approaches with greater control such as laboratory experiments. In addition, planning should begin toward establishing periodic assessments of public opinion using socio-computer indicators so that changes can be examined across time. Without such data there will be no way to systematically assess the impact of innovations in computer technology upon society.

TABLE F—Attitude on Computer by Value—Privacy of the Government (Question 4) for Student Sample

Question 4.

		Privacy	Gov.	Total
Question 1 Impersonal Computer	Yes	63	56	63
	No	36	44	37
		100 (80)	100 (16)	100 (96)

On the basis of age breakdowns from currently available data, it is possible to speculate about future trends assuming that the young and middle aged will simply move along into the future largely unchanged. For instance, as already noted, a larger share of those aged 18-29 value privacy over government's right to know. This trend seems to arise from developments in the youth culture and the various movements that the youth have spawned in recent years. It would appear that this emphasis upon privacy will persist and that privacy will have greater importance as a value in the population as a whole.

Establishing governmental databanks will be even more difficult in the future unless extremely secure safeguards are established to preserve individual privacy. While the young (18-29) tend to value privacy, they are not unusually concerned about the "threat" of government information collection. Members of this young group are even slightly less likely to have negative attitudes about computers.

The profile for the future suggested by these data is a populace more concerned for rigorous privacy related guarantees but simultaneously approving computer technology and related developments.

In projecting into the future, events and their impacts are the crucial uncertainty. The significance of frustrating events involving computer billing problems became evident in the earlier discussion. If the public were bombarded by a wave of frustrating computer experiences, a tremendous protest movement could easily ensue against computerization. On the other hand, if great care is taken in packaging computer-based products for the consumer, the public will gladly put up with "awesome thinking machines." The computer world still has its chance.

Microprogrammed significance arithmetic: A perspective and feasibility study*

by C. V. RAMAMOORTHY and M. TSUCHIYA

The University of Texas at Austin
Austin, Texas

INTRODUCTION

This study is an attempt to evaluate the feasibility of microprogrammed routines for monitoring significant digits in the numerical result of digital computers in real time. The first part is tutorial and, in the second part, microprograms for two methods of significance arithmetic are designed and evaluated.

The digital computer is a finite device that has a limit in representing numerical values; thus, in general, it maintains the most significant part of true values for computation. Therefore, errors are nearly always involved in numerical computations on a digital computer due to the finiteness of representation, truncation and round-off. Unfortunately, whether they are in the original data or generated during computation process, errors are "hidden" in the computed results. One cannot readily determine how many digits of the computed result represents the true value unless rigorous error analyses such as those by Wilkinson[1] are performed.

Significance arithmetic was suggested as a means for monitoring the significant digits in the numerical result of digital computers. If an algorithm for significance arithmetic is effectively implemented, it will provide an indication of the number of significant digits that the result retains. It will also be a powerful tool for debugging and testing numerical method for computers by tracing numerical significance at every stage of computation. Thus a study of error propagation of computational methods will be made easier. It will also pinpoint the computational stage where a large loss of significance occurs so that the computational method could be modified analytically to prevent the loss of significance and to improve the accuracy of the computed result.

SIGNIFICANCE ARITHMETICS

A number of studies have been made in the area of significance arithmetic in an effort to trace the significant digits accurately and to preserve the given number of significant digits of operands. Gray and Harrison[2] used a normalized arithmetic with an index of significance in which part of a word is used as an index to indicate explicitly the number of significant digits of the numerical value. In this method, arithmetic operations are performed in the same manner as any normalized arithmetic except an extra computation, although simple, is necessary. Metropolis and Ashenhurst[3] used unnormalized arithmetic in which numerical values are stored in an unnormalized form preserving only the significant digits. Unnormalized arithmetic is relatively simpler than other methods, but since operands in this method are not normalized, their leading zeros* must be compared with each other as well as with those of the result to adjust and preserve significance. Moore[4] proposed interval arithmetic that used two values, upper and lower bounds, to indicate the range of true value. Error bounds are computed in this method to indicate significance instead of the number of significant digits. The range for true value, i.e., the difference of the two bounds, tends to become large with a loss of significance as the number of arithmetic operations increases. Wilkinson[1] provides excellent error analyses for digital computation. His analyses, however, take a "pessimistic" approach and do not offer sharp bounds.

In this study, the first two methods are considered: namely, the normalized arithmetic with an index of significance and the unnormalized arithmetic. They are provided with simple algorithms for determining

* This work was supported by National Science Foundation Grant GJ-492 and in part by the Joint Services Electronics Program under contract AF-44620-71-C-0091.

* In Reference 3, the term "leading digits" is used since, in negative numbers, leading zeros may be represented by leading ones. In this paper, the term "leading zeros" is used because leading ones in negative number, in fact, represent "leading zeros."

the number of significant digits explicitly at each stage of computation.

The microprogrammed implementation of these algorithms are shown to be quite simple. Most importantly the computational overhead is also proved to be quite small.

DESCRIPTION OF METHODS

When the floating-point arithmetic is implemented in a computer, a normalized method is generally employed. The normalized floating-point arithmetic, however, does not provide a facility to indicate explicitly the number of significant digits in the result. It generates results with no indication as to how many of their digits might represent the true value. Since the error analysis in general is not easy, the significant digits in the result are not easily determined. Thus the idea of significant digit arithmetic or significance arithmetic is introduced.

In the significance arithmetic, the number of significant digits in the results is computed at every stage of computation and, in some cases, an adjustment is made to preserve the original significance. To realize the significance arithmetic, a number of unorthodox arithmetic methods have been proposed and experimented. Among these two methods, namely the unnormalized arithmetic by Ashenhurst[3] and the normalized arithmetic with an index of significance by Gray and Harrison,[2] were chosen for this study. In this section, the schemes used in the two methods are briefly described and illustrated with examples. The numbers in the example are represented as follows:

(exponent, mantissa) for unnormalized number;
(exponent, index, mantissa) for normalized number with index.

Significant digits of the operands are indicated by boldface types so that if an operand is **1.7320**51, for example, the first five digits **1.7320** are significant. In the example a double-length arithmetic register is assumed.

                          less significant digits).
```

As intuitively seen in the examples, both methods preserve and indicate the same amount of significance. It can be shown that both methods are in fact equivalent methods that use different number representations. Both methods use a carry out of the highest digit and a number of normalizing shifts (or equivalently a number of leading zeros in case of unnormalized arithmetic) as criteria for determining the number of significant digits for the result. Since they use the same criteria for determining an amount of significance, it may be concluded that they yield the same result.

A case for fully significant operands

A special case is where both operands have full significance, i.e., the value of operands happens to be precisely representable within the limit of the exponent-and-mantissa representation. If this is the case, the significance computation changes. Under the significance computation rule, a large gain in the number of significance is possible. Given two operands $A = (e_A, s_A, m_A)$ and $B = (e_B, s_B, m_B)$ where e_A and e_B are exponents, s_A and s_B significance, m_A and m_B mantissas of A and B, respectively, the modified rule is as follows:

addition/subtraction	$s_A + \lvert e_A - e_B \rvert$;
multiplication/division	$s_A + s_B$.

Clearly, in order to keep the result with increased significance a double-length mantissa is necessary. If it is not available, the result is rounded and its significance is reduced.

Unfortunately the increased significance in a double-length mantissa is possibly reduced to single-length significance by rounding, etc., in a subsequent computation. If a result with increased significance represented by a double-length mantissa is used for a computation with an operand with a single-length mantissa, the result will have the significance at most that of the latter operand, i.e., the significance is reduced to the single-length. Thus the implementation of the rule does not necessarily guarantee a result with higher significance.

Another problem associated with the special case is the detection of operands that represent a value exactly. Since the rule applies only when both operands have full significance, i.e., when they represent exact values, operands must be checked for their full significance at every arithmetic operation if the rule is to be applied. The test for full significance can cost a few steps and, if the test is performed on every operand used in arithmetic operations, it can be expensive in terms of computation time. Moreover, the probability of computing two operands with full significance is conceivably very low mainly due to rounding and truncation operated on intermediate results. The inclusion of the algorithm for the special case, therefore, will reduce computational efficiency of significance arithmetic and may not be practical unless a larger number of significance is highly desirable.

MICROPROGRAMMED SIGNIFICANCE ARITHMETIC: AN IMPLEMENTATION

The following is a brief description of microprograms for arithmetics in the unnormalized method and the normalized method with an index of significance. In this paper microprograms for addition and multiplications are considered and described. Division may be considered a multiplication in "reversed" order; its flow diagrams are presented. Many results observed in multiplication also apply to division.

The following assumptions are made in designing microprograms for significance arithmetic:

(1) A double-length arithmetic register that performs addition/subtraction in two clock cycles (the register for higher order part of operand will be called the upper accumulator, and the other, the lower accumulator);
(2) One's complement addition;
(3) One's complement representation for negative numbers.

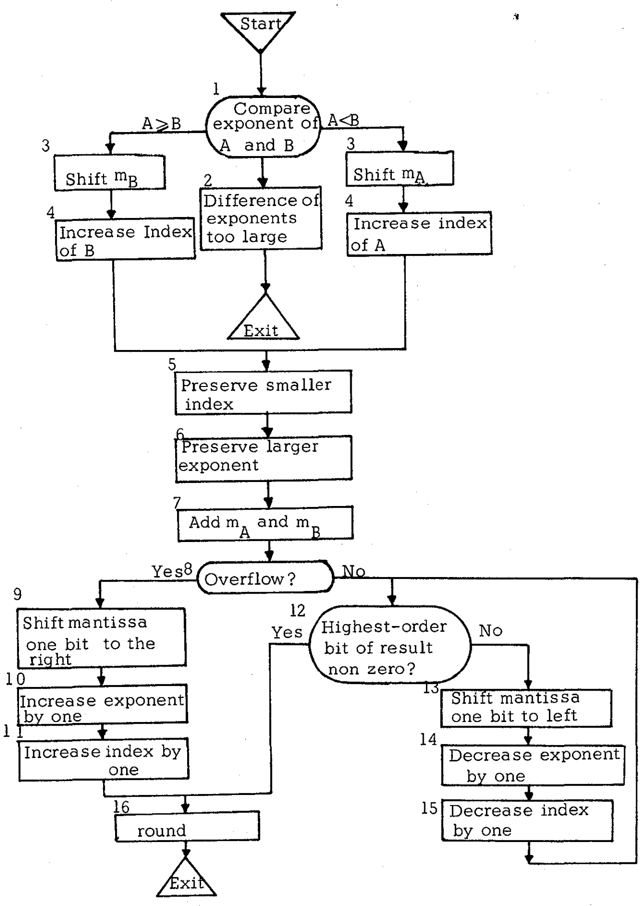

Figure 1—Normalized addition/subtraction with an index of significance

In the subsequent discussion, numbers in parentheses refer to the box bearing the same number in the flow diagram. Two operands are referred to variables "A" and "B" for convenience. The mantissas of the two operands are denoted by m_A and m_B, and the exponents e_A and e_B, respectively.

Normalized addition/subtraction with an index of significance

Addition and subtraction are carried out in a conventional manner using ones complement (Figure 1). The exponents of the two operands are compared first (1). If the difference of the two exponents is too large, i.e., if it is greater than the number of bits in mantissa, then the smaller operand is too small to have any effect as far as the mantissa and significance of the sum are concerned (2). Otherwise addition/subtraction with an index of significance commences.

Addition/subtraction starts with binary-point alignment. For binary-point alignment, the exponents of the two operands are compared (3). To compare the two exponents, their difference is computed and the sign of the difference is checked. As the mantissa of the smaller operand is shifted by the value of the difference, its lower-order bits are shifted out of the upper accumulator into the higher-order part of the lower accumulator. (A double-length arithmetic register is assumed.) For every right shift effected in binary-point alignment, the index for the smaller operand is increased

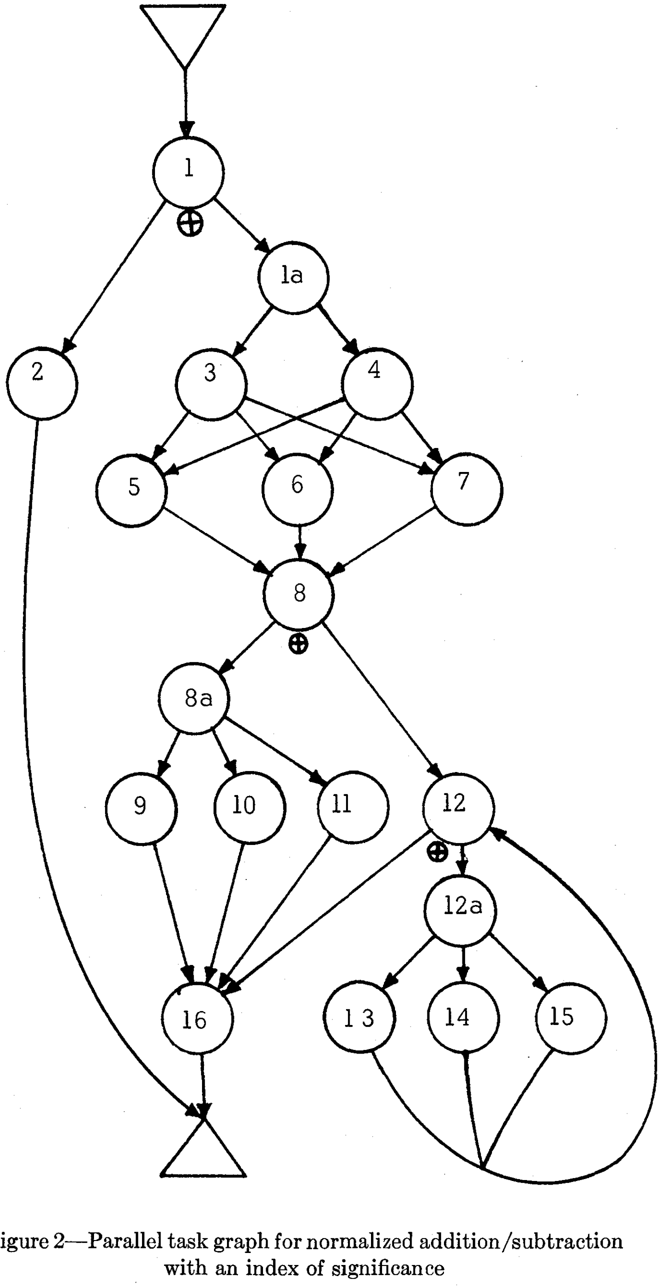

Figure 2—Parallel task graph for normalized addition/subtraction with an index of significance

by one (4). After binary-point alignment, the indicies of the two operands are compared and the smaller is kept as the basic index for the result (5). The larger of the two exponents is preserved as the basic exponent for the result (6). After the adder is cleared, the two operands are transferred to the adder for addition (7), and an overflow condition is checked (8). If there has been an overflow, the result is shifted one bit to the right while increasing the index of significance and exponent by one (9, 10, 11). If there has been no overflow, the result is normalized. To normalize, the highest mantissa bit is tested against the sign bit (12); if they are equal, the mantissa is shifted one bit to the left (13); if they are not equal, the result has been normalized. For every normalizing shift, both the index of significance and exponent are decreased by one (14, 15). The normalized result is rounded for the final result (16). The rounding is accomplished by adding one to the highest-order bit of the lower accumulator.

Where appropriate registers and data buses among them are provided in the computer architecture, more concurrency in microprogram execution is realized. If micro-operations can be executed simultaneously without conflict, they can be coded into a microinstruction for concurrent executions (Figure 2). With an adequate computer organization, the microprogram in Figure 1 can be reorganized to take advantage of parallel data paths for a faster execution. Figure 2 shows the microprogram for normalized addition with an index of significance in parallel execution. Numbers in the node of Figure 2 refer to the micro-operations bearing the same number in Figure 1. Nodes 1a, 8a, and 12a are pseudo-nodes used as a convention for the parallel task graph representation of microprograms and cost no time in execution. The "exclusive-OR" sign ⊕ between two edges out of a node indicates that either one of the edges is traversed exclusively of the other. Note that steps 3 and 4 of the microprogram in Figure 2 do not interfere with each other and can be executed concurrently rather than sequentially. Similarly steps 9, 10, and 11 as well as steps 13 and 14 can be executed in parallel.

Unnormalized addition/subtraction

The unnormalized addition procedure, nearly identical to the normalized addition, does not require normalizing the final result. Note that the normalizing loop consisting of steps 12, 13, and 14 in Figure 2 is deleted in Figure 3 for unnormalized addition.

A major difference is that unnormalized addition does not require computation of significance indicies since the unnormalized mantissa represents only significant digits.

Yes
No
7
Shift mantissa one bit right
8
Increase exponent by one
9
round
Exit

Figure 3—Unnormalized addition/subtraction

Another difference is the test for an insignificant operand (2). The number of mantissa bits is compared with the difference of two exponents in the normalized method; in the unnormalized method, it is compared with the sum of the difference of two exponents and the number of leading digits of the smaller operand. If the sum exceeds the number of bits in mantissa, the smaller operand is too small to have any effect on the result.

Possible parallelism in the unnormalized procedure is limited to steps 7 and 8 for adjustment of overflow (Figure 4). These steps are executed infrequently because unnormalized operands usually do not cause overflow. Although the unnormalized method lacks concurrent micro-operations, its microprogram is simpler and faster than the normalized method which requires the normalizing procedure.

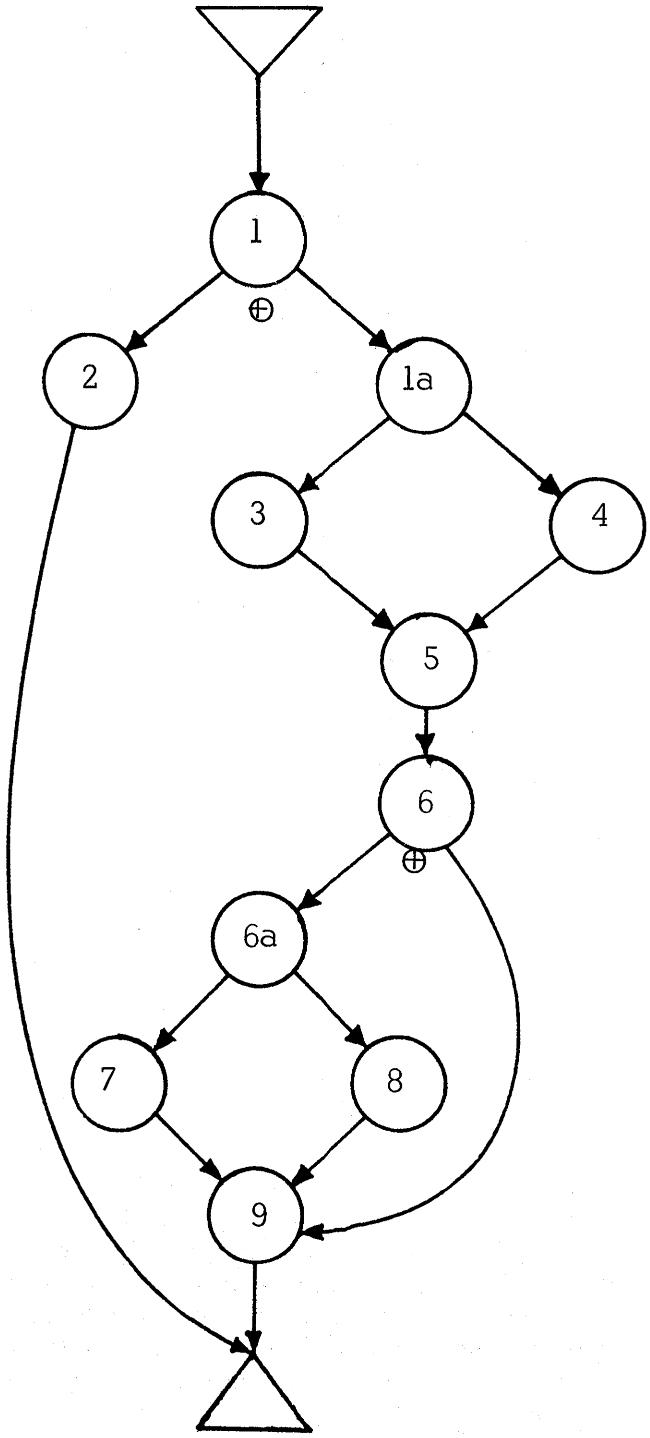

Figure 4—Parallel task graph for unnormalized addition/subtraction

Normalized multiplication with an index of significance

Normalized multiplication with an index of significance uses a conventional method: the lowest multiplier bit is examined as the multiplier is right shifted and the multiplicand is accumulated to form the product (Figure 5). The index of significance is set to the smaller of the two indicies.

The exponent of two operands are added first to form the basic exponent for the product (1). The index of

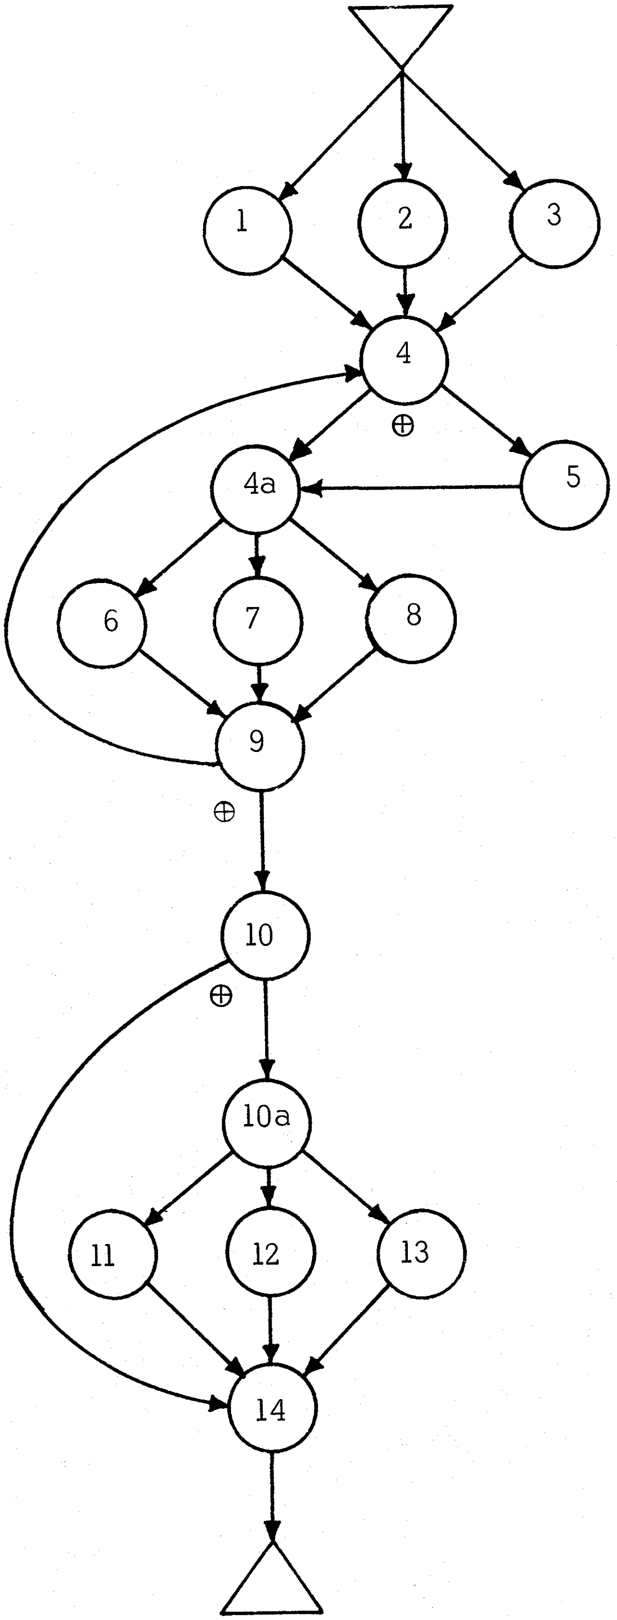

Figure 6—Parallel task graph for normalized multipl:cation with an index of significance

significance for the product is the smaller of the two (2). (See algorithm in the previous section.) The adder is cleared before the multiplication procedure commences.

The multiplier is scanned bit by bit from right to left for multiplication. If the lowest-order bit of multiplier is one, the multiplicand is added to the partial product formed in the adder; if zero, no action takes place (4, 5). The multiplier and the partial product are shifted one bit to the right for a multiplication at the next higher magnitude (6, 7). A counter counts the number of multiplier bits that have been scanned (8, 9). The result is checked for normalization (10). If a normalizing shift (at most one left shift) is necessary (11), the exponent and index are both decreased by one (12, 13). The result is rounded (14).

Clearly; steps 1, 2, and 3 are potentially parallel in the microprogram (Figure 6). Among these operations, the second that determines the smaller index requires the longest time. Similarly steps 6, 7, and 8 can be executed simultaneously. This saving is significant because these steps are loop embedded; a reduction of one step can save many cycles. For a parallel execution of steps 11, 12, and 13, at least two decrementing counters are necessary for decreasing exponent and index of significance by one.

Unnormalized multiplication

The procedure used for unnormalized multiplication is essentially the conventional multiplication procedure except the magnitude of mantissa is compared and leading zeros of the larger mantissa are counted to initialize multiplication. It takes m steps to multiply two m-bit operands. An improvement to the method suggested by Metropolis and Ashenhurst[3] by "automatically" adjusting the leading zeros in the result to that of the smaller mantissa after the multiplication procedure is completed. Where there is a carry out of the highest order significant bit (not necessarily the highest-order bit of register because of the unnormalized representation) significance is gained by one bit.

The leading zeros of the larger mantissa are counted and saved in a counter which is used later as a procedure counter for counting the number of loops executed for the multiplication proper (1). The sum of exponents is reduced by the number of leading zeros of the larger mantissa plus one (2). This subtraction enables the "automatic" adjustment of leading zeros. The subtraction by one from the sum of exponents compensates the result that is not shifted one bit to the right at the last multiplication proper loop.

Multiplication is performed in a conventional manner using shift and add operations (4-9). Note that since

Figure 7—Unnormalized multiplication

the procedure counter initially contains the number of leading zeros the multiplication loop is executed for the number of bits that represent a value in mantissa (6, 7). After the last multiplication loop is executed, the result contains either the same number of bits or one bit more to represent a value than the operand with the smaller mantissa. This is a major improvement over the original method in which a significance gain in multiplication is suppressed to preserve the number of leading zeros.

An overflow condition is checked after completing multiplication in case both operands happen to be normalized and a carry out of the highest order bit has occurred (10). If there is an overflow, the result is shifted one bit to the right and the corresponding exponent is increased by one (11, 12). A probability of the occurrence of overflow is presumably quite low, however, and these steps will be seldom executed. After an overflow condition is checked, the result is rounded to form the unnormalized product (15).

Parallelism in unnormalized multiplication may be realized in several ways (Figure 8). Steps 4 and 5 in Figure 7 are executed concurrently, or more specifically, they are constrained by step 4 execution time, and step 5 is performed at a last phase before step 4 is completed without incurring extra time. Steps 7 and 8 can be also executed concurrently when step 7 is necessary. Steps 10 and 11 can be performed concurrently if two shift registers are provided. Similarly, steps 13 and 14 can be concurrently executed. The execution time reduction by concurrency in steps 7 and 8 and steps 10 and 11 is significant because these loop steps are executed as many times as there are significant digits. A small reduction of micro-operation steps in the loop, therefore, can be a large saving in overall execution time.

EVALUATION AND COMPARISON OF METHODS

The microprogrammed algorithms for significance arithmetic are simulated on a step-by-step basis. They are compared and evaluated with regard to speed,

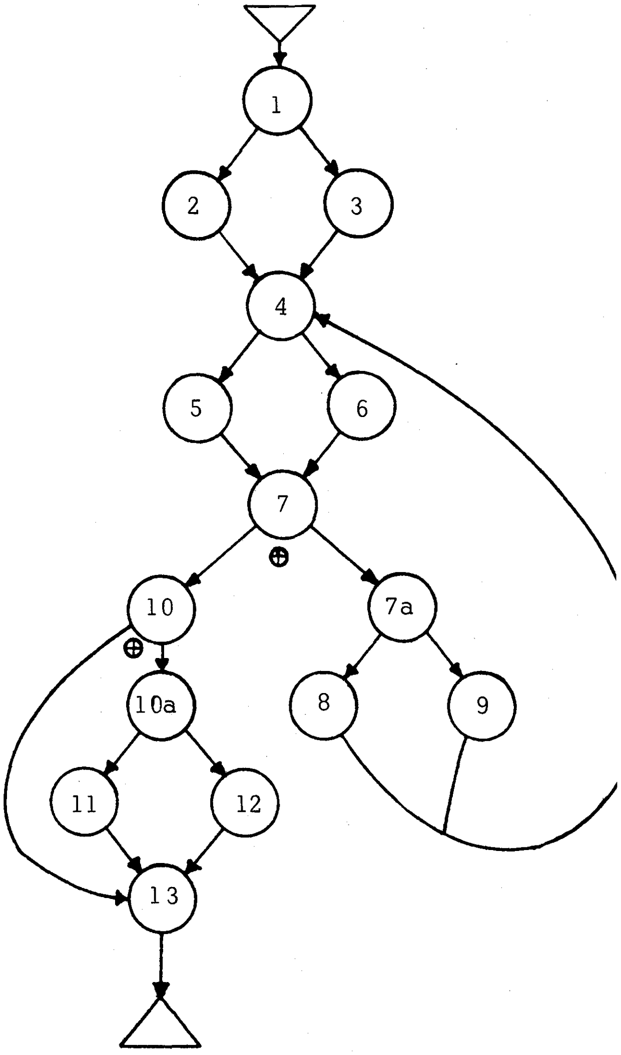

Figure 8—Parallel task graph for unnormalized multiplication

simplicity of microprogram implementation, and parallel processability. The speed of microprogram is measured in terms of the number of steps required to complete the task. The simplicity of microprogram is a capability of being represented compactly in a microprogram memory. The parallel processability is a feature that takes advantage of parallel computer structure for faster computation. The mathematical aspect of the algorithms is discussed elsewhere.[2,6]

Addition/subtraction

The procedure for addition/subtraction is similar in both methods. This is readily observed in the microprogram in Figures 1 and 3. The microprogram for the unnormalized arithmetic, however, is simpler because it does not handle the index of significance. It is also faster especially when the microprograms are executed sequentially one micro-operation at a time for the same operands. This is mainly because the unnormalized arithmetic algorithm does not require the final normalization procedure. Normalization which involves shifting of mantissa and adjusting exponent (and index, in case of the index method) can slow down the procedure if there are many digits to be normalized.

Figure 10—Unnormalized division

Another reason that the unnormalized method is faster is that it seldom generates mantissa overflow because of the unnormalized representation. A carry out of the highest bit of the larger operand (not necessarily the highest bit of mantissa) is accomodated in the leading zero space. This implies that the steps 7 and 8 of Figure 3 for a corrective shift and adjustment of exponent for overflow will be rarely executed. The occurrence of mantissa overflow depends on the operands: more specifically, it depends on the number of significant digits kept and the sign of operands. Hence in general the frequency of the occurrence of mantissa overflow is unpredictable. The comparative advantage of the unnormalized method over the index method for mantissa overflow, therefore, cannot be easily measured or determined.

The normalized arithmetic with an index of significance is relatively slower than the unnormalized method when the addition/subtraction microprograms are executed sequentially because it must compute the index of significance. The additional steps for index computation can be costly especially when there is a large amount of change in significance as a result of the computation. Consider a subtraction of two close values, for instance, where a loss of a large number of significant digits occurs. Clearly the mantissa of the computed result needs a large number of shifts for normalization, and for every normalizing step, the index of significance must be reduced by one to account for the loss of significant bit before it is readjusted by a number of significant bits recovered by the normalization.

The same argument holds for parallel execution of microprograms except for the last instance. If micro-operations of a microprogram are arranged and executed to take full advantage of multiple data paths for the maximum concurrency of micro-operations, the index and exponent adjustments can be performed concurrently provided that two additional arithmetic registers that accommodate the index and the exponent are available. The parallelism in microprogram will, therefore, reduce the disadvantage of the index method over the unnormalized method by eliminating the sequential execution of index and exponent adjustments to improve execution speed.

Multiplication

Assuming that the multiplication procedure is carried out sequentially in the Interdata 4 on two 60-bit operands, the microprogram for the index method takes about 467 cycles while that for the unnormalized method requires about 491 cycles. The multiplication procedure used, in both microprograms is essentially the same: register shift and addition of multiplicand as required. It takes m steps for the m-bit mantissa and each of m steps in turn consists of several micro-operations: a test of bits in mantissa against the sign bit, an addition of multiplicand into a partial product in the adder, a right shift of the partial product and of the multiplier, and an increment of the procedure counter by one. An obvious reason that the unnormalized method requires more time is that the unnormalized mantissa representation has more bits than the normalized number representation with an index. If the mantissa of the unnormalized representation is the same size as the normalized representation with an index, the multiplication procedure will take about 453 cycles. This reduction of cycles is due to fewer micro-operations executed for scaling leading digits of the two mantissas.

While both methods appear to take approximately the same number of steps and hence the same amount of time, the unnormalized method can be faster if the number of significant bits of one of the operands is small. If the number of significant bits for one of the operands is 34 instead of 44, for instance, then the total number of cycles required for the unnormalized method is 441 compared to 491. This reduction results from an increase in the number of leading bits which is due to the decrease in the number of significant bits. The number of leading zeros is counted and used as the procedure counter so that the multiplication proper is performed only on the significant bits. In other words, if k is the number of significant bits then only k multiplication steps are necessary. It is evident from the microprogram of Figure 5 that the larger is the number of leading bits (or the smaller is the number of significant bits), the smaller becomes the number of cycles required because the leading-zero scaling requires fewer cycles than a multiplication step.

The discussion so far is based on the sequential execution of microprograms. What would happen, then, if the microprogram can be executed in parallel or, more specifically, if the horizontal microinstruction format is available so that more than one micro-operation can be initiated at the same time? Assuming that a sufficient number of micro-operations (in our case, four or five would be sufficient) can be specified in a microinstruction, the microprograms can possibly be rearranged to take advantage of parallelism in execution. The index method in the rearranged microprogram takes 316 cycles which is the reduction of cycles by 32 percent over the sequential microprogram. The unnormalized method in the rearranged microprogram requires 326 cycles which is a reduction of 34 percent over the sequential microprogram. The reduction rate by the parallel microprogram for both methods is nearly the same. Speed up in the method originally suggested by Ashenhurst is hindered by the extra steps for leading digits adjustment of the final result. The improved method that adjusts leading digits "automatically" eliminated the extra steps providing more reduction and better execution time.

In summary, both normalized multiplication with an index of significance and unnormalized multiplication equally benefit from parallel data paths in a computer architecture. The former can perform separate computations on exponent, index, and mantissa concurrently, and the latter can perform computations on exponent and mantissa.

When sequentially executed, unnormalized multiplication can be executed faster, especially where the number of significant digits is small since leading-zero counting requires less time than multiplying significant digits. This peculiarity is nullified by the parallel execution of multiplication loop, however, so that the significance of operands does not affect execution time.

SOFTWARE VS. MICROPROGRAM

A Fortran program for a significance arithmetic algorithm has been implemented by Bright, Colhoun, and Mallory.[5] It monitors computer arithmetic upon request by a program in execution and provides a number of significant digits retained in the computed result at every stage of computation. The initial significance value may be either specified by the user or determined by the program at compilation or execution time. Their program is sizable (approximately 1400 Fortran statements). Being a large interpretive program, it also takes considerable computing time. A computation that requires a few seconds in normal mode would take several minutes for completion in significance mode. They concede that, for a very large computation, the use of the program would be "inordinately costly."

Microprogramming appears to be a solution to the problems associated with the software implementation of significance arithmetic algorithms. It offers a compact representation of algorithms for a smaller memory space requirement. It controls internal data flow at gate-level so that redundant micro-operations for machine code execution may be eliminated for a higher performance of algorithms.

Compactness of microprogram also implies enhanced speed in execution. Micro-level redundancy that exists in machine code program is eliminated to reduce the number of micro-level steps. An elimination of one redundant microinstruction can be a saving of many clock cycles in program execution if the microinstruction is in a loop, and can yield a significant saving in overall computation cost.

Microprogramming enables fineness of control of internal data flows. In particular, where the horizontal microinstruction and appropriate data paths are available, algorithms may be implemented to take full advantage of existing parallel data paths, which is not possible in software. Although the microprogram may become somewhat complex in this case, drastic reduction in execution times accrue for frequently used routines.[6]

To prove these points, algorithms for normalized arithmetic with an index of significance and unnormalized arithmetic were programmed both in the COMPASS assembly language for the CDC 6600 computer and the microprogramming language for the Interdata 4 computer. Although the assembly language provided relatively sophisitcated operations such as floating-point arithmetic, floating-point to fixed point format conversion, and various conditional operations on many registers, the program for addition with an index of significance required more than 50 instructions and unnormalized addition approximately 30 instructions. In order for the fairness of evaluations the following modifications were assumed for the Interdata 4 computer:

1. the machine operates on 60-bit operands;
2. eight arithmetic registers;
3. eight index registers;
4. multiple-bit shift available so that any number of bits may be shifted in three cycles.

A microprogrammed emulator is defined for each machine code operation using the microprogramming language of the Interdata 4 computer. The microinstruction of Interdata 4 uses a vertical instruction format similar to a machine code and consists of primitive and simple operations such as register-to-register transfers, simple tests for a register condition, one-bit shift, etc. Most instructions are executed in one clock cycle of 400 nanoseconds; some in two clock cycles.

The assembly language programs for the two algorithms were translated into equivalent microprograms via a set of microprogrammed emulators. The emulator-translated microprogram for addition with an index of significance consisted of 113 microinstructions, and unnormalized addition 70 microinstructions. They were simulated on two operands A and B with the following characteristics:

1. $|A|>|B|$;
2. index of significance of A is greater than that of B;
3. difference of the exponents of A and B is five;
4. result requires one-bit left shift for normalization.

The execution times of the addition with an index of significance and unnormalized addition on these operands are 119 and 69 cycles, respectively. The index method requires nearly twice as much time as the unnormalized method for bookkeeping operations such as extracting exponent, index and mantissa to perform computation, shifting, testing, etc., separately on each part.

The same algorithms were hand-coded directly in the Interdata 4 microprogramming code for a comparison with the software programs. In these directly-coded microprograms, much redundancy introduced in the emulator-translated microprograms was eliminated. The index method was coded in 78 microinstructions and the unnormalized method in 51 microinstructions. For the

TABLE I—Estimated Execution Time (in Interdata 4 clock cycles)

	Normalized Arithmetic with an Index of Significance			Unnormalized arithmetic		
	Addition	Multiplication	Division	Addition	Multiplication	Division
Software	119	633	1210	69	655	1350
Sequential Microprogram	68	467	780	43	491	810
Parallel Microprogram	35	316	510	27	326	540

same operands, the microprogram for addition with an index of significance takes 68 cycles whereas that for unnormalized addition uses 43 cycles. Comparing execution times of microprogrammed algorithm with that of software programmed algorithm, reduction realized by hand-coded microprograms is remarkable. Microprogramming the algorithms, about 43 percent of execution time is saved for the index method and about 37 percent is saved for the unnormalized method. In other words, the speed of performing significance arithmetic can be increased by approximately 40 percent by directly microprogramming.

Note that the execution of the Interdata microprograms is strictly sequential. If parallel data paths at gate-level are available, a better execution time reduction rate may be expected. Assuming that the microprograms coded for the Interdata 4 can be executed in "ideal" parallel, i.e., any possible parallelism in the microprograms may be realized, the index method for the two operands would take 35 cycles and the unnormalized method 27 cycles. Reductions realized in this case are nearly 70 percent and 61 percent, respectively, over software programmed algorithms, and approximately 49 percent and 37 percent over sequential microprograms. It may be anticipated that a further comparison of the parallel microprogram with a higher level language program for these algorithms would yield more than 80 percent reduction in execution time.

The estimated execution times of the other arithmetics is shown in Table I. Since execution time varies depending upon particular operands, an amount of significance, etc., times shown are approximate. The estimated execution times of normalized arithmetic with an index of significance are based on 44-bit mantissas and those of unnormalized arithmetic are based on 48-bit mantissas.

To illustrate the consequence of execution time reduction in significance arithmetic realizable by microprogramming, the overhead execution times for $n \times n$ matrix computation are estimated. Although the execution time for arithmetic operations varies according to the value of operands, an assumption is made that the execution times computed in the simulation and shown in Table 1 are about an average.

For an $n \times n$ matrix addition, n^2 additions are necessary. When normalized addition with an index of significance is used it would take $119 \times n^2$ cycles for a software program and $68 \times n^2$ cycles for a sequential microprogram. For $n=10$, this would mean 11,700 cycles for a software program and 6,800 cycles for a microprogram. Furthermore, it is conceivable that the difference becomes much larger if a large number of bits must be shifted for normalizing. Unnormalized addition would take approximately $69 \times n^2$ cycles in a software program and $43 \times n^2$ cycles in a microprogram. For $n=10$, the software program for unnormalized matrix addition takes approximately 6,900 cycles and the microprogram 4,300 cycles.

An $n \times n$ matrix multiplication requires n^3 multiplications and $n^2(n-1)$ additions. This would mean that multiplying two $n \times n$ matrices using normalized arithmetic with an index of significance takes

$$633 \times n^3 + 119 \times n^2(n-1) \text{ cycles in software}$$

and

$$467 \times n^3 + 68 \times n^2(n-1) \text{ cycles in microprogram.}$$

Using unnormalized arithmetic, the same matrix multiplication would take

$$655 \times n^3 + 69 \times n^2(n-1) \text{ cycles in software}$$

and

$$491 \times n^3 + 43 \times n^2(n-1) \text{ cycles in microprogram.}$$

From these execution time estimates, it is readily observed that a small amount of reduction at microprogram level may be significant in the overall efficiency of computation.

REQUIREMENTS FOR COMPUTER ORGANIZATION

There are a number of desirable features in computer organization for an effective significance arithmetic. Some of them may coincide with the numerical analysts' wishes in the design of computers for numerical computations such as a large word-size, multiple-length arithmetic registers, etc. The requirements for computer organization here, however, are considered from the standpoint of microprogramming.

The first requirement in computer organization for significance arithmetic is a double-length register to preserve significance. Wilkinson shows that if only a single-length arithmetic register is available rounding errors propagates to widen error bounds and to reduce significance.[1] Besides preserving significance, a double-length register may be used for double-precision arithmetic for greater accuracy.

A small arithmetic register large enough for computing exponent and index of significance is desirable for parallel execution of microprograms. With this register available, mantissa and exponent (and index of significance) can be computed simultaneously. For a faster normalized arithmetic with an index of significance, two such arithmetic registers may be necessary: one for exponent computation, the other for index computation. They are particularly useful in normalization in the index method. Normalization calls for left shifts of mantissa and, for every shift, reduction of exponent and index values. The two registers are used for the exponent and index computations concurrently with the mantissa shift operation to reduce overall execution time.

Two or more registers capable of shifting one bit at a time are necessary. They have many uses in both normalized and unnormalized arithmetics. They may be used in multiplication for a multiplier and partial product, in division for a dividend (and partial remainder) and a partial quotient, and in normalization. At least one of them should be able to shift its content in a group of bits at a time. Such register would reduce a time requirement in binary-point alignment for addition/subtraction in which a shift of many bits is often necessary.

Three or more mask registers for extracting any part of the register content are desirable. If they can be set to extract any part of the register content, the separation of exponent, index, and mantissa for separate computation is done faster.

A high-speed, alterable microprogram memory is desirable. It permits flexible specifications of control. When a new algorithm for significance arithmetic becomes available, it may be microprogrammed to replace the old microprogrammed algorithm without hardware rewiring. Thus, the alterable microprogram memory will prevent obsolescence of a machine with a small cost for remicroprogramming control specifications.

The microinstruction format should be horizontal. The horizontal microinstruction format permits specifying simultaneous activities of multiple data paths; it permits elemental control for efficient executions. Microprogram coding scheme must be simple, however, so that basic controls can be specified easily. If the microprogram operation code is encoded as in the case of Honeywell H4200, microprogramming becomes, somewhat restricted in terms of specifying data paths. Therefore, a more general microprogramming method and supporting tools such as microprogram interpreter, simulator, etc., are desirable for easier microprogramming.

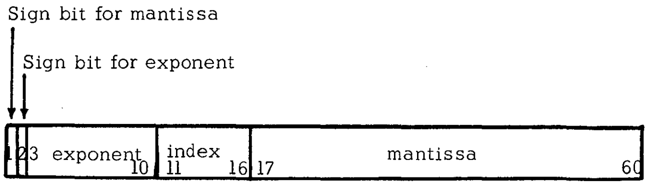

Figure 11a—Format for normalized arithmetic with an index of significance

The machine code instruction format should have a provision for specifying the number of significant digits. Basically the following machine code instructions are desirable for significance arithmetic: the input instruction for specifying a number of significant digits of input data; the significance arithmetic operation code separate from the regular arithmetic instruction; the output instruction to output the number of significant digits. The input instruction is a pseudo code that simply defines a constant and its significant digits. The significance arithmetic operation code may be the regular arithmetic instruction with its tag field set to indicate the significant arithmetic mode. The output instruction to extract and output the number of significant digits may be used to print out the number of significant digits. It may be also used to pass the number of significant digits to a routine that monitors significance and determines the next action such as a use of multiple-precision arithmetic, etc.

A possible format for a number representation in a 60-bit word for significance arithmetic with an index is shown in Figure 11a. It consists of two sign bits, one for exponent, the other for mantissa, eight bits for exponent, six bits for an index of significance, and 44 bits for mantissa. A format for the unnormalized number representation in a 60-bit word is shown in Figure 11b. It consists of a sign bit for exponent, a sign bit for

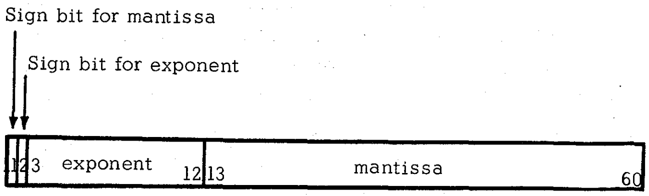

Figure 11b —Format for unnormalized arithmetic

TABLE II—Comparisons of the Two Significance Arithmetic Methods

	memory requirement	execution speed	microprogram simplicity	parallelism in procedure	range of representable numbers
Index method	larger	nearly the same	slightly complex	more parallelism	smaller
Unnormalized method	smaller	faster add/sub	simpler	less parallelism	larger

mantissa, ten bits for exponent, and 48 bits for mantissa. Clearly, for the same word size, the unnormalized format has a potential capacity for maintaining a larger number of significant digit (because of a larger mantissa) and representing a wider range of numbers (because of a larger field for exponent).

None of the requirements discussed so far is extreme or special-purpose oriented. Most of the desirable features are in fact provided by the existing, general-purpose computer except the alterable microprogram memory. A general speculation, however, is that the alterable, high-speed microprogram memory will be available at a reasonable cost in the near future with the advancement of memory technology. It will be used more widely as better microprogramming techniques are developed. In conclusion, the results suggest that the existing microprogrammable computers are reasonably well suited for microprogram implementing significance arithmetic.

CONCLUSION

Microprograms have been designed and shown in flow diagrams for the two significance arithmetic methods: normalized arithmetic with an index of significance and unnormalized arithmetic. The two methods are compared in terms of speed, simplicity in microprograms, and effects in computer organization.

Software implementation and microprogram implementation of significance arithmetic are also compared to justify the microprogrammed implementation. A software implementation of significance arithmetic appears to require a formidable amount of overhead computation.

The results of this study suggest many advantages for the microprogrammed implementation of significance arithmetic. Whereas the unnormalized method is considerably faster in addition than the index method, the index method is more suitable to a computer with parallel processable characteristics. The microprogram using computational parallelism for the index method is slightly simpler than that of the unnormalized method. Although the difference in execution time between the two methods is small, it can be significant over a long period of time especially when arithmetic functions are used more frequently in the computation.

Where memory requirements are of concern, the choice seems apparent. If the sizes of exponent and mantissa are fixed, the index method requires additional bits for the index of significance. If the mantissa consists of m bits, it requires $\lceil \log_2 m \rceil$* additional bits for the index of every operand. For an n×n matrix, this would mean that at least $\lceil \log_2 m \rceil \times n^2$ additional bits are necessary.

If on the other hand the exponent, index, and mantissa are packed into a fixed word size, the size of exponent and/or mantissa fields becomes smaller for the index number representation. The index method in this case would suffer in the range of representable numbers due to smaller exponent and mantissa fields. A smaller size for mantissa would also mean less accuracy in representing numbers.

The observations and comparisons discussed above are summarized in Table II. The entry comments in the table are for the two methods relative to each other.

In conclusion, our studies have shown beyond doubt that significance arithmetic can be implemented in microprograms for a performance that costs little overhead oveı comparable regular floating-point arithmetic.

Architectural considerations of a signal processor under microprogram control

by Y. S. WU

*International Business Machines Corporation**
Gaithersburg, Maryland

INTRODUCTION

The application of microprogramming to seismic, acoustic and radar processing is well-known.[1,2,3,4] The system architecture required to address wide bandwidth signal processing problems is of a general form shown in Figure 1. In order to provide the high throughput which is required by digital signal processing, parallelism is generally accepted as the proper design concept for the signal processing arithmetic element. A microprogram processor (or a host processor) could be used to control the arithmetic element which can be either an associative processor,[5] functional memory,[6] parallel ensemble,[7] matrix array processor[8] or a vector processor.[9] The efficient design of the microprogram processor is the key to insure the high duty cycle utilization of the expensive arithmetic element hardware. Parallel architectures fall far short of their expectations because of the control problem associated with keeping all the hardware usefully occupied all the time.[10]

This paper surveys basic digital signal processing algorithms. It proposes a signal processing architecture consisting of a microprogrammed control processor (MCP), a highly efficient sequential signal processing arithmetic unit (SPAU) and necessary buffer memories. Emphasis is placed on the MCP architecture because of its importance in enhancing the system performance. An application example, optimum processing[11] in frequency domain, is given to verify the applicability of the architecture.

Hardware technology surveys, and fabrication and packaging considerations are beyond the scope of this paper. The firmware and microprogramming support software discussions are also omitted.

BASIC DIGITAL SIGNAL PROCESSING ALGORITHMS

A wealth of literature, including several very good text books is available in signal processing and digital signal processing.[12,13,14] A brief description of some of the processing algorithms is included here. In general, linear filter theory and spectrum analysis techniques form the basis of digital signal processing. Time-domain and frequency domain equivalence of processing is widely assumed. In practice, time-domain digital processing is only used in real time applications with relatively short sample data block. The fast Fourier transform (fFt) algorithm[15,16] provides the efficient digital processing link between time and frequency domains, and frequency domain processing is preferred for narrow-band analysis with fine resolution and large quantities of input data.

Time-domain processing

Consider a sampled signal $\{x(t_n)\}$, where $t_n=nT$, $n=0, 1, \ldots n$ and T is the sample period. A linear digital filter is written as:

$$y(t_n) = \sum_{m=0}^{N} h(t_m)x(t_{n-m}) \tag{1}$$

where $\{y(t_n)\}$ are filtered outputs of $\{x(t_n)\}$ and $\{h(t_n)\}$ are sampled impulse responses of the filter.

Similarly, the correlation function of $\{f(t_n)\}$ and $\{g(t_n)\}$ can be written as:

$$l(t_n) = \sum_{m=-N}^{N} f(t_{m+n})g(t_m) \tag{2}$$

Another type of time-domain processing, which is known as recursive filter, is commonly used for limited number of samples to compute successive value of out-

* Presently employed at Naval Research Laboratory, Washington, D.C.

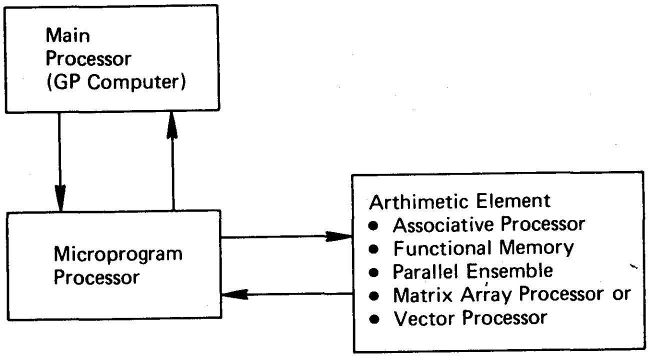

Figure 1—System organization

puts. Let $\{x(t_n)\}$ be the input signal samples, then the filtered outputs $\{y(t_n)\}$ are expressed by the linear difference equation:

$$y(t_n) = \sum_{k=1}^{N} W_k y(t_{n-k}) + \sum_{k=0}^{r} \lambda_k x(t_{n-k}) \qquad (3)$$

where $\{w_k\}$ and $\{\lambda_k\}$ are weighting or filter coefficients of the recursive filter.

For N sample points, time-domain processing requires N^2 multiply-sum operations. Therefore, real time application of time-domain processing is limited to short sample data blocks only. Typically, N equals 64 or less.

Frequency domain processing

Let $\{X(f_i)\}$ be the discrete Fourier transform of a signal $\{x(t_n)\}$ that

$$X(f_j) = \sum_{n=0}^{N-1} x(t_n) \exp(-i2\pi f_j t_n) \qquad (4)$$

where $i=\sqrt{-1}$, $j=0, 1, 2, \ldots N-1$ and $f_j=j(1/NT)$.

This discrete transform involves a couple of assumptions. Equally spaced time samples are assumed. Also the sampling rate must be above the Nyquist rate, twice the frequency of the highest frequency in the waveform being sampled. When these criteria are met, the discrete Fourier transform has parallel properties to the continuous transform. The original waveform can be completely recreated from the samples. Transformations between the time and frequency domains are performed by using the discrete transform and its inverse. It can be shown that the equivalent frequency domain digital filter in equation (1) can be written as:

$$Y(f_j) = X(f_j)H(f_j) \qquad (5)$$

where $\{Y(f_j)\}$ and $\{H(f_j)\}$ are discrete Fourier transforms of $\{y(t_n)\}$ and $\{h(t_n)\}$ respectively.

Similarly, the equivalent correlation function in frequency domain can be shown as:

$$\Phi(f_j)=\bar{F}(f_j)G(f_j) \qquad (6)$$

where $\{\bar{F}(f_j)\}$ is the complex conjugate of the discrete Fourier transform of $\{f(t_n)\}$.

As a special case, the power spectrum density function is:

$$|F(f_j)|^2=\bar{F}(f_j)F(f_j) \qquad (7)$$

It is seen that for N frequency domain samples, the equivalent digital filtering or correlation function requires N complex multiplications instead of N^2 product-sum operations in the time-domain. Tremendous computational savings for large N can be achieved if an efficient processing link between time domain and frequency domain is established. The fast Fourier transform algorithm is this missing link.

Fast fourier transform

Since 1965, a great deal of attention has been given to the *fFt* algorithm by the digital signal processing community. Interested readers can find detailed derivations and variations of the algorithm in references listed in the Bibliography.[13,15,16,17] A simple derivation is included below.

Let's rewrite the discrete Fourier transform expression shown in equation (4).

$$A_r = \sum_{k=0}^{N-1} x_k \exp(2\pi irk/N) = \sum_{k=0}^{N-1} x_k W^{rk} \qquad (8)$$

where: $i = \sqrt{-1}$

$W = \exp(2\pi i/N)$

N = number of samples

r = harmonic number $= 0, 1, \ldots, N-1$

k = time-sample number $= 0, 1, \ldots, N-1$

Thus A_r is the rth coefficient of the Fourier transform and x_k is the kth sample of the time series.

The samples, x_k, may be complex, and the coefficients, A_r, are almost always complex.

Working through an example in which $N=8$ will illustrate some of the calculation short cuts.

In this case: $j=0, 1, \ldots, 7$

$k=0, 1, \ldots, 7$

To put these into binary form:

$$j=j_2(2^2)+j_1(2^1)+j_0$$

$$k=k_2(2^2)+k_1(2^1)+k_0$$

where: $j_0, j_1, j_2, k_0, k_1, k_2=0, 1$

Thus:

$$A(j_2, j_1, j_0)$$

$$=\sum_{k_0=0}^{1}\sum_{k_1=0}^{1}\sum_{k_2=0}^{1}\chi(k_2, k_1, k_0)[W^{(j_24+j_12+j_0)(k_24+k_12+k_0)}] \quad (10)$$

Now the W can be broken down further:

$$W^{(j_24+j_12+j_0)k_24}=[W^{8(j_22+j_1)k_2}]W^{j_0k_24}$$

$$W^{(j_24+j_12+j_0)k_12}=[W^{8j_2k_1}]W^{(j_12+j_0)k_12}$$

$$W^{(j_24+j_12+j_0)k_0}=W^{(j_24+j_12+j_0)k_0} \quad (11)$$

Since $W^8=[\exp(2\pi i/8)]^8=\exp(2\pi i)=1$, the bracketed terms equal one, and can be dropped from the computation. (Note that $[\exp(2\pi i)]^2=1^2=1$.) This saves many calculations.

Then $A(j_2, j_1, j_0)$ can be obtained by sequentially calculating the xs as follows:

$$\chi_1(j_0, k_1, k_0)=\sum_{k_2=0}^{1}(k_2, k_1, k_0)W^{j_0k_24}$$

$$\chi_2(j_0, j_1, k_0)=\sum_{k_1=0}^{1}1(j_0, k_i, k_0)W^{(j_12+j_0)k_12}$$

$$\chi_3(j_0, j_1, j_2)=\sum_{k_0=0}^{1}=\chi_2(j_0, j_1, k_0)W^{(j_24+j_12+j_0)k_0}$$

$$A(j_2, j_1, j_0)=\chi_3(j_0, j_1, j_2)$$

Once these computation savings were found, one may generalize that for N point fast Fourier transform $\frac{1}{2}N\log_2N$ complex multiplications and summations are required. For the equivalent digital filter operation in equation (1), $N(1+\log_2N)$ complex multiplications are performed including the *fFt* on input samples and the inverse transform to obtain time domain filtered outputs. Comparing with N^2 operations required for (1), this is a worthwhile saving in processing load, when N is large.

What are the basic operations?

Product-sum and complex multiplications!

A PROPOSED SIGNAL PROCESSOR ORGANIZATION

The basic arithmetic operation performed by a signal processor is the high speed multiplication in the form of product-sum for time-domain processing and complex multiply for the frequency-domain computations and the *fFt* algorithm. These operations are always performed on arrays or blocks of sensor data. In other words, signal processing deals exclusively with 'structured' data. A system architect faces:

1. The design of a high speed **S**ignal **P**rocessing **A**rithmetic **U**nit (SPAU).
2. The problem of how to keep this arithmetic unit efficiently and usefully busy.

The latter poses a bigger challenge because it dictates the system through-put by collecting and controlling sensor inputs, and structuring the input data in a manner that can be most efficiently accepted by the SPAU. Typical functions are:

- I/O control
- Multiplexing or Decommutation
- Data conditioning
- Scaling
- Orthogonal addressing
- Format conversion
- Data buffering, blocking and packing.

The above listed preprocessing requirements for a SPAU are characterized by:

- Relatively simple algorithms
- Highly iterative operations
- Low precision

The advantages of using a **M**icroprogrammed **C**ontrol **P**rocessor (MCP) rather than special purpose hardware for these interface functions are the lower cost of such a general purpose architecture and the flexibility provided by the ability to change the microprogram. Furthermore, microprogramming implementation of these functions offers 5-10 times performance gain over a conventional general purpose computer of comparable technology.[1,2,3] In addition, macro signal processing functions can be provided by properly sequencing the SPAU under microprogram control. Some of these

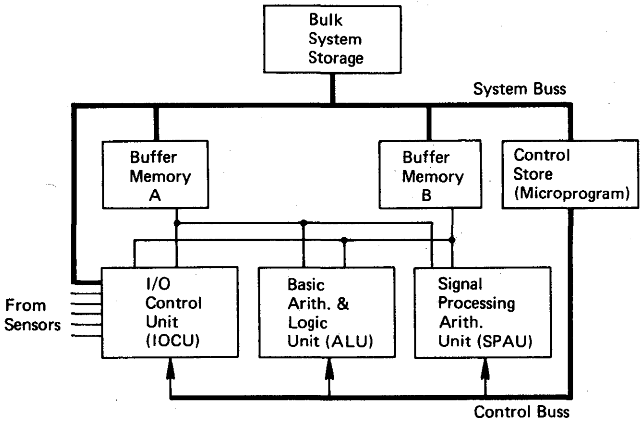

Figure 2—Functional diagram of a microprogrammed signal processor

macros could be:

- Convolution Filter
- Recursive Filter
- Beam Forming
- FFT
- Inverse FFT
- Correlations
- Power Spectrum
- Filter
- Unpack
- Matrix Operations

By requiring the system to be under microprogrammed control, the designer is permitting a single piece of hardware to be specialized to a particular type of signal processing calculation by allowing for the design of an optimum 'instruction set' for that calculation to be loaded into the control store of the MCP.

Figure 2 depicts the functional diagram of a signal processor under microprogram control. The major components are System Storage, MCP, and SPAU.

System storage hierarchy

The structured nature of signal processing requires a block (or page) of data to be operated upon by the SPAU. Therefore, SPAU performance specifications define the buffer speed requirements for each 'page' and the system through-put requirement determines the transfer rate between the system bulk store and the buffer memories. A system storage hierarchy is implied. As to the microprogrammed Control Store (CS), one may consider each signal processing kernel as a module (or page) with highly repetitive execution duty cycle. If Writable Control Store (WCS) is considered, a dynamic paging hierarchy can again be established for the microprogram execution.[18,19] Since both data and the programs are sequential and block in nature for signal processing, no cache requirement is foreseen. For relatively long data blocks, buffer paging with respect to the system bulk storage can be accomplished through the MCP I/O control unit. No additional paging hardware will be required.

Buffer memories

At least two independent buffer memories will be required because of the over taxing demands on buffer memory cycles by the pipe-lined SPAU operations while MCP ALU and IOCU are preparing the next block of data for SPAU consumption. Two buffer memories in conjunction with MCP can only support a SPAU with a 4-cycle basic operation. If a 2-cycle SPAU is required, four independent buffer memories will be needed to achieve the desired performance.

A 64-bit buffer memory interface is proposed for the purpose of increasing real time instantaneous signal input bandwidth as well as enhancing the paging interface efficiency with the bulk system storage. Experience indicated that each buffer memory should be expandable vertically in 256 by 64-bit words increments up to 4K words. 1K to 2K 64-bit words buffer size is commonly seen. It is intended that the buffer memory is the same monolithic storage used for the microprogram control store for commonality and logistic simplicity. The speed of the buffer memory is defined by the operational requirement of SPAU.

Control store

A 64-bit wide control store compatible with the buffer memory is used for the microprogram storage. Each micro-instruction is capable of executing the following operations in parallel:

- Access the Buffer Memories for One or More Operands
- Manipulate Local Registers and Arithmetic Registers
- Perform Arithmetic and Logic Functions
- Decode and Status Sensing
- Decision Making
- Form Next Micro-Instruction Address
- Other Special Controls

Allowing multiple micro-instruction formats, one can easily reduce the micro-instruction width to 32-bit with a degradation of MCP performance by less than 15 percent. Double fetch of micro-instructions can be considered; however, microprogramming will be more difficult in this case.

Since writable control store is used in the system, dynamic paging of microprograms will be considered. Tight kernels are characteristic for MCP microprograms in the signal processing environment. Small page size (i.e., 64 micro-instructions) may be adequate for a dynamic control store size of not exceeding 1K 64-bit words.

Bulk system storage

Bulk System Storage can be provided as an I/O attachment to the MCP-SPAU signal processing system in the stand alone case. Or, the signal processing subsystem can be considered as interfacing through the bulk system storage with the central computer complex. In this case, bulk system storage can be a part of the shared CPU main memory or auxiliary large core storage (LCS).

The speed requirement of the bulk system storage is dictated by the type of processing performed in the MCP-SPAU. Assume a block of data with N points are first transformed into N spectral elements in the frequency domain and then filtered by N corresponding filter coefficients; the following are observed:

Data Transfers—

Bulk System Storage to MCP-SPAU

N	Input Data Points
N	Filter Coefficients

MCP-SPAU to Bulk System Storage

N	Filtered Outputs

Computations—

$N+\frac{1}{2}N \log_2 N$	Complex Multiplications

If single cycle data transfer and 2-cycle complex multiply are assumed, the speed ratio between the bulk system storage and the buffer memories is obtained as $(2+\log_2 N)/3$. When $N=1024$, the speed ratio equals 4. This allows bulk system storage bandwidth to be 4 times slower than the buffer memory speed.

Local stores

Local storages will be provided in MCP and SPAU data flows for internal arithmetic operations. Further discussions are deferred until later sections.

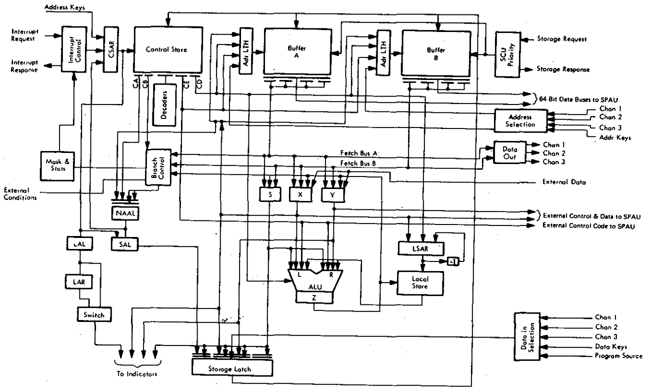

Figure 3—Microprogrammed control processor data flow (MCP)

Microprogrammed control processor (MCP) architecture

The architecture of the MCP is oriented toward its signal processing application as an interface and control processor. The salient features of the MCP required by this application are:

a. High-speed buffer and channels
b. Efficient interrupt scheme
c. Simple external interfaces
d. Ease of microprogramming

These design goals were achieved by:

a. Using two independent monolithic storage units as buffer memories and linking them with a wide 64-bit channel interface.
b. Using only three registers in the data flow and matching the storage cycle time with the internal processing time in order to permit the interrupt overhead operation (save and restore) to be performed in three micro-instructions.
c. Using a monolithic read-write storage as a microprogram control store. A 64-bit microprogram instruction provides a control format that is 5 to 10 times more powerful than typical 16-bit instructions found in minicomputers and provides the computing power necessary to perform the interface tasks. A read-write control store provides the ease of program modification required to efficiently debug the operational microprograms. It also offers dynamic paging of microprograms through the system storage hierarchy.

The basic data flow is shown in Figure 3. The functional units include:

a. Sequence Unit. The sequence unit is that portion of the machine which controls the sequence of logical operations by determining the order in which control words are addressed from the control store. The sequence unit operations are controlled by the control store word, storage bus condition, data flow conditions, machine status, and channel conditions. The address for each control store word access is assembled by the sequence unit from the above controlling sources in the next address assembly register (NAAR). The save address latch (SAL) holds assembled addresses for storage during interrupt processing. The last address register (LAR) holds the previous cycle control store address register (CSAR) when a machine stop occurs.

b. Buffer Memory Control and Bussing. Each of the basic buffer memories has a word width of 64 bits, used as four 16-bit words in the data flow. The buffer control unit (BCU) serves as an interface between the buffer memory and the various devices that use storage, such as I/O channels, the MCP data flow, and any other direct access devices such as SPAU that may be connected to it. The BCU includes a priority determination unit, an addressing unit, a storage bus, and fetch busses.

c. Data Flow. The data flow includes three 16-bit registers that provide the necessary buffering between the storage bus and the arithmetic and logic unit (ALU). They are destination registers for data fetch and ALU operations. Input selection is under direct control of the control store. All three registers have connections to the storage bus to allow them to be saved following an interrupt. Selection of operands to the ALU is controlled by a control store field. The ALU is a conventional 16-bit parallel adder and logic unit that performs a function on the selected left (L) and right (R) operands. 16-bits represents a 96 db dynamic range. Physical measurements or control signals seldom require more than 16-bit precision. Microprogrammed double-precision can be used for rare exceptions. The ALU output (Z) is latched when the function is completed and held through the late part of the control cycle, when the result is transferred to the destination register. The registers are set late in the control cycle and are held for an ALU operation in the next cycle. The ALU functions include adding, shifting, and logical operations.

d. Local Storage. A 16 word Local Storage is contained in the data flow. The local store provides 16 bit inputs to the ALU. The local store write register has an input from the ALU latch. Local store is addressed from the Local Store Address Register (LSAR). The LSAR has inputs from the X register, the CD field, and the LSAR decrementer. The Local Store can be accessed and written in one MCP cycle. It can be expanded to 32 words. Or, a second local store can be added to achieve the operations of two independent register stacks within one MCP ALU cycle.

e. Literals. Two 16-bit literals are available to the ALU for generation of constants and buffer memory addresses.

f. Interrupt Processing. Interrupt processing consists of saving program status data that would be destroyed in processing the interrupt, and restoring conditions so that the interrupted program may be continued after the interrupt has been processed. The save operation is performed in one micro-instruction:

SCXYS(O)

This micro-instruction stores the CSAR, X register, Y register, S register, stats, and masks in four consecutive locations in both buffer memories beginning at address 000_{16}. The restore operation requires two micro-instructions:

1. A(O) = X, B(1) = Y

   This loads the Y register with the vaule to be restored into S and places the CSAR value to be restored into the X register.

2. A(2) = X, B(3) = Y, Y = S, RTN

   This restores X, Y, and S registers; RTN forces CSAR to be loaded from prior X register value returning to the next address of the routine that was interrupted and also restores stats and masks.

The restore operation is interruptable. Interrupts of MCP can be generated by I/O channels, program stats and SPAU completion. There are four programmable interrupt priority levels.

Signal processing arithmetic unit (SPAU)

In preprocessing, it is observed that there is no requirement for a hardware multiplier in interface or control functions. However, an extremely high duty cycle multiplier is necessary to satisfy signal processing requirements. Furthermore, a 'structured' multiplier will be needed in this case.

In order to accommodate both time domain and frequency domain operations, the SPAU is designed to execute the following basic operation with implicit addressing:

$$D_i \leftarrow \pm A_i * B_i \pm C_i$$

where $i = 1, 2, 3, \ldots 4096$ and A, B, and C are all complex numbers

Although the SPAU provides a basic 16×16 complex multiplier, it is hardware equivalent to four 16×16 real multiplier or one 32×32 fixed point multiplier. Under the MCP microprogram control, the SPAU can function as desired in various configurations when application arises. For special case *fFt* operations, block floating point format may be assumed with 12-bit mantissa and 4-bit scaling.

The SPAU buffered operations can be interrupted by the MCP when MCP ALU registers require a single multiply operation, i.e., MCP register mode has priority over the normal buffered mode of SPAU. The SPAU buffered operations are initiated by MCP microprograms and SPAU interrupts the MCP on completion.

The SPAU design includes the necessary pipeline to assume an asynchronous operational speed. The basic SPAU operation requires two to four buffer memory cycles dependent upon number of independent buffer memories used in the system. Some special functions are included in the SPAU design such as *fFt* address generation and conjugate multiply.

The parallel matrix multiplier logic of SPAU is very straightforward. However, the amount of hardware in terms of logic gate counts is probably twice the MCP ALU/IOCU combined. It is almost anti-climactic to state again the importance of the 'lean' MCP design in order to keep the 'fat' SPAU usefully busy.

AN APPLICATION EXAMPLE—ADAPTIVE SPATIAL PROCESSING

The function flow of the application example is shown in Figure 4. The mathematical computations required to achieve the 'optimum' processing are described below.

The sensor input signals $x_K(t)$ are first transformed into spectral elements in frequency domain that

$$\{X_k(f_i)\} = FFT\{x_k(i)\} \tag{13}$$

Then the frequency domain inputs are filtered to obtain the desired beam outputs

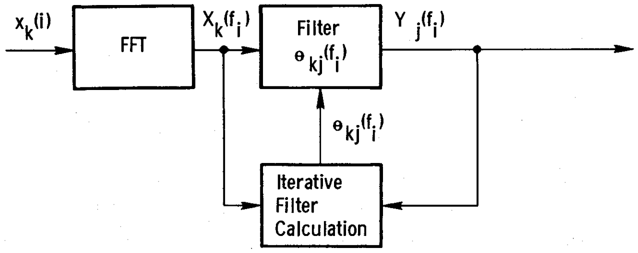

Figure 4—Adaptive spatial processing

$$Y_j(f_i) = \sum_{k=1}^{k} \theta_{kj}(f_i) X_k(f_i) \tag{14}$$

Where $Y_j(f_i)$ is the jth beam output and $\theta_{Kj}(f_i)$ are optimum filter coefficients including spatial processing in the frequency domain. These filter coefficients are updated through iterative gradient search process to minimize the output noise power. The output power spectrum is then computed

$$\{P_j(f_i)\} = \{\,|\,Y_j(f_i)\,|^2\} \tag{15}$$

Notice the block array forms of data which are efficiently processed by the SPAU. The MCP will control the paging and I/O for the system.

The optimum gradient search algorithm first computes the gradient for minimization as an input-output cross correlation function $Z_{Kj}(f_i)$ that

$$Z_{kj}(f_i) = Y_j(f_{i_0m})\{\exp(j2\pi f_i \tau_{jk}) X_k(f_{N-i}) - X_j(f_{N-i})\} \tag{16}$$

where $X_j(f_{N-i})$ are average beam outputs computed much less frequency. Notice the spatial term $\exp(j2\pi f_i \tau_{jk})$ in the equation and $j = \sqrt{-1}$ in the exponent instead of subscripted j. In order to maximize the output noise power change between mth and $(m-1)$th iteration, an iteration step size $a_j(m)$ is chosen that

$$a_j(m) = \frac{\sum_{i=1}^{N} Y_j(f_{N-i};m) Q_j(f_i;m)}{\sum_{i=1}^{N} |\,Q_j(f_i;m)\,|^2} \tag{17}$$

where

$$Q_j(f_i;m) = \sum_{k=1}^{k} X_k(f_i) \exp(j2\pi f_i \tau_{jk}) Z_{kj}(f_i) \tag{18}$$

then the iterative processing is completed by

$$\theta_{kj}(f_i;m)=\theta_{kj}(f_i;m-1)-a_j(m)Q_j(f_i;m) \qquad (19)$$

and

$$Y_j(f_i;m)=Y_j(f_i;m-1)-a_j(m)Q_j(f_i;m)$$

In addition to loop controls for the gradient search algorithm, the MCP will handle orthogonal addressing and organize the optimum filter coefficients in such a manner which can be efficiently retrieved from the bulk system storage.

The distributed processing load of this application to MCP and SPAU is normalized to MCP total processing load and tabulated below:

	Percent		
	MCP Load	4-cycle SPAU Load	2-cycle SPAU Load
FFT		9.7	4.9
Filter	9.8	69.7	35.0
Iterative Search	86.0	17.0	8.6
Power Spectrum	4.2	0.4	0.2
Total	100	96.8	48.7

It is noted that for the adaptive spatial processing 2-cycle SPAU will not be needed unless an additional MCP unit is included in the system. The 2-buffer memory configuration as indicated in Figure 2 will be applicable to this problem. The load balancing between MCP and SPAU is accomplished by the heavy involvement of MCP microprograms in the various processing loop controls of the gradient search algorithm to compute the optimum filter coefficients. For less demanding MCP control role in other signal processing applications, the 2-cycle SPAU with four buffer memories can handle higher through-put when needed. Additional MCP processing can also be applied to post detection computations which are not described in this example.

CONCLUSION

The Microprogrammed Control Processor and the Signal Processing Arithmetic Unit architecture presented in this paper blends economy, flexibility and performance in one design. It can truly be a general purpose signal processor. If ECL and bi-polar memories are used for implementation, 50 nanoseconds microinstruction time and 100 nanoseconds complex multiplication speed can be achieved for ground based applications. The hardware size in terms of logic gate counts is approximately one tenth of that of a commercially available general purpose computer with equivalent performance.

ACKNOWLEDGMENT

The author wishes to express his sincere gratitude to many people who participated in applying microprogramming to signal processing problems. In particular, he would like to thank R. G. Baron and S. G. Francisco of IBM for their pioneer work in seismic and acoustic processing, R. A. Rieth of Teledyne-Brown and J. W. Fisher of Bell Telephone Laboratories for their active involvement in radar processing and G. L. Kratz of IBM for general microprogrammed processor architecture work during the past five years.

A building block approach to multiprocessing

by R. L. DAVIS, S. ZUCKER and C. M. CAMPBELL

Burroughs Corporation
Paoli, Pennsylvania

INTRODUCTION

Today most computing systems have dedicated, self-contained, single processors. When the load on the system exceeds its processing capabilities, it is necessary to replace the original system with one of greater capacity. It would be far better if the original system had been modular in nature, so that additional processing modules could be added in a multiprocessing configuration with the growth in processing requirements, just as memory modules or I/O devices are added with the growth in storage or peripheral requirements. Multiprocessing systems are not new, but they have been previously limited by the processing time consumed in controlling the processor modules. With the advent of microprogrammed computers, however, control functions can now be implemented in microcode, and executed at a much faster rate than has been previously possible. In addition, microprogrammed computers are simpler and therefore more reliable than conventional computers.

This paper describes a structure for connecting and controlling a multiprocessor system using a building block technique. The hardware is modular and includes microprogrammable processors called "Interpreters", memory modules, and devices. Each Interpreter is interconnected with every memory module and every device via a data exchange network called a "Switch Interlock".

The current operating system is a simple but comprehensive control program which allows for all the basic capabilities of operating systems emphasizing multiprocessing, multiprogramming and error recovery. Plans are being developed for an extended operating system which would be a set of independent units of microcode selected from a library of such units for each individual system. The building block approach has been used by both the hardware and software implementors of the system.

MULTIPROCESSOR INTERCONNECTION

A major goal in multiprocessor system design is to increase system efficiency by the sharing of available resources in some optimal manner. The primary resource, main memory, may be more effectively shared when split into several memory "modules". A technique for reducing delays in accessing data in main memory is allowing concurrent access to different memory modules. With this concurrent access capability present, an attempt is made to assign tasks and data to memory modules so as to reduce conflicts between processors attempting to access the same memory module. Nevertheless, since some conflicts are unavoidable, a second technique (reduction of conflict resolution time) is required. These two techniques are largely a function of the multiprocessor interconnection scheme which has been discussed by Curtin[3] and others.[4,5]

Figure 1 shows three basic functional interconnection schemes. These are described in more detail in Curtin.[3]

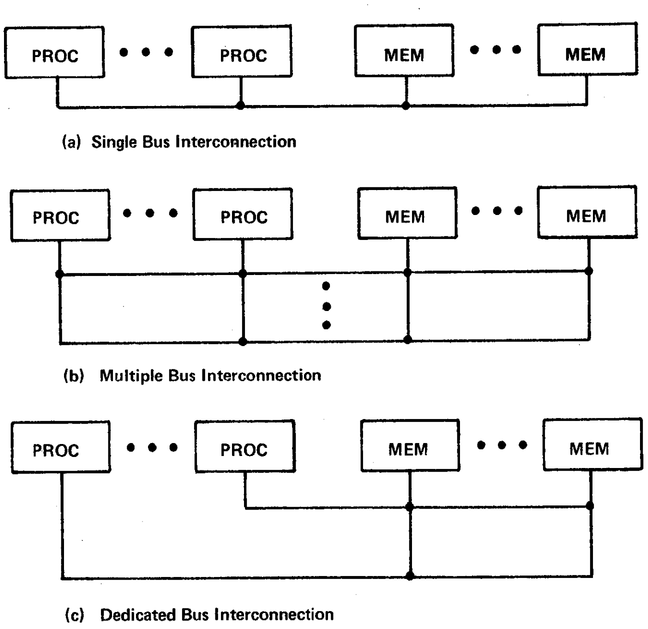
The disadvantages of the single bus approach (Figure 1) for many processors are:

(1) the obvious bottleneck in information transfer between processors and memory modules due to both bus contention and memory contention
(2) the catastrophic failure mode due to a single component failure in the bus.

A solution to the first problem has been to increase the frequency of operation of the bus.[3,6]

The multiple bus approach is merely an extension of the single bus approach where all processors contend for use of any available (non-busy) bus. The advantages are redundancy and allowing an appropriate number of buses (less than the number of processors) to handle the traffic between processors and memory modules.

The third approach utilizes a dedicated bus structure (one per processor). Although this approach requires more buses, it requires neither the logic nor, more im-



(a) Single Bus Interconnection

(b) Multiple Bus Interconnection

(c) Dedicated Bus Interconnection

Figure 1—Functional multiprocessor interconnection schemes

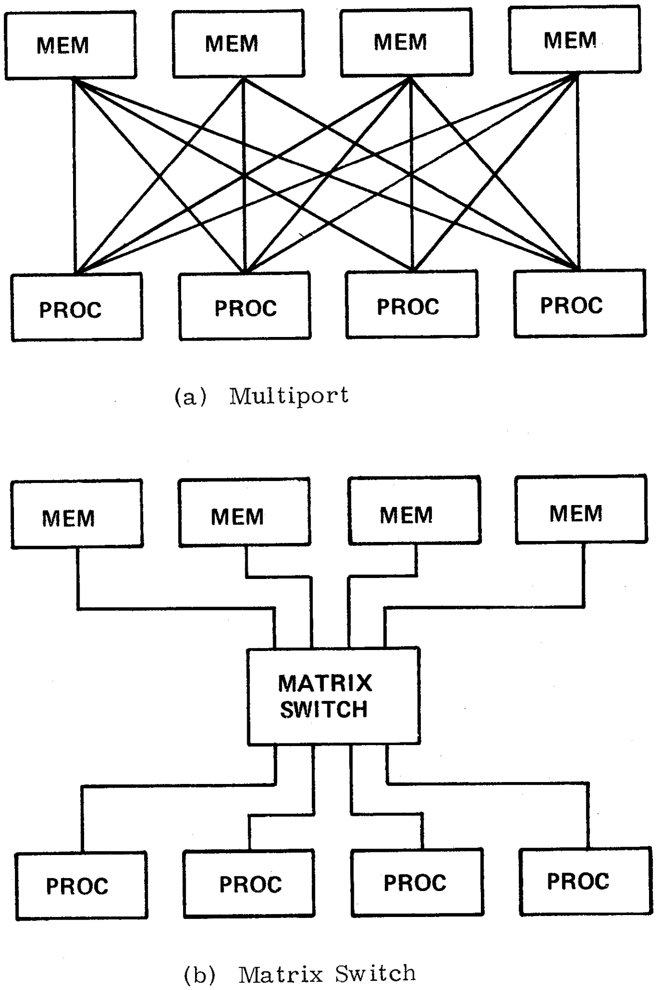
portantly, the time for resolving priority between processors requesting the use of a bus. Proponents of this approach contend that the time penalty for resolving conflicts for access to a memory module is enough of a price to pay without having to wait for the availability of a bus.

In a Hughes report,[5] the authors distinguish the physical differences between two multiprocessor interconnection schemes. The two approaches (one called multiport and the other called matrix switch) are shown in Figure 2.

The Hughes report characterizes the two connection approaches as follows:

> "In the multiport approach, the access control logic for each module is contained within that module, and intercabling is required between each processor and memory pair. Thus, the total number of interconnecting cables is the product of the number of processors and the number of memories. Each module must be designed to accommodate the maximum computer configuration.
>
> "In the matrix switch approach, the same interconnection capability is achieved by placing the access control logic for each module in a separate module. The addition of this module to the system is compensated [for] by reducing the intercables required to the sum of the processors and memories rather than the product and by not penalizing the other modules with maximum switching logic.
>
> "There generally is no speed differential between multiport and matrix arrangements. The major difference lies in the ability to grow in wiring complexity. Multiprocessors with multiport arrangements are generally wired, at production time, to the maximum purchased configuration. Future subsystem expansion generally requires depot level rewiring. This problem generally does not exist with the matrix arrangement. The maximum capacity is wired in but the switching logic complement reflects the purchased system. Subsystem expansion entails purchase of added processor/memory modules (and necessary cabinetry if required) plus the required switch matrix logic cards."

An important additional point is that even though all parts of the matrix switch are co-located, they must be designed such that the failure of one node is equivalent



(a) Multiport

(b) Matrix Switch

Figure 2—Physical multiprocessor interconnection schemes

to failure of only one element attached to the matrix switch. For example, failure of a processor-related node must not disable paths from any other processor to any memory module.

Apparent from the arguments in the Hughes report is the desire to reduce the number of wires interconnecting the processors and memory modules. A way to reduce the wiring (in addition to the use of the matrix switch) is by using serial transmission of partial words at a frequency several times that of the processors. This technique has been used by Meng[6] and Curtin.[3] The tradeoff here is between the cost of the transmitting and receiving shift registers and the extra logic necessary for timing and control of the serial transmission versus the cost of the wiring and logic for the extra interconnection nodes for a fully parallel transmission path.

Another factor adversely affecting efficiency in a multiprocessing system is a variation in the amount of computation versus I/O processing that must be done. In previous multiprocessing systems I/O functions and data processing functions have been performed in physically different hardware modules with devices being attached only to the I/O controllers (Figure 3). (This technique is typical of Burroughs D825, B 5500, or B 6700.) In the Burroughs Multi-Interpreter system,[1,2] however, processing and I/O control functions are all performed by identical Interpreters whose writable microprogram memory can be reloaded to change their function. This technique allows a configuration (Figure 4) in which the devices are attached to the same exchange as the memories and processors.

Figure 3—Centralized multiprocessor system

Switch Interlock

The Multi-Interpreter interconnection scheme for forming a multiprocessor is called a "Switch Interlock:" a dedicated bus, matrix switch with an optional amount of serial transmission.

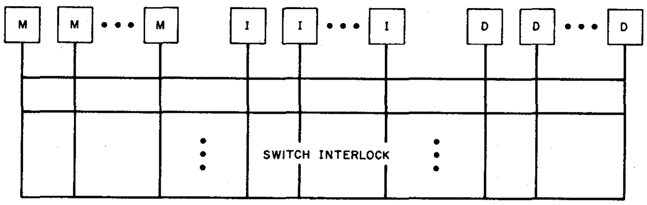

Figure 4—Distributed multiprocessing interpreter system

The Switch Interlock is a set of hardware building blocks for connecting many Interpreters to many devices and to many memory modules. Connection between Interpreters and devices is by reservation with the Interpreter having exclusive use of the (locked) device until specifically released. Connection with a memory module is for the duration of a single data word exchange, but is maintained until some other module is requested or some other Interpreter requests that module.

In any such system it is important to keep the wires and logic in the crosspoints to a minimum, while still maintaining a specified transfer rate. This is achieved by serial transmission of several partial words in parallel through the crosspoints.

Consistent with the building block philosophy of Interpreter-based systems, the Switch Interlock is partitioned to permit modular expansion for incremental numbers of Interpreters, memory modules or devices and modular selection of the amount of parallelism in the transfer of address and data through the

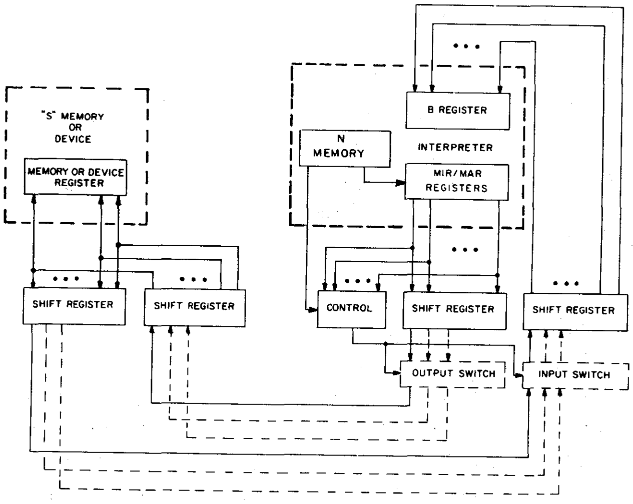

Figure 5—Implementation of switch interlock

Switch Interlock from fully parallel to fully serial. Functionally, the Switch Interlock consists of parallel-serial conversion registers for each Interpreter, input and output selection gates, parallel-serial conversion registers for each memory module and each device, and associated control logic. Figure 5 outlines the implementation of the Switch Interlock and shows the functional logic units repeated for each Interpreter, memory module, and device. The bit expandability of the Switch Interlock is shown by dashed lines between the input/output switches and the shift registers associated with the memory module, devices, and Interpreters.

The six basic Switch Interlock modules are described below:

(1) Memory/Device Controls (MDC)

The MDC is an interface between the Interpreter and the controls described below (MC and DC), and the control for the high frequency clock used for the serial transmission of data. There is one MDC per Interpreter.

(2) Memory Controls (MC)

The MC resolves conflicts between Interpreters requesting the use of the same memory module and maintains an established connection after completion of the operation until some other module is requested or some other Interpreter requests that memory module. This unit handles up to four Interpreters and up to eight memory modules. System expansion using this module may be in number of Interpreters or in number of memory modules.

(3) Device Controls (DC)

The DC resolves conflicts between Interpreters trying to lock to a device and checks the lock status of any Interpreter attempting a device operation. This unit handles up to four Interpreters and up to eight devices. System expansion using this module may be in number of Interpreters or in number of devices.

(4) Output Switch Network (OSN)

The OSN sends data and control from Interpreters to addressed memory modules (i.e., the OSN is a "demultiplexer"). This unit handles wires for up to four Interpreters and eight devices or memory modules. The number of wires for an OSN (and for an ISN) depends upon both the packaging and the "serialization" selected for the application.

(5) Input Switch Network (ISN)

The ISN returns data from addressed devices or memory modules to the Interpreters (i.e., the ISN is a "multiplexer"). This unit also handles wires for up to four Interpreters and up to eight devices or memory modules.

Shift Register (SR)

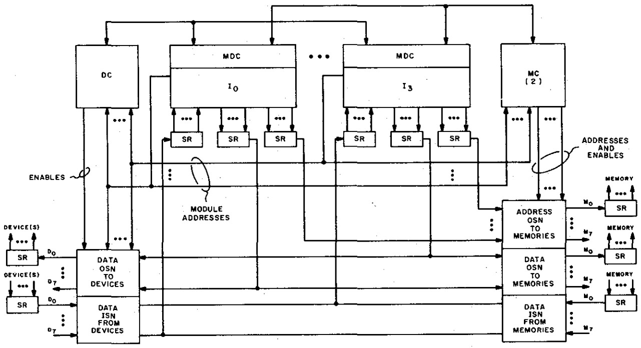
These units are optional and are parallel-to-serial shift registers or serial-to-parallel shift registers using a high frequency clock. These are used for serial transmission of data through the ISN's and OSN's. Their size, number and location are determined by system parameters.

Switch Interlock Block Diagram

Figure 6 is a block diagram of a Switch Interlock connecting up to four Interpreters to eight devices and eight memory modules. The shift registers shown are optional and may be eliminated with the resulting increase in the width of the ISN and OSN transfer paths. Although it is not indicated by this figure, the Switch Interlock is expandable in terms of number of Interpreters, devices, memory modules, and path widths.

Overall Switch Interlock Control

In an Interpreter based system utilizing one or more Interpreters, only Interpreters can issue control signals



NOTE: The widths of the ISN/OSN's are dependent upon the number of bits being transmitted serially.

Figure 6—Switch interlock

to access memories or devices. A memory module or device cannot initiate a path through the Switch Interlock. It may, however, provide a signal to the Interpreter via a display register or other similar external request device. Transfers between devices and memories must be via and under the control of an Interpreter.

Controls are routed from the Interpreters through the MDC to the MC and the DC which, in turn, check availability, determine priority and perform the other functions that are characteristic of the Switch Interlock. Data and addresses do not pass through the MDC.

Switch Interlock Timing

Events are initiated by the Interpreter for access to memories or devices. The Interpreter awaits return signals from the MDC. Upon receipt of these signals, it proceeds with its program. Lacking such positive return signals, it will either wait, or retry continuously, depending upon the Interpreter program (and not on the Switch Interlock). Any timeout waiting for a response may be performed by either the program or a device that will force a STEP in the micropogram after a preset length of time.

Among the significant signals which are meaningful responses to an Interpreter and testable as conditions are the following:

Switch Interlock has Accepted Information	The address and data output registers of the Interpreter may be reloaded and a memory or device has been connected.
Read Complete	Data are available to be gated into the input data register of the Interpreter.

The rationale for this "handshaking" approach is consistent with the overall Interpreter-based system design which permits the maximum latitude in the selection of memory and device speeds. Thus the microprogrammer has the ability (as well as the responsibility) to provide the timing constraints for any system configuration.

Device Operations

The philosophy of device operations is based upon an Interpreter using a device for a "long" period of time without interruption. This is accomplished by "locking" an Interpreter to a device. The ground-rules for device operations are listed below:

(1) An Interpreter must be locked to a device to which a read or a write is issued.
(2) An Interpreter may be locked to several devices at the same time.
(3) A device can only be locked to one Interpreter at a time.
(4) When an Interpreter is finished using a device, it should be unlocked so other Interpreters can use it. The exception is the case where devices locked to a failed Interpreter might be unlocked with a "privileged" instruction by another operative Interpreter.

Memory Operations

Memory modules normally cannot be locked and are assumed to require minimum access time and a short "hold" time by any single Interpreter. Conflicts in access to the same module are resolved in favor of the Interpreter that last accessed the module, or otherwise in favor of the highest priority requesting Interpreter. Once access is granted, it continues until that memory operation is complete. When one access is complete, the highest priority request is honored from those Interpreters then in contention. The Interpreter completing access is not able to compete again for one clock. Thus the two highest priority Interpreters are assured of access. Lower priority Interpreters may have their access rate significantly curtailed. This problem is resolved through careful allocation of data to memory modules.

Other Multi-Interpreter System Hardware

The executive concept described in the latter part of this paper requires special hardware features. Although in a multiple Interpreter system more than one Interpreter can execute executive programs at one time, certain tables used by the executive must be locked for modification by only one Interpreter at a time. The Interpreter remains in this "table modifying" state for a short time, thus minimizing executive conflict delays. The locking capability is implemented with two "global condition bits" per Interpreter which are chained to other Interpreters in a priority scheme. These global condition bits are 2 of the 16 testable condition bits in each Interpreter. Each bit can be set in only one Interpreter at a time and must be programmatically reset (the other condition bits in each Interpreter are reset

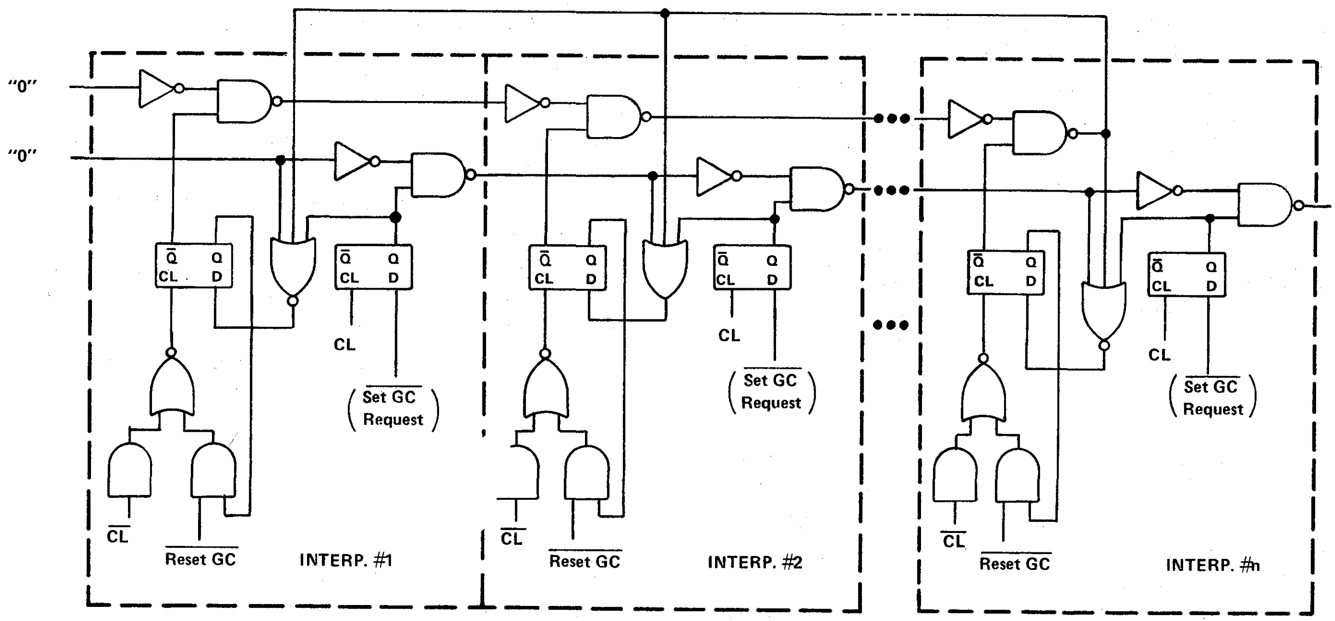


Figure 7—Global condition priority resolver

when they are tested). An Interpreter instruction containing the "Set Global Condition Bit" operation will set the specified global condition bit in that Interpreter only if that bit is not set in any Interpreter and no other higher (wired) priority Interpreter is requesting the same bit to be set in its own Interpreter.

Figure 7 shows the method of resolving priorities for each of the global condition bits. The instruction to set a global condition bit is actually a *request* to set a global condition bit. This request is latched for one clock time during which time a decision is made to honor this request or not. The global condition bits are programmatically reset independent of other Interpreters.

The top string of horizontally connected gates (Figure 7) OR's is the corresponding global condition bit from all Interpreters together. The other string of horizontally connected gates in the Interpreters is the wired global condition setting priority. This priority could be wired differently for the two global condition bits. It should be noted that in a system with many Interpreters, these two "carry" chains could have a delay long enough to affect the Interpreter clock rate. In these cases, a carry-lookahead scheme could be used to speed up this path.

It should also be noted that such a scheme could be implemented alternately via programming using Dijkstra's semaphores,[7] or using memories with a read-modify-write cycle to insure one processor wasn't reading a memory location in the interval between a read of that location by another processor and a subsequent write of a modified value.

One more of the testable condition bits in each Interpreter is wired to provide an additional inter-Interpreter signal. This bit is called the Interrupt Interpreters bit and is simultaneously set in all Interpreters by an operation originating from any Interpreter. This bit is reset in an Interpreter when tested in that Interpreter.

The global condition bits and the interrupt Interpreters bit are the only multiprocessing hardware features which are part of an Interpreter. Special purpose logic in an Interpreter is thus minimized, making it inexpensive and flexible enough to be used across a wide spectrum of architectures from simple stand-alone device controllers through multiprocessors. This versatility increases the quantity of Interpreters being produced, which in turn lowers the unit cost of an Interpreter.

Special devices (connected through the Switch Interlock) needed for multiprocessing are an interrupt display register and a real-time clock with time-out capability. The interrupt display register is needed due to the limited number of externally settable condition bits in each Interpreter. Such a display register is read as a device by any Interpreter. The response of the display register is a function of the interrupt handling philosophy of the particular application and the design of such a device could be varied without affecting the basic design of the Interpreter or the Switch Interlock.

The same philosophy is true of the real-time clock. Here, the intent of such a device is to provide an external counter for all Interpreters as well as a means of forcing a program STEP in an Interpreter if that Interpreter didn't periodically reset its real-time clock. This would prevent an Interpreter from waiting forever for a response from an inoperative memory or device.

MULTI-INTERPRETER CONTROL PROGRAM

The Multi-Interpreter Control Program is a simple, yet comprehensive, operating system characterized by the following capabilities:

(1) Multiprogramming and multiprocessing
(2) Fully automatic operation with manual intervention capability.
(3) Error recovery with no loss of data.

Multiprogramming and multiprocessing have characterized Burroughs operating systems for many years. In previous systems, input/output functions and data processing functions have been performed in physically different hardware modules; I/O modules for the former and processor modules for the latter. In the Multi-Interpreter System, however, I/O control and processing functions are all performed by identical Interpreters, and any Interpreter can perform any function simply by a reloading of its microprogram memory. In the Multi-Interpreter Control Program I/O operations simply become tasks which are indistinguishable to the control program from data processing tasks except that they require the possession of one or two I/O devices before they can begin to run. (A task is defined as an independent microprogram and its associated "S" level program and data, which performs explicit functions for the solution of user problems.) Whenever an Interpreter is available it queries the scheduling tables for the highest priority ready-to-run task, which may be an I/O task, a processing task, or a task which combines both processing and I/O functions.

The control program operates automatically, as well as under the control of the operator. The operator may enter new tasks, delete old ones, or change the priority of any task. He may add or delete hardware modules, and call for diagnostic programs to be run. The operator enters his commands through either the card reader or the alphanumeric display console.

The Multi-Interpreter Control Program includes an automatic error detection and recovery capability. All data is stored redundantly to avoid loss of data should a failure occur. The control program maintains this redundancy, in such a way that a restart point is maintained at all times for every task.

Figure 8 defines the flow of tasks through an Interpreter.

Figure 8—Flow of tasks through an interpreter

Task scheduling and initiation

Every time an Interpreter has no task to perform it scans a Task Table and locates the highest priority ready-to-run task. If there is no ready-to-run task this Interpreter runs the diagnostic program, then (if the diagnostic program indicates no malfunction) again attempts to schedule a task. When the Interpreter finds a task which can be run the appropriate table entries are updated. The Interpreter then loads its microprogram memory with the task's code and begins to execute this code. The task code must periodically cause the Interpreter to "report in" to a central "timeout" table.

Task termination

The task retains the Interpreter until the task is due to be suspended (assuming that a timeout does not occur). The task first stores its state, then causes the Interpreter to load its microprogram memory with a portion of the control program. This recopies changed memory areas to ensure the redundancy required for error recovery, deallocates resources which the suspended task had used, and updates system tables. Then the Interpreter looks for another task.

Supervisory control

The operator can add or delete tasks or resources as well as enter the data and code which individual tasks require. Commands and data may be entered via either the card reader or an alphanumeric display. Each of these devices is "owned" by a system task which inputs data for the control program and for the other tasks in the system. Each entry via the card reader begins with a control card which specifies the nature of the entry. When the entry is data or program, the control card specifies the task and the area in that task where subsequent cards are to be loaded.

Commands and data are entered from the alphanumeric display in essentially the same manner as from the card reader, a line on the display corresponding to a card.

Error recovery

The hardware of the Multi-Interpreter System detects failures in memory modules and in I/O devices. When an I/O device fails, it is indicated as "not available" and a message to this effect is sent to the operator (via both printer and display). The device will remain "not available" until the operator enters a message to the contrary. The task whose running caused the malfunction to be detected is immediately aborted, but it will again run when the needed I/O device or an alternate is available. The redundant copies of storage areas serve as the restart point for this rerun. (The primary copies cannot be used as the task was aborted at other than a normal suspension point, hence not at a valid restart point.)

When the core memory module fails while a task is using it, the Interpreter which was running this task marks the failed module "not available", and causes the initiation of an error message to the operator. The task which was being run is aborted. This task will be reinitiated from the redundant core memory areas. Interpreter failures are detected in either of two ways: by the diagnostic program or by a timeout method, in which every Interpreter "checks in" to a central table at periodic intervals, and every Interpreter checks that every other Interpreter is checking in on schedule. When an Interpreter fails it halts (or is halted), and the task (if any) which it had been running is aborted, and will eventually be reinitiated at its restart point by an operative Interpreter.

The system can thus recover from a failure with no loss of data, provided the primary and alternate storage areas of a task are not both lost.

Tables

The operation of the Multi-Interpreter Control Program can be seen in more detail by examining the tables which it utilizes. These tables are divided into two classifications: system (global) tables, and task tables. The former are located in core memory in a segment called the "System Control Segment", and the latter for each task are located in a "Task Control Segment" for that task.

For error-recovery purposes all of these tables are stored redundantly in two different memory modules. Therefore there are actually two "System Control Segments", a primary one and an alternate one. The two copies are identical at all times and whenever one is updated the other is also. In a system that includes bulk storage this redundancy would be maintained in the bulk storage, and only one copy of any segment would be in core memory when the task is running.

The tables for each task are similarly stored redundantly so that there are two copies of each Task Control Segment. Included in each Task Control Segment are pointers to all of the data and program areas which this task may use. These areas may comprise one segment or many contiguous segments, and may be used either solely by this task or shared with other tasks. Each such area is also stored redundantly.

Figure 9 illustrates how the core memory is utilized, and shows the System Control Segment and its relationship to the Task Control Segments. (The term "segment" refers to a 256 word area of core memory.) The System Control Segment includes a pointer to each Task Control Segment, which in turn includes the pointers to each area used by the task.

Memory modules are presently paired, where both modules of the pair are allocated identically, so that the primary Task Control Segment and the redundant Task Control Segment for the same task have the same segment number. The same applies to data and program areas.

System control segment

The System Control Segment is illustrated in more detail in Figure 10. This segment is always located in segment zero (the first segment) of some memory module. Its redundant copy is always located in segment zero of some other module. Segment zero in all modules is reserved for possible use as the System Control Segment or its alternate copy. If the module containing the prime or redundant copy of the control segment should fail, any remaining module is selected and its segment zero is overwritten with the contents of the System Control Segment so that redundancy is immediately restored. Word zero in segment zero of every memory module contains pointers to both the prime and al-

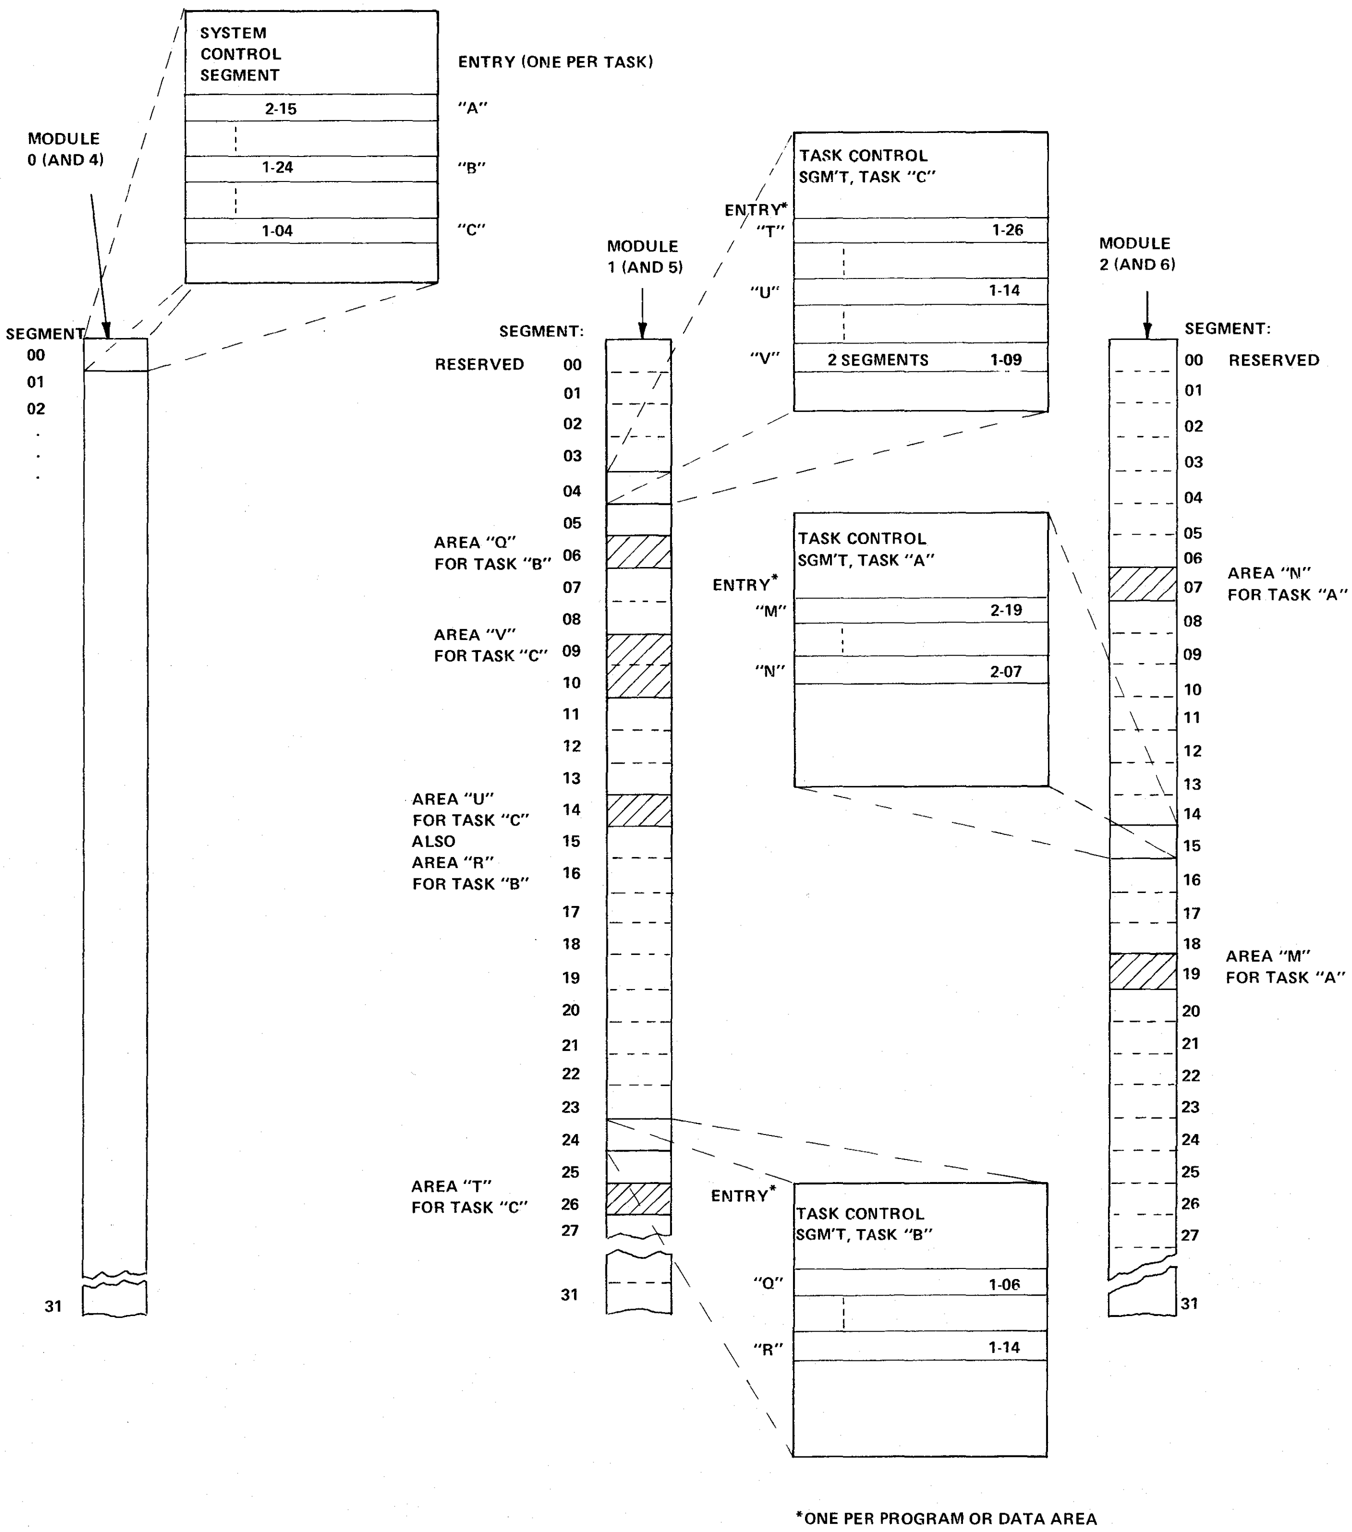

Figure 9—Memory utilization

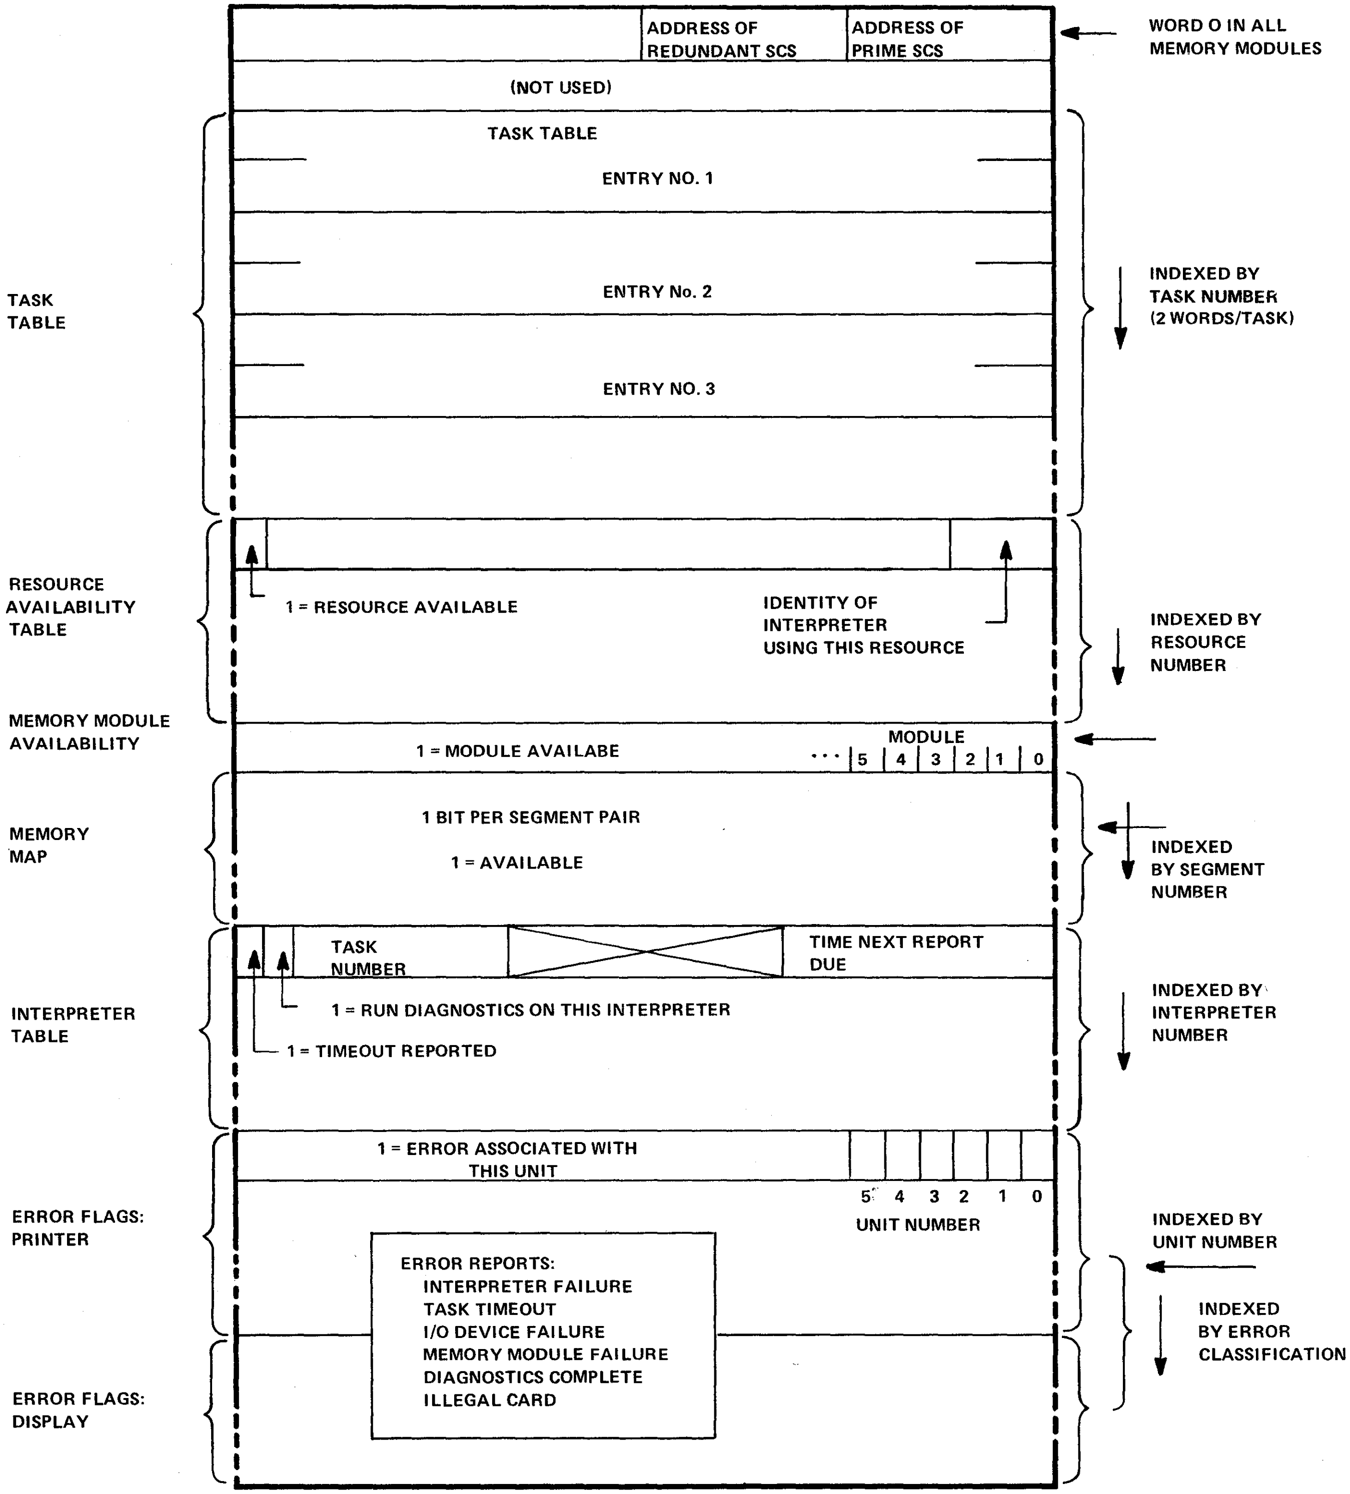

Figure 10—System control segment

ternate System Control Segments, so that any Interpreter can "find its way back" to the System Control Segment should it become "lost" because of a memory module failure. Word zero of the System Control Segment itself is no exception, and includes these pointers.

Resource Availability Table

This table contains one entry for every hardware resource. The entry includes a flag-bit, which indicates whether this resource is available or in use, and a field which, when the resource is in use, gives the identity of the Interpreter which is using it.

Memory Module Availability Table

This one-word table consists of one bit for every memory module in the system. This bit indicates whether or not the module is "up" (available for use).

Memory Map Table

This table contains one bit for every usable segment in core memory. A "1" in the bit position corresponding to a particular segment means that the segment is unassigned. Since modules are paired, a single bit in this table actually represents two segments, the prime segment and the segment in the paired module which holds the redundant copy.

Interpreter Table

This table has one entry for every Interpreter, and is used primarily to implement the "reporting" scheme used to detect Interpreter malfunctions. Every task run on the system is written so that, if it must run for "N" or more seconds, the Interpreter will "report in" to its entry in the Interpreter Table at intervals of less than "N" seconds. This reporting consists of replacing the "Time Next Report Due" field with the present time plus "N" seconds. Every Interpreter, when it completes its present task and is ready to find a new one, scans the Interpreter Table (after first updating its own entry in this table), looking for overdue entries. If any are found, they are reported to the supervisor. In addition, the most significant bit in the entry which was found overdue is set, so that other Interpreters will not make this same report.

Each entry in the Interpreter Table also includes two other fields. The first of these is a 1-bit field indicating that diagnostics are to be run on this Interpreter. This bit becomes set from a command entered by the supervisor. When set, the Interpreter will run diagnostics at the completion of the present task. Once diagnostics have been run the Interpreter causes a message to be sent to the supervisor indicating the test results, and then resets the "Run Diagnostics" bit.

The final field in an Interpreter Table entry gives the identity of the task which that Interpreter is currently running.

Error Flags Table

This table indicates the error messages which are to be sent to the operator. Such messages are sent both via the line printer and via an alphanumeric CRT display which is only used by the operator. Each portion of the table consists of one word for every type of error. Within each such word, the individual bits form an indexed vector which indicates more specific error information, normally the unit number of the failed unit. When any type of error is detected, the appropriate bit is set in both the display and printer portions of the table. The actual printout is accomplished by a specific task, the Error-Print task. This task (tagged "to be run") runs as soon as the printer and an Interpreter are available. When this task runs it scans the entire printer portion of the Error Flags Table, and for each bit encountered formats and prints the appropriate message and then resets the bit. This process continues until all of the bits are reset. There is also an Error Display task which functions in this same way to display error messages on the CRT screen.

Changing the System Control Segment

Whenever any change to a table in the System Control Segment must be made, the segment is locked. (This locking is implemented using the "global condition" bits found in every Multi-Interpreter System.) The required writing then takes place, to both the prime and the redundant copy of the table, and the segment is then unlocked.

The task table

The Task Table contains information about every task in the system. Figure 11 indicates the contents of an entry in this table, which consists of two words. The first word contains the information which an Interpreter in the process of finding a new task must examine to determine whether this task is the one which should be

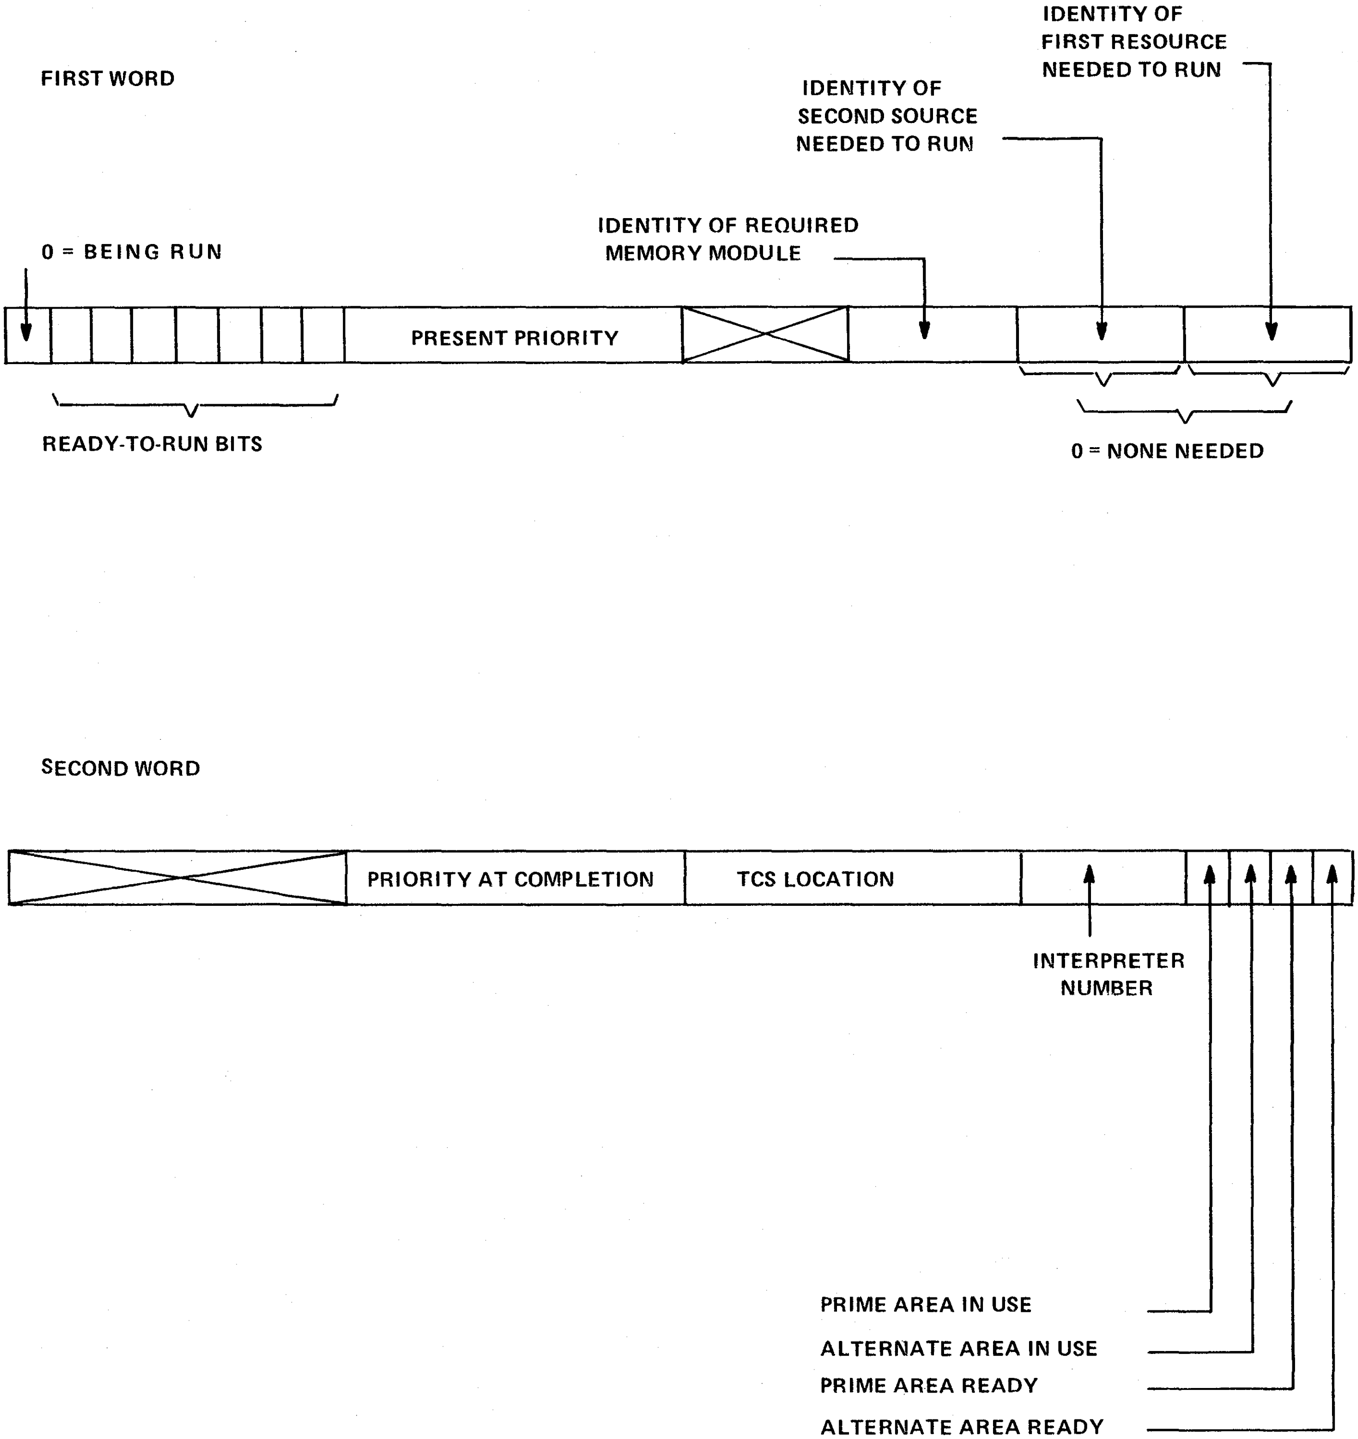

Figure 11—Task table entry

selected. The most significant bit in this first word is the "not-running" bit. This bit is reset whenever the task is running and set at all other times. Next are the "ready-to-run" bits. These bits must all be ones for the task to be scheduled. If one or more of its bits are zero, the task lacks something, other than an I/O device, which it requires for running. For example, if the task requires data to be supplied by some other task, one of its ready-to-run bits would remain reset until the completion of the other task. Similarly, if the task in question is awaiting data from the card reader, a bit will be left reset and will be set by the Card Reader Task after the data has been loaded. These bits have no system-wide assignments, but are assigned for each application. All unassigned bits remain set at all times. Any task can reset any of its own bits, and can, upon its suspension, set bits for other tasks.

The next field in the Task Table Entry is the "present-priority" field. Each task has a priority, and that ready-to-run task with the highest priority is the one which is selected.

In order for a task to be "ready-to-run", not only must all of its ready-to-run bits be set, but also the core memory which it requires, and any I/O devices which it may need must be available. The remaining fields of the first Task Table Entry word deal with these items. There is a field which specifies the memory which this task requires, and two fields which can specify up to two I/O devices which it also requires. Before the task can be considered "ready-to-run", the required areas of memory, and all required I/O devices must be available.

The second word of the Task Table Entry contains additional information about the task. The first such field specifies the priority to which the task reverts after it has completed running. (A priority-at-completion of zero indicates that the task is to be dropped from the system at completion.) Next is the location of the Task Control Segment for this task, as discussed in connection with Figure 9. Another field contains the identity of the Interpreter which is running this task.

The final field in the Task Table Entry gives the status of the core memory areas used by this task. The

Figure 12—Task control segment

Task Control Segment and all program and data areas associated with task exist in two different memory modules. When the task runs, only one module is actually used, and the other holds the state of this task as it existed after it was last processed. This then serves as a "restart point" should the present processing be prematurely terminated by a failure. This alternate area is not changed until this present processing has been successfully terminated and the primary copy of the task's Task Control Segment updated to form a consistent whole which can itself be used as a restart point. Only then is the Task Control Segment and all data areas copied from the primary to the alternate module.

Task control segment

Figure 12 indicates the contents of the Task Control Segment. The first field points to the end of the Reference Area, since the size of the Reference Area may differ from task to task. (The otherwise unused end of the segment may be used as a work area by the task.) The second field gives the address of this module, so that, when the task is completed, word zero of segment zero can be found. (This word must be accessed in order to locate the System Control Segment.) The third field in this first word gives the identity of the present task, and enables the Task Table Entry for this task to be located once the System Control Segment has been found.

The next section of the Task Control Segment holds the state of the task, and also task parameters. First is the address of the task code at which the task is to be restarted. This task code then interprets the remainder of the state information, if any.

The next section of the Task Control Segment contains a copy of the Task Table Entry (from the System Control Segment), put there by the control program when the task is initiated. The task may then conveniently modify its Task Table Entry. For example, the task may reset one or more of its "ready-to-run" bits, may indicate the identity of an I/O device which is required for further processing, or may even change its priority. When the task is suspended, and it runs until it suspends itself (unless it is suspended because of a time-out), the Task Table Entry in the System Control Segment will be updated by the control program to correspond to the Task Table Entry as found in the Task Control Segment.

In addition to modifying its own Task Table Entry, the task may, upon its suspension, cause Task Table Entries for other tasks to have one or more ready-to-run bits set. This is accomplished through the next word in the Task Control Area. This word allows the task to specify up to four other tasks, and to supply a bit pattern to be "ored" with the ready-to-run bits for each of these tasks. In this way the completion of one task can be used to initiate another.

The final section in the Task Control Segment is the reference area, which points to data and program segments which this task may use. Each reference area, in addition to specifying the address of the segment(s) to which it refers, also contains a "read-only" bit, and the control program does not update the alternate copy of any entry so tagged.

In summary, the Multi-Interpreter Control Program allows any number of Interpreters to operate concurrently in a multiprocessing and multiprogramming mode, allows tasks and hardware modules to be added and deleted by the operator, and provides error recovery capability.

A BUILDING BLOCK APPROACH TO SOFTWARE

There are two approaches that may be followed when developing an operating system for a multiprocessor with microprogrammable Interpreters. One is an approach taken in the paper by Davis and Zucker[1] as well as B. J. Huberman[8] where a machine language is developed. This language includes instructions which aid in the development of an operating system. Since operating systems are organized about tables, lists, queues and stacks the machine language developed allows for easy handling of tables and other data structures.

We have presently chosen to take a building block approach. The Multi-Interpreter Control Program which is our current system, presents the operating system as a set of modules which may be obtained and run by an Interpreter when needed. A new technique currently under development generates an operating system which is basically a set of independent "S" instructions which may be used by any task on a defined configuration of firmware and hardware.

The building block approach used in the hardware implementation of the multiprocessor is also being followed for the software development. A simple flexible method of system configuration is defined. This system has the ability to automatically select the appropriate units, either system microcode or system tables, from a prestored library of such units. This technique permits using only those units necessary to perform all the desired system functions for a particular set of tasks. System functions are requested as needed from a Parts List. The appropriate units are selected from the list to form a customized system from a set of standard building blocks.

A primary design criteria of the operating system (Manager) are flexibility, simplicity and reliability. The operating system must be flexible enough for all classes of problems to fit within its structure. All tasks must be able to access all facilities provided by the system with a given configuration of the hardware. Simplicity is necessary to allow the system to be maintained, changed, tested and initially coded with relative ease. The system architecture must be sufficiently straightforward so that the users can easily comprehend its structure and operation. The manager must also be reliable and the recoding of a single unit should not affect the rest of the system.

To achieve the above criteria a modular, distributed system manager has been defined. Each unit is a separate group of microinstructions designed to run in a multiprogrammed mix and must be validated as a standalone program. Extreme attention must be paid to modularity, allowing new units to be plugged in without causing bugs in the rest of the system. Just as the multiprocessor's hardware flexibility lies in its easily changeable hardware configuration so should the multiprocessor's software flexibility lie in its easily changeable software configuration.

The system is composed of a single structure, and a set of conventions for using this structure. Although systems will differ, both in type of units and hardware, the set of conventions and the general structure will always be used in the same way. The specific units needed for the manager functions will be plugged into the structure as needed.

The three segments defining the operating system are the Locator, the Parts List and the units. The units are the function modules of the system which do the desired operations for the users. This collection of modules is both programs and data (tables) normally thought of as

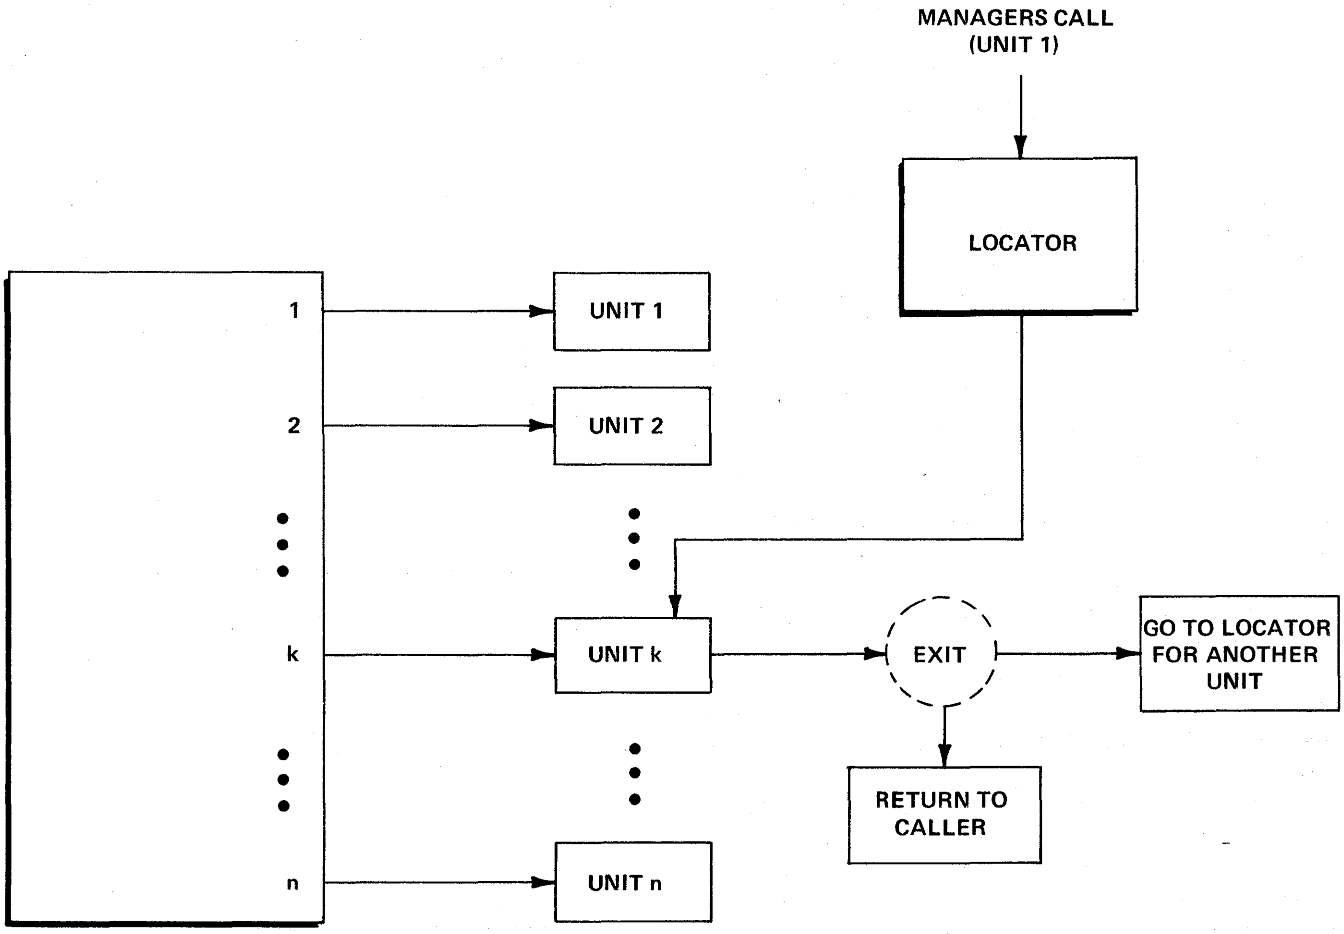

Figure 13—System manager

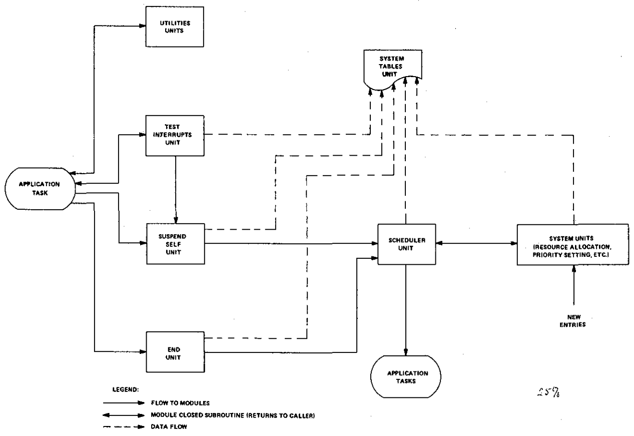

Figure 14—Program traffic in a processor

the operating system. The tasks may select a unit through the Locator. The Locator is a part of all tasks and can access all units with a parameter called the unit number which locates the required unit using the Parts List. The Parts List is a table containing the location of all units associated with a system. Each time a new system is required, a new Parts List and a new set of units are developed. However, the Locator remains the same for all systems independent of the kind of hardware or software in use (Figure 13).

The traffic flow within a single processor is shown in Figure 14. Each task will require the use of the system units to perform some known utilities for them. This includes functions like memory allocation, I/O formatting, conversions, editing, debugging, resource allocation, channel checking, etc. The utility units perform a function and then return to the caller.

Interrupts are soft in a Multi-Interpreter System. Testing for interrupts is processed by a standard interrupt testing unit called by a task. The detection of an interrupt may suspend the caller task or it may call another unit to process the interrupt before returning to the caller. User tasks may suspend themselves or be completed by calling the Suspend Self or End units. When a program has been suspended or ended the next highest priority program ready to run is selected by the scheduler unit.

When an Interpreter task is assembled, a Source Table is developed for all of the manager hardware dependent subroutines it may use, as well as all of the functions needed by its Interpreter. This table becomes input information to the operating system Librarian (Figure 15). Each microprogrammed task has such a table developed before it can run. When the task must access the library units, it indexes into the Source Table. The Source Table defines the library unit needed. Source Tables for all tasks are used as inputs to the Operating System Librarian. This information is used with a catalog of units to develop the Parts List for the system.

Each Source Table is modified to become a list of pointers to the Parts List (Figure 16) and to the allocation portion of the Locator in microprogram memory. As each unit is referenced during a task run, the Source Table addresses the allocation part of the Locator. Space is allocated in microprogram memory. The address pointing to the allocation routine is changed to point to the desired unit now transferred into microprogram memory. The unit can now be executed. Unless this unit is deallocated from microprogram memory, the Source Table now can point directly to the unit address in this memory.

To locate a unit for allocation in microprogram memory, the allocator uses the pointer in the Source Table to locate the pointer in the Parts List which points to the unit. When the unit is present in main memory it need only be copied into the required location in microprogram memory. When the unit is not present it must

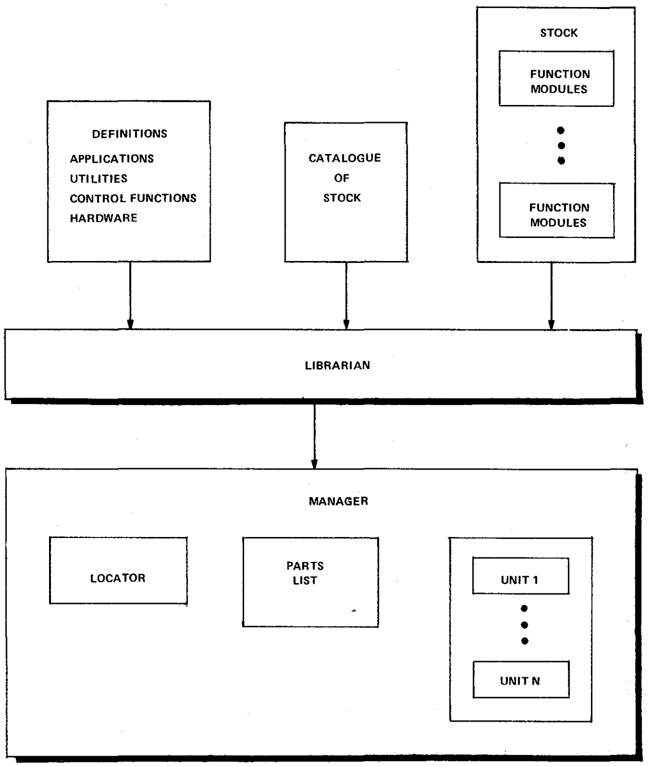

Figure 15—Automatic development of manager

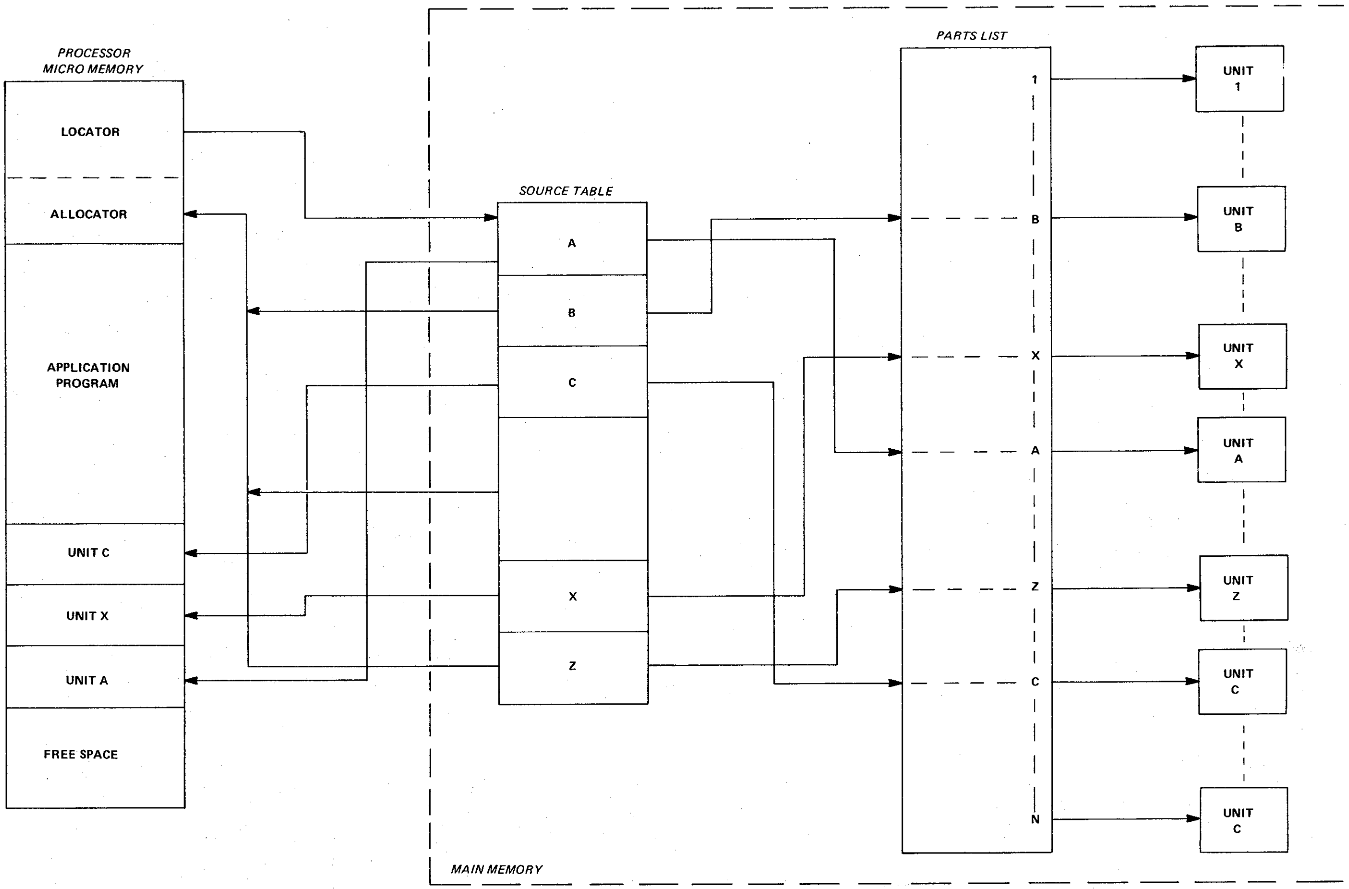

Figure 16—Single local manager

be read into memory from a peripheral device as defined in the Parts List. This device will be defined by the file directory (Figure 17) so that units may be accessed through a hierarchy of storage in a recursive manner.

Since all units of code in the Parts List are reentrant, all processors may have the same code at the same time without interfering with one another (provided they use different work areas). The work area is unique for each task and within each work area is a unique Source Table. Figure 18 shows the distributed local operating system with many Interpreters. Each Interprecer is: executing a different task, working in a unique work area, using a unique Source Table. All Interpreters share the same Parts List and have identical Locator sections. Any one unit can be unique to a task or shared by many tasks.

Since all system tasks are independent of each other, the parts that bind the system together are the system tables. These contain the important interfaces of the system and the means of communication between Interpreters and/or processes. The system tables define the three main attributes of the system: the tasks to run, the resources available, and the Interpreters running.

A Task Table is used for scheduling and termination of tasks at the global level. All information pertaining to the state, selection criteria, needs, and scheduling of a task will be found in this table. Intertask communication and task Interpreter communication is performed in the Task Table.

The Resource Table provides the information for allocating system resources among the different tasks by the various units.

An Interpreter Table contains information pertaining to each individual Interpreter. The Interpreters check on each other for the detection of malfunctioning hardware, as well as inter-Interpreter communication via this Table. An Interpreter may also use its table entry as temporary storage or for storing information about future tasks (e.g., an Interpreter may have to run routine diagnostics at the completion of its present task).

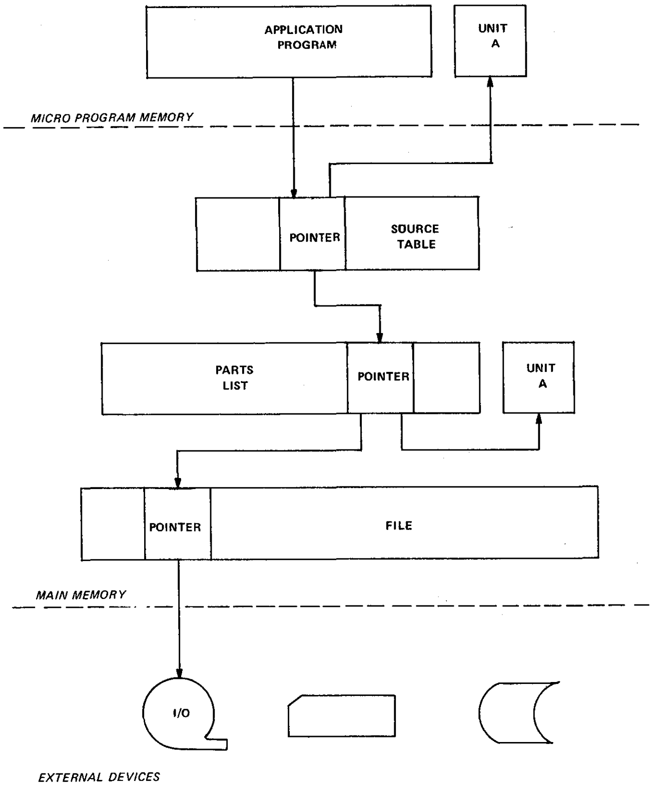

Figure 17—Accessing a unit

The building block approach assembles an operating system from a series of directly executable "S" instructions, called units, which can be executed by any task. These units may be different for different systems. A system which would want an I/O module could assign a high priority task the role of doing this job. Then all I/O system units would become descriptor building units or communication units instead of direct execution I/O units. In some systems, tasks would do their own I/O by having direct execution Parts List units while other tasks in the same system might assume an I/O module and pass descriptors to an I/O Task using other units.

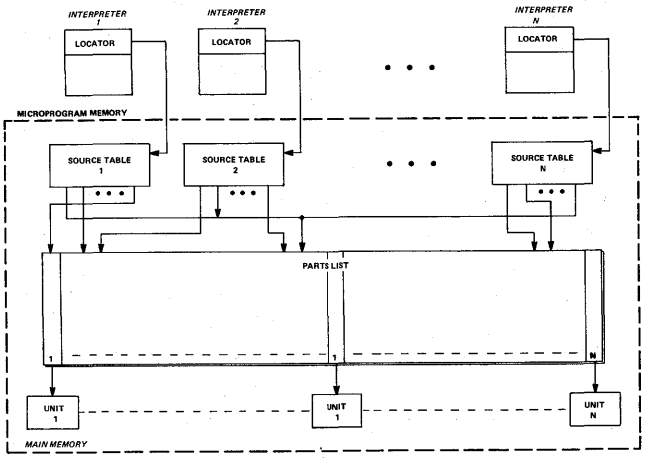

Figure 18—Distributed local managers system

Those tasks of an operating system which stand alone (e.g., I/O processor, system loaders, external communicators, etc.) are called and entered in the task table as if they were an application task with a high priority. Their ready to run bits can be set and reset by the system units.

The structure of the building block type operating system is a systematic way of constructing a manager so that its functions can be applied with identical units at all levels in a hierarchy of operating systems (e.g., course scheduling can be done at a global level while finer scheduling can be used at the next level). An Interpreter may use a unit to select a system for emulation, the task being that system's Operating System. Using the resources assigned to it at the global level, this Interpreter may choose to run its own set of tasks (which look like data to the global system). The Operating System of an emulation may be totally in the "S" language being interpreted or it may be running global units from the Parts List on its own resources assigned to it at the global level.

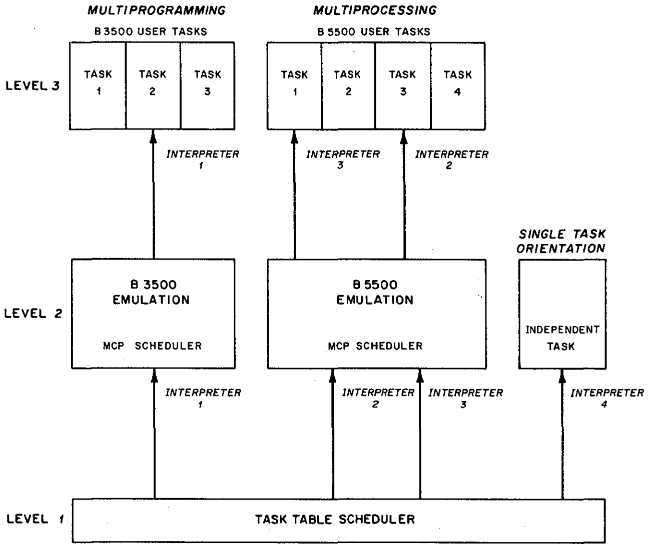

Figure 19—Interpreter control level

Figure 19 shows the control levels an Interpreter goes through to execute a user task. Interpreter 1 has been given resources and is scheduled at level 1 to run a B 3500 emulation. The initial task to be run is the operating system for the B 3500 called the MCP. It in turn receives data about the tasks to be run on a B 3500. The MCP sets up the tasks and executes them in a multiprogramming environment. Figure 19 shows task 2 as running. Interpreter 1 is now running a B 3500 program and is a B 3500 system which is totally independent of the rest of the system except for reporting status or requesting more resources.

Interpreters 2 and 3 have both been scheduled to become a B 5500 system. These Interpreters now have become a multiprocessing B 5500 system running the MCP and the B 5500 tasks. Interpreter 3 is running task 1 and Interpreter 2 is running task 3 of the B 5500 system's tasks in the B 5500 schedule.

Interpreter 4 has selected a task oriented emulation. This is a microprogram specifically oriented to doing a specific job. It needs no operating system but uses the units available to it in the Parts List for executing common functions or manager type functions.

A task must decide how critical its need is for quick access to a system unit. It may decide a unit is important and once it is located and stored in microprogram memory it is left there for the duration of the task. A task which is required to process real time interrupts may want the interrupt testing unit to be a part of its code and not have to indirectly address the unit via its Source Table. Such a task may directly assemble the interrupt unit from the library into its microprogram memory. Other units which are less critical will be brought from main memory each time they are accessed.

CONCLUSIONS

Microprogrammed systems in the past have been relatively simple and primarily suitable for small, dedicated tasks. A technique has been needed to interconnect many small microprogrammed processors into one system, and to control this array of processors so that it can dynamically and efficiently share a large load. This paper has presented such a technique. The Switch Interlock allows an array of Interpreters to be integrated into a unified system with many memories and peripheral devices. The type of software described here provides a means for controlling this unified system, and allows control programs to be "custom-tailored" to each application, providing maximum efficiency. Thus the flexibility of microprogramming can now be applied to large scale systems, and virtually any size system may be constructed with a smooth evolution from a small system to a large one. A degree of reliability and of simplicity in logistics and maintenance not previously possible in medium or large scale systems is provided due to repeated use of a small number of relatively simple module types.

Microprogrammed multiprocessing systems thus appear well suited for a wide variety of data processing applications.

INTRODUCTION

What is microprogramming?

Digital computing systems have traditionally been described as being composed of the five basic units: input, output, memory, arithmetic/logic, and control (see Figure 1). Machine instructions and data communicated among these units (as indicated by the solid lines in the figure) are generally well-known and understood. The control signals (as indicated by dashed lines in the figure), are generally less well-known and understood except by the system designer. These control signals generated in the control unit determine the information flow and timing of the system.

Microprogramming is a term associated with the orderly and systematic approach to the design of the control unit. The functions of the control unit include:

1. Fetching the next machine instruction to be executed from memory
2. Decoding the machine instruction and providing each microstep control
3. Controlling the gating of data paths to perform the specified operation
4. Changing the machine state to allow fetching of the next instruction.

The conventional control unit is designed using flip-flops (e.g., registers and counters) and gating in a relatively irregular *ad hoc* manner. By contrast the control unit of a microprogrammable computer is implemented using well structured memory elements; thus providing a means for well organized and flexible control.

Microprogramming is therefore a technique for implementing the control function of a digital computing system as sequences of control signals that are organized on a word basis and stored in a memory unit.

It should be noted that if this memory is alterable, then microprogramming allows the modification of the system architecture as observed at the machine language level. Thus, the same hardware may be made to appear as a variety of system structures; thereby achieving optimum processing capability for each task to be performed. The ability to alter the microprogram memory is called dynamic microprogramming as compared to static microprogramming which uses read only memories.

As can be seen in the following brief historical review, the concept of microprogramming was not widely accepted except academically during the 1950s. The primary reason for this was its high cost of implementation, especially the cost of control memories. From the mid-1960s to the present there has been a definite trend toward microprogrammable processors and more recently to dynamic microprogramming. This effort has been inspired by rapid advances in technology, especially control memories.

Brief historical review of microprogramming

1951 Wilkes[1] objective was "to provide a systematic approach and an orderly approach to designing the control section of any computing system." He likened the execution of the individual steps within a machine instruction to the execution of the individual instructions in a program; hence the term microprogramming. This view is hardware design oriented.

Lincoln Lab (see Van der Poel[2]) with different emphasis used the term microprogramming to describe a system in which the individual bits in an instruction directly control certain gates in the processor. The objective here was to provide the programmer with a larger

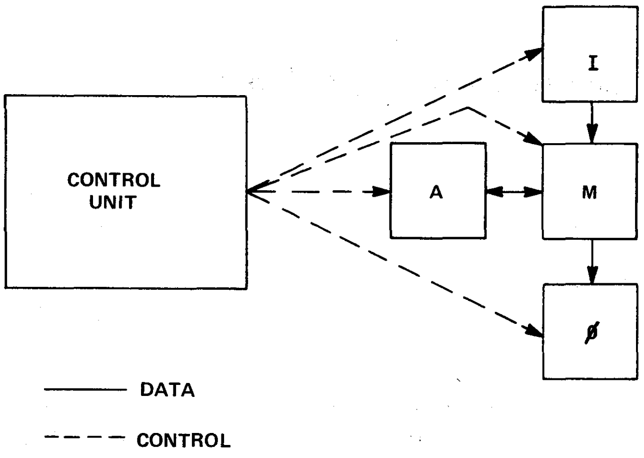

Figure 1—Five basic functional units of digital computing system

instruction repertoire. This view is software design oriented.

1956/7 Glantz[3] and Mercer[4] pointed out that through microprogram modifications the processor instruction set may be varied.

1958-1960 Blankenbaker,[5] Dinneen,[6] and Kampe[7] described simple computers based on Wilkes' model.

1961-1964 Great international interest was shown from U.S., U.K., Italy, Japan, Russia, Australia and France.

Feb. 1964 In Datamation[8–12] five articles appeared on microprogramming with emphasis on how it might extend the computing capacity of small machines.

1964 IBM System 360 (Stevens[13]) demonstrated that through microprogramming, computers of different power with compatible instruction sets could be provided (used read only storage).

1965 Melbourne and Pugmire[14] described microprogramming support for compiling and interpreting higher level programming languages.

1965 McGee and Peterson[15] pointed out the advantage of using an elementary microprogrammed computer as a peripheral controller, i.e., as an interface between computers and peripheral devices.

1965-1966 Green[16] and Tucker[17] described emulation of one machine on another through microprogramming.

1967 Opler[18] coined the term "firmware" for microprograms designed to support software and suggests the increased usage of microprogramming and describes its advantages.

1967 Hawryszkiewycz[19] discussed microprogram support through special instructions for problem oriented languages.

1967 Rose[20] described a microprogrammed graphical interface computer.

1968 Lawson[21] discussed program language oriented instruction streams.

1969 Wilkes[22] and Rosin[23] provided surveys of the microprogramming advances.

There were also announcements of many new microprogrammed computers (e.g., Standard Computer—Rakoczi[24]).

1970 Husson[25] provided the first textbook on microprogramming.

1971 Tucker and Flynn[26] pointed out advantages of adapting the machine to the task through microprogramming.

July 1971 The IEEE Transactions on Computers offered a special issue on microprogramming.

Interpreter design philosophy

The main objectives in the design of Burroughs' Interpreter were simplicity, versatility, technology independence, and modularity. The reasons for these objectives and their realization in the resulting machine are stated in Table I.

The basic concepts that characterize the Interpreter are its modular structure using simple building blocks and its application to a wide range of tasks through its dynamic microprogramming.

A system is composed of a number of Interpreters, main memories, input/output devices, and a data exchange called the switch interlock. The switch interlock allows each Interpreter to communicate with all memories and devices and consists of controllable data paths and conflict resolution logic for access to these paths. The switch interlock (described in a companion paper) is an extension of the designs that have been used successfully for many years in Burroughs' multiprocessing systems (e.g., B 5500 and D 825).

INTERPRETER HARDWARE BUILDING BLOCKS

The Interpreter is composed of three logic package types; namely, the **L**ogic **U**nit (LU), the **C**ontrol **U**nit (CU), and the **M**emory **C**ontrol **U**nit (MCU). The microprograms which provide the control functions are contained in two conventional memories; namely, the

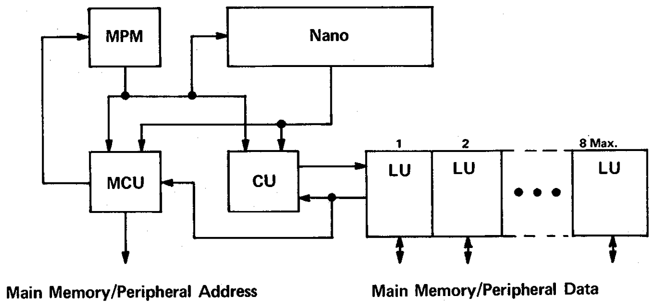
TABLE I

Desired Characteristic	Reasons for Objectives	Resulting Characteristics
Simplicity	Omission of special functions not applicable over a wide range of applications Ease of maintainability: Training Documentation Spare parts	Each Interpreter consists of: a. Three logic package types (each less than 1000 gates) Logic Unit (LU) – Control Unit (CU) – Memory Control Unit (MCU) – b. Standard memories for microprogram storage (e.g. Read/Write or Read Only)
Versatility	Increase volume of production resulting in reduction of cost Decrease design time and effort by eliminating the need for new hardware developments for each new product	Peripheral controller I/O controller Central processor Special function processor Emulator of existing systems Direct execution of languages
Technology Independence	To provide smooth transition to LSI when economically justified To meet variety of system cost/performance requirements with optimum circuitry	Partitioning allows implementation in variety of packaging schemes (e.g., SSI, MSI, LSI) Performance may be varied by simply implementing in different circuit family (e.g. MOS, TTL, ECL)
Modularity	System – to provide smooth and unlimited system growth Internal – to provide a variety of machine word sizes as needed by the application	System modularity provided by modular Switch Interlock Internal modularity provided by use of multiple logic units (LU).

Microprogram Memory (MPM) and the Nano program Memory (Nano or NM). These units and their interconnections are shown in Figure 2.

The unique split memory scheme for microprogram memories allows a significant reduction in the number of bits for the microinstruction storage. It should be noted, however, that a single microprogram memory scheme (MPM and Nano combined) may also be used potentially increasing the clock rate of the system. In addition, the cycle rates of the memories may also be altered, to gain speed or reduce cost, without any redesign of the logic packages. In fact, a variety of memory organizations (single memory and different split memory configurations) and memory speeds have been implemented thus providing a range of cost/speed trade-offs.

The LU performs the shifting and the arithmetic and logic functions required, as well as providing a set of scratch pad registers and the data interfaces to and from the Switch Interlock (SWI). Of primary importance is the modularity of the LU, providing expansion of the word length in 8-bit increments from 8 bits through 64 bits using the same functional unit. The CU contains a condition register, logic for testing the conditions, a shift amount register for controlling shift operations in the LU, and part of the control register used for storage of some of the control signals to be sent to the LU. The MCU provides addressing logic to the Switch Interlock for data accesses, controls for the selection of microinstructions, literal storage, and counter operation. This unit is also expandable when larger addressing capability is required.



Each Interpreter consists of:

- Three types of logic packages
  - ▲ Logic Unit (LU)
    - – Registers A1/A2/A3/B/MIR
  - ▲ Control Unit (CU)
    - – Registers SAR/Command/Condition
  - ▲ Memory Control Unit (MCU)
    - – Registers MPCR/AMPCR; BR1/BR2/MAR; LIT/CTR
- Two memory packages (standard available units — R/W or R/O)
  - ▲ Microprogram Memory (MPM)
  - ▲ Nanoinstruction Memory (Nano)

Figure 2—Interpreter building blocks

Logic unit (LU)

A functional block diagram emphasizing the LU is shown in Figure 3. Registers A1, A2, and A3 are functionally identical. They temporarily store data within the Interpreter and serve as a primary input to the adder. Selection gates permit the contents of any A registers to be used as one of the inputs to the adder. Any of the A registers can be loaded from the output of the barrel switch.

The B register is the primary external input interface (from the Switch Interlock). It also serves as the second input to the adder, and can collect certain side effects of arithmetic operations. The B register may be loaded with any of the following (one per instruction):

1. The barrel switch output
2. The adder output
3. The external data from the Switch Interlock (or control panel switches)
4. The MIR output (the MIR is the output data register to the Switch Interlock)
5. The carry complements of four- or eight-bit groups (with selected zeros for use in decimal arithmetic or character processing)
6. The barrel switch output ORed with two, three, or four above.

The output of the B register has true/complement selection gates which are controlled in three separate sections: the most significant bit, the least significant bit, and all the remaining central bits. Each of these parts is controlled independently, and may be either all ZEROs, all ONEs, the true contents or the complement (ONEs complement) of the contents of the respective bits of the B register.

The MIR buffers information being written to main system memory or a peripheral device. It is loaded from the barrel switch output and its output is sent to the Switch Interlock, or to the B register.

The adder in the LU is a modified version of a straightforward carry look-ahead adder. Inputs to the adder are from selection gates which allow various combinations of the A, B and Z inputs. The A input is from the A register output selection gates and the B input is from the B register true complement selection gates. The Z input is an external input to the LU and can be:

1. The output of the counter in the MCU into the most significant eight bits with all other bits being ZEROs.
2. The output of the literal register in the MCU into the least significant eight bits with all other bits being ZEROs.
3. An optional input (depending upon the word length) into the middle bytes (which only exists in Interpreters that have word lengths greater than 16 bits) with the most and least significant bytes being ZEROs.
4. The output of the AMPCR in the MCU into the least significant 12 bits with all other bits being ZEROs.
5. ALL ZEROs.

Using various combinations of inputs to the selection gates, any two of the three inputs can be added together, or can be added together with an additional ONE added to the least significant bit. Also, all binary Boolean operations between any two adder inputs can be performed.

The barrel switch is a matrix of gates that shifts a parallel input data word any number of places to the left or right, either end-off or end-around.

The output of the barrel switch is connected to:

1. The A registers (A1, A2, A3)
2. The B register
3. Memory Information Register (MIR)
4. Least significant 16 bits of MCU (registers BR1, BR2, MAR, AMPCR, CTR)
5. Least significant three to six bits to CU (depending on word length) for the shift amount register (SAR).

Control unit (*CU*)

This unit has five major sections (shown in Figure 4): the shift amount register (SAR), the condition register (COND), part of the control register (CR), the MPM content decoding and the clock control.

The functions of the SAR and its associated logic are:

1. To load shift amounts into the SAR to be used in the shifting operations.
2. To generate the required controls for the barrel switch to perform the shift operation indicated by the controls from the Nanomemory.
3. To generate the "word length complement" of the SAR contents, where the "complement" is defined as the amount that will restore the bits of a word to their original position after an end-around shift of N followed by an end-around of the "complement" of N.

The condition register (COND) section of the CU performs four major functions:

1. Stores 12 resettable condition bits in the condition register. The 12 bits of the condition register are used as error indicators, interrupts, status indicators, and lockout indicators.
2. Selects 1 of 16 condition bits; 12 from the condition register and 4 dynamically generated during the present clock time (by the previous instruction being completed) in the Logic Unit for use in performing conditional operations.
3. Decodes bits from the memory for resetting, setting or requesting the setting of certain bits in the condition register.
4. Resolves priority among Interpreters in the setting of global condition (GC) bits which provides a facility for inter-Interpreter lock-out control.

The control register is a 36-bit register that stores the

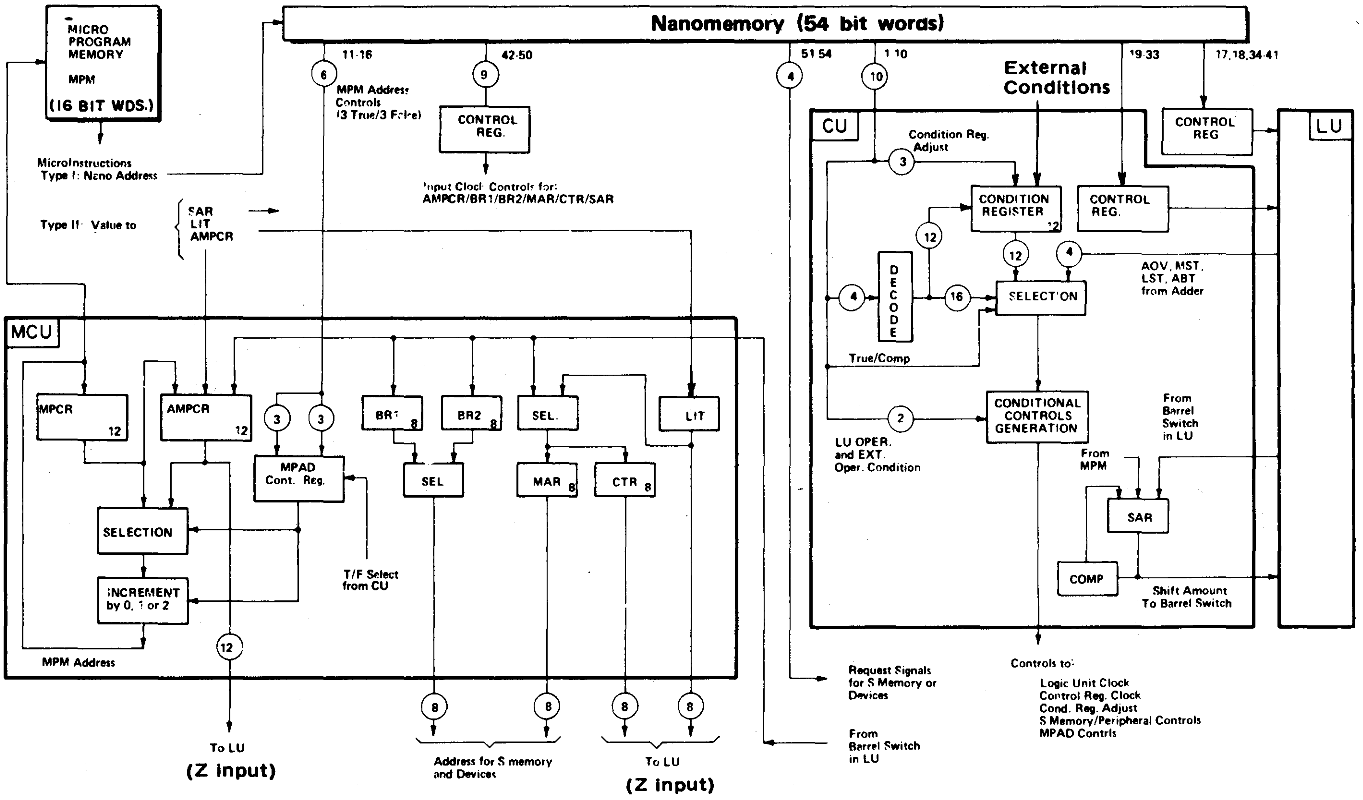

Figure 4—MCU/CU block diagram

subset of the control signals from the memory that are used in the LU, CU and MCU for controlling the execution phase of a microinstruction.

The MPM content decoding determines the use of the MPM as a Type I instruction (address) or as a Type II instruction (literal) based upon the first four bits of the MPM. Several decoding options are available.

Memory control unit (MCU)

One MCU is required for an Interpreter (providing access to 2^{16} words maximum) but a second MCU may be added to provide additional memory addressing capability (2^{32} words maximum). This unit has three major sections (shown in Figure 4):

1. The microprogram address section contains a microprogram count register (MPCR), the alternate microprogram count register (AMPCR), the incrementer, the microprogram address controls register, and their associated control logic. This section is used to address the MPM for the sequencing of the microinstructions. The AMPCR content may be used as input to the adder.
2. The memory/device address section contains the memory address register (MAR), base registers one and two (BR1, BR2), the output selection gates, and the associated control logic.
3. The Z register section contains registers which are the Z inputs to the LU adder: a loadable counter (CTR), the literal register (LIT), selection gates for the loadable counter and their associated control logic.

Interpreter operation

The operation of the Interpreter is described assuming a split MPM (16 bits)/Nano (54 bits) memory scheme (see Figure 5). During each clock, a microinstruction is read from the MPM. The first few bits of this microinstruction indicate which of two types of instruction it is. If it is a Type I instruction, the remaining bits of the MPM word specify a Nanomemory address to be accessed. The Nanomemory is then initiated and its output, a set of 54 bits, provides the control functions as indicated in Table II.

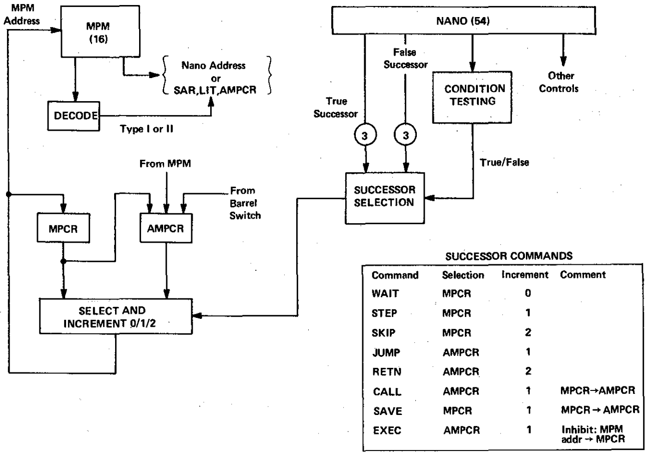
If the microinstruction is Type II (again specified by the first few bits of the MPM word), the remaining bits of the MPM word are stored into one of three registers; namely, the SAR, LIT, or the AMPCR. The determination of which register is to be loaded is also specified by the first bits of the MPM word. The Nanomemory is not accessed during a Type II operation. A Type II microinstruction has an implicit STEP successor.

The sequencing of microprogram instructions is controlled by the following procedure: The Nanomemory provides information to the condition testing logic indicating which condition is to be tested. The condition testing logic provides a True/False signal to the successor selection logic which selects between the three True and three False successor bits (also from the Nanomemory). The three selected bits (True/False) provide eight possible successor command combinations also shown in Figure 5.

The eight successor commands and their associated interpretations are:

Wait	Repeat the current instruction
Step	Step to the next instruction
Skip	Skip the next instruction
Jump	Jump to another area of MPM (as specified by AMPCR)
Retn	Return from Micro subroutine
Call	Call a Micro subroutine
Save	Save the address of the head of a loop
Exec	Execute one instruction out of sequence

The particular chosen successor command then provides controls used in the selection (MPCR/AMPCR) and incrementing logic which generates the next MPM address. Except for the EXEC command the MPCR is loaded with this MPM address.



SUCCESSOR COMMANDS

Command	Selection	Increment	Comment
WAIT	MPCR	0	
STEP	MPCR	1	
SKIP	MPCR	2	
JUMP	AMPCR	1	
RETN	AMPCR	2	
CALL	AMPCR	1	MPCR→AMPCR
SAVE	MPCR	1	MPCR→AMPCR
EXEC	AMPCR	1	Inhibit: MPM addr→MPCR

Figure 5—Microprogram instruction sequencing

TABLE II—Nanocodes

Nano-Bits	
1- 4	Select a condition
5	Selects true or complement of condition
6	Specifies conditional or unconditional LU operation
7	Specifies conditional or unconditional external operation (memory or device)
8-10	Specify set/reset of condition
11-16	Microprogram address controls (wait, skip, step, etc.) for true and false successor
17-26	Selects A, B, and/or Z adder inputs
27	Carry control
28-31	Select Boolean or basic arithmetic operations
32-33	Select shift operation
34-36	Select inputs to A registers
37-40	Select inputs to B register
41	Enables input to MIR
42	Enables input to AMPCR
43-48	Enable and select input to address registers and counter (MAR, BR1, BR2, CTR)
49-50	Select SAR preset
51-54	Select external operations (read, write, lock, etc.)

Each Type I microinstruction requires two clock intervals for its completion. The first (phase I) involves the fetching of the instruction from the MPM/Nanomemories and the second (Phase 3) executes the fetched instruction. Figure 6 illustrates these two basic phases (1 and 3) of each Type I microinstruction.

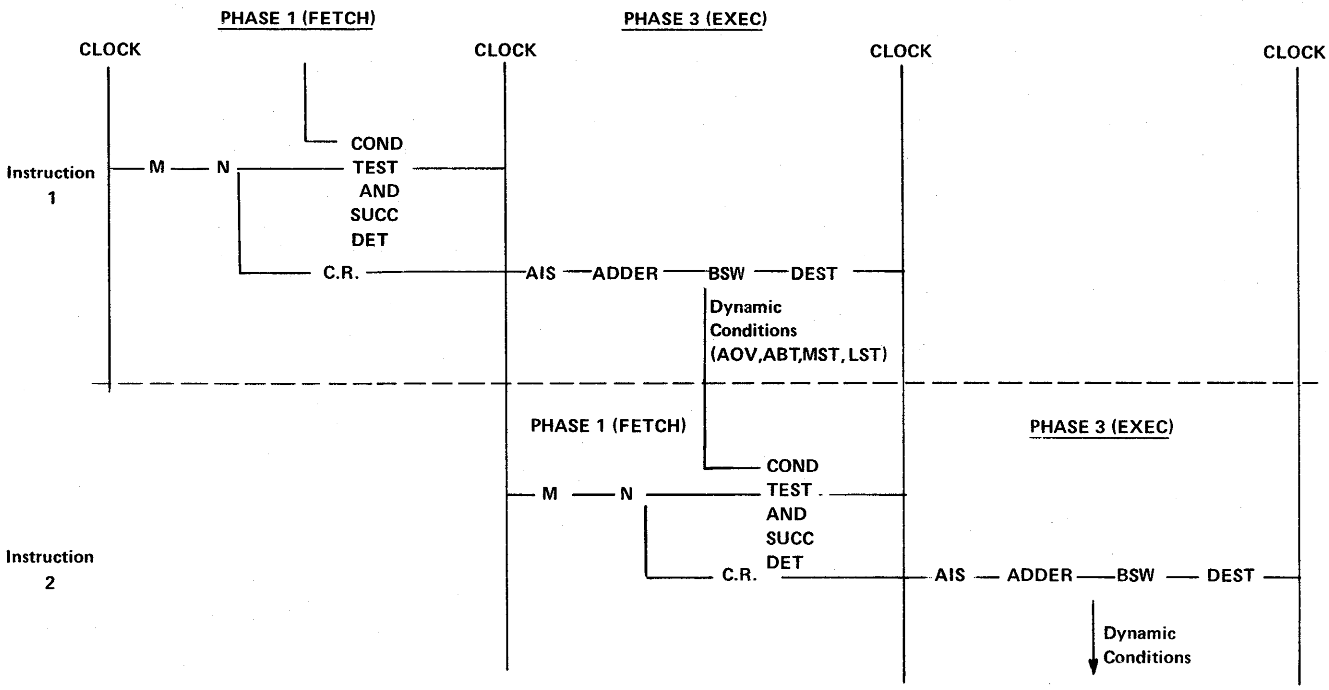
It should be noted that each phase 3 (execution) clock interval of instruction I is overlapped with phase 1 (fetch) clock interval of instruction I+1. Hence, the performance of each microinstruction requires effectively one clock interval.

As seen in Figure 6 the fetch phase involves: MPM memory accessing, Nanomemory accessing, the logic for condition testing and successor determination and in parallel the logic for loading the control register.

The execute phase includes adder input selections, adder function, barrel switch shifting of the adder output, and the destination register(s) loading. Figure 7 shows various timing examples for Type I and Type II instruction sequences.

INTERPRETER MICROPROGRAMMING

The pattern of 1s and 0s in the MPM and Nanomemories (together with the data) determine the operation of the Interpreter. The microprogrammer is concerned with the generation of these patterns to provide the desired control functions. However, instead of actually writing these patterns the microprogrammer is assisted by a microtranslator (or assembler) that allows



M = MPM ACCESS TIME
N = NANO ACCESS TIME
COND TEST AND SUCC DET. = CONDITION TEST AND SUCCESSOR DETERMINATION
BSW = BARREL SWITCH
DEST = BARREL SWITCH OUTPUT DESTINATIONS;I.E., REGISTERS (B, CTR, ETC.) AND THEIR INPUT LOGIC
C.R. = COMMAND REGISTER AND ASSOCIATED LOGIC
AIS = ADDER INPUT SELECTION FROM COMMAND REGISTER

Figure 6—Timing analysis, Type I instructions

him to write microinstructions mnemonically. The microtranslator then scans these instructions and produces the pattern of 1s and 0s to be placed into the MPM and Nanomemories.

Figure 8 indicates the ease with which one can learn to microprogram the machine and the simplicity of the microprogram structure. The high degree of parallelism extant in the Interpreter is also evident from the powerful statements that can be expressed. For example, the following actions may be expressed and performed in one instruction:

- test a condition (for either True or False)
- set/reset a condition
- initiate an external operation (e.g., memory read)
- perform an add operation
- shift the result of the add
- store the results in a number of registers
- increment a counter
- complement the shift amount
- choose the successor microinstruction

It is also possible to perform these operations conditionally or unconditionally as suggested in Figure 8. The group A and group B portions (either, neither, or both) of the microinstruction may be placed before the condition test portion of the instruction. This will result in that portion (A and/or B) being performed unconditionally.

The following four microinstruction examples illustrate both the parallelism and the conditional/unconditional properties of the microinstructions.

(1) If NOT LST then set LC1, MR1; A1+B+1C→A2, MIR, CSAR, INC; Step else Jump
(2) Set LC1, MR1; If NOT LST then A1+B+1C→A2, MIR, CSAR, INC; Step else Jump
(3) A1+B+1C→A2, MIR, CSAR, INC; If NOT LST then Set LC1, MR1; Step else Jump
(4) Set LC1, MR1; A1+B+1C→A2, MIR, CSAR, INC; if NOT LST then; Step else Jump

In (1) the LST bit is tested and if not true, the local

Type II — Loads any of 3 specified registers (no nano memory access, step successor)
Four variations

k → SAR
k → LIT
k → AMPCR
k_1 → SAR; k_2→ LIT

Figure 8—Microinstruction types

condition 1 (LC1) is set, memory read is initiated (MR1), the function A1+B+1 is performed in the adder and the adder output is shifted circular and the result stored in both the A2 and MIR registers, the content of the shift amount register is complemented (CSAR), the counter is incremented (INC), and the true successor (STEP) is selected.

In (2) the LC1 is set and the memory read is initiated (MR1) unconditionally (i.e., without considering the LST bit). The remaining functions are conditionally performed as in (1).

In (3), the functions A1+B+1C→A2, MIR, CSAR, INC are performed unconditionally but set LC1 and MR1 are performed conditionally.

In (4) the functions Set LC1, MR1, A1+B+1C→ A2, MIR, CSAR, INC are all performed unconditionally and only the successors Step and Jump depend upon the LST test.

The Interpreter microprogramming reference card (Figure 9) specifies the use of each of the MPM and Nano bits and defines the meaning of the mnemonics found in the microprogram examples.

Two simple examples demonstrating the microprogramming of the Interpreter are shown in Figure 10 Binary Multiply and Figure 12 Fibonacci Series generation. The comments serve to explain the function of each microinstruction step. Figure 11 shows the microtranslator output (1 and 0 patterns for MPM and Nano) for the Binary Multiply example.

INTERPRETER APPLICATIONS

General

As mentioned earlier, one of the design objectives was to provide versatility so that a wide range of applications may be performed. The tasks to which the Interpreter has been successfully applied include peripheral controllers, emulators, high level language executors, and special function operators. This versatility allows the Interpreter to attack not only a wide range of problem areas but also every phase of a problem solution.

As indicated in Figure 13 a data processing facility receives programs written in either machine language or a high level language (e.g., Algol, Cobol, Fortran) and data upon which these programs operate. If the program is written in a high level language, then a compilation (or preprocessing) phase may be performed to translate this program into machine language form before execution. Each phase of this problem solution operation—recognition, code generation and execution—can be performed by a microprogrammed processor; in fact, each phase can be tuned to optimally perform the task.

Three main data processing functions to which the Interpreter may be applied are: Emulation of existing or hypothetical machines, "direct execution" of high level languages, and problem solution through microprogram "tuning" of the machine to the problem. These three function areas—emulation, "direct execution," problem "tuning"—will now be defined and the Interpreter approach to their implementation will be described.

Emulation

In a conventional (non-microprogrammable) computer, the control unit is designed using a fixed set of flip-flops and decoders to perform the execution phase of the operation. The execution phase includes the fetching of machine instructions, calculation of effective operand addresses, and the provision of each microstep command in the performance of the machine instruction.

Emulation is defined in this paper as the ability to execute machine language programs intended for one machine (the emulated machine) on another machine (the host machine). Within this broad definition, any machine with certain basic capabilities can emulate any other machine; however, a measure of the efficiency of operation is generally implied when the term emulation is used. For example, if a conventional computer

Figure 9—Interpreter microprogramming reference card

```
Assumptions

    (1)  Sign-magnitude number representation

    (2)  Multiplier in A3; multiplicand in B

    (3)  Double length product required with resulting
         most significant part, with sign, in B and least
         significant part in A3

1.    A3 XOR B→ ;if LC1

2.    $B_{0TT}$→ A2; if MST then Set LC1

      Comment: Step 1 resets LC1. Steps 1 and conditional part of 2
      check signs; if different, LC1 is set.

3.    $B_{000}$→B, LCTR

      Comment: Steps 2 and 3 transfer multiplicand (0 sign) to A2
      and clear B.

4.    "N"→LIT; 1→SAR

      Comment: Steps 3 and 4 load the counter with the number
      (N = magnitude length) to be used in terminating the multiply
      loop and load the shift amount register with 1.

5.    A3 R→A3; Save

      Comment: Begins test at least bit of multiplier and sets up loop.

6.    LOOP: If not LST then $B_{0TT}$C→B skip else step

7.    A2 + $B_{0TT}$C→B

8.    A3 OR $B_{T00}$R→A3, INC; if not COV then jump else step

      Comment: 6 through 8 - inner loop of multiply (average 2.5
      clocks/bit).

9.    If not LC1 then $B_{0TT}$ → B; skip else step

10.   $B_{1TT}$→B

      Comment: If LC1 = 0, the signs were the same, hence force sign bit
      of result in B to be a 0.
```

Figure 10—Example of microprogram for binary multiply

emulates another computer, the emulation efficiency is generally very poor since for each machine language instruction of the emulated machine there corresponds a sequence of machine instructions to be executed on the host machine. This relatively inefficient operation for conventional computers with fixed machine instructions (called simulation in IBM literature—see Husson[25] and Tucker[17]) turns out to be significantly more efficient on microprogrammable computers. In a microprogrammed machine, the controls for performing the fetching and execution of the machine instructions of the emulated machine consist of a sequence of microinstructions which allows the increased efficiency.

There are a number of attributes of the Interpreter which make it uniquely appropriate for emulation applications. In addition to the obvious flexibility allowed by microprogramming, the following features of the Interpreter contribute significantly to an effective emulation capability:

1. Modularly variable logic unit word length permits configuring the emulator machine for most effective match with the emulated machine.
2. The barrel switch provides for arbitrary length shifts in a single clock time, a very effective facility for instruction "break-apart" and address calculation.
3. Powerful and extremely flexible microinstructions. There is no fixed, limited-size instruction repertoire; rather, the Interpreter's nanoinstruction provides practically unlimited flexibility in instruction composition. The microinstructions of some machines have a rather elemental capability; here, it is possible to compose microinstructions of relatively great power. A single micro-nanoinstruction may specify selective condition testing and setting, conditional or unconditional logic unit operations between selected registers, optional shifting, literal loading of certain registers, and independently conditional or unconditional memory or device read-write operations.
4. The zoned B-register selection affords convenient testing and setting of special bits.
5. Condition setting and testing allows ease of communication with peripherals and memories.
6. Multiple units for a variety of system functions and multiprocessing may be interconnected via

Figure 11—Example of microtranslator output

Assumptions:

A1 contains starting address for storing of series

A2 contains the number representing the length of the series to be computed

1. A1 → MAR1

   Comment: Load starting address of series into address register

2. B_{000} → B, MIR

3. B_{001} → A3; MW1

   Comment: Load initial element of series (0) into A3 and MIR and write it into starting address. Load second element of series (1) into B.

4. A2 → CTR;SAVE

   Comment: Load counter with length of series; the counter will be incremented for each generation of an element of the series; COV will signify completion. The SAVE sets up the loop.

5. LOOP: If SAI then A1 + 1 → A1, MAR1, INC, Step else Wait

   Comment: Set up the next address and increment counter

6. A3 + B → MIR

   Comment: Generate new element in series and place in MIR

7. B → A3; BMI, MW1; If NOT COV then Jump else Step

   Comment: Write new element into next address
   Transfer i − 1 element to A3
   Transfer i element to B
   Test counter overflow for completion (go to LOOP, if not done)

8. DONE:

General operating procedure

1. **Instruction fetch - fetches next machine instruction to be interpreted**
2. **Instruction decode - separates the op code field in the machine instruction.**
3. **Pass control to appropriate op code routine - using the Directory as a pointer.**
4. **Execute the specified op code routine - using the general routines (esp. addressing) as needed.**
5. **Return control to the instruction fetch routine**

Figure 14—Emulation—MPM map and operating procedure

to efficiently cover a broad range of applications from simple controllers to complex processors or computer systems.

It is important to realize that the machine being emulated may be either an existing or a hypothetical machine. The basic items necessary to define a machine and hence to emulate it are:

1. memory structure (registers, stacks, etc.),
2. machine language format (0, 1, 2, 3 address) including effective operand address calculation, and
3. operation codes and their functional meaning (instructions for arithmetic, branching, etc.).

The process of writing an emulation therefore, involves the following analyses and the microprogramming of these basic items:

1. Mapping the registers (stacks, etc.) from the emulated machine onto the host machine,
2. Analysis of the machine language format and addressing structure,
3. Analysis of each operation code defined in the machine language.

All the registers of the emulated machine must be mapped onto the host machine; that is, each register must have a corresponding register on the host machine. The most frequently used registers are mapped onto the registers within the Interpreter Logic Unit (e.g., registers A1, A2, A3). The remaining registers are stored either in the main system memory or in special high speed registers depending on the desired emulation speed. The machine language format may be 0, 1, 2, 3 address or variable length for increased code density, and may involve indexing, indirection, relative addressing, stacks, and complex address conversions. Figure 14 shows the general microprogram requirements (MPM Map) and operating procedure for the emulation task.

Direct execution

The term "direct execution" has a variety of meanings resulting from the possible divisions of effort in the preprocessing and execution phases of the data processing operation. It may be understood that a machine "directly executes" a high level language (HLL) if a program written in that HLL is submitted to the machine and results occur without regard to how this has been accomplished. Under this broad definition, any machine that has a compiler for this HLL would be considered a "direct executor" of that HLL and this represents one extreme. The amount of preprocessing in this case is quite significant since an entire compiler is required before execution begins.

At the other extreme, practically no preprocessing occurs and the entire HLL program resides in the system (e.g., memory or disc) as it was written (i.e., one-to-one correspondence with the characters of the input code). Each character scanned in the input source string causes an appropriate action. Although this definition involves no significant preprocessing, it is probably only of academic interest because of its slow inefficient operation. It appears that some amount of preprocessing is desirable and that an optimum degree of preprocessing may be arrived at for each environment and/or application.

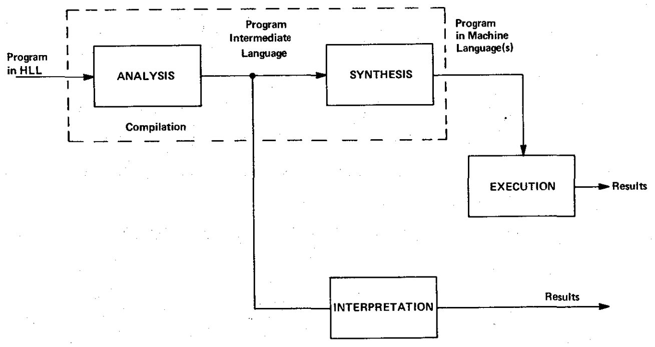

Figure 15—Direct execution of HLL

Figure 15 shows two approaches for arriving at results from a program written in a HLL. The one path involves the standard compilation process followed by an emulation and the other path involves interpretation.

Compilation consists of two basic functions: Analysis and Synthesis. The Analysis function depends upon the HLL and includes the scanner (of the input source string of characters) and the syntax recognizer which determines when a syntactic element of the HLL has been obtained. The output of this analysis is a program in intermediate language form which is usually in Polish postfix notion with tables indicating an internal representation of each element of the input string. This intermediate program has basically a one-to-one correspondence to the input HLL program.

The Synthesis function depends upon the machine that performs the execution phase and consists primarily of code generation. The input is the intermediate language program and the output is a program in the machine language of the execution machine. The code generation is generally a one-to-many mapping from intermediate to machine language.

The term Interpretation generally involves two functions—Analysis and Execution; that is, translation of a HLL program into an intermediate (or internal) form and execution of the program directly in this intermediate form without a translation to a machine language. The Analysis is basically the same as that described above for the compilation process. The meaning of the term Interpretation will be limited in the following discussion to the second part; that is, the execution of the program in its intermediate form.

An Interpretation is often slower in execution time than the equivalent execution of a machine language program. This might not always be the case in a microprogrammed environment, when the control structure of the HLL is significantly different from that of the host machine language, or when a significant portion of the execution time is spent in standard system routines. Interpretation does provide a better facility for development of new programs through built-in functions (e.g., debugging tools).

The functions involved with "direct execution"—Analysis, Synthesis, Interpretation—may all be more effectively performed in a microprogrammed environment. For each function, a set of microprograms may be developed to provide a significant increase in operating speed (see Tucker and Flynn[26]).

A combination of approaches is also easily implemented on a microprogrammed machine. The Interpretation approach may be used during the program development phase and depending upon its operating performance, it may be used for the repeated "production" phase. The compilation approach may be desired for the "production" phase if the execution of a machine language program is of higher performance than the Interpretation approach. The microprogrammed machine provides great versatility here also. In addition to providing a highly efficient compilation process, the machine code output may be modified until an "optimum" machine is defined for the application and/or high level language. This machine would then be emulated on the same Interpreter as described earlier ("Emulation").

The designing of conventional machines to match a particular high level language has been demonstrated to provide high performance. Two examples of this are the Burroughs B 5500 for the ALGOL language and the B 3500 for the COBOL language. A number of the HLL features are reflected in these architectures; for examples: The B 5500 run time stack in which the calling environment resides matches the ALGOL block structure and recursive procedures.

The B 5500 code stream is a reverse Polish notation corresponding to order of expression execution with intermixed operators, literals, operand calls, and descriptor calls. This not only matches the ALGOL operator precedence but also results in increased code density.

The B 5500 operand fetch is driven by data descriptor so that uniform codes can be used for call by name, value, and reference parameters.

The B 5500 performs arithmetic on real numbers, treating integers as zero exponent reals and Booleans as a real 0 or 1 thus providing uniform data representation.

The B 5500 stores arrays as a hierarchy of vectors that contain bases of the next lower level of arrays thus providing for the ALGOL N-dimensional dynamic arrays.

The B 3500 operators work on packed, unpacked, and mixed stored forms of decimal or character data thereby providing convenient management of COBOL variable length operands. The COBOL editing and moving operations are provided for by the primitive B 3500 instructions for character string editing and moving.

The ability to structure a machine for a particular language is enhanced through microprogramming; hence, these same capabilities may be more easily implemented than on the conventional machine.

Tuning the machine for the problem

In the past, conventional machines with fixed instruction sets were used with a force fit approach to solve a given problem. Furthermore, the language and computers (including instruction sets) were developed independently and were based on different requirements and constraints. The language design depended on the user and application and the computer hardware depended primarily on cost and general performance relative to all potential problems. At the juncture, a sometimes complex preprocessor (compiler) was required to make compatible the two designs.

Microprogrammed machines offer the unique opportunity to modify the system architecture to optimally solve a given problem. Languages may still be designed with the application and user in mind but the computer now may also be designed to be compatible with the application and the language. As a result, (1) the language is ideal for the user and application; (2) the preprocessing is significantly simpler because both ends (i.e., language and machine) are flexible, and (3) the machine provides an optimum solution to the problem by matching the language and application requirements.

Among the many advantages to this tuning to the problem approach in addition to this increased system performance is the fast turn around time from problem statement to problem solution. Machine hardware does not have to be built for each new application since the hardware is off-the-shelf and only the microprograms must be developed. This also allows a delayed binding of the required system specification until the problem is clearly defined. As a matter of fact, no permanent binding is ever required since the microprograms may be modified (expanded/contracted) at any time to meet new system needs.

Two basic methods for initiating the implementation of this tuning to the problem approach are: (1) design on paper the ideal machine and/or language for the particular task and then emulate that machine and/or directly execute the language and (2) use an existing machine and/or language as the starting point and emulate the machine or directly execute the language. In either case, the process of tuning is generally iterative in nature. The application programs may be executed using monitoring techniques to detect and gather a variety of statistics about the program. This monitoring is very easily implemented on a microprogrammed machine and may be used for examples (1) to analyze the operation code usage and (2) to determine the slow areas within the program where most of the time of execution is spent. This information may then be used to modify the instruction set by adding or deleting operation codes to the original set. In addition to the instruction sets that may be modified to optimize performance, the data may also be specified as to data types, word lengths, etc., depending on the data structures and accuracies required. The machine structure may also be modified (e.g., adding stacks or general

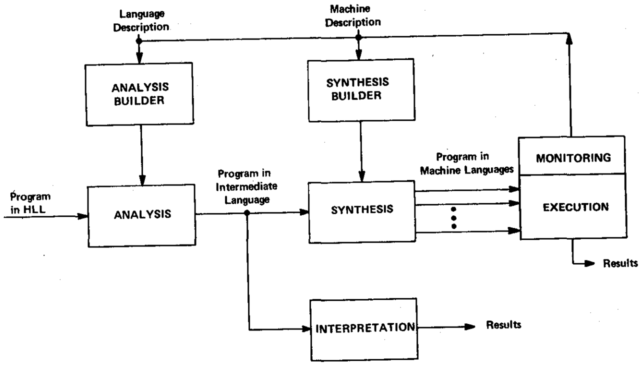

Figure 16—Tuning the machine for the problem

registers, indexing) and the machine language instruction format altered.

Figure 16 indicates a method used for tuning to the problem. The language description is entered into the Analysis Builder and the machine description is entered into the Synthesis Builder. The function of the Analysis and Synthesis Builders is to develop the internal tables (syntax recognition, etc.), machine code segments, etc., for use by the Analysis and Synthesis sections. This building function is presently performed manually but may eventually be performed with computer assistance. The functions of the Analysis, Synthesis, Interpretation and Execution sections are basically the same as previously described ("Direct Execution"). The prime enhancement here is the Monitoring of the Execution function and the feed-back of information for the language and machine descriptions. This allows iteration on the language and machine descriptions until an optimum solution is attained. The result is a language and machine ideal to solve the given problem. Any number of different machines may be emulated by simply modifying the microprogram set.

As an example of this process, let us assume that an emulation of some existing or hypothetical machine (simple or complex) exists. The application program may be run and statistics gathered (by monitoring) concerning this program. The monitoring for dynamic operation code usage, for example, requires only about 10 lines of microcode. The gathered statistics can indicate the execution areas where most of the processing time is spent; that is, the section(s) of machine language instructions most used. The function of this section(s) of machine instructions may then be specified, a single new machine instruction may be defined to perform this same function, and microcode may be developed to emulate this new machine instruction. This process of enhancing the original machine language allows a reduction in main memory requirements for the application program in addition to increasing the performance by a factor of 10 to 20. The estimated speed improvements were stated by Tucker and Flynn[26] in their comparison of the IBM360/50 and their suggested microprogrammed machine. The examples that they chose for demonstrating the increase in performance were: array element address calculation, Fibonacci series generation, and a table search algorithm. Interpreter analyses of these and other examples tend to verify these order of magnitude performance improvements.

INTRODUCTION

Since the early 1960s the literature[9,32] reveals increasing concern with effectiveness of information processing systems and our ability to predict influences of system parameters. A recent survey paper[38] discusses methods of performance evaluation related to three practical goals: selection of the best among several existing systems; design of a not-yet existing system; and analysis of an existing accessible system. The classification of goals is useful, but we can point to neither the models nor the measures nor the measurement tools to allow reliable judgments with respect to those three important goals at this time.

We choose to discuss three issues which do not fall cleanly into Lucas' categories but which are certain to influence our ability to evaluate computer systems in the 1970s. The three issues are: effectiveness of models of computer systems; requirements to be met by measurement experiments; and application of modeling and measurement to the user interface with computer systems.

The first section provides a context for the other sections by reviewing parameters which make computing systems more or less powerful. The second section gives a critique of the state of modeling. The third section characterizes measurement tools. The fourth section discusses the role of measurement at the user interface.

COMPUTER POWER

We consider a computer system to be composed of: a centralized hardware configuration; a set of terminals for entry and exit of user programs and data; an operating system; public programs and data bases; user programs and data; and users and user protocol for entry and exit.

There is no accepted measure for global power or performance of computer systems. There is even no accepted measure for computer cost. Only when a subsystem or subfunction is isolated does it become possible to determine key parameters. However, it is useful to hypothesize such measures and consider influences on them.

Let us, therefore, define a conceptual measure which we call computer system power, P, as a multivariate polynomial function whose coefficients are significance weights. We would, of course, like to have a set of orthogonal functions whose independent variables correspond to measurable parameters but that state of happiness is not apparently within reach. In an attempt to exemplify our philosophy, the authors discuss a set of variables which should influence P keeping in mind that derivation of a figure of merit would require dividing P by some measure of cost.

We intuitively *expect* computer system power to increase if the:

- execution time of any CPU instruction is decreased
- access time of any memory subsystem is decreased
- transfer rate to or from any memory subsystem is increased
- transmission rate of any buss structure is increased
- transfer rate to and from any input or output device is increased
- delay in resource availability is decreased
- error recovery time is decreased
- number of useful public programs is increased
- performance of any public program is increased
- access time to any public data base is decreased
- arrival, execution, and departure rates of user programs are increased
- execution time or resource requirement of any user program is decreased

* This research was supported by the National Science Foundation, Grant No. GJ 809.

- number of effective users increases
- amount of protocol for any user decreases

In a deeper, even more qualitative sense, we expect a computer system to be more powerful if the following conditions hold:

- system manager has a model permitting adaptation to changing load
- errors and system imbalances are reported to maintainers and developers
- program documentation and measurements permit modification with few side effects
- average number of user runs before correct execution is decreased
- the quality of any user program increases in the sense that there is more effective use of a source language on a given computer system.

Although the above observations are useful in stating expected events of concern they ignore interactions between such events and give no indication of weighted importance of the individual events. We further characterize our systems by the following simple remarks.

If the time required for every physical transition to reach its new stable state were halved, we would expect throughput of the system to double. If only some of the events were reduced in transition time, we could no longer guarantee that there would be a reduction in computation time because the scheduling of events is a function of starting and stopping times of concurrent processes. Anti-intuitive anomalies[23,3] are disturbing but do not keep us from conjecturing that they occur only infrequently. If we neglect anomalies, then we cannot expect change in execution time of any one instruction or any one routine or any one compiler to produce a decimal order of magnitude change in a sensibly weighted function of the above parameters. Given reasonable measurement tools and design of measurement experiments we conjecture that somewhere between 10 percent and 50 percent improvement in performance can be accomplished for most systems by changes in assignment and sequencing of resources. Although these percentages do not seem dramatic in their impact, the absolute number of dollars or number of computer hours which would become available is far from negligible.

In contrast with the heuristic probing and tuning of a given system, much greater impact is possible at the user interface with a computer system and by advances in models, particularly validated models of our computer systems. For example, we would guess that there are more than 10 attempts to run a program during its development before it runs once "correctly." For complex programs the ratio of number-of-correct-runs to number-of-runs can approach zero. Hence, if the user interface can be altered so as to increase the probability of a correct run, large benefits may result.

The effect of model development is a more sophisticated and qualitative issue. It is self evident that to the extent that we can predict behavior of even a subsystem through modeling, we can hope to isolate important parameters and the way they affect performance. In fact, only through modeling efforts can we generalize experimental results at one center to apply to many others. Furthermore, it has been recognized that simulation is the most widely used tool in evaluation of systems. If simulation depends upon precise imitation of a computer system, its development cost is generally prohibitive and it is fraught will all the unreliability associated with one-shot development. Effective simulation depends upon validated approximate models of systems and of user programs. Creation of such strong models is the most difficult of our tasks. However, the very process of validating or invalidating simplifying assumptions used in models can lead to new algorithms and improved models. Margolin, Parmelee and Schatzoff[39] very competently demonstrate this effect in their recent study of free-storage management algorithms.

In this section we have taken cognizance of the fact that there is no simple (or even complex) formula for computer performance. The reader's attention has been focussed on the last five in the list of factors affecting computer performance because they offer so much more return. The following sections review work in analytic modeling, measurement, and the user interface.

CRITIQUE OF ANALYTIC MODELING

Any system design, any measurement project or any resource allocation strategy is based on some conception of the environment in which it operates. That conception is a model. It is beneficial to have such models explicitly stated so that they can be explored, tested, criticized and revised. Even better, though not often achieved to the extent desired, is a formal analysis of the models.

Models and methods of analysis vary greatly. Our concern here is with probabalistic models of systems and processes and also with discrete graph models of programs. The goals of these analyses are both insight and quantitative results to influence the design of systems, resource allocation strategies and possibly the design of languages.

While most will argue that the goals of such analyses are inherently worthwhile and must be pursued, there is widespread dissatisfaction with the current state of the field. Basically, there are three major areas of dissatisfaction. First, the models are generally oversimplified in order to make them mathematically tractable. This obviously makes the results questionable and brings us to the second major failing which is that analytic results are often not validated by measurement or simulation. Moreover, in cases where system evaluation studies are carried out, the existing models do not seem powerful enough to provide a uniform basis for measurements. The third major criticism is that most of the literature on analytic modeling is a collection of analyses of specialized models. This points up the lack of very general powerful results which would allow analysis to become an engineering tool. As it is now, each new situation almost always requires a separate analysis by an expert.

While the above are substantial criticisms, this is not to say that analysis has not had its impact. We can cite, for example, the working set model of program behavior,[12] the work on stack algorithms,[41] studies of time-sharing and multiprogramming system resource allocation and analyses of I/O scheduling,[42,49] the work on data transmission systems and on networks[11,35,19] and the work on graph models of programs.[40,26,27,33,14,24,7,10,22]

Promising areas of research

Multiple resource models

Much analytic work has dealt with single resource models. The reason for this is clearly that most of the analytic tools which are available apply to single resource environments. The computer system analyst is typically not a mathematician developing new tools but is generally engaged in applying existing tools. Nevertheless, computer systems are multiple resource systems and we must learn to analyze such systems.

Some recent studies of multiple resource models of computer systems have been made using results by Gordon and Newell.[21] The general model considered by Gordon and Newell is one in which customers (or jobs) require only one resource at a time, but move from one resource to another. An example is illustrated in Figure 1 for three resources.

The nodes in this figure represent resources and the arcs represent possible transitions from one resource to another. When a customer has finished at resource i he moves to (requires) resource j next with probability P_{ij}. The arcs are labeled with these probabilities. The service time at each resource is assumed to be exponentially distributed. This is a closed system meaning that the number of customers in the system remains fixed. Gordon and Newell have found expressions for the equilibrium distribution of customers in service or queued at each resource. This allows one, for example, to calculate the utilization of the various resources.

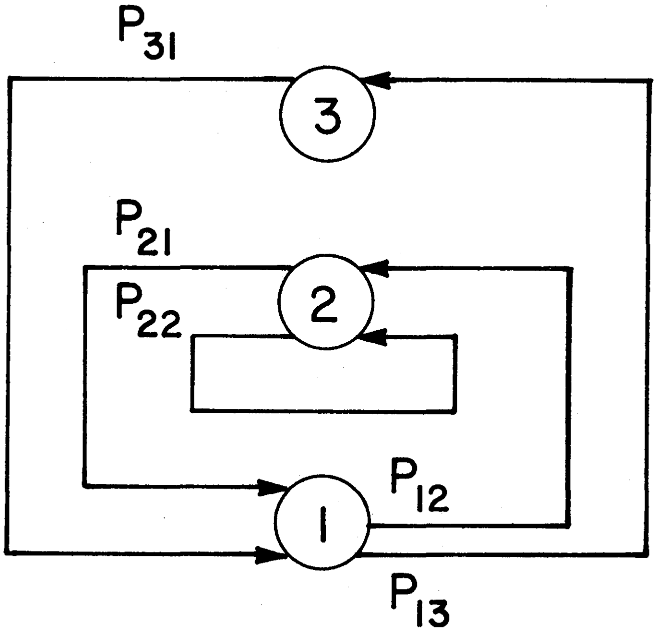

Figure 1—Example network of queues model

Moore[43] and Buzen[8] have applied this model to multiprogramming systems. Moore measured the MTS system to obtain the transition probabilities and mean service times of the resources and then used the model to estimate system parameters such as resource utilizations. The relatively close agreement to measured system parameters leads one to believe that the model can be used to predict the effect of some changes in system configuration. In using the model in this way, one must be careful that the proposed changes do not significantly affect the basic behavior of the customers. Buzen used the same model to gain insight into resource allocation in multiple resource models of computer systems. His studies include the investigation of buffering and the effects of paging algorithms. Both Moore and Buzen have used the model to try to give a meaningful formal definition to the term "bottleneck." It is of interest that they arrive at different definitions of a bottleneck. The reader is referred to the references for details.

While the studies mentioned above are clearly advances in the study of computer system models there are numerous open questions. For example, the model does not allow the representation of the simultaneous use of several resources such as memory and CPU. Also there is no means for representing the synchronization of events such as a process doing buffered I/O. Another limitation is that the customers in the system are assumed to have the same statistical behiavor, i.e., the transition probabilities and service time distribution are the same for all customers.

Bounds and approximations

Every evaluation technique makes use of approximations. These approximations may arise, for example: in estimating the system parameters, user and program behavior; or in simplifying the model of the system itself. There is clearly a tradeoff between types of approximations. By simplifying a model one might be able to handle more general types of user and program behavior. Much of the analytic work has been concerned with exact mathematical solutions to models which are themselves gross approximations.

An area which is beginning to be explored is that of approximate solutions to more general models. For example, Gaver has used the diffusion approximation for the analysis of heavily loaded resources in queueing studies.[20] The basic technique is to consider that the work arrival process is not the arrival of discrete customers requiring service but rather a work arrival flow. This work arrival flow is a continuous process with the same mean and variance as the original process. Another example of the use of approximations is the work by Kimbleton and Moore on the analysis of systems with a limiting resource.[34]

It is clear that the use of any approximation requires validation of the results. This may take the form of comparing results with measurements of an actual system, simulation, or obtaining bounds on the error in results. Bounds may also be applied in a different manner. Much has been written on the analysis of time-sharing scheduling algorithms and their effects on response times. Kleinrock, Muntz and Hsu[36] have reported on results which in effect demonstrate the bounds on response time characteristics for any CPU scheduling algorithm which does not make use of *a priori* knowledge of customers service times. The importance of the bounds is that one can see the limits of the variation in response characteristics that are possible by varying the scheduling algorithm and the extent to which these limits have been approached.

Program behavior

A major problem that must be dealt with in any evaluation effort concerned with computer systems is program behavior. Even when using approaches such as benchmarking or trace-driven modeling there is the problem of selection of programs which are in some sense representative of the total population of programs that will be run on the system.

Studies of memory management in particular have had to explicitly include models of program behavior. The early work in this area[2,12] stressed very general but powerful aspects of program behavior such as "locality" and "working set." More recent work deals with more explicit models of the generation of reference strings which assume more about program behavior but correspondingly allow for more detailed analysis.[13] It is hoped that these models will permit more detailed studies of multiprogramming and procedure sharing.

It is interesting to note that the bulk of this work has been directed toward finding models which can represent the universe of possible programs. More particular:y, the goals of this research have been to isolate parameters characterizing program behavior to which memory management is sensitive and to compare the effectiveness of various memory management strategies. This approach is in line with a common theme which runs through most of the work on resource allocation strategies in computer systems. That is, we see most allocation strategies attempting to work well over the total population of programs possibly utilizing measurements of recent past history of the process to predict the near future. Outside of work arising from graph models of parallel programs[5,6,51] very little has been done to utilize *a priori* information about a process. Many systems do make *a priori* distinctions between batch and interactive processes. It seems reasonable though that much more information may be available which would be useful in allocating resources. For example, it has been suggested that the time-slice and paging algorithm parameters be tailored to the process.[46] Use of *a priori* information assumes that the process is available for analysis prior to execution. This is a valid assumption for production jobs, system processes, and to some degree for all jobs at compile time. Since these processes consume a significant portion of the system resources, gains in efficiency in managing such processes might result in major gains in total efficiency. There are many open problems associated with this approach:

1. Is there a conflict with a program design goal of program modularity? How is information about separately compiled procedures to be combined?

2. Should processes be permitted to advise the system as to their resource needs? How does the system protect itself against false information?
3. How to manage resources effectively for processes which provide a priori information, and also for processes without associated *a priori* information?
4. What kind of *a priori* information is actually useful to management of a system: how costly is it to obtain and utilize effectively?
5. How predictable are the resource requirements of processes?

While this approach has received only some slight mention in the literature, it appears to be a fertile area for research.

Graph models of programs provide an abstraction of program structure governing flow of control and demand for resources.[51,10,18,22] They permit a representation fitting somewhere between the full detail of actual programs and parametric or stochastic representations of them. Most work using graph models has been concerned with *concurrent processing*. However, the graph model analyses explicitly reveal sets of independent tasks which become candidates for alternate sequencing *in sequential systems*.

Ideally, we search for models of systems and program behavior which provide principles guiding synthesis of configurations along with well founded resource management strategies. Measurement must validate effectiveness of such strategies. The diversity of computations further demands that measured parameters be provided to operating systems and users in order to permit adaptation to dynamic variations in system behavior and to unavoidable anomalies in systems and languages.

Studies during the latter half of the '60s showed how little attention had been given to measurability in the man-made universe of computer systems. The next section characterizes some of the problems in measurement.

MEASUREMENT OF INFORMATION PROCESSING SYSTEMS

Tools for measurement of computer systems must satisfy all of the following requirements: detection of prescribed events; recording of detected events; retrieval of accumulated records; data reduction; and display.

We comment on each in turn.

Detection

We start by rejecting the absurdity of observing all of the states of a system under observation since it would imply detecting the state of every input, every memory element and every output every time there was a change, along with the time at which the change occurred. Hence, any set of measurement tools must include means of selecting a subset of system states.

Hardware measurement tools provide a prescribed number of sensing probes which may be physically placed on selected register or buss points in a machine under observation. Measurement system registers along with programmed comparators and basic logical operations permit further filtering by allowing detection of a subset of the events sensed by the probes. Even with such filtering the rate of change of detected states may be excessive. If the response time of hardware measurement elements is insufficient, basic circuit changes would be required to make the measurement feasible. If bandwidth is insufficient, it is sometimes possible to introduce a sampling signal and thereby further reduce the number of detected events. *In the absence of interaction with software monitor programs, a hardware monitor is clearly limited in its utility.* To be convinced of this, one need only consider the kind of program status information change which is observable by probes only when it appears in the form of an operand during the course of computation. Hardware detection can have the virtue of introducing no artifact into the measured system and of being able to detect events whose states are not accessible to measurement programs. Sampled detection may be made more effective by allowing interference with the observed process. If a sampling signal enforces a proper interruption, observed data may be sequentially sensed by detection circuits. The recently reported "Neurotron" monitor[1] is the most interesting implemented hardware monitor, and its design shows the foresight of enabling interaction with software monitor programs.

Software measurement tools consist of programs which detect selected events by virtue of their insertion at state-change points in the sequential computational process.[17,47,31] This detection process introduces artifact in execution time, in space required for measurement program storage, and sometimes (e.g., synchronization with asynchronous cyclic processes) in qualitative side effects on existing computational processes. In a sampling mode, measurement programs can have their in-line artifact reduced by disturbing the flow of computation only at a sampling time. At a sampling time, measurement programs may be brought in to check as large a set of memory states as is needed and then control is returned to the observed system. In the absence of hardware support, a software monitor is limited to observation of those system states which have affected memory contents. In one case, careful analysis of measurement of PL/I functions of an IBM 360/91[50] revealed anomalies in recorded system states which can best be characterized as artifact introduced by OS/360 when it inserts code associated with I/O interrupts into the code being measured.

It has become clear that we are not faced with mutually exclusive alternatives of hardware detection tools or software detection tools. Rather how much of each; how they are integrated; and how they are made available to experimenters. A paper by Nemeth and Rovner[45] presents a pleasing example of the power of combined hardware and software in the hands of a user. They point out that facilities introduced for hardware debugging are often the kind useful in later program measurements.

Recording

If an event of interest has been detected, its occurrence must affect memory contents. Such action may be as simple as incrementing a counter or as complex as storing a lot of state information for later analysis. In the case of nondisturbing hardware measurements, external storage must be provided and the transfer rate must be able to keep up with the rate of change-of-state information observed by a set of probes and associated circuits. In the case of software measurements, sufficient memory space must either be provided to record all relevant state information, or else preprocessing reduction programs must be called in to reduce storage requirements.

Retrieval

In the construction of any large system, both a data gathering and retrieval system must be incorporated into the basic design. Failure to do so will limit the amount of instrumentation available later when efficiency questions arise. For example, in a large programming system which has transient program segments, data gathering is easily inserted into any program segment; however, unless a standard data storing program is available, the data gathered cannot be easily retrieved. The IBM PL/I F-level compiler is an example of a programming system broken into transient program segments. It fails to have a data storing program with adequate bandwidth to support meaningful measurement activity.

Data Reduction

The amount and kind of data reduction is determined by the goal of the measurement experiment and limitations of measurement tool capabilities in detection, recording and preparation for retrieval. For example, assume that we want to obtain a history of utilization of routines in order to decide which should be kept in primary storage and which should be kept in backup storage. Assume, further, that every time a routine is called: the name of the called routine, the time of day, and the name of the user is recorded. It would not be very meaningful to generate only a history showing the times at which each routine in the system was used by each user. Data reduction would be required to determine, for example, the total number of such uses, an ordering of routines by number of uses, a determination of the number of routines involved in, say 50 percent, of the uses and their names, etc.

Display

The goal of the data reduction process is defined by the specified form of display or feedback to the experimenter. If measurement is being made for feedback to an operating system for use in resource allocation, parameter values must be delivered to memory cells to be accessed by the operating system. If measurement is made for accounting purposes or, more generally, to provide the user with feedback about his quality of use and system response, results should be merged into user and system manager files. If measurement is made for operator control and management, simple alphanumeric displays are common. For experimental analysis of system behavior, CRT displays, graphs and computer printout are generally required.

Measurement Methodology

The complexity of computer systems dictates special care in the planning of measurement experiments. If the results of experiments are not reproducible, they are of little value. If any assumptions made are not recorded and validated, the results cannot be generalized and applied at another time or place. A large body of statistical theory is available providing methods for abstracting properties out of individual data points, but applicability must be carefully checked. We have little hope of adhering to principles if we do not have a measurement language to prescribe measurement experiments as sequences of commented operations which are appropriately integrated with observed data. The latter step needs wait upon creative development of measurement tools and their test in meaningful experiments. Measurement capability must be explicitly included during periods of system design and must be available for inclusion in user program design. Digital computer systems and programs are properly characterized as complexes of very elementary functions. Full systems or programs, therefore, generally require partition in order to manage the synthesis process. Each partition introduces possible measures of validity of output, of performance and of cost. Means for measurement should be checked at that point in design and a value judgment made if excessive artifact would be introduced by the measurement process.

If a system contains the structure and primitive operations satisfying the five requirements discussed in this section, it carries the tools for adaptability. We conjecture that much more than the 10 percent to 50 percent improvement alluded to in the Introduction becomes attainable—particularly when measurement tools can influence user behavior.

COMPUTER POWER AND USER INTERFACE

In the seventies some stronger effort must be directed toward increasing computer power by a reduction of the complexity of the user interface.

Operating systems and **H**igher **L**evel **L**anguages are tools designed to give the user control of the portion of a computer system he needs. With the exception of work done at SDC,[28,29] little reported effort has been devoted to the human engineering aspects of these tools. During the last decade, while hardware made a dramatic increase in power, the management tasks required of the operating system increased from trivial to highly complex. At the same time, the users were required to supply (in unnatural form like JCL) more of the parameters which would allow effective management decisions to be made by the operating system. These user-supplied parameters have increased the burden of complexity at the user interface—and reduced the amount of useful work a user can accomplish in a given period of time.

For example, much of the attraction of APL/360 is its simplification of the operating system interface along with the addition of immediate execution of its concise powerful primitives. A batch oriented FORTRAN user perceives this as a tremendous increase in his computer power. A more sophisticated user might see APL as a powerful desk calculator which provides immediate access to functions similar to functions he already commands, less accessibly, in other languages.

Another user interface problem exists at the level of higher level languages. As more advanced hardware becomes available to the user, he seeks to solve more complex problems. When a problem grows beyond a manageable point, the user segments the problem into pieces plus associated linkages. In doing so, however, he introduces a new set of communication problems; a change in one program which affects an interface can now wreak havoc in another "completed" portion of the problem solution. Higher level languages have been lax in the types of program interconnections (and interactions) allowed.

An example of the problems of creating a large programming system are reported by Belady and Lehman using data from the development of OS/360.[4] While this study concerned programs written in assembly language for the IBM 360, the properties which produce the error rates and modification ratios reported in their paper are characteristics of all large programming systems today.

Several techniques for improving the probabilities that a program can be made error free are available in the literature. One of the earliest is Dijkstra's "Notes on Structured Programming,"[16] and also "THE Programming System."[15] His system breaks the problem into shells of "pearls" or "primitive" operations. Each shell is built using the "primitives" of the next lower level. This system attempts to minimize interactions, forces the programmer to produce generalized functions which can be tested, and allows easy instrumentation because of the segregation of functions.

Some disadvantages of such a hierarchical scheme make its practical application difficult. Such a scheme increases initial development time because it forces developers to completely understand the structure of the system being built and to predefine the proper function for each hierarchy. Transitions between levels may be costly. Functions at the lowest level are the most general and, therefore, the most frequently used. Small inefficiencies in these functions, or in the method of traversing levels of the structural hierarchy, magnify costs dramatically and force the user away from centralized functions. This defeats the original purpose of the organization.

Another disadvantage of a hierarchical scheme is that while instrumentation of the system is easy, interpretation of the measurements is generally not. Measurement results could change drastically if the organization of the program were modified. Therefore, it is hard to tell how much of what goes on is due to the structural hierarchy and how much is due to the intrinsic properties of the program. Such knowledge points a way toward improvement.

Figure 3a—Most frequent PL/C errors

Present studies of forced program structure and program proofs of correctness may begin to provide models on which HLL designers may base their proposals. However, any major changes should be designed to improve the user's system so that each program submittal can be a learning experience. In this way a programming system can be called upon to point out unusual events; draw the programmer's attention toward possible errors; and yet, not produce volumes of output which would be costly to print and which a programmer would refuse to read.

Work at Cornell toward producing compilers which correct human failings rather than punish them has culminated in a highly functional, rapid compiling, and very permissive PL/I student-oriented compiler called PL/C.[44] This compiler does spelling correction of keywords, automatic insertion of missing punctuation, etc. In addition automatic collection of some statistics is done at execution time. For example, each label causes a count to be maintained of the number of times execution passed through that labeled statement. Compilers such as these increase computer power by reducing the complexity of the user interface.

Implementations of HLLs could further help a programmer by giving an optional cross reference listing showing locations where a variable is changed, could be changed, or just referenced. Items could be flagged if they were never referenced or set; only referenced; or only set. In the first two cases spelling correction might be applicable. Statements which use expensive library subroutines or other costly language features could be flagged. Measurement nodes could be easy to insert and operate. These should, in turn, produce meaningful data which relate directly to questions the programmer wanted to ask.

But such discussions have only beat around the bush itself. The real problem, the bush, is the higher level language. The real questions are: What features are error prone? What features of the language allow automatic validity checking of what is written? How can these properties be identified and measured? How can the knowledge of these things be used to reduce complexity of the user interface so that the user perceives an increase in his computer power? Which language constructs are seldom used, adding unnecessary complexity and unreliability?

Efforts to measure the human engineering aspects of computer language use[37] and to provide feedback

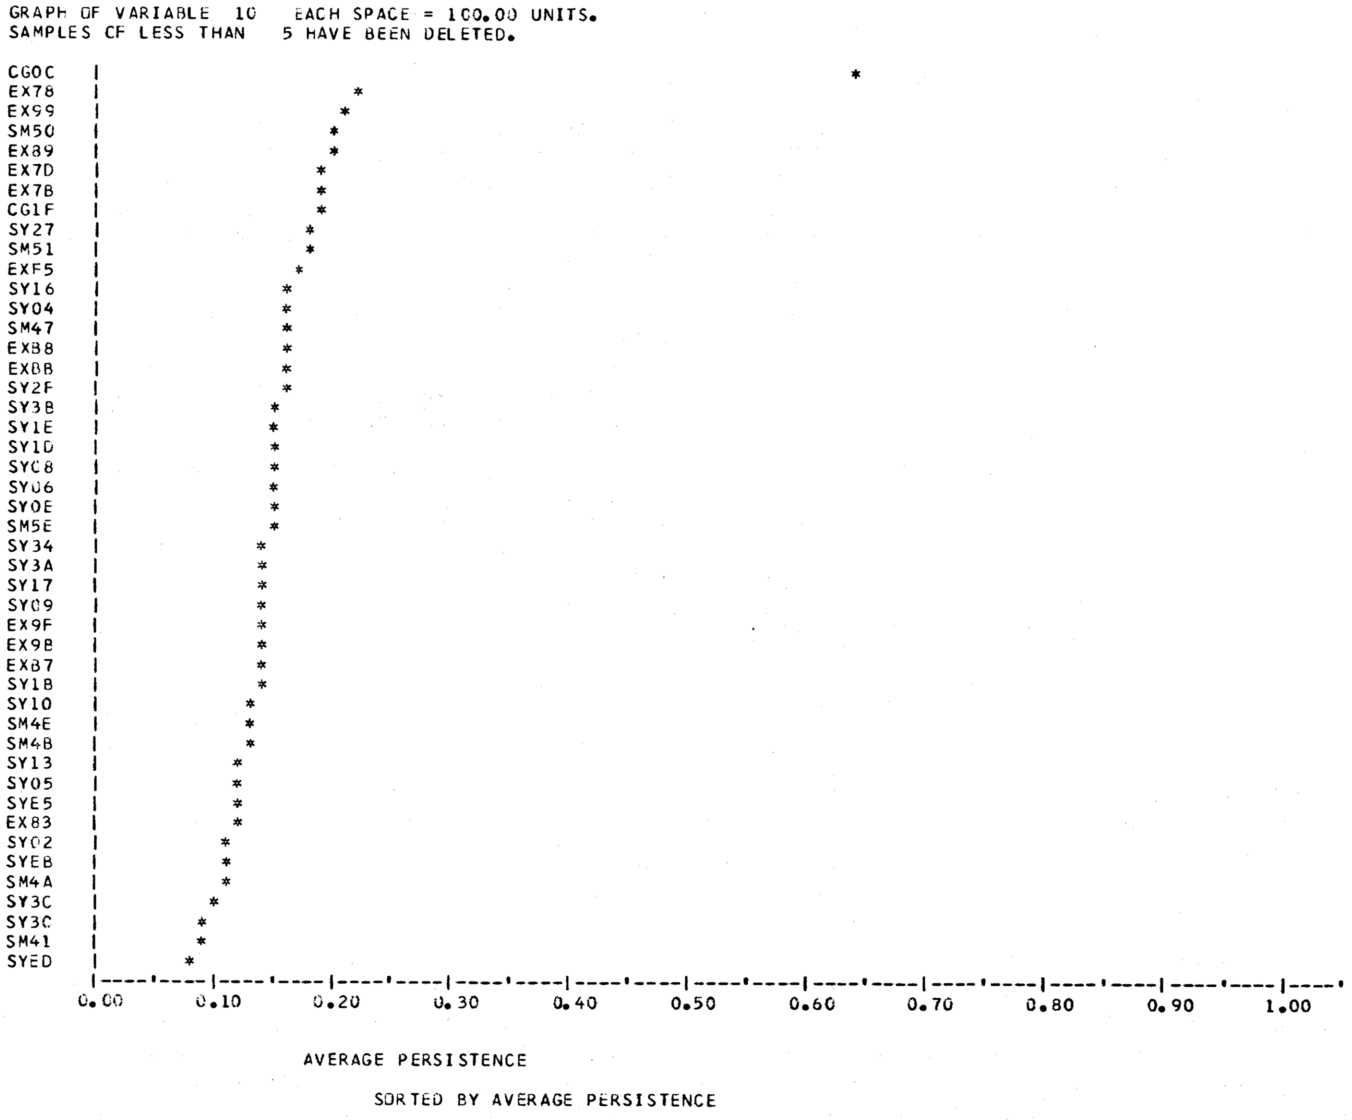

Figure 3b

into the design stages of higher level languages and the control and command languages of the operating system may provide major increases in computer power by:

- increasing the number of users who can bring problems to the machine
- decreasing the number of problem submissions necessary to bring a job to completion

Work is in progress at SDC,[28,29,48] moving toward a man-machine symbiosis. These little publicized approaches to measurement of human problem solving and computer languages have just begun to scratch the surface of this very important area. Work at UCLA has attempted to identify properties of PL/I which are prone to human error. As a first approximation, error rates and persistence curves of various errors identified in students' use of the IBM PL/I F-level compiler[30] is presented in Figure 2. Corresponding results for errors found by Cornell's PL/C compiler are presented in Figure 3. Figure 2a shows a table of the number of occurrences of the most frequent PL/I error types recorded during compilation and during execution times. Figure 2b displays the persistence of errors by PL/I type during the student runs. The vertical coordinate is the error type ordered by the magnitude of PERSISTENCE RATIO. The horizontal coordinate is the PERSISTENCE RATIO and was calculated as an average of (number of sequential trials during which the particular error persisted) divided by the total number of trials. If an error type did not occur in at least 5 problem assignments it was arbitrarily deleted to keep the displayed range of values reasonable. Figures 3a and 3b display the same properties for assignments using PL/C. A total of 128 problem assignments completed by 28 students are included in the statistics. Follow-up work is intended to lead more deeply into language design and hopefully into new techniques for automatically localizing errors in a program.

The basic technique for doing this is to allow the programmer to specify more information than the HLL processor needs to compile the program. An example would be identifiers of the form "CONSTANT" in a PL/I data attribute syntax. CONSTANTs as opposed to variables, would only be set by an initial attribute and would be illegal as a left-hand side of an assignment or as an argument of a pseudo-variable. In addition, the program could be considered as having this attribute. At several points in a program (e.g., block exit time) these constants would be checked to see if their value had changed. If any had, a warning would be printed; the correct value restored; and the program would continue. Such a new PL/I data type allows automatic checking for consistency to localize errors and yet is almost painless for a programmer to use. When a program is debugged, it is easy to turn off this kind of checking for the sake of more efficient performance. In a hardware environment like the MULTICS GE 645, these errors can be detected dynamically when illegal accesses occur.

Debugging tools should be designed into the language and taught as part of the language, because the majority of the time a programmer deals with a language, he is also dealing with an incorrect program. Subscript checking, trace information, validity checking at periodic intervals, time and count information, formatted displays of all program information and selective store and fetch recording are the kinds of things which should be available to the HLL programmer.

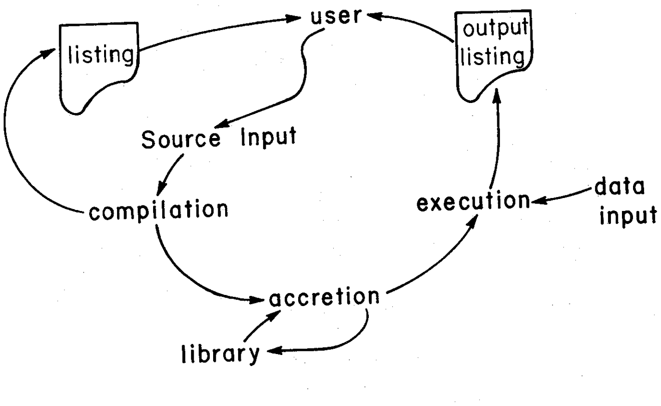

Figure 4a—Information flow in a standard HLL job

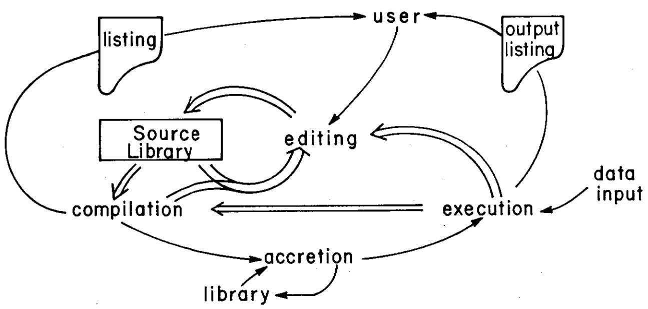

Figure 4b—Modified information flow to augment feedback in a HLL job

In addition, measurement tools should be immediately accessible to any user without burdening others, so that if questions of efficiency are raised they can be answered simply and quickly. Some of the measurement tools which seem important are: (1) flow charts or tables as optional output which would stress intermodule dependencies; (2) time and count control statements which could be output, reset and inactivated under program control, and would create output automatically if the program terminated abnormally or without expressly outputting the data gathered; (3) program size should be easily accessible by the program dynamically and summaries of available space should be available at program termination.

In order to increase the complexity of the programming problems which users can handle, languages must be allowed to accommodate personal ways of expressing concepts. To do this, at the very minimum, new data types should be available for the programmer to define as well as operators which use these data types. This begins to syntactically approach the Dijkstra concepts and to allow easier application of hierarchically structured programs. Hopefully these approaches will increase the user's computer power by making the development of his programs easier.

The programming system itself should be restructured so that more information is available to a HLL processor. Figure 4a shows the diagram of information flow in a usual batch oriented system. The source code is compiled; the resulting object code is passed to the accretion step where library or previously compiled programs are added to it; and the resulting load module is passed to the execution phase; finally, output from execution is passed back to the user. To provide more automated feedback, Figure 4b shows information flow in a system where statistical summaries of one execution are available to the next compilation. In addition, the accretion step spends much more of its time checking linkage conventions and the validity of argument-parameter choices. This programming system has an edit/compile time library which is designed to help make changes easy. For example, it keeps "COMMON" declarations uniform (read EXTERNAL if you are a PL/I programmer) and it also uses information from the compiler to point the user at syntax errors and information from the execution phase to point the user at semantic errors.

Such modifications can reduce errors and speed the development of programs by improving communication between what are now considered separate program steps. However, the most important changes, across all the proposed modifications, are those changes which will allow the programmer to receive only those pieces of information relevant to the level at which he is programming (i.e., making changes). This would provide dynamic help; help where the programming language acts as an extension of the users' mind to assist in problem solving and optimization.

It is important to view these changes which move toward dynamic assistance in terms of costs. Each change must cost something in execution time overhead. Some of the more powerful features like selective fetch and store monitoring must be expensive. However, if these features were found valuable, then modification to hardware might diminish costs dramatically. Integrating these techniques into HLLs must be inherently costly because implementation and testing of human interaction with these diagnostic features are difficult to execute in any controlled way—much work must rest on subjective evaluation of users' behavior. Integration of aids into HLL translators must be initially done without those very aids which are deemed necessary to help programmers modify programs. Therefore, any change is fraught with risks caused by lack of checks in current systems. Obviously bootstrapping is called for and we can expect many passes before achieving effective tools.

The development of richer higher level languages on the one hand, and the development of debugging services and error correcting compilers on the other, exert forces in the direction of increasing performance at the user interface. With appropriate use of models and measurement much more improvement may be obtained.

SUMMARY

Computer systems are different from other systems by virtue of the dynamic fashion in which our comprehension of their behavior may be built into their operation. If validated models are developed, they may then be built into the system itself to serve adaptive resource allocation algorithms. If measurement tools are effectively integrated, they may be made available to the user to improve the quality of his use of programming languages. If the user is, in fact, a team developing programming systems, the modeling and measurement facilities may serve to make much more complex programs possible because a model of programs being built is, itself, generally too complex for a group of unaided humans to manage in an error free way. In the above paper we have sought to open up these questions.

We have not had much experience with effective modeling and measurement. There is an immense amount of data to be observed in a computer system. Cost-effectiveness of performance measurement must be considered. As one of our reviewers put it, "This reviewer has seen some measurement studies lead to system improvements which will pay off sometime in 2018." Hopefully the 1970s will see more effective modeling and measurement introduced into the design process and selectively carried into developed systems to he`p both interna! process management and the enrichment of external usↄ through the user interface.

INTRODUCTION

In a memory hierarchy various storage devices are structured into various levels. By convention, information at storage level i may be accessed and stored in less time than information at storage level $i+1$. Since a smaller access time generally implies a greater cost per bit of storage, storage level i will generally be smaller than storage level $i+1$. An example of such an arrangement with four levels is a system with core, drum, disc and tape memory devices.

A storage level is called *directly addressable* if the information stored at that level may be utilized by the processor directly, without first being moved to another level. For example, in the core, drum, disc, tape hierarchy only the core memory is directly addressable, since information at the other levels must be moved into the core before it can be used by the processor. If a memory hierarchy contains two or more directly addressable storage levels, then these levels may themselves form a directly addressable hierarchy.

Recently a device called "large-core storage" has come into use. This device utilizes the familiar principles of core operation, only it is designed to have a greater access and cycle time, and consequently it is less expensive per bit. This allows a larger memory to be built for a given cost, so that large-core storage may be considered as a replacement for drum memory in a storage hierarchy. A four-level hierarchy might be formed using core, large-core, disc and tape. In this case storage levels 1 and 2 would form a directly addressable hierarchy.

Let us consider this directly addressable hierarchy in more detail. Information in the large-core store can be accessed in one of two ways. It can be moved from large-core to core (as if the large-core were not directly addressable), and then accessed from the core. Alternatively, the information can be accessed directly in the large core. Assuming that the information is moved in fixed-size units called pages, the following question presents itself: should a page be moved from large-core to core when it is needed, or should it be addressed in the large-core directly?

Algorithms which attempt to resolve this question will be considered below. Such an algorithm will be called a *page promotion procedure*, since its function is to promote a page to a more favorable position in the memory hierarchy. Although the following discussion will be in terms of a core, large-core hierarchy, some of the results might be applied to any directly addressable hierarchy with two or more levels.

In a way this question resolves itself quite simply. There is a certain overhead associated with moving a page from large-core to core. However, once a page has been moved it may be addressed by the processor in a shorter time. Thus a page should be moved if it is addressed often enough that the shorter access time of the core more than defrays the overhead costs associated with moving the page. In other words, those pages which are addressed more often (termed the more

active pages) should be moved. The problem is to determine which pages are the more active.

Algorithms which detect the high activity pages may be divided into two types. Algorithms of the first type simply assume that page activity is known prior to processing. This is a reasonable assumption for programs of known characteristics. For example, it may be known that certain pages in a compiler or in an operating system are more active than are others. This approach has been implemented by Vareha, Rutledge and Gold[3] at Carnegie-Mellon University, and by Freeman[1,2] at the Triangle Universities Computation Center.

Algorithms of the second type depend upon the statistical properties of page activity, although they assume no *a priori* knowledge of the activity of any particular page.* Such an algorithm must be used when a program is not run often enough to become "known" in the sense of the first approach discussed above. Even when a program is known, algorithms of this second type may still be effective and may be simpler to implement. The page promotion procedures to be studied below are algorithms of this second type.

In the next section we will introduce some experimental data concerning the page activity of several programs. The two sections following this are devoted to an analysis of page promotion procedures. In these two sections, the experimental data will be used to test the effectiveness of the procedures.

EXPERIMENTAL DATA

In the previous discussion it was tacitly assumed that certain pages of a program will be addressed more often than will others. If this is not so, then the page promotion procedure is pointless. We will now present some experimental evidence which shows, at least for several programs, that some pages are indeed addressed more often than are others.

We consider the behavior of four programs, each of which addresses memory for both instructions and data. Let J be the number of pages addressed, and let N_j be the number of times page j is addressed ($j=1, \ldots J$), where a page is addressed either to access information or to store it away. For each program there are two sets of J and $N_1, \ldots N_J$ defined, one for instruction pages and one for data pages. Let the pages be numbered so that $N_j \leq N_{j+1}$ ($j=1, \ldots, J-1$), and define $N=N_1+N_2+\cdots+N_J$. Some of the properties of these four programs are summarized in Table I.

For a given program consider the x percent of the pages (either instructions or data) which are the most active. We wish to determine the percent of the total activity which these pages account for. Since $N_j \leq N_{j+1}$, this can be obtained as:

$$\text{Percent of Pages} = 100(k/J),$$

$$\text{Percent of Activity} = 100 \sum_{j=J-k+1}^{J} N_j \Big/ N,$$

where $k=1, 2, \ldots J$.

Figure 1 shows this result for the instruction and data pages of the four programs studied. Note that some pages are much more active than are others. Typically, the 50 percent of the pages which are the most active account for about 95 percent of all the activity. Thus, at least for these four programs, it is apparent that a page promotion procedure could be effective, if one can be devised. We will now discuss one such algorithm.

A SEQUENCE-INDEPENDENT ALGORITHM

For a given program, suppose that all of the pages are in large-core storage at the start of processing. Each time a page is addressed, assume that there is a fixed probability P that the page will be moved from large-core to core. Once a page has been moved, assume that it remains in core storage until processing is finished.

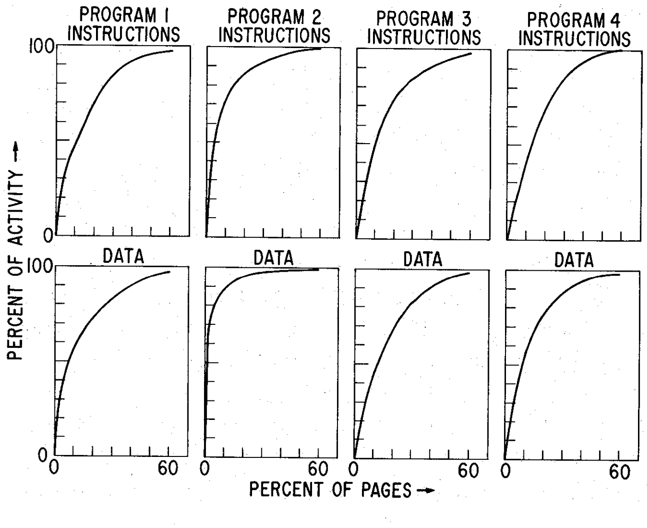

Figure 1—Page activity of the most active pages

* It might be noted that this classification of algorithms has an analogue in other resource scheduling problems. For example, in queueing theory the shortest-remaining-processing-time discipline requires an *a priori* knowledge of the processing time of each job; while the round-robin discipline achieves its effect due to the statistical properties of the distribution of processing times, with no *a priori* knowledge of the processing time of any particular job.

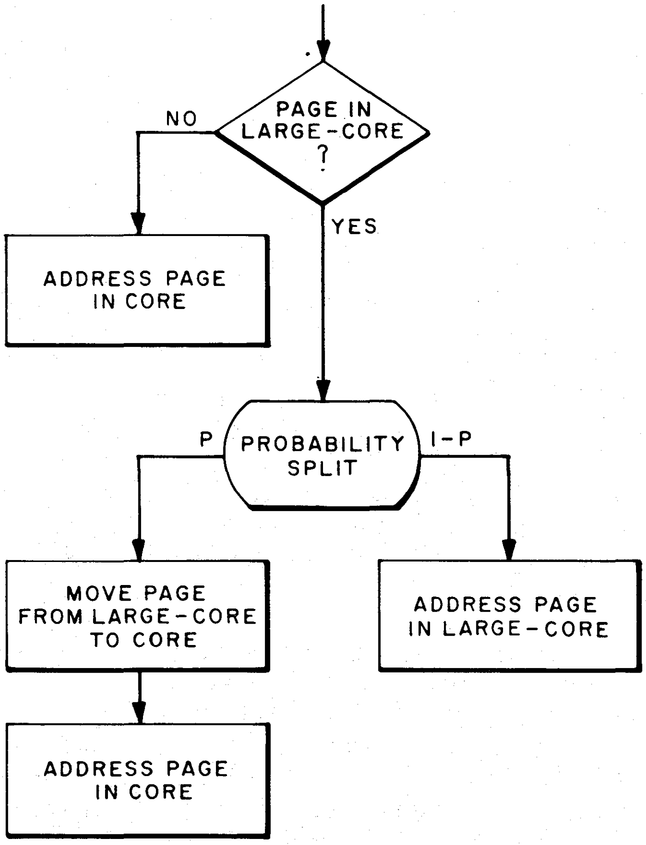

Figure 2—Sequence-independent algorithm

This, in brief, is the sequence-independent page promotion procedure which will be studied below. A flow chart of this algorithm is shown in Figure 2.

This algorithm is called "sequence-independent" because it acts on each page in a way which is independent of its action on all the other pages, so it does not depend upon the particular sequence in which the pages are addressed. This aspect will be considered in more detail when we discuss "sequence-dependent" algorithms below.

From a hardware standpoint, the implementation of the sequence-independent algorithm should be relatively straightforward. Suppose that we have a page-oriented machine which supports a translation between virtual and real page addresses. Then whenever a byte of any page is addressed, this translation function must be performed. At that time, a real-address limit comparison may be made to determine if the page is in large-core storage or core storage. If the page is in large-core, the output of a random number generator may be obtained from a special register. Assume that this output has a uniform distribution between 0 and 1. Then if the random number is between 0 and P, the page may be marked to be moved from large-core to core. This may be done by generating a page-fault interrupt and temporarily suspending the program using the page, just as if the page were on a drum or disc. While this is taking place, the random number generator may place a new number (independent of the previous one) into the special register. It should also be possible to place the probability P under program control, perhaps by keeping P in another special register.

It is clear that this algorithm will tend to detect the higher activity pages in the following sense. Given that a page is addressed more often, it stands a greater chance of *eventually* being moved from large-core to core. However, when it is moved, most of the addressing of the page may have already taken place. While it is clear that the algorithm will tend to tell which *were* the most active pages, it is not clear that it will indicate this while they still *are*. In other words, the algorithm itself must use the activity of the pages to select those pages with the higher activity. Thus there is a danger that the algorithm will "use up" the activity in the selection process, leaving little or none remaining after the page is selected. For any particular program, this question can be answered by the analysis to follow.

For a given program, suppose that page j is addressed N_j times, each time using the page promotion procedure described in Figure 2. Define:

λ_j The expected number of times page j is addressed in the large-core storage.

ϕ_j The probability that page j will not be moved from large-core storage to core storage.

It will be shown in Appendix I that:

$$\lambda_j = [(1-P)(1-(1-P)^{N_j})]/P,$$

$$\phi_j = (1-P)^{N_j}.$$

For the arbitrary program in question, we further define:

PA The expected percent of the N times that memory is addressed which will be directed to core storage.

PP The expected percent of the pages which will be moved from large-core storage to core storage.

Since the algorithm acts upon each page in an independent fashion, it follows that:

$$PA = 100\left[N - \sum_{j=1}^{J} \lambda_j\right] \Big/ N,$$

$$PP = 100\left[J - \sum_{j=1}^{J} \phi_j\right] \Big/ J.$$

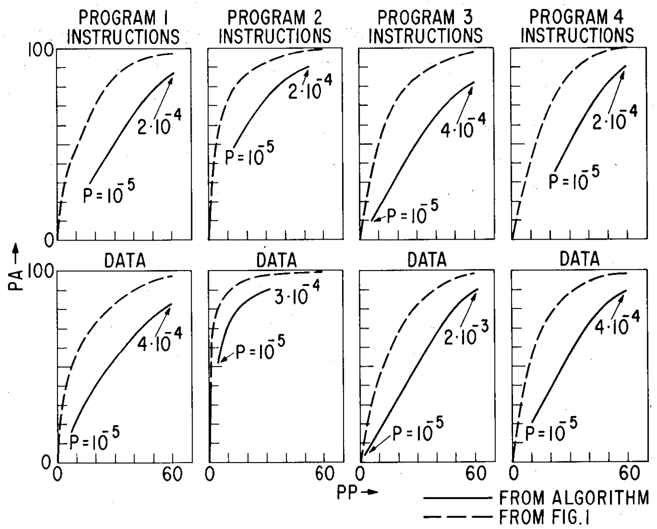

Figure 3—Effect of the sequence-independent algorithm

At the start of processing all the pages of a program are assumed to be in large-core storage. The page promotion procedure will cause a certain number of these pages to be moved from large-core to core. The expected percent of the pages which will be moved is *PP*. Because these pages are moved, a certain percent of the *N* times that memory is addressed will be directed to core storage. The expected value of this percentage is *PA*. We are willing to move a certain percentage of the pages from large-core to core, i.e., we are willing to accept a certain value of *PP*. For this value, we wish *PA* to be as large as possible. The value of *PA* will be increased by the extent to which the more active pages are selected soon enough.

Suppose that we are willing to move x percent of the pages from large-core to core. Then any random selection of x percent of the pages would account for an expected x percent of the activity. Thus a page promotion procedure in which $PA = PP$ is really useless, while one in which $PA < PP$ is less than useless.

Suppose that we are willing to move x percent of the pages from large-core to core, and that we know the activity of each page prior to processing. Then we would simply move the x percent of the pages which are the most active. For the four programs discussed in the previous section, Figure 1 shows the percent of the total addressing activity which would be directed to the core memory. For these programs, Figure 1 also provides an upper bound on the value of *PA* obtainable from the page promotion procedure for any given *PP*.

Applying the above equations for *PA* and *PP* to the data for the four programs discussed in the previous section, we obtain Figure 3. Since the performance of the page promotion procedure can be varied by changing the value of the probability *P*, various points on the curves are obtained by using various values of this parameter. The data from Figure 1 is also included in Figure 3, in order to compare the best possible performance of the procedure with the expected performance.

Various conclusions may be drawn from Figure 3. As an example, if we are willing to move 50 percent of the pages from large-core to core, then:

(1) By random selection of the pages prior to any processing, we could expect 50 percent of the addressing to be directed to core storage.
(2) Using the page promotion procedure, we could expect about 80 percent of the addressing to be directed to core storage.
(3) If we had perfect knowledge of the page activity prior to processing, we could expect about 95 percent of the addressing to be directed to core storage.

In this sense, the page promotion procedure is about $(80-50)/(95-50) = 2/3$ as effective as it possibly can be (when operating in the range of $PP = 50$ percent, on the four program studied). For smaller values of *PP*, similar conclusions could be drawn. However $PP = 50$ percent is an interesting value, since it reduces the page traffic between large-core and core by one half, and since at this value *PA* is about 80 percent, which is large enough to be of interest.

We note that *PA* and *PP* are expected values, so there is no reason to believe that the page promotion procedure will produce these values on any particular run of any particular program. However, it is assumed that a system using this procedure would process a large number of jobs. Thus, on the average, the specified values of *PA* and *PP* could be achieved.

A SEQUENCE-DEPENDENT ALGORITHM

Suppose that we modify the algorithm of the previous section in the following way. Let us replace the constant probability *P* by a probability P_k which is a function of k, the number of pages already moved from large-core to core. Such a modification would not be difficult to implement, since we have already assumed that *P* can be placed under program control. Such an algorithm will be termed *sequence dependent*, since the algorithm depends not only upon the number of times each of the various pages is addressed (the $N_1, N_2, \ldots N_J$), but also upon the sequence in which the pages are addressed as well.

In particular, we shall be interested in the sequence-dependent algorithm in which:

$$P_k = \begin{bmatrix} P & k=0, 1, \ldots, K-1 \\ 0 & k=K \end{bmatrix} \qquad (1)$$

This algorithm operates just like the sequence-independent algorithm until K pages have been moved from large-core to core. At this point the procedure simply shuts down, and no more pages may be moved. We are interested in this algorithm because it guarantees that no more than K pages will be moved from large-core to core. With the sequence-independent algorithm there is always the possibility that most or even all of the J pages will be moved. Let us now consider the extent to which this guaranty degrades the performance of the original sequence-independent algorithm.

In studying the sequence-independent algorithm it was only necessary to know the J integers N_1, N_2, $\ldots$, N_J, which are the counts of how many times the various pages are addressed. In order to study the sequence-dependent algorithm, it might appear that we must know the sequence in which the pages are addressed. This sequence could be characterized by a sequence of N integers, where integer n ($n=1, \ldots, N$) is j ($1 \leq j \leq J$), indicating that page j is the object of memory reference n. Using this approach, we could take the characterization of any particular sequence and find expressions for PA and PP.

An alternative approach would be to proceed as follows. For a program with a given N_1, N_2, $\ldots$, N_J, there are

$$N!/(N_1!\,N_2! \cdots N_J!)$$

different sequences in which the pages may be addressed. We shall establish that one of these sequences (called the *MIN* sequence) causes PA to take on its smallest value. If we can show that the sequence-dependent algorithm will still perform well under this sequence, then we can be assured that the algorithm will perform at least as well under all the other possible sequences.

There are several advantages to this second approach. One advantage, of course, is that less data is involved in the analysis of any particular program. To characterize a sequence we need N (the number of times addressed) data points, while with this second approach we will need only J (the number of pages).

There is a more fundamental reason for preferring this second approach. If the sequence-dependent algorithm were analyzed for one specific sequence, then we would have to consider the possibility that a slight change in this sequence might affect the performance of the algorithm. By showing that the algorithm will work across all possible sequences, we are depending upon a program property which is somehow less "fragile" than the addressing sequence, namely the addressing counts $N_1, N_2, \ldots, N_J$.

Let us now discuss the *MIN* sequence. Suppose that we have a sequence-dependent algorithm of the type specified by Equation (1), with given values for P and K. Consider a sequence of the following type: each time a page is to be addressed, the page is selected so that no other page has fewer remaining times to be addressed. Intuitively, with this sequence there is the greatest probability that the algorithm will move those pages with the least remaining activity. Since by convention $N_j \leq N_{j+1}$, one such sequence of this type is the one in which all of the addressing of page j is performed prior to any of the addressing of page $j+1$ ($j=1, 2, \ldots, J-1$). This particular sequence will be called the *MIN* sequence. In Appendix II we will show that of all the possible sequences with a given $N_1, N_2, \ldots, N_J$, the *MIN* sequence does indeed minimize PA.

We now wish to find expressions for:

PA^* The value of PA (the percent of the addressing activity directed to core storage) when the sequence-dependent algorithm is used with the *MIN* sequence.

PP^* The value of PP (the percent of the pages moved from large-core to core) when the sequence-dependent algorithm is used with the *MIN* sequence.

In the *MIN* sequence all the addressing of page j is performed at one time—just after the addressing of page $j-1$ has been completed and just before the addressing of page $j+1$ begins. We therefore define the following for the *MIN* sequence:

$R_{j,k}$ The probability that core storage contains exactly k pages just prior to the time that the addressing of page j begins.

$\lambda_{j,k}$ The expected number of times that page j is addressed in the large-core storage, given that core storage contains exactly k pages just prior to the time that the addressing of page j begins.

$\phi_{j,k}$ The probability that page j will not be moved from large-core storage to core storage, given that core storage contains exactly k pages just prior to the time that the addressing of page j begins.

It then follows that:

$$PA^* = 100\left[N - \sum_{j=1}^{J} \sum_{k=0}^{j-1} R_{j,k}\lambda_{j,k}\right] \bigg/ N, \qquad (2)$$

$$PP^* = 100\left[J - \sum_{j=1}^{J} \sum_{k=0}^{j-1} R_{j,k}\phi_{j,k}\right] \bigg/ J. \qquad (3)$$

From Appendix I we know that:

$$\lambda_{j,k} = [(1-P_k)(1-(1-P_k)^{N_j})]/P_k,$$

$$\phi_{j,k} = (1-P_k)^{N_j}.$$

The probabilities $R_{j,k}$ may be computed by an algorithm to be developed in Appendix III. Using this algorithm and the above four equations, PA^* and PP^* may be determined.

Although this method may be used to compute PA^* and PP^* for any sequence-dependent algorithm, we will limit our interest to the algorithm specified by Equation (1). Thus each time a page in large-core storage is addressed, there is a probability P that the page will be moved to core storage. When K pages have been moved, the promotion procedure will be terminated and no more page movement will take place.

To use this procedure the parameters K and P must be set. To set K let us suppose that there is a certain maximum percentage of the pages which we wish to move from large-core to core. Let this percentage be called PP_{MAX}. Then:

$$K = [PP_{MAX}/100] \cdot J. \qquad (4)$$

Consider now the problem of setting P. Suppose that we wish to set P so that PP^* will be about 50 percent. For the four programs that we have studied, the value

$$P = 100/N \qquad (5)$$

has been found to be satisfactory. When N (the total number of addressing references) is larger, then P must be smaller to achieve the same effect. If N is not known, then, of course, P cannot be set by an equation such as (5). If a program is to operate for a given time slice, then N is known. In other cases, it may still be possible to set P by some adaptive process, while monitoring the performance of the system. Further, some fixed value of P may produce good overall performance, since it is not necessary for the algorithm to perform satisfactorily for any particular program, but only on the average.

Assuming the MIN sequence for the four programs, Table II shows the result of using the sequence-dependent algorithm specified by Equation (1) with the parameters set by Equations (4) and (5). For comparison, Table II also shows the result of the sequence-independent algorithm, which may also be interpreted as the sequence-dependent algorithm with $PP_{MAX} = 100$ percent. We see that at $PP_{MAX} = 60$ percent there is little degeneration of performance over the sequence-independent algorithm (i.e., little decrease in the value of PA^* over PA), while at $PP_{MAX} = 50$ percent the degeneration is significant. Using the mean of the results for the four programs, we see that with the sequence-dependent algorithm we can expect to move 45.2 percent of the pages from large-core to core, while we can expect to direct 77.3 percent of all the addressing to core storage. Furthermore, we can guarantee that no more than 60 percent of the pages will be moved.

SUMMARY AND CONCLUSIONS

This paper was concerned with page movement in a directly addressable memory hierarchy. A two-level hierarchy was studied, so the question arose as to which pages should be moved from the second to the first level, and which pages should be addressed in the second level directly. One approach is to move those pages which are used more often, since access time to the first level store is less. The problem is to determine which pages are the most active. Some procedures to detect the high activity pages were developed. These algorithms assume no knowledge of the page activity prior to processing.

The behavior of four programs was studied, and it was shown that some pages were used far more often than were others. For example, it was shown that the 50 percent of the pages which are the most active account for about 95 percent of all the activity. These data on program behavior were then used to test the procedures.

The first procedure was termed "sequence-independent," since although it depends upon the relative number of times each page is addressed, it does not depend upon the sequence in which the addressing takes place. Using this algorithm, it was found that by moving an expected 50 percent of the pages from the

TABLE II—Effect of the sequence-dependent algorithm

$$P = \frac{100}{N} \qquad K = \frac{PP_{MAX}}{100} \cdot J$$

second to the first level store, one could expect to direct about 80 percent of the addressing references to the first level store. Since the most active 50 percent of the pages account for about 95 percent of all the activity, and since any arbitrary but random selection of 50 percent of the pages would account for an expected 50 percent of the activity, this algorithm may be said to be about two-thirds as effective as it possibly can be.

Sequence-dependent procedures were then studied, with the emphasis on one such algorithm in particular. This algorithm operates just like the sequence-independent algorithm, until a fixed number of pages have been moved. At this point the algorithm shuts down, and no more page movement takes place. Unlike the sequence-independent algorithm, this procedure guarantees that no more than a certain number of pages will be moved. Just as in the case of the sequence-independent algorithm, we found that this procedure can be adjusted to move about 50 percent of the pages from the second to the first level store, while expecting to direct about 80 percent of the addressing references to the first level store. Furthermore, with this algorithm we can guarantee that no more than 60 percent of the pages will be moved.

Thus the page promotion procedures appear to be effective, at least within the limited context in which they have been studied above. Of course, such a procedure would only be one element of a complete hierarchy management algorithm. This complete algorithm must be concerned with many other issues, such as the removal of pages from core storage and the management of page traffic with slower peripherals such as disks. Thus these preliminary experiments are encouraging, but they need to be carried much further, in order that the utility of the page promotion procedures may be judged within the context of a complete system.

APPENDIX I

Suppose that a page is addressed S times, each time using the page promotion procedure described in Figure 2. Define:

λ The expected number of times the page is addressed in the large-core storage.

ϕ The probability that the page will not be moved from large-core storage to core storage.

We wish to show that:

$$\lambda=[(1-P)(1-(1-P)^S)]/P, \qquad (6)$$

$$\phi=(1-P)^S. \qquad (7)$$

To establish Equations (6) and (7), we note that the page will be addressed exactly:

0 times in large-core with probability P,
1 time in large-core with probability $(1-P)P$,
2 times in large-core with probability $(1-P)^2P$,
⋮
$S-1$ times in large-core with probability $(1-P)^{S-1}P$,
S times in large-core with probability $(1-P)^S$.

Then:

$$\phi=(1-P)^S,$$

$$\lambda=0\cdot P+\sum_{s=1}^{S-1}[s\cdot(1-P)^sP]+S(1-P)^S \qquad (8)$$

This establishes Equation (7). The equation for λ must now be reduced further. It is not difficult to show that:

$$\sum_{s=1}^{S-1} s(1-P)^s=[1-P-(1-P)^S]/P^2 -[(S-1)(1-P)^S]/P.$$

Using this result in Equation (8):

$$\lambda=P\left[\frac{1-P-(1-P)^S}{P^2}-\frac{(S-1)(1-P)^S}{P}\right]+S(1-P)^S,$$

$$\lambda=\frac{1-P-(1-P)^S+P(1-P)^S}{P},$$

$$\lambda=\frac{(1-P)(1-(1-P)^S)}{P},$$

which establishes Equation (6).

APPENDIX II

Consider a program with a given $N_1, N_2, \ldots, N_J$. Suppose that a sequence-dependent algorithm is in use and that:

$$P_k=\left[\begin{array}{ll} P & k=0,1,\ldots,K-1 \\ & \\ 0 & k=K. \end{array}\right.$$

There are $N!/(N_1!\, N_2! \cdots N_J!)$ different sequences in which the pages may be addressed. Of these, there is one sequence in which all of the addressing references to page j are performed prior to any of the references to page $j+1$ $(j=1, 2, \ldots, J-1)$. This particular sequence is called the *MIN* sequence. Since $N_j \leq N_{j+1}$ it follows that whenever a page is to be addressed in the *MIN* sequence, a page is selected so that no other page has fewer remaining times to be addressed. We wish to show that of all the possible sequences with a given $N_1, N_2, \ldots, N_J$, the *MIN* sequence minimizes PA.

For a given program, define:

NA The number of times that core memory is addressed.

Since NA is a random variable, it follows that:

$$PA^* = 100E(NA)/N.$$

Thus it will suffice to show that the *MIN* sequence minimizes $E(NA)$.

Define:

α_k The probability that the sequence-dependent algorithm will move exactly k pages from large-core to core.

$E(NA \mid k)$ The expected value of NA, given that exactly k pages are moved from large-core to core.

It then follows that:

$$E(NA) = \sum_{k=0}^{K} E(NA \mid k)\alpha_k.$$

For a given $N_1, N_2, \ldots, N_J$, we will now show that the α_k are independent of the addressing sequence. It will then suffice to show that the *MIN* sequence minimizes $E(NA \mid k)$.

Define:

β_k The probability that the sequence-*independent* algorithm will move exactly k pages from large-core to core.

Then

$$\alpha_k = \beta_k \text{ for } k=0, 1, \ldots, K-1,$$

$$\alpha_k = \sum_{j=K}^{J} \beta_k.$$

For a given $N_1, N_2, \ldots, N_J$, the β_k are independent of the addressing sequence. From the above two equations, it therefore follows that the α_k are independent of the sequence too.

We must now show, for arbitrary k, that the *MIN* sequence minimizes $E(NA \mid k)$. Define:

$\gamma_{j,k}$ The probability that page j is moved from large-core to core, given that exactly k pages are moved.

ζ_j The expected contribution of page j to $E(NA)$, given that it is moved from large-core to core.

Then:

$$E(NA \mid k) = \sum_{j=1}^{J} \zeta_j \gamma_{j,k}. \tag{9}$$

Let us consider ζ_j first. We are given that within N_j addressing references, page j is moved from large-core to core. At each of these references there is a probability P that the page will be moved, if it has not been moved previously. It therefore follows from Equations (6) and (7) of Appendix I that:

$$\zeta_j(1-\phi_j) = N_j - \lambda_j,$$

$$\zeta_j(1-(1-P)^{N_j}) = N_j - [(1-P)(1-(1-P)^{N_j})]/P,$$

$$\zeta_j = N_j/[1-(1-P)^{N_j}] - [[1-P]/P].$$

It can be shown that ζ_j is an increasing function of increasing N_j (if $0<P\leq 1$). Since $N_1 \leq N_2 \leq \cdots \leq N_J$, it therefore follows that:

$$\zeta_1 \leq \zeta_2 \leq \cdots \leq \zeta_J. \tag{10}$$

Note also that ζ_j is not a function of the addressing sequence.

Let us now discuss $\gamma_{j,k}$. The expected number of pages moved from large-core to core is:

$$\sum_{j=1}^{J} [1\gamma_{j,k} + 0(1-\gamma_{j,k})].$$

But it is known that k pages are moved, so:

$$\sum_{j=1}^{J} \gamma_{j,k} = k, \tag{11}$$

where k is a constant.

We are now in a position to complete the proof. Gathering our results from Equations (9) through (11), we have:

$$E(NA \mid k) = \zeta_1\gamma_{1,k} + \zeta_2\gamma_{2,k} + \cdots + \zeta_J\gamma_{J,k},$$

$$\zeta_1 \leq \zeta_2 \leq \cdots \leq \zeta_J,$$

$$\gamma_{1,k} + \gamma_{2,k} + \cdots + \gamma_{J,k} = \text{CONSTANT}.$$

It therefore follows that $E(NA \mid k)$ is minimized by making $\gamma_{1,k}$ as large as possible. Given this, $\gamma_{2,k}$ must be made as large as possible, and so on. It is obvious that this will be accomplished by the *MIN* sequence. Thus the *MIN* sequence minimizes $E(NA \mid k)$, which implies that it minimizes $E(NA)$, which implies that it minimizes PA, which completes the proof.

APPENDIX III

Suppose that the sequence-dependent algorithm is in use, and that pages are addressed in the *MIN* sequence. We wish to devise a method for computing:

$R_{j,k}$ The probability that core storage contains exactly k pages just prior to the time that the addressing of page j begins.

Prior to the first time that page 1 is addressed there are no pages in core memory, so for $j=1$:

$$R_{1,0}=1.$$

Consider now the case when $j>1$. The only way that there can be no pages in core memory just prior to the first time page j is addressed is for there to be no pages in core memory just prior to the first time page $j-1$ is addressed, and for page $j-1$ to remain in large-core. Thus:

$$R_{j,0}=R_{j-1,0}\phi_{j-1,0},$$

where $\phi_{j,k}$ is the probability that page j will remain in large-core when addressed N_j times by the page promotion procedure using P_k. We know from Equation (7) that:

$$\phi_{j,k}=(1-P_k)^{N_j}.$$

For $k\geq 1$ there are exactly two ways in which there can be k pages in core memory just prior to page j being addressed for the first time:

(1) There can be $k-1$ pages in core memory just prior to page $j-1$ being addressed, and page $j-1$ can be moved from large-core to core.

(2) There can be k pages in core memory just prior to page $j-1$ being addressed, and page $j-1$ can remain in large-core.

Thus:

$$R_{j,k}=R_{j-1,k-1}(1-\phi_{j-1,k-1})+R_{j-1,k}\phi_{j-1,k}.$$

When $k=j-1$ this becomes:

$$R_{j,j-1}=R_{j-1,j-2}(1-\phi_{j-1,j-2})+R_{j-1,j-1}\phi_{j-1,j-1},$$

but $R_{j-1,j-1}=0$, so:

$$R_{j,j-1}=R_{j-1,j-2}(1-\phi_{j-1,j-2}).$$

In summary, $R_{j,k}$ may be computed for increasing values of j by using the following equations:

IF $j=1$: $R_{1,0}=1.$

IF $j>1$: $R_{j,0}=R_{j-1,0}\phi_{j-1,0},$

$$R_{j,k}=R_{j-1,k-1}(1-\phi_{j-1,k-1})+R_{j-1,k}\phi_{j-1,k} \quad \text{for } k=1,2,\ldots,j-2,$$

$$R_{j,j-1}=R_{j-1,j-2}(1-\phi_{j-1,j-2}).$$

For $j=1, \ldots, J$ and $k=0, 1, \ldots, j-1$, the $R_{j,k}$ may then be used in Equations (2) and (3) to compute PA^* and PP^*.

Validation of a trace-driven CDC 6400 simulation

by J. D. NOE and G. J. NUTT

University of Washington
Seattle, Washington

INTRODUCTION

A computer center typically faces questions of how to deal with a growing load in the face of tight financial constraints and with the need for lead time for planning ways to meet the demand. The needs may be met by altering the equipment configuration, changing priority algorithms and other features of the operating system, controlling the time scheduling of various classes of job load, or perhaps shifting load from one machine to another if the center is large enough to have such a capability. It is often difficult to gather enough data and insight to show the direction these changes should go and to support the decision to do so. One useful set of tools is provided by simulation backed up by measurements required for validation. However, it is all too common to find that fear of interruptions of the computing center's service to user, combined with an overworked systems programming staff, prevents insertion of the desired measurement probes into the operating system. Then one is restricted to measures that can be derived from the normal accounting log, or "Dayfile", and to software probes that can be injected in the guise of user's programs. In spite of these limitations, useful results can be obtained, and this paper describes validation of a simulation model of a multiprogramming system, the Control Data 6400, making use of these restricted measurements.

The level of detail included in the model affects the degree of confidence one can place on the results of the simulation. It is necessary to represent the system accurately at the level of detail needed to support the predictions of interest. This implies not only enough detail to include the system resources that may be altered, but also enough detail to faithfully represent the interaction of these resources. In a complex system this becomes an important factor since the change in one area may have surprising effects in another part of the system. This argues for inclusion of finer detail.

A counter argument relates to high cost, which is a frequently-discussed difficulty with simulation. However, cost is a relative matter. There is no point in spending money to simulate or measure a system unless the resulting changes lead to savings well in excess of expense; but, when one is dealing with systems costing on the order of fifty to one hundred thousand dollars per month, plus supporting expenses equal or greater to that amount, a relatively small increase in efficiency can more than pay for a useful amount of simulation and measurement effort. It is still important to hold down the cost of simulation and one way of doing so is to avoid more detail in the model than is necessary.

These points, of course, lead to a compromise in the choice of what to include in such a model, and as will be explained later in the paper, we found that the process of validating the model and examining the sensitivity to various parameters gave useful insight on the level of detail that was necessary.

THE CONTROL DATA 6400

Many descriptions of the Control Data 6000 Series exist and there is no point in repeating a lengthy discussion (see Thornton,[1] Control Data,[2,3] MacDougall,[4] Noe[5]). Only the salient features of the system will be described here in order to remind readers of its general structure.

The Control Data 6400 is a multiprogrammed, file-oriented system, using a central processor, ten peripheral processors and twelve channels, a central memory of up to 131K 60-bit words is available to the system and to the user programs. Each peripheral processor has 4K memory (12 bits per word) for its local use. The peripheral processors communicate with the central processor through central memory and they take over many system tasks, such as communicating with the I/O equipment. Concurrent users' programs within the system become files on disk and these files are placed in queues for the needed resources. As the programs are executed, output files are built and transferred to disk for scheduling of output printers and card punches. Programs are executed from central memory by the central processor, using peripheral processors as necessary for subsidiary tasks. A group of eight control points or communication areas is set aside in lower central memory. One of these is unique and is used by the system to keep track of currently unused resources. The others of these may be occupied by users' jobs or by system programs such as JANUS and IMPORT/EXPORT for communication with users' programs. Each control point, 200 octal words in length, stores information unique to the job, such as register contents, program counter, etc., that is needed when the central processor is switched from one job to another.

A variety of operating systems for the CDC 6400 exists. The one on which this simulation is based is SCOPE 3.2 with some modifications that are local to the University of Washington Computer Center. One of these modifications is the disk image (DI) option. This option, when used on a tape request control card, causes the system to first search the disk directory to see if that tape has been copied onto disk. If so, the disk file is used. If not, the operator is requested to mount a tape, which is then copied to disk and retained there for some period of time, (e.g., eight hours). This modification is advantageous in an environment in which many calls may be made for the same tape during any given day, providing disk saturation is not a factor. Another modification is the addition of a staging queue. Jobs that require magnetic tape are held on disk in this queue until the operator has mounted the reel on the tape drive; then they are allowed to proceed into the input queue where they wait for central memory and for a control point.

A feature of the operating system that has been necessary to this simulation and validation study is the system Dayfile. This file accumulates data on individual jobs, such as time into the card reader, time of exit from the input queue, amount of central processor time used, time into the output queue and time off the system. This file, which was originally designed for accounting purposes, provides a significant amount of information that can be used for describing the job load in the trace driven simulator and it will be discussed more fully in subsequent paragraphs.

THE APPROACH

The general approach taken in this study was to develop a simulation at the level of detail that shows the interaction between tasks and system resources. The Dayfile was analyzed to obtain trace data, i.e., to show how the actual job load on any given day made use of the system resources. Validation runs were then made by driving the simulation model with trace data from various days to provide a range of load conditions.

Provisions are included in the simulation model to represent the input job load either as individual jobs (to allow driving the model with the trace data) or as job classes (to drive the model with distributions representative of groups of jobs). Only the former method is reported on in this paper, because it is restricted to a discussion of the model and its validation. The use of job classes will be discussed in a separate paper reporting on use of the model to explore effects of load variations.

This work was done under a number of constraints that limited some of the things we would like to have done. It was important not to interfere with the service being provided by the Computer Center. In particular, it was not possible to insert probes in the system monitor, or to dedicate a peripheral processor to the measurement role, as has been done in work by others (see Stevens,[6] Control Data,[7] and Sherman[8]). As a result, we were unable to include disk statistics among the parameters used to describe jobs, except in a very general way. Disk accesses were not modeled in detail although their overall effect on job flow was accounted for in the simulation through the time interval a job stayed at a control point.

In spite of these constraints, a considerable amount of information was available through the Dayfile and inasmuch as the constraints under which we were operating are not uncommon, it may be of interest to others to see how much can be done without the freedom to alter the system programs for measurement purposes.

DESIGN OF THE SIMULATION

In general structure, the simulation parallels the operating system and allows parameter choices representing a range of available operating system and hardware options. The level of detail of the model is restricted to focus on system resources that may be altered, omitting wherever possible the inclusion of resources for which no decisions may be made. Execution speed of the model is approximately fifty times faster than the real system, i.e., one hour of real system operation is represented by 70 seconds of operation of the model (see Nutt[9] for a detailed description).

The model is written in ANSI FORTRAN and

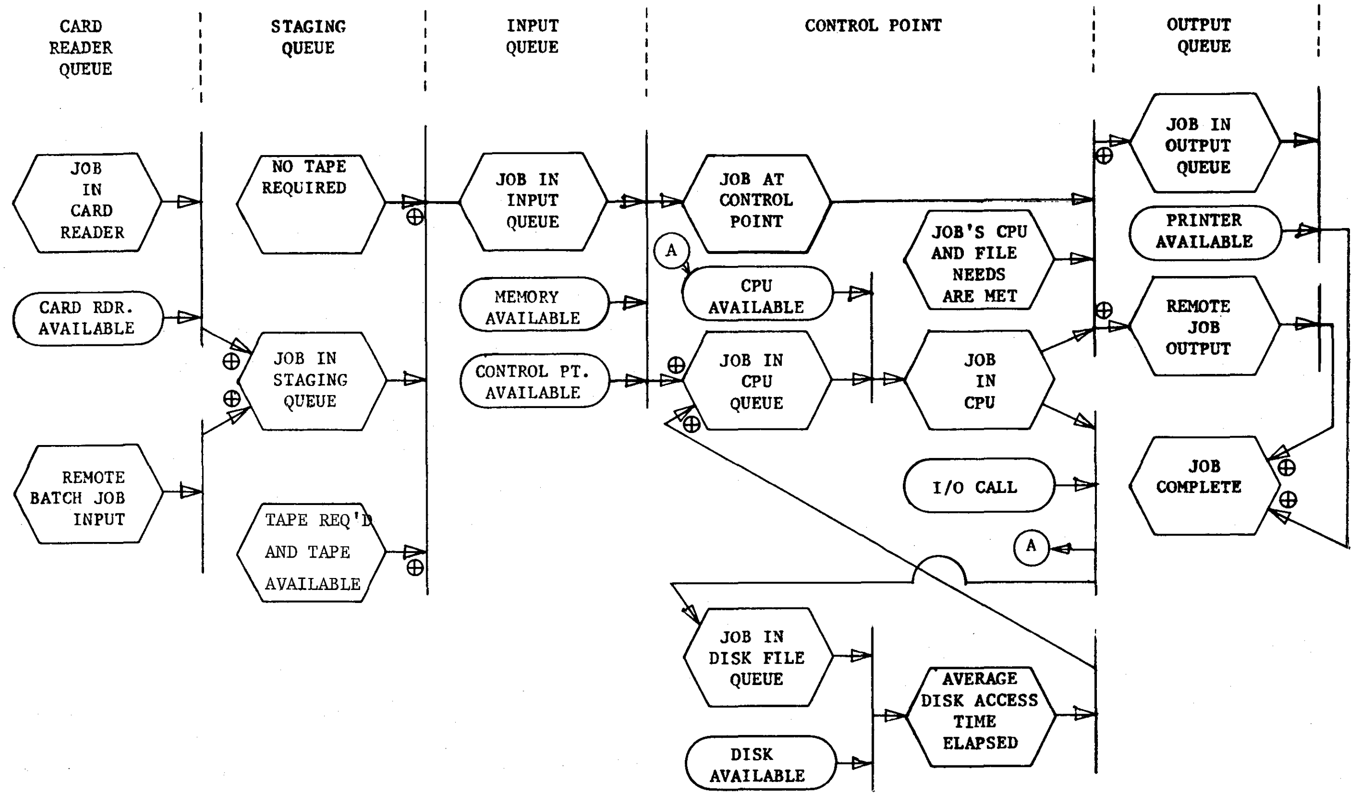

Figure 1—Modified Petri net of simulated CDC 6400

its general structure is similar to BASYS (see MacDougal[10]). ANSI FORTRAN was used rather than a specialized simulation language for two reasons: first it made the program available on both the CDC 6400 and on the XDS Sigma 5 (for which we had no discrete system simulation language compiler); second, since this was done in a learning environment in a university, the use of FORTRAN gave an opportunity to learn more about the details of queue handling and sequence timing that are obscured by the automatic features of simulation languages.

The model is trace-driven, i.e., jobs are represented by the resources they require. It then provides data about jobs that are dependent on system efficiency, such as turnaround, job dwell-time at control points and dwell-time in input and output queues. It also provides data on system performance such as queue lengths, the number of control points in use, CPU utilization, and the amount of central memory occupied by all jobs at sample intervals.

The system actually simulated is shown in Figure 1. The notation is that of the modified Petri net, as introduced in Reference 5. To generate a simulation, it is essential to have a clear representation of the system being modeled. The modified Petri net notation is used because it shows the computer structure under the influence of the operating system.* For the purposes of the present description, it should be adequate to note that the vertical lines are *transitions*. When the necessary input conditions (denoted by incoming arrows) exist, the transition "fires" causing the output conditions to come into being (denoted by outgoing arrows). Arrows marked at either end with the symbol "⊕" denote EXCLUSIVE OR; arrows with no symbol attached denote AND . . . i.e., two or more are required. Note that different symbols may exist at the two ends (input or output) of an arrow.

As an example of the interpretation of Figure 1, "JOB IN CARD READER" represents the existence of one or more jobs in the card reader. Whenever the "CARD READER AVAILABLE" and "JOB IN

* At the state of development of the notation used here, the system representation by Petri nets is qualitative. Further work is in progress to add quantitative features to the modified Petri nets.

18. Time of Entry into Output Queue
19. Time Job Vacated Machine

CARD READER" conditions are true, the associated transition is fired, causing a job to be removed from the card reader and to be placed in the staging queue ("JOB IN STAGING QUEUE"). Note that the staging queue can accept jobs from the card reader *or* the remote input, but not both simultaneously. The use of EXCLUSIVE OR when leaving the staging queue is interpreted as follows: When "JOB IN STAGING QUEUE" is true *and* no tape is required, the next transition fires, altering job status to "JOB IN INPUT QUEUE." *Or* (exclusive) when a "tape job" is in the staging queue *and* a tape is assigned to it, the transition fires.

In making use of the model, it is important to be aware of system resources that are not included. Most important are channels, peripheral processors, and the details of disk access (disk file activity is accounted for only in length of dwell-time of jobs at a control point*). A most important reason for not including channels and peripheral processors is that the number of each available is fixed, i.e., addition of channels and peripheral processors is not among the decisions that might be implemented by the Computer Center. Therefore, it was pointless to examine simulation results dependent on changes in the number of these units. However, it is important to bear in mind that before deciding upon some system changes suggested by the simulator, one should make measurements to see if the proposed change is likely to cause saturation in channel or PPU usage, thereby shifting the bottleneck out of the "range of view" of the simulation.

A principal feature of the simulation model is the method used to describe the job load driving the system. Because this method provided flexibility, it aided validation of the model as well as extrapolation into future situations of interest. Visualize an array in which each row describes a job during the period it is active in the system. As jobs exit from the system, they are removed

TABLE II—Outputs from Simulator

Job Statistics:

Mean and standard deviation for the group of jobs streaming through the simulator are provided for all the characteristics listed in Table 1. In addition, histograms of the distributions are printed for

- Central Memory (average of compilation phase and execution phase)
- Processor Times (central and peripheral)
- Length of time in Rollout status
- Time on Control Point
- Time in Output Queue
- Time in combined Staging and Input queues
- Turnaround Time (from card entry to vacating machine)

Complete trace on each job as it progressed through the model was provided.

Queue Statistics:

- Card Reader Queue
- Staging Queue
- Input Queue
- Central Processor Queue
- Output Queue
- Rollout Queue (i.e., jobs awaiting Rollin)

Resource Utilization: Accumulated busy-time for

- Card Readers and Punch
- Line Printers
- Magnetic Tapes
- Central Processor
- Control Points

* Specifically, an average disk access time was used, as measured by a software probe entered as a user's job. The number of accesses per job was approximated by dividing the job's peripheral processor time by the average access time. The measurement program was written, and the data gathered, by Geoffrey C. Leach, University of Washington.

from the array to provide room for new jobs to be added. Therefore, the array size need be large enough only to handle the currently active jobs rather than all the jobs entered within a given simulation run. The columns in this array represent the trace characteristics of each job, and their contents are listed in Table I. Some of these columns (1 through 14) must be prespecified to describe the job; they may contain positive numbers representing the actual value of the parameter, or may contain negative integers indicating that a value is to be obtained by the simulator system from a distribution identified by the negative integer. This feature allows driving the model with either actual trace data extracted from the Dayfile of the real system, or from data approximated by distributions that represent a job mix, or possibly some combination of the two.

Columns 15 through 19 in the job array show characteristics that may be prespecified (again from actual values or from distributions), or may be calculated by the simulator. This flexibility is helpful during validation of the model since it allows one initially to drive the model with predetermined data, thus force-fitting it to behave like the real system; and then one can back off as confidence is gained, and let the simulator provide more and more of the parameters. This has proven to be a very useful tool during model validation. It is also useful for taking care of "peculiar" jobs, such as control programs that handle terminals and other I/O and which appear to the system as long-term "user" jobs rather than as part of the operating system.

Based upon these input statistics for individual jobs and on the simulator's calculation of the time each job requires to go from point to point in the system, data are gathered on the overall operation of the multiprogrammed system and the nature of the aggregate results provided are listed in Table II.

VALIDATION OF MODEL

General

The procedure followed to validate the model is shown schematically in Figure 2, which starts from the tape containing the Dayfile, i.e., the CDC 6400 normal record of the day's operation, originally conceived as an accounting tool. The Dayfile does not exist in a format suitable to drive the simulator, since entries are ordered according to clock time and information on a unit job is scattered throughout the file. The program DFPREP extracts the proper parameters for each job, creating a new file of properly formatted trace data selected over the time period being examined. As DFPREP reads the Dayfile and creates input for the simulator, it analyzes the data to provide statistics on system performance and on the jobs entered into the system. The trace data are used to drive the simulator, entering only the input descriptions of the job into the simulator and asking it to provide simulated system performance.

Figure 2—System validation procedure

The process just described sounds deceptively simple. In actual fact, getting the simulated model to agree with measured performance over a range of parameters and job mixes proved to be a complex and time-consuming process. The authors suspect that this is a typical situation and accounts for the fact that the extensive literature describing simulation of computer systems is rather sparsely populated by papers on validation.

On the other hand, this validation phase proved to be very valuable, not only in terms of the essential point of building confidence in the realism of the simulator's performance, but also in the better understanding of the system and of the model that was gained during the validation process. For example, during validation it became clear that it was necessary to extend the model to include jobs that bypassed part of the system, e.g., a remote batch capability that bypasses the card reader queue and the output queue had

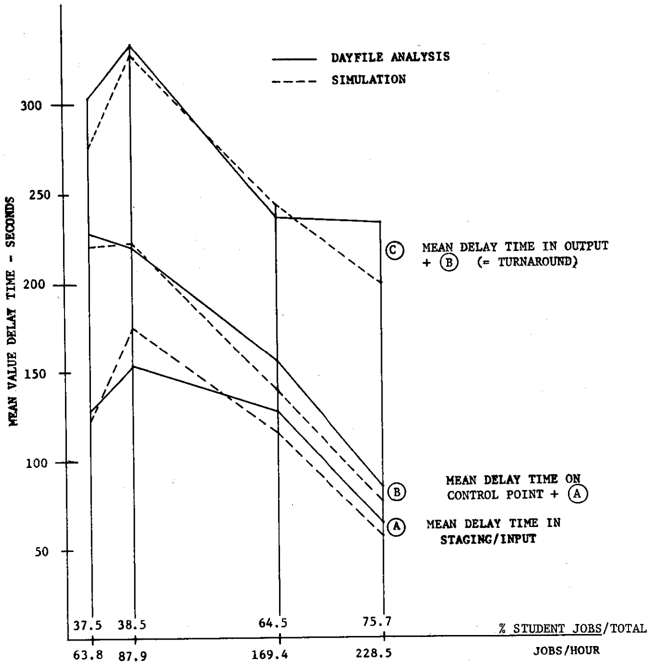

Figure 3—Comparison of simulated and actual job delays

grown in importance in actual system use so that it was necessary to incorporate it. Also, the sensitivity of the system to the manner in which magnetic tapes were handled became apparent as did the effect of the disk image (DI) option. Some errors in the model, in the control point area and in central memory field length variation, were detected and corrected as a result of validation. It was found necessary to approximate the number and duration of disk accesses in order to properly fragment each job's use of the CPU. It also became apparent that it is important to be able to precondition the state of the simulated system when starting it in the middle of the day's operation. In other words, the start-up transient in the simulation, which seems to be on the order of fifteen minutes to one-half hour of simulated time, can obscure the results if one attempts to simulate two or three hours of mid-day performance without preloading the system.

In retrospect, it is tempting to say that some of the points that needed changing should have been included in the model as originally constructed. Yet, we would argue against going overboard in this direction. The question is one of performance sensitivity to a given system feature. If one initially attempts to include so much detail that all significant factors are likely to be in the model as originally constructed, one is certain to end up with a number of unnecessary details that only serve to lengthen the program writing, debugging, validation, and execution time. The authors believe it makes far more sense to construct a model along reasonably simple lines, containing flexibility for injecting needed changes, then adding features when the validation process shows them to be necessary.

Interestingly enough, some of the most difficult things to validate in the model involved human actions and human judgment, particularly the time required to fetch and mount magnetic tapes, and the criteria used by the operators in deciding when to place a program in rollout status (i.e., removing it from contention for core memory and for the CPU) were subject to wide variations. On the other hand, inclusion of these factors was necessary for realism and will provide ways to test some operational procedures and policies that might be applied.

Validation data

Validation and alteration of the model finally converged to a point where reasonable confidence in the model was established. To illustrate this, data are presented that cover four different job mixes and job densities chosen to represent two extremes in computer usage and an intermediate case. One extreme was near the end of an academic quarter, during which the system was used heavily by students trying to finish problems and term projects. The other extreme was between academic quarters when the student load had decreased significantly, leaving a predominance of research jobs and system development jobs running on the machine. The mixes ranged from a low of 37.5 percent student jobs up to a high of 75.7 percent student jobs. The job densities covered a range greater than 3.5

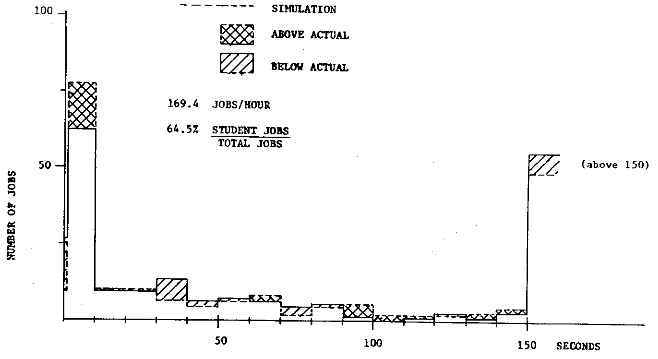

Figure 4—Job dwell time in staging plus input queue

to one in jobs per hour, and included densities near the current record day for this installation.

Figure 3 summarizes the mean values of delay times as the jobs progressed through the system. It shows comparison values for the real and simulated system for each of the four load conditions. The lower curve (A) in Figure 3 shows average delay times through the combined staging and input queues. The next higher curve (B) adds control point dwell times to the staging and input delays. The top curve (C) adds output queue times to the cumulative delays and thus represents turnaround times, i.e., time between entering the card reader and ejection from the line printer.

A word of warning about Figure 3: Do *not* interpret it as "how delay time varies as a function of rate of job flow"; instead, interpret it as "for the specific cases (job mix and density), how do the real and simulated systems compare?" The reason for this is that the higher densities shown in this figure correspond to cases in which a higher proportion of student jobs were run. These jobs on student account numbers are predominantly short jobs with three or four pages of listing and less than ten seconds central processing time (see Hunt[11]).

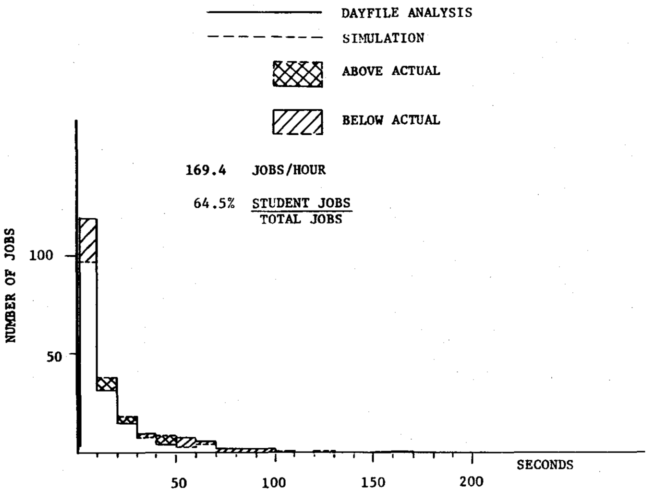

Figure 5—Job dwell time at control point

The set of points corresponding to the highest job density (and highest student job proportion) proved initially to be very troublesome. Upon closer investigation the difficulty proved to stem from tape jobs. For some reason the standard deviation in tape fetch and mount time for that day was unusually high (greater than three times the mean value). For the other days, the standard deviation ranged from 1.63 to 2.25 times the mean value. Therefore, for that troublesome day, the tape jobs were pre-specified in the model, to allow validation of its performance on the remaining, more normal job load.

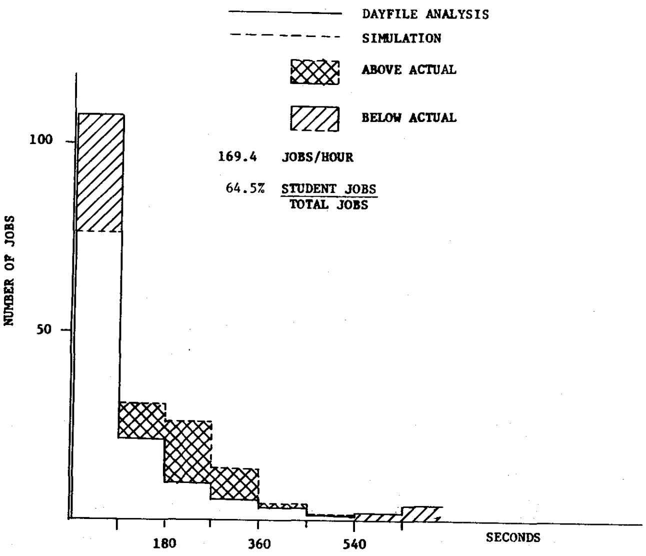

Figure 6—Job dwell time in output queue

In Figure 3 the middle curves (B) are critical, since control point occupancy time directly influences memory and the number of control points available. During validation overall results were found to be most sensitive to agreement in this area. Figure 3 shows only the mean values. The variation in these values is quite great and comparison of the distributions of results is important to the validation. Figures 4 through 7 com-

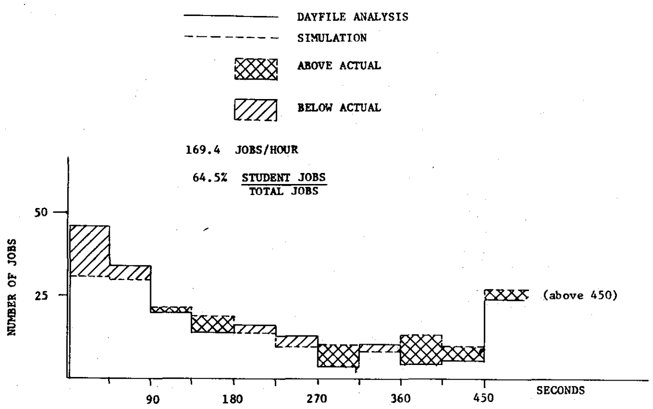

Figure 7—Job turnaround time

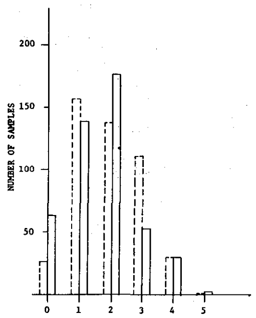

Figure 8—Number of control points in use at sample times

pare the simulated and actual distributions for the various queues and for overall turnaround time for the job load corresponding to 169.4 jobs per hour and 64.5 percent student jobs. The agreement between simulated and actual mean values for this case, as shown in Figure 3, is within 9 percent through the staging and input queue, 11 percent when the control point dwell time is added, and 4 percent for overall turnaround time. The agreement in the distributions, as shown in Figures 4 through 7, shows that the model is operating quite well over a wide range in values. Figures 8 and 9 show similar comparisons between the number of control points and the amount of memory in use in the simulation and in the actual system. These are sample data with the samples not synchronized between the real and simulated systems. A sample was taken approximately every ten seconds and the total run during which comparison was made lasted for two hours.

The agreement of the distribution for this particular load case was representative for the other cases and they are not repeated here. The goal was to verify the model to within 10 to 15 percent. This was generally achieved over the range of loads and over a range of parameters within the model. There are some exceptions, but they are generally understood. For example, the simulation of the 169.4 jobs/hour and 64.5 percent student jobs assumed that there was a constant availability of two line printers. Analysis showed this not to be the case. In the actual system only one line printer was operating initially. Twenty minutes later, another line printer was turned on, and 25 minutes after this event, 3 line printers were operational for a short period of time. Also there were cases where some very unusual system development jobs appeared in the real system and they were not accounted for in the simulation; however, these cases are understood to the point where they do not detract from the confidence in the model to predict performance for the major types of jobs that are important in this environment.

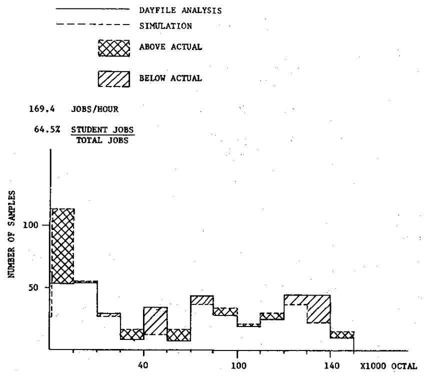

Figure 9—Memory in use at sample times

SUMMARY

At this point, the model is ready for use in experiments to examine the effects of changes in load and system configuration, and these are proceeding.

Perhaps the most important point established so far is that it is possible to gather enough data to validate a useful model, even under the stringent conditions imposed by a non-interruptible computing service center. There is no doubt, though, that special software and hardware measurements would be useful. For one thing, this would provide validation data for a more detailed simulation of the disk system.

The model as it now stands can be used to predict the effects of changes in job arrival density or in job nature. Effects of changes in job CP use and memory use (estimated and actual), number of cards, lines printed, tapes and disk image usage can be observed. Some configuration changes that can be studied include those in central memory, central processor speed or numbers, line printers, card readers, tapes, and number of control points. Scheduling algorithms for these resources can be varied, and the effects of a variety of operational policies can be observed, such as tape-handling, rollout, and control of types and schedules of jobs submitted to the system.

INTRODUCTION

The techniques of multiprogramming originated in an attempt to better utilize a computer system's resources. Multiprogramming supervisory systems are usually rather complicated and their performance is still poorly understood. Some of the reasons why performance should be analyzed are given in Reference 1. It is possible to monitor the system with hardware devices, but analysis must often wait several hours or days before it can be performed. Also, there are quantities that are impossible to reach with conventional hardware monitoring devices. In particular, process identities are lost. This means that some kind of software monitoring method must be envisaged.

A number of articles[2,3,4,5] have discussed different approaches to software measuring. Since operating systems must compute great quantities of information during their operation, it is clear that the best informed piece of software of the system must be the supervisor itself. In the case of CP-67,[10] the system used at the Institute of Applied Mathematics of the University of Grenoble, a simple approach to monitoring can be used.

CP-67 runs on an IBM System 360/67, which is a machine having the dynamic address translation feature. CP-67 creates the time-sharing environment by generating virtual machines. The real resources of the system (CPU, main memory, channels, etc.) are shared among the users concurrently logged-in onto the system. After a virtual machine is generated the user loads in his virtual computer the operating system of his choice, e.g., CMS, OS/360 or even CP-67. Only the real CP-67 runs in supervisor, non-interruptible mode. All the generated virtual machines run in problem state, and the computer is enabled for I/O and timer interrupts while they are active. Privileged instructions executed by a virtual machine cause a program interrupt to CP-67 which analyzes it and determines the action to be taken.

Of special interest are the paging and dispatching algorithms employed by CP-67.[10] For our purposes it suffices to mention that when processes request the system resources (for example, CPU and main memory) they are divided into two sets, interactive and non-interactive, depending on their type of activity. Those members of each set who have been allocated main memory belong to the active class. When a process causes a page fault, the paging algorithm tries to find a page not in use by someone in the active class. If no page is found satisfying this criterion it will choose the first page it finds, in what amounts to essentially random replacement.

Virtual machines communicate with CP-67 by means of the diagnose instruction.[10] Thus, it is possible for a virtual measuring machine to demand the information contained in special locations within CP-67. The information is updated by CP-67, but the data collection and treatment is done by the measuring machine. The treatment includes writing the data in a disk file and displaying the more important information in a CRT or a console.

The transfer of information by the diagnose instruction and the data treatment are imputed to the measuring machine, which is viewed as just another process

* Presently a visitor at IBM France Scientific Center.

by the supervisor. Furthermore, the virtual machine is dormant waiting for a timer interrupt during the comparatively long intervals between two measurements. The supervisor overhead in running this measuring system is updating the information kept in CP's counters and the process management associated with the virtual measuring machine.

The variables chosen to be observed can be classified as follows:

1. Variables of identification which identify each measure. They are: date, time of day, ordinal number of the present measure.
2. Instantaneous variables. They have a meaning only at the moment at which the measure is taken. There is no relationship between values taken at different times. They are: number of virtual pages in drums and in disks, number of users logged-in, interval between two measures.
3. Cumulative variables. When the operating system is loaded these variables are set to zero. They are incremented by the system. The difference between two values is divided by the time interval between two measures. They are: time in problem state, time in supervisor state, time in wait state, number of pages read per second, number of pages written per second, number of pages "stolen" from the members of the active class per second (see paging and dispatching description), number of virtual machine I/O operations per second, number of CP-67 I/O operations per second, number of privileged instructions per second.
4. Variables of integration. These are variables whose instantaneous value, or even the difference between two values, lacks significance. Instead it is their time average value that is relevant. For example, the number of processes in the active lists may be the same at the moment of two successive activations of the measuring machine. Yet, during this time interval the multiprogramming level has changed often, reflecting the fact that user processes block and become active again. It has been found necessary to form the time integral of the number of users in the active class. This is the only case where relatively many instructions (about 30) have been added to the system's code. The quantities that must be treated this way are: lengths of queues of the active class, lengths of channel I/O request queues.

The results presented correspond to measures taken during the month of July 1971. The system configuration included 512 K 8-bit bytes. Also, two drums used solely for paging, both on the same channel, and two disk units each consisting of 8 disk packs. Each disk unit has its own selector channel. The system measured was CP-67 version 3 level 0. The computer system is run under control of CP-67 from 8:00 to 12:00 and from 15:00 to 18:00. The time interval between measures was set to 100 seconds of virtual time. Because virtual clocks run slower than real clocks this gives real time intervals of between 100 to about 140 seconds. About 2500 sets of measures were collected in the four-week period analyzed in this report.

It is very difficult to give a characterization, even approximately, of the system load. Heavily used components are PL/1, Fortran, Assembler, Lisp and various other languages. Also context editors and debugging aids that run interpretively. Most virtual memories have either 64 pages or 128 pages. Peak loads correspond to about 40 terminals simultaneously logged in, though several of these virtual machines may be running multiaccess systems of their own, such as APL or (virtual) CP-67.

DISCUSSION OF RESULTS

Direct, on-line visualization has proved invaluable in discovering anomalous system behavior. The first lesson we learned is that the system has a tendency to thrash when the number of logged-in consoles exceeds a certain value. The symptoms are a low CPU efficiency and a large number of pages stolen from the members of the active class. Thrashing has been amply discussed in Reference 9 and is well-known to be caused by increasing the multiprogramming level beyond a certain

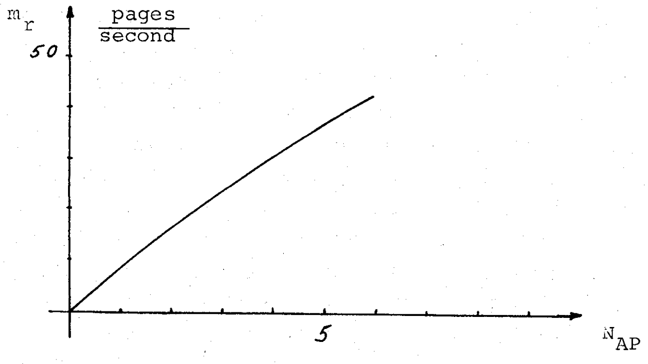

Figure 1—Real page fault rate: m_r
vs.
Multiprogramming level: N_{AP}

point. This causes an increase in the page fault rate, which brings an increase in the traverse time (the time necessary to bring a missing page in memory). This leads to a decrease in total processing time. As far as we know, no experimental data has previously been published on this phenomenon.

There are other conditions whose influence on system behavior would have been very difficult to determine without the CRT display. The supervisor time grows when a virtual machine writes on its console, or, more generally, on a virtual device attached to the virtual multiplexor channel. The supervisor time can easily reach 70 percent or more of the total time when programs write large amounts of data using the multiplexor channel. Another effect which is easily discernible is the degradation in performance brought about by insufficient drum space for paging.

Among the interesting results concerning the system is the low CPU problem state utilization, about 25 percent. Another result is the time the machine spends in supervisor state, which is about 35 percent of the total time. These values are well in agreement with values obtained by a hardware monitoring device, and other values reported in Reference 6. This means that the system, although unbalanced, is not CPU bound.

Some of the results concern thrashing and thrashing conditions. Explanations of thrashing have to do with number of processes actively competing for the resources. Paging rates have been given in References 6 and 7, yet they are given as a function of the number of logged-in users, not as a function of the multiprogramming level.

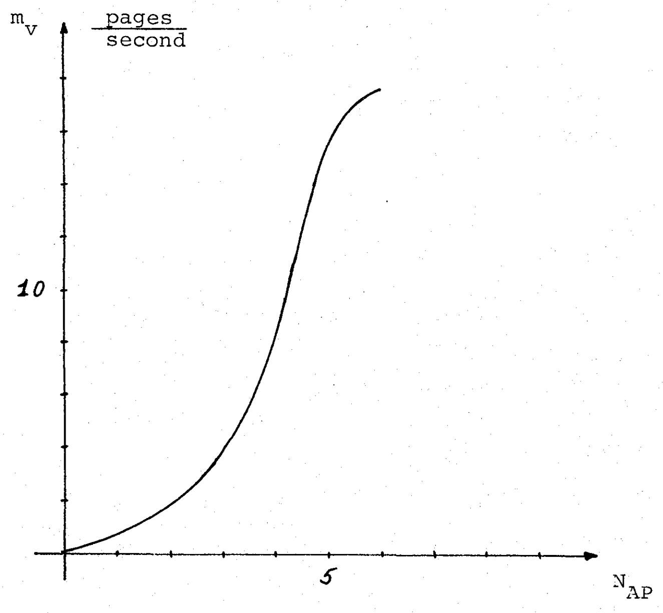

Figure 2—Real stolen page rate: m_v
vs.
Multiprogramming level: N_{AP}

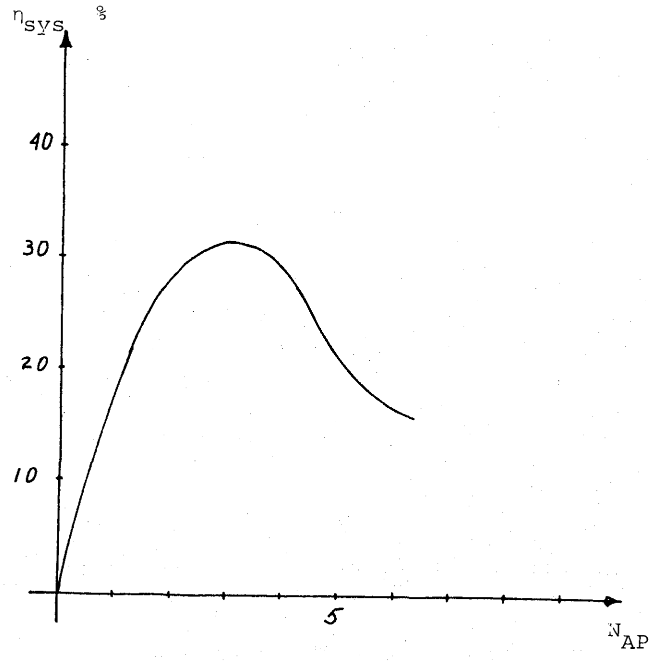

Figure 3—System efficiency: η_{sys}
vs.
Multiprogramming level: N_{AP}

Figure 1 is a plot of m_r, the number of page faults per second of real time, as a function of N_{AP} the mean number of active processes, i.e., the mean multiprogramming level. Figure 2 is a plot of m_v, the number of pages stolen from users in the active class, per second of real time. There is nothing dramatic about m_r, certainly not the steep change that should take place when a certain multiprogramming level is exceeded. Rather, the curve keeps its nearly constant slope in the region shown. Figure 2 indicates that as the multiprogramming level is increased, more and more pages are stolen from the processes in the active class. It has also been found that 70 percent of the pages chosen to be replaced have been modified and must first be written on the drum.

Figure 3 shows the percentage of real time spent in problem state, which we shall call efficiency, as a function of N_{AP}. The maximum efficiency is attained for values of N_{AP} between 2.5 and 4. The efficiency decreases as the multiprogramming level is increased beyond 4. This is well in agreement with thrashing behavior, and it suggests that thrashing sets in at this point. Figure 2 confirms this impression.

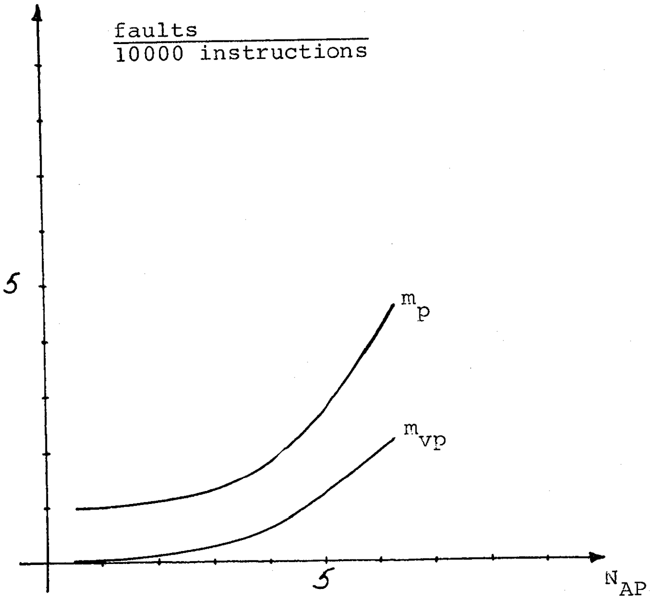

Figure 4—Virtual page fault rate: m_p
Virtual stolen page rate: m_{vp}
vs.
Multiprogramming level: N_{AP}

From Figures 1, 2 and 3, Figure 4 can be deduced. Knowing that the CPU can execute 600 000 instructions per second, Figure 4 gives m_p the expected number of page faults per instruction executed. This curve is the thrashing curve of Denning.[9] The sudden change in slope occurs for values of N_{AP} between 3.5 and 4. Before these values, m_p varies comparatively little. A change in multiprogramming level from 4 to 4.5 brings about a change in m_p four times as great as a change from 3 to 3.5. The lower curve gives m_{vp}, the number of pages stolen per instruction executed. If we subtract m_{vp} from m_p it is apparent that the number of page faults per instruction executed would grow less rapidly if no pages were stolen.

We can conclude that, from the standpoint of paging rate behavior, the system follows what amounts essentially to a working set policy before it gets into memory saturation and thrashing. Afterwards two combined effects take place. One of them is the increase in paging rate because there are, on the average, less pages available in memory for each process. The second effect is due to the paging algorithm that takes the decision of stealing pages which will soon be referenced again. This will make the paging rate still greater.

Any discussion concerning system efficiency must perforce take into account the fact that programs request I/O operations during their execution. If a program executes V virtual time units it will need a total real time of

$$T = V + (Vm_p)T_p + (Vm_{io})T_{io}$$

where the quantities m_p and T_p are respectively, the number of page faults per unit of virtual time and the transfer time of a page fault expressed in virtual time units. A complete discussion of these quantities is found in Reference 9. Similarly, m_{io} and T_{io} are the number of I/O operations per unit virtual time demanded by the process and the time necessary to process one such request. The discussion of the factors affecting these two parameters parallels that of m_p and T_p. It is interesting, however, to notice that m_{io} depends only on the process being considered.

Hence, the process efficiency will be

$$\eta_T = \frac{V}{T} = \frac{1}{1 + m_pT_p + m_{io}T_{io}}$$

In order to simplify the discussion we can assume that T_p and T_{io} are composed only of seek time and/or rotational delay plus data transfer time. We can also include the time spent in the queue waiting for the request to be processed. The overhead in T_p and T_{io} is supposed to be small. Measurement of the paging and disk file channel queues indicate that before thrashing no queues are formed at the I/O channels. Unfortunately this condition does not last long, for when N_{AP} grows the transfer time T_p grows, because longer queues form. There is, in addition, the increase in m_p due to thrashing. In the limit we will have

$$m_pT_p \gg 1 + m_{io}T_{io}$$

Before thrashing the system efficiency grows linearly with N_{AP}

$$\eta_{sys} = \frac{N_{AP}}{1 + m_pT_p + m_{io}T_{io}}$$

As the multiprogramming level is increased longer queues form at the paging channel. If the drum is organized as a FCFS drum, like in CP-67, there will eventually be $N_{AP} - 1$ requests in the queue, each request requiring T_p time units to be served. If T_D is the time the channel is engaged serving one request we would have

$$T_p = (N_{AP} - 1)T_D + T_D = N_{AP}T_D$$

The quantity m_p can be expressed as $A + B\ N_{AP}$, A, B constant.

Consequently,

$$\eta_{sys} \simeq \frac{1}{AT_D + BT_DN_{AP}}$$

And the efficiency decreases hyperbolically with N_{AP}. We can then distinguish three regions in the response of the system's efficiency to an increase of the multiprogramming level. In the first region it behaves nearly linearly, in the third region it decreases hyperbolically and in the in-between region it will grow slowly until reaching the maximum possible efficiency (see Figure 3).

The influence of the multiprogramming level on system efficiency has been discussed in Reference 11. However, that model is exceedingly simplified and neither the variation in paging rate nor I/O operations are taken into account. But it is pointed out that some optimum multiprogramming level must exist. Some experimental data are given in Reference 8 but the CPU is near saturation at the measured points.

Proceeding in the same manner as for m_p we find that m_{io} is practically constant. Its value has been found to be

$$m_{io} = 0.1 \times 10^{-3} \text{ requests per instruction}$$

Typically the time necessary to process an I/O request is about 50 000 instructions. Since no queues are ever found at the disk channels the product $m_{io}T_{io}$ can be assumed to remain essentially constant.

Figure 5 shows the experimental values for n_{WD}, the number of requests waiting to be served by the drum channel, as a function of N_{AP}. To obtain a mathematical model of the system is a more difficult question. Most feedback queuing models assume exponentially distributed service times, which is not the case of the drum. Another model is given in Reference 12 where the drum's service time can be a constant or a random variable. However, in this model file I/O operations are not taken into account. The model discussed in Reference 13 does take into account disk I/O operations, but the I/O request sequence and operations are fixed. Thus it is of no avail in our case. In view of the paucity of existing mathematical models we feel justified in applying the simple M/G/1 queuing model to the drum. The data transfer time of the drum is 3.5 msec for a page and a complete revolution is made in 17 msec. Using the Khinchine-Pollaczek formulae we can find the theoretical curve plotted also in Figure 5. The curves diverge after $N_{AP}=3$, which is about the point where the system begins thrashing.

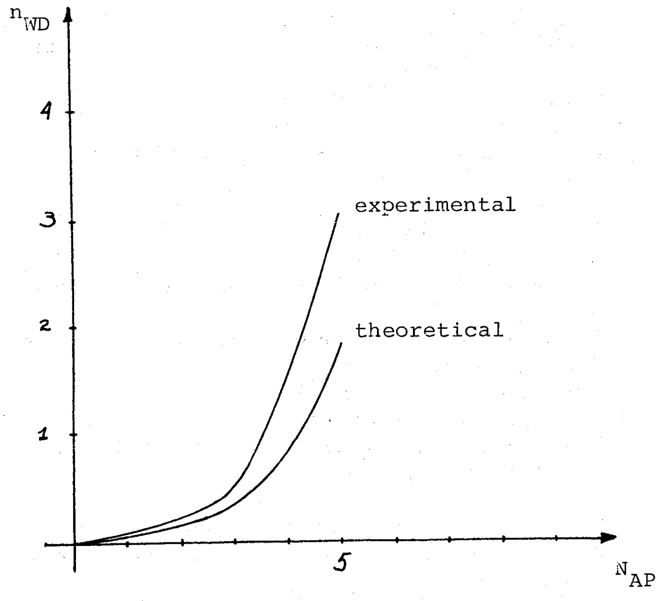

Figure 5—Size of drum wait queue: n_{WD}
vs.
Multiprogramming level: N_{AP}

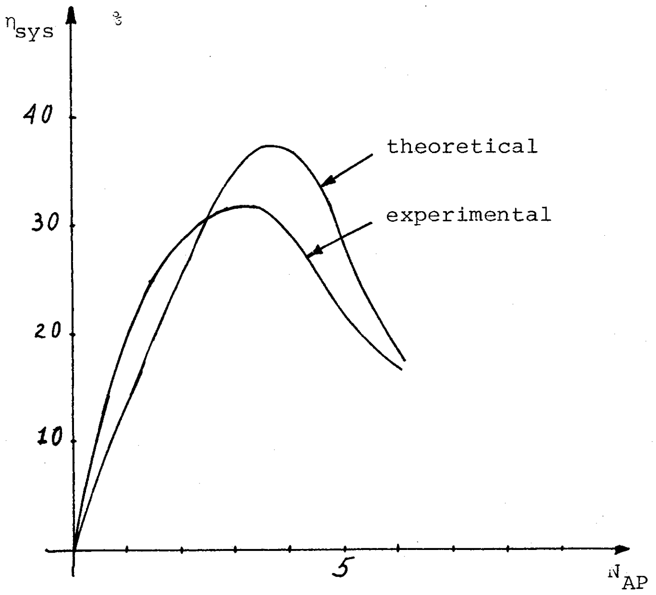

Figure 6—System efficiency: η_{sys}
vs.
Multiprogramming level: N_{AP}

Figure 6 compares the experimental values obtained by using the results of the M/G/1 model for T_p and the measured values for m_p. For small N_{AP} the curve is very sensitive to $m_{io}T_{io}$. Further measurements are necessary in order to obtain better estimates of program behavior. As N_{AP} grows, the number of requests actually waiting in the drum queue is greater than the calculated value and their difference causes the theoretical curve to be an upper bound on the system efficiency.

Figure 7 shows the cumulative distribution function for N_{AP}. The average multiprogramming level never

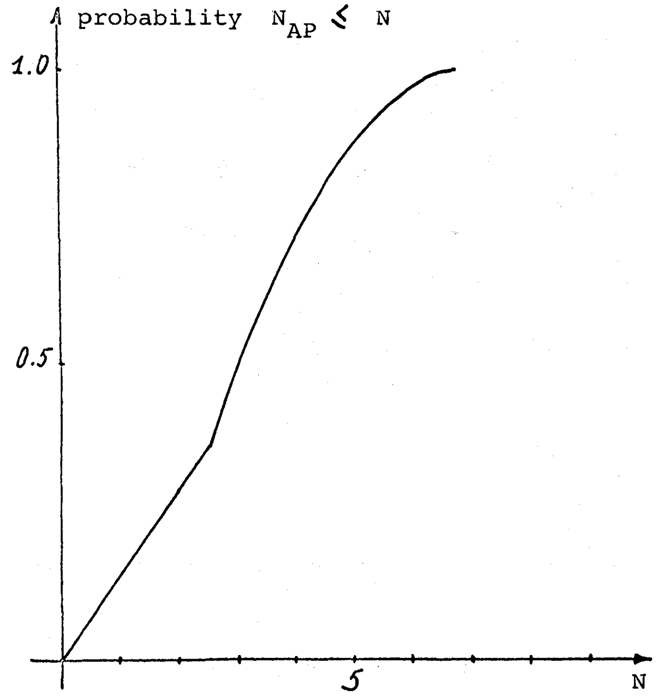

Figure 7—Cumulative distribution function for N_{AP}

reached 7 in this case. All values between 0 and 2.5 have the same probability of occurrence. The most probable value is the same as the mean value and it is 3.0. Assuming the thrashing threshold to be at $N_{AP}=3.5$ we find that the probability of thrashing is 40 percent. There is only a 25 percent probability of being in the optimum region $(2.5 \leq N_{AP} \leq 3.5)$. Of course the multiprogramming level depends on what the users are doing. It seems that 35 percent of the time the multiprogramming level is less than 2.5, meaning that the users are not active enough to impose a heavier load on the system. From the efficiency standpoint it seems that, should the service demand be large enough, it is better to tolerate some thrashing (e.g., $N_{AP}=4.0$) than to be overly anxious to avoid it, imposing, for example, $N_{AP}=2.0$.

CONCLUSION AND FUTURE WORK

The system described permits evaluation of the behavior of CP-67 in a given environment. The limiting factor was found to be main memory, since neither the CPU nor the I/O channels were saturated. Main memory has been increased to 1024K bytes, and the measurement system has permitted evaluation of the new configuration.

Since the original dispatcher does not prevent thrashing, it has been modified to follow a working set policy. Data are being collected to analyze its behavior. In particular, more information is needed about process resource demand and I/O behavior.

ACKNOWLEDGMENTS

The authors are indebted to Mr. M. Peltier and Mr. C. Hans, of IBM France Scientific Center, for their guidance and stimulating criticism. Professor B. Arden, presently visiting Grenoble University, has been kind enough to suggest some modifications. A. Fusi, of IBM Italy Scientific Center, and J. P. LeHeiget, of Grenoble University, collaborated in the initial design of the measurement system. Many friends have reviewed this report and the anonymous referees have provided constructive suggestions.

The work of the first author has been supported by a research grant from IBM Svenska A.B. and a scholarship from the French Government.

LSI and minicomputer system architecture

by L. SELIGMAN

Data General Corporation
Southboro, Massachusetts

INTRODUCTION

The direct impact of Large Scale Integration (LSI) on minicomputer system architecture has been and will continue to be evolutionary and incremental, not revolutionary.

LSI has been applied to minicomputers most effectively in the form of an incrementally improved technology. When well understood, it has offered predictable cost reductions and performance improvements. It has been most successful commercially when combined with other factors such as improved core memory technology and imaginative new approaches to minicomputer packaging. While the combination of these factors has been steadily driving prices down and performance and reliability up, we are not likely to see the bottom drop out of prices. There will not be a full scale minicomputer in every gas pump in the near future; nor will there be such dramatic improvements in minicomputer performance that minis will replace large System 360s one for one.

INDUSTRY MATURITY

Although technological advances, including increased use of LSI, have improved both price and performance, the recent maturing of the industry has had a more dramatic impact on the minicomputer market; thus, it has also had an indirect impact on the technological base of the industry.

A few years ago, there were many companies selling minis. The cost of entering the market was low, and many of these companies enjoyed some initial success. In the last few years, however, price competition has increased significantly, and the number of manufacturers has shrunk. Concurrently, the OEM minicomputer market has grown, such that, while there are many fewer companies in this business today, those who remain are each manufacturing thousands of units a year. These large minicomputer manufacturers are necessarily becoming very manufacturing-oriented. Their production methodology is growing to resemble that used in producing consumer electronics. Indeed, as Figure 1 shows, a modern mini with 32,000 16-bit words of memory and several peripheral controllers is about the same size as a stero receiver.

Volume production of such a complex product has been facilitated by the improved reliability provided by the new technology. In fact, the greatly increased reliability of the modern mini, based in part on the use of LSI, has been a major factor in its proliferation, especially in real-time systems.

The basic cycle of a maturing industry—larger market, fewer manufacturers, better product, higher volume, increased manufacturing orientation—has naturally driven prices down and opened new application areas.

The indirect impact of LSI grows out of the business cycle as each of the minicomputer manufacturers remaining use many more integrated circuits. The successful manufacture of complex integrated circuitry requires high volume to obtain the high yields required to achieve profitability. Without large volumes, LSI manufacture is burdened with high prices, low yields, stalled development programs, and money-losing sales efforts. However, as minicomputers begin to use more LSI—more because the product design calls for more LSI per unit, and because more units are being made—large IC production develops. At this point the snowball effect begins to work beneficially. There are large circuits requirements, higher yield, lower costs, larger orders. This process is very much in keeping with the evolutionary character of changes in mini price/performance. That is, the manufacturers are increasing their use of LSI technology in predictable, evolutionary way, and not as a means to a breakthrough.

A third element in the growing maturity of the industry has been the diffusion of computer-oriented professionals into most industries. Many of the students

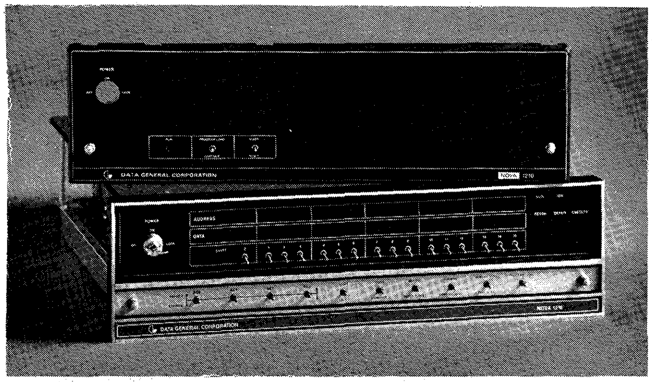

Figure 1—A modern minicomputer with 32,000 words of memory and several peripheral controllers requires only $5\frac{1}{4}''$ of rack space

who had hands-on experience with minicomputers in the university environment will apply this experience to the development of minicomputer based systems for specific applications that had not previously used computers, and they contribute a wealth of ideas to the industry itself.

EFFECT OF LSI

While the result of these technological and business developments has been an evolutionary improvement in the price, performance, and reliability of minicomputers, the effect of the improvement has been revolutionary in one important area—the basic architecture of medium-scale computer-based systems.

There have been two elements in the revolution. First, the minis are real and system designers can trust them. They have become inexpensive, so inexpensive that they are impossible to ignore; and they are reliable, largely because they contain far fewer components and are built in long production runs. For those applications with emphasis on logical decision making, their performance is comparable to large-scale systems.[1]

Thus, system designers are using minicomputers in new applications such as front ends or preprocessors for large business data processing installations; at various levels in hierarchical communications systems; in small, dedicated accounting systems; and in groups in real-time control applications.

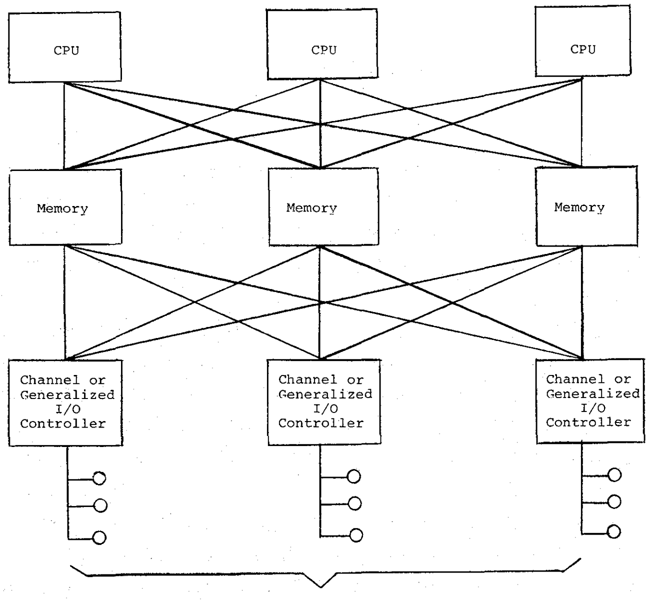
The second part of the revolution is more interesting and is developed in detail in this paper. As the minis have become faster, more reliable, and less expensive, they have forced changes in the traditional perception of a computer system. Today most minicomputer processors comprise a relatively small part of the cost of the system. Peripheral devices and their controllers, the system hardware package, and the software to run it all costs as much or more than the basic CPU/memory package.

It no longer makes sense to hold a strictly processor centered view nor does it make economic sense to base all design decisions on a requirement to keep the central processor busy all the time. The low total costs of modern minis make multiprocessor minicomputer systems a practical alternative to large multitask monoprocessors, especially in real-time systems which can be partitioned into individual functional tasks.

MULTIPROCESSOR CONFIGURATIONS

The use of multiple minicomputers, each performing some relatively independent function as part of an overall system, is a natural extension of the concept of the dedicated realtime minicomputer that has evolved over the past several years. This technique is in sharp contrast to the traditional approach to a real-time application, which consists of dropping the entire time-critical package onto a single processor. The alternative approach outlined here substitutes an individual minicomputer for each of the natural functional subsystems of a large-scale application, interconnecting the miniprocessors through an adequate communications path.

The "traditional" or general multiprocessor system is a cross-connected network of processors, memory, and I/O controllers (channels); this configuration



CPU
CPU
CPU
Memory
Memory
Memory
Channel or Generalized I/O Controller
Channel or Generalized I/O Controller
Channel or Generalized I/O Controller

Figure 2a—Traditional multiprocessor

shown in Figure 2, is widely described in the literature[2] and is most often proposed for the multitask environment.

A number of problems have arisen in the completion of the development programs for these systems. Very high utilization is considered imperative for these systems, and a sophisticated multiprogramming executive is required to keep the processor busy. Use of a large executive control program is acceptable so long as the costs of resource allocation and optimization do not exceed the savings which can be attributed to its use. This goal has not always been realized,[3] although a good deal of research has been done on "balanced" resource allocation.[4] Minicomputer multiprocessor systems will inherit similar problems if configured in the traditional patterns. In addition, these problems would have to be solved in light of the particular constraints imposed by minicomputers, especially the amount of software development resources which can be applied economically.

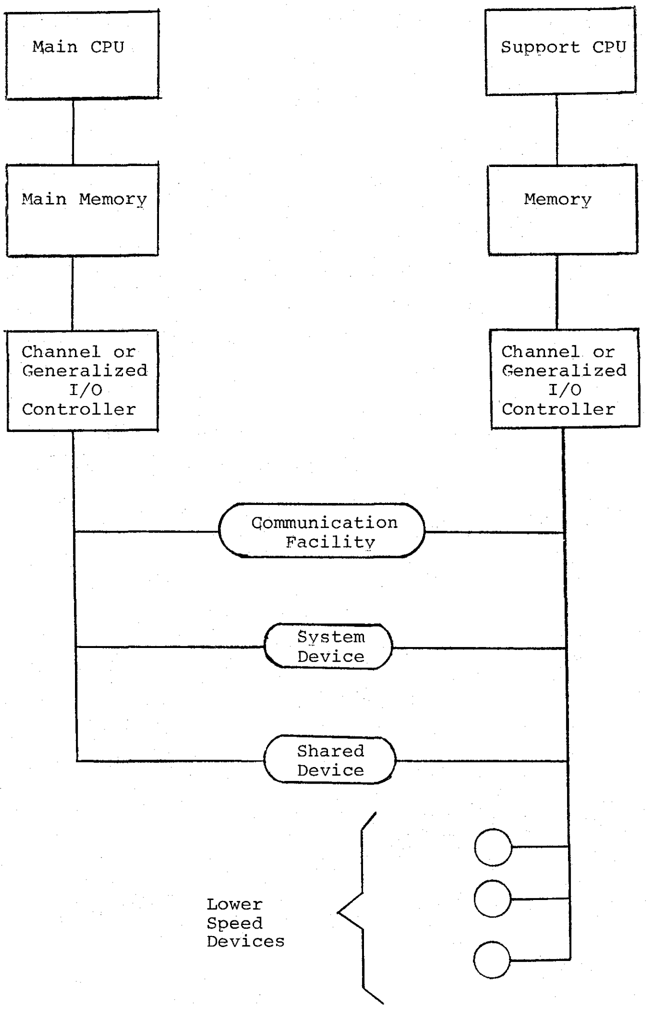


Figure 2b—Associated support processor

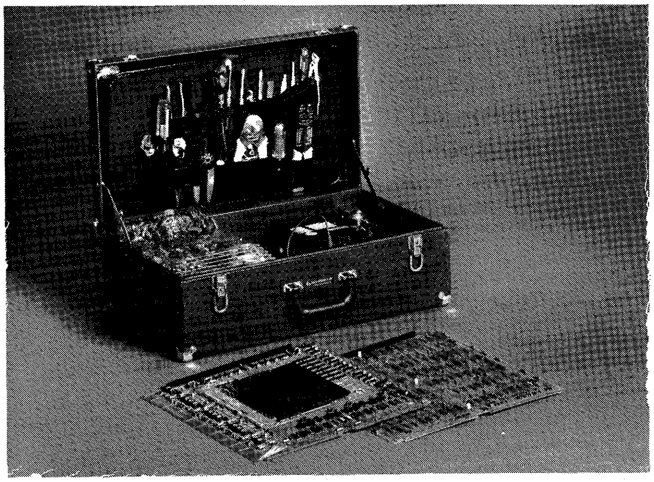

Figure 3—Processor and memory subassemblies

While there are a number of these traditional multiprocessor systems in use today, many more multiprocessor systems are organized in the form of a main processor and one or more smaller support processors. The processor cost in each system is often sufficiently low compared to the cost of the peripherals required to support the data base that it is economical to increase capacity with additional processors.

This associated support processor concept is less elegant, but it has been more successful commercially, mainly because the program development efforts required to make it operational are within the resources of the various manufacturers. The support processors function primarily in the I/O area, freeing the main processor to perform computational functions, while communications, file maintenance, and most I/O activities are handled elsewhere. Even without an explicitly programmed support processor, a typical large scale system is a multiprocessor in that the data channels and some of the peripheral subsystems (especially the disk) contain a substantial instruction processing capacity.

The increased use of LSI imposes some new economic constraints, especially in regards to multiprocessor configurations, on minicomputer systems engineering. The cost of the central processing or memory units are so low that one is forced to view them as modules. In fact, in the case of the Nova 1200 series, as shown in Figure 3, the processor is a single replaceable printed circuit card as is an 8192-word memory module. Other modules, for example a magnetic tape or disk controller, are about equally complex as a processor. Since the manufacturing volume of the processor module is higher than the others, its sales price can be lower. Thus, the use of multiple processors need not add significantly to the system cost.

Once it is decided that a multiple processor approach is the most suitable for a particular application, the intramodule connection facility must be selected. Due to the small physical size and low cost of the modules, the interconnection facility and the mechanical package(s) must be low in cost or much of the potential economic advantage of LSI is lost. Yet, the interconnection facility must support the extremely high combined data rates found at the processor-memory interfaces.

The generalized crossbar interconnection scheme used in the traditional multiprocessor does not meet these needs. Nor does there seem to be a general solution to the multiprocessor system design problem. One does not simply replace a single $200,000 large scale processor with 50 or fewer $4,000 minis, however tempting. However, a number of specialized minicomputer systems have been developed with the concept of the mini as a system element, and some general principles can be abstracted from these designs. As implemented on the minis, none are multiprogramming systems but by necessity they would have been if they had been implemented on a one or two processor large scale machine. They are all organized in a form similar to the associative support processor concept. A processor and sufficient storage to hold its application program and data buffers form a module. Several of these modules are connected via a high speed interconnection bus, so that data and control information can be passed among the several functional programs.

THE PROCESSOR/STORAGE MODULE

The processor/storage module approach of Figure 4 (PSM) calls for the loose interconnection of a number of such modules into a single system according to a partition of the overall application into functional tasks. The modules operate independently but are tied together via an interconnection bus that allows a number of concurrent intermodule logical communications links to be established. Processing is thereby distributed across the system rather than concentrated at a central point.

The logical basis of the PSM approach is "locality", which is the observed phenomenon that the memory address patterns generated by a processor are not random but exhibit a strong clustering. This principle has led to the development of many storage hierarchy systems ranging from cache memories in modern large scale machines[5] to various overlay systems like the chaining feature in Fortran to demand paging timesharing systems. The success or failure of these various approaches depends on the relationship between the amount of locality encountered and the overhead incurred on nonlocal references. The general problem is difficult to model mathematically, although in recent years several approaches show promise.

Locality requires, especially in real time systems, that certain portions of the program be resident in primary (low access time, executable) memory; other portions can be brought in as needed. Minicomputer economics are such that each memory partition might just as well have a processor associated with it. One would then think of the memory as defining a function, specializing a processor for a task just as read-only control memory has been used to define the function performed by microprogrammable controllers.

The interconnected processor/storage module organization described here constrains the programs written to a form that is highly local. Like chaining in Fortran, intermodule references are quite explicit and, hence, visible to the individual programmer who most optimally partition the program.

Not all of the individual minicomputer subprograms need come directly from a partitioning of the task. A PSM can be used as a flexible, programmable controller to enhance the performance of peripheral equipment. In the message switching system example below, the disk control program and associated processor, together with a simplified hardware controller, perform many of the more sophisticated key search functions that would, in a large scale system, be performed in part by the file controller itself. The major advantage of the mini as a controller is that it can be programmed by the user for its particular task rather than micro-programmed at

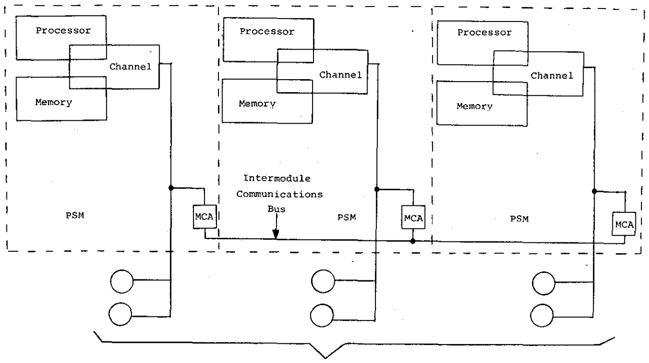

Figure 4—Processor/storage module system organization

the factory for a generalized task. It is far easier to modify a factory supplied operating system than to alter firmware.

In addition, programs can be swapped in and out of a physical memory through the inter-module communication facility. In such a situation, one module would have secondary storage associated with it and would distribute programs on request (or by some scheduling algorithm) to other modules. In essence, it would act as a (micro-) programmable multi-port disk controller serving many processors and would perform certain system level executive functions.

The hardware actually used to interconnect the processor is termed a multiprocessor communications adapter (MCA). One MCA is attached to the I/O bus of each computer in the system, and the adapters are connected together by a common communication bus which is time-division multiplexed among the adapters. Although a single circuit module, an MCA actually contains independent receiver and transmitter subsections, allowing simultaneous reception and transmission of data. Each interface is connected separately to the data channel. The program need only set up an interface for receiving or sending, and all transfers to and from memory are then handled automatically by the channel hardware. A processor with an adapter can establish a link between its transmitter and any receiver it designates, provided that the receiver adapter has been initialized for reception.

A number of logical links concurrently share the single communications bus using time-partioning multiplexer circuitry built into the adapters. If there are N logical links established and communications is proceeding on all, each link receives 1/N of the communications bus time. The bandwidth of the bus is 500 KHz (1 million bytes per second). However, this rate will only be obtained when a large number of links are active concurrently as data rates are primarily determined by the processor's channel facilities. The typical data rate on a single link for a pair of Nova-line computers with high speed data channel feature is 150 KHz.

Each adapter has a unique identifying number assigned to it. These codes are used to specify the number of a second adapter to which the first is to be logically connected. Upon receipt of the first data word from some transmitting adapter, the identifying number of the transmitter is set into the receiver adapter status register; the receiver will subsequently accept further data only from the transmitter, i.e., it "locks" to that transmitter. It must be explicitly unlocked by the receiving processor's program.

A number of the specifications of the MCA arise from the need for the whole system to remain functional despite a hardware or software failure. The transmitter registers must be initialized by the transmitting processor; and the receiver registers must be initialized by the receiving processor. Thus, a transmitter cannot force data into a receiving processor at addresses not specified by the receiver. Transmission of a block terminates when the number of words transferred satisfies the transmitter or receiver with the shorter word count. In addition, a receiving processor is not only protected against a failing transmitter as described above, but the hardware is arranged so that any of the interconnected computers can be stopped or have their power switched off without affecting the other computers still in operation. If a processor adapter attempts to transmit data to an unavailable receiver adapter, a timeout interrupt will occur after a delay of approximately 10 milliseconds. If the receiver is unavailable because it is linked to another transmitter, the transmitter may be restarted for further attempts or the data may be routed to a different receiver.

The size and nature of the data transmission can follow any convention established by the user; no particular structure is forced by the hardware design. In a relatively simple system in which the size and nature of the data block to be transferred is always known in advance, the receiver can simply initialize itself to accept the next block at the completion of the previous transmission.

If the exact size and nature of the data blocks is determined dynamically, a control block specifying the nature of a transfer can be transmitted before the actual data block. With such a convention, the receiver initializes itself to accept a control block of standard format and unlocks itself. The first word transferred to the receiver locks it to the sending transmitter by setting the transmitter's code into its status register, locking it to that adapter transmitter until explicitly unlocked by the program. Thus, once the first word in a control block is accepted, the receiver is locked to that transmitter and can be initialized to accept subsequent data blocks from the appropriate transmitter.

Alternatively, the control block from adapter A to adapter B can be a request for data. Adapter B's transmitter can be started sending the desired data while its receiver is reinitialized to accept a new control block. The hardware itself does not distinguish between a data and a control block.

The first sample system using the PSM approach is shown in Figure 5. The function of the system is small scale message switching and it uses the separate control and data block technique. Separate processors handle: (1) interfacing to synchronous and asynchronous lines, (2) disk queuing, and (3) executive and journal func-

Queuing Module, Disk Controller, and MCA.

Figure 5—Small-scale message switch

tions. The system is an analog of its large scale predecessors in the sense that PSM's duplicate the functional software components.

The synchronous and asynchronous line control processors duplicate the functions of a transmission control unit as well as the functions of the line-control and polling-sequence subprograms normally run in the central processor. The number of processors required for these functions is determined by the total combined line rate supported. It can vary from one to several depending on the capacity of the rest of the system. Similarly, the disk processor duplicates the key search functions performed by more sophisticated large scale computer disk subsystems. It also decreases effective disk access time since it can use its core (up to 64K bytes) as a data buffer in three ways. First, write operations as seen by the line control processors are virtually immediate, as the data can be passed through the MCA at 300 K bytes/sec. to a primary memory buffer area for future writing on the disk. Second, the queuing processor can optimize the order of seeks to the disk, thereby reducing disk latency. Finally, if sufficient primary memory buffering space is available, the queuing processor can look ahead in the queue for output messages. In some cases, a message accepted by the queuing processor would be output directly from primary memory if it had not yet been written on disk. All of these techniques are possible in a single large scale processor as well as in the multiple mini configuration; however, they are less practical, due to the relatively higher price of the needed primary memory and limited processing time available.

For lines using the bisynchronous communication discipline, the synchronous line processor is definitely needed. The control sequences required by that communication discipline are complex and expensive to implement in hardware. By using software drivers, not only can the control procedures be handled for a large number of lines, but a variety of other line disciplines can also be accommodated (i.e., "foreign" terminals can easily be added to a system.)

The journal and executive/monitoring functions are traditional. As the disk is basically organized as a ring buffer, older messages can be copied from it onto tape during the system's idle periods in order to keep as much space as possible available on disk. A second tape keeps a permanent record, including sequence numbers, terminal ID's, etc., of system activity. The executive function is primarily active in case of error, rebuilding the system after error through journal tapes; it also responds to system level messages, such as requests for retransmission of an earlier message.

The significant point is that new functions and applications modules are not limited by total computational capacity, because additional processor modules can be added as necessary.

A second example of the PSM approach is the experimental multiprocessor small computer system developed at the Plessy Laboratories for the control of a small telephone exchange.[6] The design is inherently extensible and allows for better performance for both voice and data users since the processing capability is distributed among the several processor/memory modules, the number of which can be varied according to the size of the switching network being controlled. The modules are interconnected via a "ring highway" data transmission path similar to the previously described multiprocessor communications adapter.

The organization of the control programs for the multiprocessor complex is almost identical to the organization used in the (essentially) single processor telephone exchange control developed at Bell Laboratories.

In both cases, large tables stored in memory define the state of the switching network itself, and individual, table-driven functional programs are run to implement the various stages in the completion of a call. The major difference between the two approaches is that a spatial distribution of programs across several processors is used in the former, while a time division of the processor is used in the Bell System No. 1 ESS. The amount of interprogram data movement is proportional to the number of calls that can be completed per second. This number is relatively small, since it is limited by the electromechanical nature of the switching equipment. A detailed description of the functions performed is beyond the scope of this paper, but such tasks as dial pules accumulation, network computation, billing, and trunk signaling are typical.

A second important distinction between the Plessy and Bell systems results from different goals influencing the tradeoffs between the costs and benefits of redundancy and error detection. The micro-synchronism of the two computers used in No. 1 ESS allows for the immediate detection of hardware errors at the cost of doubling the amount of hardware required. The PSM approach allows as few as one additional module to be used for lower cost redundancy but does not provide as good error detection. Dual micro-synchronous processors could, of course, be used as modules in the PSM approach which is probably less susceptible to software errors. In addition, many of the real-time problems encountered in a time-division, traditional multitask system can be avoided because modules can be added as the traffic load increases. In fact, as in the message switching system, the modular design facilitates the duplication of a module or application program when use of that program exceeds the available subsystem capacity.

SUMMARY

A number of technical and economic arguments have been presented for the use of multiprocessor minicomputer systems. It is hoped that the examples given will spur the development of a methodology for system design.

Approaching the minicomputer on a silicon chip—Progress and expectations for LSI circuits

by H. G. RUDENBERG

Arthur D. Little, Inc.
Cambridge, Massachusetts

INTRODUCTION

Technological progress in semiconductor integrated circuits during the last five years has been truly astounding, and the results of this progress are being aggressively exploited in the designs of new minicomputers. During the 1960s, effort in minicomputer design was concentrated on applying the low price, high speed, and ever-increasing complexity offered by the integrated circuit industries to the original architectures so as to provide greater speed and particularly lower cost. Much of this effort consisted of substituting first MSI and now LSI circuits for the simpler integrated circuits with which previous minicomputers were implemented without greatly changing either architecture or structure and programs. With such substitution, however, tremendous decreases in system cost and some increases in speed were accomplished. Most recently, new structures and architecture are being examined so as to further extend the capabilities as well as economy of minicomputers.

Especially impressive has been the impact of LSI on small, portable electronic calculators; one can readily expect a revolutionary impact soon on minicomputers. For example, during 1969-70, the electronic calculators then sold required five separate MOS/LSI devices. Present calculators function with two or three different devices, and one now being developed performs all calculating functions with a single large MOS/LSI device. In these examples, modern LSI semiconductor technology has created the LSI calculator-on-a-chip, which requires only the input keys, output display, and power supply in order to provide the four major mathematical functions for up to sixteen digits. Soon we shall similarly see the microcomputer and the minicomputer-on-a-chip or possibly two or three chips for separate memory logic and interface. A microcomputer of modest capability using four-bit words has already been conceived and implemented.

Before attempting to evaluate the possibilities and assess the likely impact of recent advances in LSI technology on the minicomputer field, we shall examine the progress made to date and, from this, draw inferences about likely developments over the next several years.

PRESENT ACCOMPLISHMENTS

Performance improvements

The great progress achieved by the semiconductor industry during recent years has been widely documented. LSI circuits underwent considerable improvements between 1965 and 1970, as shown in Table I.

TABLE I—Best Characteristics Available in Integrated Circuits or LSI

Function	1965-66	1970-71	Factor of Improvement
Switching delay (nanoseconds)	12	1.2	10:1
Device complexity per chip			
Gate circuits			
Bipolar	12–16	150	1:10
MOS	100	5–10,000	1:100
Bit density			
Bipolar	4	256	1:64
MOS	32	1,024	1:32
Price per device package	$2.00	20¢	10:1
Per gate or circuit function			
Bipolar	$1.00	4¢	25:1
MOS	$0.30	2¢	15:1
Per memory bit (RAM)			
Bipolar	$4.00	6¢	65:1
MOS	$1.00	1¢	100:1

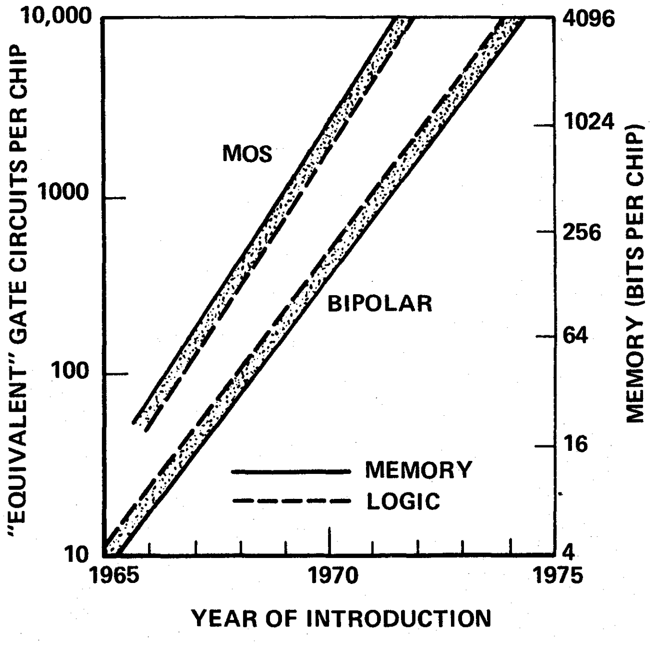
SOURCE: ADL

Figure 1—Speed of bipolar integrated circuits versus year of introduction

These improvements can also be seen from Figures 1–3, which present the achievements in speed, complexity, and price of LSI circuits during this period and project their trends to 1975.

Trade-off relationships

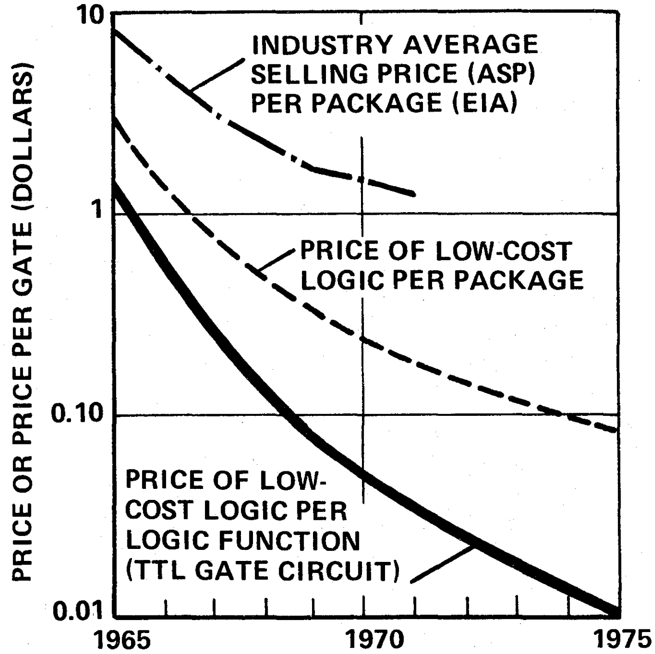
The data of Figures 1-3 and Table I represent peak achievements of devices offered by the industry; naturally, not all of these peak achievements can be obtained simultaneously from the same device. However, by examining commercial offerings more closely, trade-off curves depicting the available relationships between several of these factors can be determined which describe the data available for any technology at a given time.



SOURCE: ADL

Figure 2—Complexity of LSI and IC versus year of introduction

Of considerable interest are the performance trade-offs against price. With increasing circuit function complexity, the price of mass-produced bipolar logic gate circuits will obviously increase due to the decreasing yields obtained for large, complex silicon devices. Ultimately, when device size or complexity measured by the number of gate circuits per module rises into the hundreds, the yields become low and cost of production rises disproportionately rapidly. Figure 4 depicts this relationship for some commonly purchased TTL circuits. These prices represent recent quotations for quantities of ½ to 1 million units per year and are believed representative of the present status.



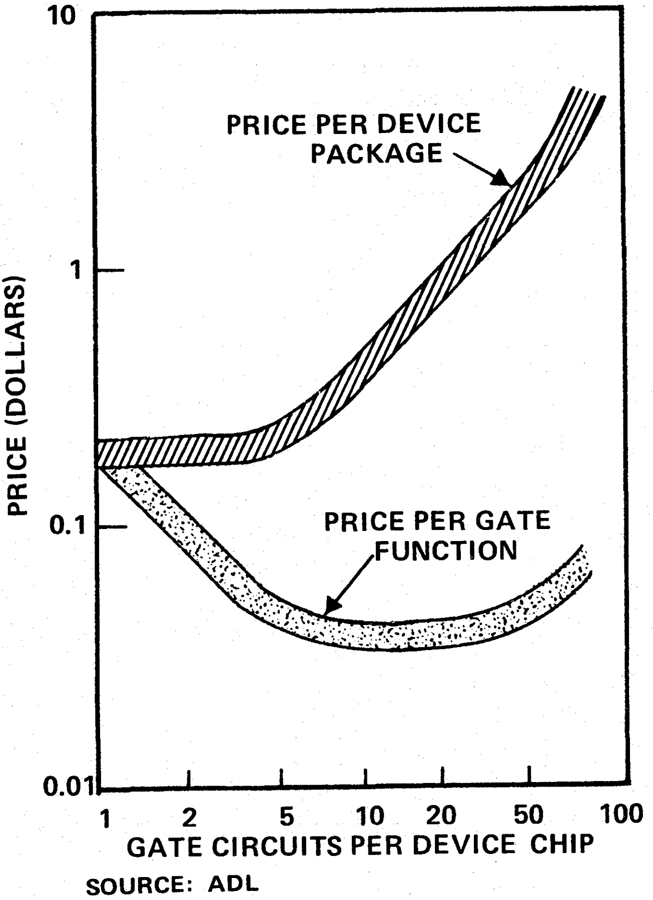
SOURCE: ADL, EIA

Figure 3—Price of bipolar logic circuits

A more useful picture is obtained by dividing the price by the number of gate circuits contained on each chip, thereby obtaining the price per circuit function. In mid-range, this price of bipolar TTL circuits ranges between 3¢ and 4¢ per circuit function. It is readily seen that for devices of low complexity one primarily pays for the packaging; in devices of high complexity, yields become of overwhelming importance and actually raise the price per circuit function.

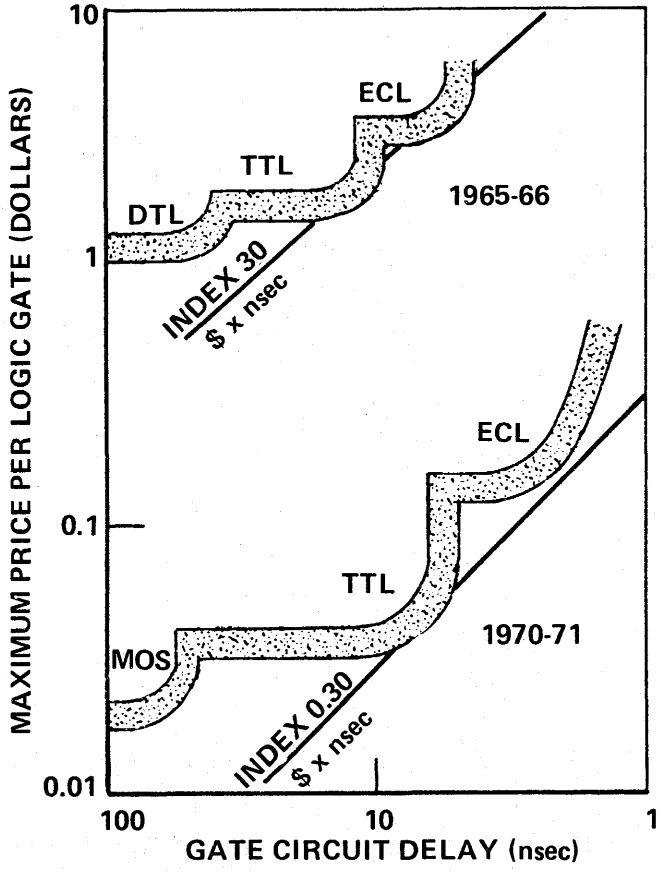
This mid-range price has decreased greatly from year to year and depends, of course, on the volume of purchasing, the type of package (such as military or commercial), and other factors as well as the circuit technology used in implementing the logic functions. Figure 3 illustrates the time development of this economic figure of merit for logic, the price per gate function. In 1965-66, the cheapest logic circuits readily available were DTL circuits, whereas at present the cheapest bipolar integrated circuits are TTL, and some still less expensive logic circuits are MOS. It is seen that the reduction applies to the cheapest units available as well as to the average for the industry; the latter is generally three or four times higher, since it represents also the effect of smaller unit volume of some types as well as military and specialized packaging.

In a like fashion, one may survey the price/speed relationship by plotting such minimum function prices of present offerings against the gate circuit delay or speed (Figure 5). This shows the enormous improvement achieved during the last five years in both lowered prices and faster performance. A similar survey of memory bit prices (Figure 6) also illustrates a dramatic improvement.



SOURCE: ADL

Figure 4—TTL logic price (1971) versus complexity



SOURCE: ADL

Figure 5—Price per logic gate versus speed (delay)

Price/performance index

These classes of devices may be compared by means of a price/performance index. The "present best" figure is obtained by multiplying the price per bit or gate function times the gate or access delay. The result is a price/performance index number representative of the cost per unit speed of the individual logic and memory components. When plotted against time as in Figure 7, it illustrates the dramatic improvement in price/performance achieved by industry during the late 1960s. It would be too much to hope that this

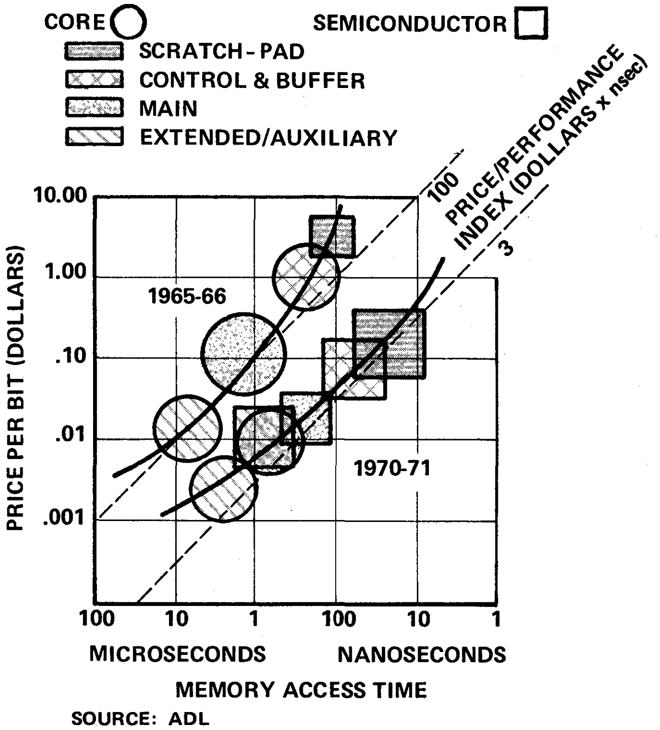


Figure 6—Memory component price versus speed (access time)

revolutionary trend will continue for the next five years; nevertheless, we expect considerable further improvement on which to base new component offerings, even though we have barely begun to utilize all of the performance now available from LSI circuits.

APPLICATIONS TO MINICOMPUTERS

The earliest applications of LSI have been in logic. This has usually entailed straightforward translation of the transistor circuits of the earliest minicomputers to integrated circuits and now to LSI. Thousands of transistors are normally manufactured by the semiconductor producer on a single wafer and then cut apart and packaged individually, only to be wired together again on a circuit board. In the innovation of integrated circuits, the interconnections are placed over the transistors. The wafers can then be cut into groups of devices that are already interconnected internally. With more recent improvements in semiconductor technology, these groups or circuit functions of the integrated circuit were not cut apart but were further integrated and interconnected on the same silicon chip, leading to large-scale integrated circuits or LSI. The masks also had to be shrunk so that a complex LSI circuit could still be squeezed onto a silicon chip perhaps ⅛ inch square. This development naturally also greatly simplified the assembly of minicomputers and of all other types of electronic systems, as dozens, even hundreds, of packages containing LSI circuits need only to be mounted and further interconnected to comprise a highly capable electronic computing system.

At present, more inventive applications are being developed to capitalize further upon the circuitry which can be included along with the conventional serial logic of an integrated circuit semiconductor chip. One example is the selection, multiplexing, and decoding circuits which permit channeling appropriate outputs of the LSI logic to the several communication buses that interconnect various portions of a minicomputer.

A major part of the circuitry of every minicomputer is concerned with memory. Cores were initially used for this function, but a considerable number of integrated circuits were needed to perform the addressing, drive, and sense functions necessary for utilizing core with a few thousand words. At present, LSI semiconductors are becoming price competitive with core memories

TABLE II—Implementation of Small Computing Machines with Logic Circuits

	Avg. no. of Circuit Functions			No. of LSI and IC Device Packages	
	Transistors 1965-66	IC's 1970-71	Increase	1970-71	Decrease
Small computer	10,000	30,000	1:3	1,000	10:1
Minicomputer	2,000	5,000	1:2.5	100	20:1
Terminal (simple)	600	1,000	1:1.7	30	20:1
Desk calculator	200	300	1:1.5	3 (soon 1)	66:1 (200:1)

(Figure 6) and with their associated interface circuits for memories of a size suitable for minicomputers. Thus, in the future, semiconductor memories are likely to be used extensively. However, a somewhat different systems organization will be necessary to allow for the refresh and access or cycle timing required for dynamic MOS memories.

Serial shift registers and read-only memories are also being used in addition to random-access semiconductor memories. The most recent trend we have observed is the inclusion of specialized ROM devices to provide fixed microprogramming or look-up tables for special functions and sequences.

Figure 8—Functional complexity of computers

The considerable reduction in package count attainable through the use of LSI semiconductors is shown in Table II. Between 1965-66 and 1970-71, while the functional complexity of minicomputers at least doubled, the actual package count of comparable machines decreased by a factor of 20 through the aggressive inclusion of LSI circuits for most electronic functions.

Figure 8 illustrates the number of circuit functions generally utilized in minicomputers and various other classes of equipment at a given time. Of course, considerable variations from this generalization are sometimes encountered. The ensuing count of logic and memory LSI packages is projected into the future in Figure 9. This figure, however, presents a rather optimistic situation on the assumption that available LSI technology is utilized fully with custom circuits. As this assumption is not always economically justified, actual machines may lag this curve and use more but simpler standard integrated circuit devices to achieve interfacing and control with integrated circuits and LSI circuits already available.

Figure 9—Lower limit of LSI and IC devices in minicomputers

TECHNOLOGICAL IMPLEMENTATION

Since the initial development of simple integrated circuits, a number of processes and circuit technologies have been adapted to semiconductor integrated circuits and more recently to LSI. During most of the decade, bipolar integrated circuits were fabricated using planar diffusion processes. Logic circuits developed from resistor-transistor logic (RTL) to diode-transistor logic (DTL), transistor-transistor logic (TTL), and now, for the fastest speed, emitter-coupled logic (ECL) or common-mode logic (CML). For a considerable time to come, TTL will be the most popular bipolar technology for minicomputers, as it is available in a wide range of devices at reasonable speed and low price. Most recently, several process variations, such as "collector diffusion isolation," are being developed to a practical status to provide lower cost bipolar devices for simpler processes, albeit at somewhat lower speed.

Since 1965 a form of transistor other than the bipolar transistor, termed the metal-oxide-semiconductor transistor (MOS), has been developed for practical applications in silicon devices. As now implemented, the various forms of MOS technology have a smaller cell area for each function and require fewer processes for manufacture (which leads to higher yields), but they are slower than bipolar integrated circuits. Thus, MOS is exceedingly well suited to LSI, and especially to economic use in minicomputers.

Initially, most MOS devices used the P-channel process; now a few memory circuits use the more difficult N-channel process giving higher speed, and a complementary (C-MOS) structure utilizing both N- and P-channels has been perfected. The latter, while somewhat more expensive to fabricate than P-MOS, nevertheless is expected to be cheaper and a little slower than TTL. C-MOS is especially attractive for its low power drain and high noise immunity. Thus, it may well become the preferred device of the future, promising a good compromise in optimizing price/performance trade-offs among different semiconductor technologies.

IMPLICATIONS

The present impact of LSI is a restructuring of the organization and partitioning of minicomputers. To arrive at a useful architecture, the minicomputer must be partitioned according to the availability of LSI circuits and the efficient use of these building blocks throughout the minicomputer, as well as to preserve compatibility with programs previously used. Four directions are observable at this time:

Intermingling of memory and logic. Each LSI semiconductor memory circuit can now be basically self-contained (with address, decoding, drive, and sense circuits where needed) in an economical size. This circuit will also include chip-select for power control or input selection as well as output busing or multiplexing control. Thus, the semiconductor memory circuit can be placed within this system wherever it is needed, not where the economics of core circuits sharing such peripherals dictates.

Utilization of high internal communication speed. Because a minicomputer does not need to operate at the highest speed of large machines, it can benefit somewhat from the speed/price trade-off. The great improvement in price/performance index of both LSI logic and semiconductor memory can provide much more capable small computers containing only a few functional blocks. Furthermore, as this index at a given time is relatively insensitive to the particular speed and performance compromise, a relatively few high-speed memory and logic circuits used serially may be as economical (in terms of component cost) as a larger number of slower components having longer delays. This permits trade-offs between hierarchical memory levels and shared high-speed logic against larger parallel or interleaved logic and memory circuits to obtain a structure most suited for specific application.

Use of read-only memories and programmable ROM's "firmware." This is now the case even in minicomputers. Microprogrammed memories and array logic are especially simple to implement in the short word lengths that suffice for minicomputers. The same reasons of short word length might even lead to consideration of content-addressable memories in future special-purpose computers, whereas such memories are still much too complex for use in general-purpose machines having long words and large instruction sets. In short, the present size of LSI logic and memory arrays is ideally suited to the design of small computing systems.

Further reduction of package count. With the development of a wider range of LSI to implement all functions or subsystems desired for minicomputers, a further drastic reduction of package count can be projected. We anticipate that minicomputers will be designed in the future with as few as 10-20 LSI complex circuits for all memory, logic, and control functions, yet which have capabilities exceeding their present counterparts.

Already we have seen electronic calculators shrunk to a single LSI device. A four-bit microcomputer that uses as few as four different single LSI devices is now available, and we should soon see further applications of semiconductor LSI to the next generation of highly compact minicomputers.

The external access network of a modular computer system*

by JESSE T. QUATSE, PIERRE GAULENE and DONALD DODGE

University of California
Berkeley, California

INTRODUCTION

A modular time-sharing computer system, called PRIME, is currently under development at the University of California, Berkeley. Basically, PRIME consists of sets of modules such as processors, primary memory modules, and disk drives, which are dynamically reconfigured into separate subsystems. One ramification of the architectural approach is the need for a medium to accommodate three classes of communications:

(1) those between any processor and any other processor,
(2) those between any processor and any disk drive, external computer system, or other device in the facility pool, and
(3) those between primary memory and any device in the facility pool.

This paper describes the External Access Network (EAN) which was developed for this purpose. The EAN is specialized by certain PRIME implementation constraints. Otherwise, it is adaptable to any system having similar design objectives, or to aggregates of independent computer systems at the same site, which share a similar facility pool and which require system to system communications.

Such systems are computer networks in the sense used by Bell and Newell[1]: that at least two computers, not connected through primary memory, must communicate with each other through messages. Although primary memory is a shared resource in the PRIME system, specific measures are taken to prevent interprocessor communications through shared primary memory pages. It was thought that subsystem integrity would be more easily protected if messages are passed between processors through the EAN. In general, separate computer systems can be interconnected by a network like the EAN if they are reasonably close spacially, close enough to make high data transfer rates economically feasible. For example, the computer network at the Lawrence Radiation Labs at Livermore[2] satisfies this requirement. However, it does not necessarily require the availability and security features of the EAN. One PDP-6 is used as a centralized switching computer, a situation which will be seen to be contrary to the PRIME architectural approach. A system more similar to PRIME in some respects is the Burroughs D825,[3] although it is not a computer network by the definition we have adopted. Primary memory is the medium for interprocessor communications; and an external access network, called the "Automatic Input/Output Exchange", is used for communications between a facility pool and primary memory. The D825 and PRIME share important design objectives, availability being one of them. The similarities are reflected in the external access networks of the two systems. However, there are major differences. They stem from an additional objective of the PRIME system design: to ensure date security to time-sharing users. This leads to protection mechanisms described in the text of this paper and to the fact that the PRIME processors do not communicate through primary memory.

Distances profoundly affect the channel capacity and therefore the functional properties of a network. The EAN is to be distinguished from the many networks designed to operate over great distances. Some similarities do exist in the message formatting, as described for the EAN later in the text. For example, the end of message tag and the source and destination identifier are not new.[4] However, these networks are constrained to lower channel capacities. One very high capacity

* The views and conclusions contained in this document are those of the authors and should not be interpreted as necessarily representing the official policies, either expressed or implied, of the Advanced Research Projects Agency or the U.S. Government. long distance network is based upon 1.5 Mbaud links,[5] as opposed to the approximately 20 Mbaud links of the EAN. The ARPA network uses more economic 50 Kbaud links.[6] Another distinctive feature of long distance networks is the way in which availability is achieved. In order to provide routing alternatives, the ARPA network has a much more complex structure than is necessary for the EAN. Also, the ARPA network uses the store-and-forward method to accommodate a non-fully connected structure. The EAN uses a relatively simple structure and has no need to store-and-forward messages.

Thus, the EAN is significantly different from other networks. The difference arises from differing design objectives, principally the high channel capacity, availability, and data security features of PRIME. The design objectives of PRIME, and its implementation, are outlined in the text and related to the EAN. The EAN structure and components are described. Network control sequences are given and the results are summarized.

SYSTEM ASPECTS

The design objectives most important to this paper are high availability and high data security. Availability implies that the system remains in continuous operation, suffering as little performance degradation as possible, during the occurrence of any single hardware or software failure. The PRIME system represents an attempt to achieve high availability without recourse to component redundancy.[7] Instead, the approach is to develop a modular system which utilizes system resources as efficiently as possible, but which is capable of continuous operation whenever individual modules fail. In addition to continuous operation, the system must be capable of maintaining data security in the presence of hardware or software failures. By data security, we mean that the data of any one user is protected from unwanted intrusions by any other user.

The overall implementation is described by another paper in this conference proceedings.[8] In summary, modules such as processors, primary memory, and disk drives, are dynamically reconfigured into separate subsystems while the system is running. One subsystem is designated to run the control monitor which defines subsystem configurations by allocating and scheduling system resources. Its processor is called the *Control Processor.* The others are called *Problem Processors.* Error detection mechanisms, distributed throughout the system, enable the Control Processor to reconfigure subsystems to exclude a faulty module. When the Contiol Processor is suspected of faulty operation, it is automatically replaced by one of the fault-free Problem Processors. The loss of any one module thereby degrades system performance by, at most, the loss of one subsystem.

The fault detection and system reconfiguration capabilities both rely upon two hardware entities: the primary memory map and the EAN. The map serves to partition memory into non-overlapping sets of pages, one set per processor. Subsystems are not permitted to share pages because to do so would considerably complicate the methods used for insuring data security. Instead, interprocessor messages are passed through the EAN where various consistency checks are thought to be more easily implemented. Mechanisms necessary for the isolation of subsystems must be built into the EAN.

An additional objective arises from the fact that the EAN must ensure subsystem integrity while accommodating valid reconfiguration and valid message flow between subsystems. Mechanisms are described later in this paper which aid in the detection and isolation of failures which could lead to the penetration of subsystem boundaries. The subject is treated separately by another paper.[9] Features which ensure availability are described in broad terms here, with many implementation details being omitted. For example, the switching characteristics of the EAN are largely determined by a unit called the Switch Matrix. In order to circumvent catastrophic power failures, each circuit card of the Switch Matrix is powered by a separate supply. The loss of one supply removes one subsystem, but no more. Full details on the Switch Matrix can be found elsewhere.[10]

Other design objectives and PRIME implementation features effected the design of the EAN. Evolvability is generally accepted as a desirable system feature. In our case, evolvability assumes an added significance. PRIME is intended to be an experimental system, a computer laboratory for the study of various implementations of a basic architectural approach. Therefore, the number and types of devices to be interconnected by the EAN could not have been predicted with certainty at the outset. Our strategy was to establish reasonable limits on the growth of the main resources, and to strive for simplicity and generality at the EAN interfaces. Readily available packaging hardware was then chosen which permitted the EAN implementation to meet or exceed the requirements determined by our strategy.

Figure 1 shows the initial configuration of the PRIME system. The main resources are primary

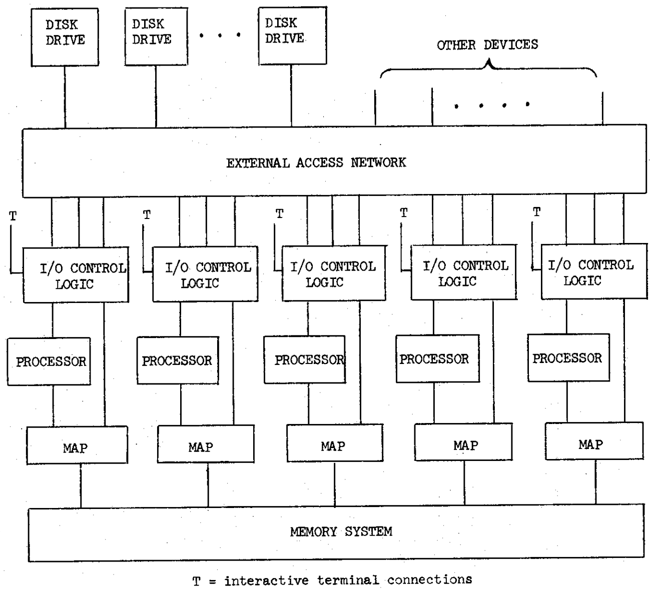

Figure 1—A block diagram of the PRIME system

memory, processors, and secondary storage. In this paper, we group resources in greater detail so that the functional characteristics of the EAN can be better understood. We distinguish between four kinds of resources: primary memory, the processors, the interactive terminals, and the facility pool. The primary memory resource includes the entire bank of MOS memory modules,[11] the memory maps, and the memory part of the I/O control logic shown in Figure 1, although the latter two are physically housed in the processor cabinets. The processor resource includes the five META 4 processors,[12] and all hardware dedicated to the processors (for example, the processor part of the I/O control logic shown in Figure 1). Current plans call for the interactive terminals to be connected directly to the processors, where characters are assembled and relayed to the Control Processor through the EAN. All other resources are referred to in this paper as devices of the facility pool.

The EAN has been scaled to the numbers of processors and devices ever to be found in the PRIME system. Preliminary estimates of the balance of tasks between Problem Processors and the Control Processor indicated that one Control Processor can service approximately four Problem Processors. With an initial system of five processors, a failure in any one results in a total system degradation of 25 percent or less, an availability level which seems acceptable for our purposes. For these reasons, we have permitted our packaging constraints to limit the number of processors to eight. Beyond eight processors, plug-in expansion is no longer possible; but the next eight require only minor redesign. Each processor has been provided with three independent connections to the EAN. Typically, two will be used to control on-going transfers between primary memory and two independent disk drives. The third remains available for interprocessor communications or for communications with other devices within a subsystem. Thus, an eight processor maximum implies a maximum of 24 EAN nodes to be dedicated to processors.

A system with eight processors is estimated to require no more that 20 disk drives of the CDS 215 class.[13] Other devices currently planned for the facility pool include magnetic tape units, a time of day clock, a line printer, and three other computers: an XDS 940, a PDP-5, and a Datapoint 2200. The extensive language repertoire of the XDS 940 on campus will be accessed, at least initially, by means of a 50 Kbaud link to the EAN. The PDP-5 will be used as the processor for a graphic terminal. The Datapoint 2200 is part of the PRIME maintenance and measurement system. Thus, at least 26 devices can be counted. In addition, as will become apparent later, communications between PRIME subsystems require at least one EAN node which otherwise would be used for devices. Therefore, the packaging constraints were permitted to limit to 32 the number of EAN nodes dedicated to devices in the facility pool.

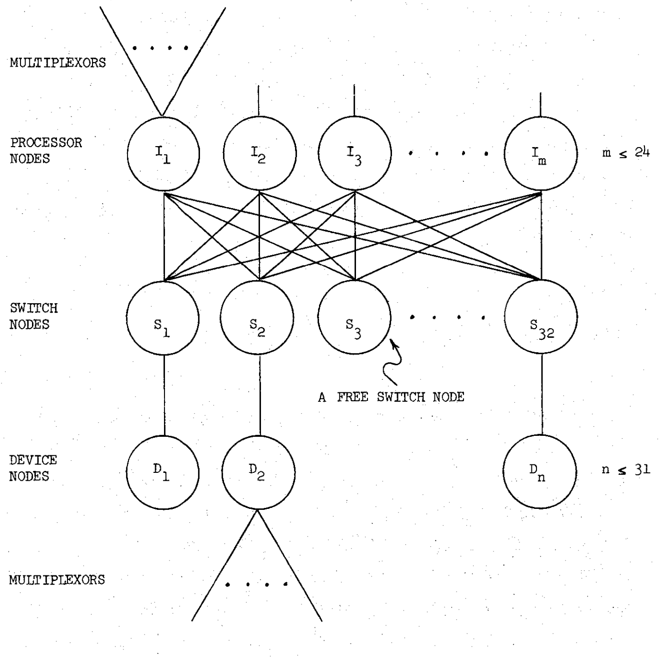

Figure 2—The structure of the EAN

THE EAN STRUCTURE

The EAN has the very simple structure shown in Figure 2. Each path through the EAN consists of two *terminal nodes* linked together by a *switch node.* Terminal nodes serve the purpose of attaching devices to the EAN. A device can be attached to more than one terminal node; but each terminal node is attached to only one device. As explained in a later section of the paper, this device can be a multiplexor which interfaces several devices. Terminal nodes are designated as either *device nodes* or *processor nodes.* Each device node is attached to one switch node. Switch nodes which are not attached to device nodes are called free switch nodes. Each processor node is attached to all switch nodes, but at any one time, at most one switch node can be selected by any one processor node.

A link between a processor node and a device node is established by the processor node selecting the corresponding switch node. A link between two processor nodes is established by both processor nodes selecting the same free switch node. The partitioning into subsystems, and therefore the establishing of links within the EAN, is determined by the Control Processor. However, the dynamic designation of the Control Processor prevents the selection of switch nodes from being done by one centralized control node. Distributing the selection control over all processor nodes makes it necessary for the Control Processor to specify which switch node a Problem Processor should select. Mechanisms are built into each terminal node to guarantee that the Problem Processor has made the correct connection. Therefore the Control Processor retains control of the EAN and acts as if it were the only processor which could establish links. The distinction between processor nodes and device nodes is made for economic reasons. Not all terminal nodes need to provide switch node selection logic and the hardware cost is not negligible.

THE EAN TERMINAL NODES

As is suggested by Figure 3, terminal nodes consist of one, two, or three ports. Each serves a different function. A terminal node is customized to a processor or a particular device by the choice of ports to be included in it. In general, every processor and device is considered to be a collection of registers interfaced to the EAN, usually including at least the equivalent of registers for data input, data output, instruction input, and status output. The interfaces are simplified by providing the *Standard Message Port* (SMP) for register to register transfers. The SMP transfers single words, having fixed length and format. A word may be directed to or from registers within the SMP itself, for purposes of error detection and reporting. All terminal nodes have one SMP.

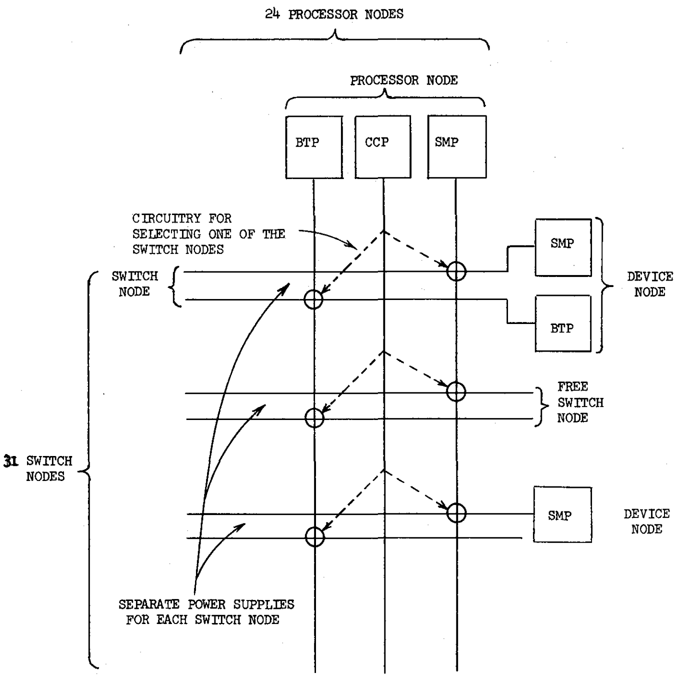

Figure 3—Components of the EAN

A terminal node may or may not include a *Block Transfer Port* (BTP) for transfers between primary memory and devices in the facility pool. The BTP has no fixed word length, transmission format, or error checking capability. Consequently, more complexity is required of an interface to the BTP; but fewer constraints are placed on its design. The purpose is to provide a network channel which has a very high channel capacity and a wide range of operating characteristics. Very high data transfer rates are necessary in order to accommodate disk transfers. A wide range of operating characteristics are necessary because the device controllers of PRIME are not centralized at the devices. In general, the controller logic resides partially at the device and partially in the memory channels. The controller micro-code resides in the micro-code of the processors. Distributed controllers are preferred to centralized controllers for economic reasons. Memory channels and processor micro-code can be shared by all devices.

Each processor node has one *Call Control Port*

(CCP) which is used to select switch nodes, as previously described. The following sections outline the functioning of each port.

Call Control Port (CCP)

A link between a processor and a device is created by the selection of the appropriate switch node through the Call Control Port of the processor node. Two processors create a link to each other by individually selecting the same free switch node through their own Call Control Ports.

The CCP has one more function: to disconnect a processor node from all other nodes. In effect this operation selects a non-existent free switch node.

Block Transfer Port (BTP)

The number of signal lines connecting two terminal nodes must be as small as possible because the number of decoding, driving, and receiving gates increases as the product of the number of processor nodes and the number of device nodes. The BTP was chosen to be 2-bits wide, the minimal width which provides the desired generality and channel capacity. Transmission modes can be full-duplex with one line devoted to each direction, half-duplex with data on one line and clock on the other, or half-duplex two-bit parallel with clock and data interspersed. Maximum transmission rates are expected to be 20 Mbauds total, including clock. This capacity is approximately one-third of the primary memory speed.

In PRIME, a BTP is used to transfer data between primary memory and disk drives of the CDS 215 class. The channel capacity of each drive has been doubled to 5 Mbauds (data) by accessing two surfaces in parallel. One head transfers words with even addresses on one line while the other head transfers words with odd addresses on the other line. These words are accessed from primary memory asynchronously for each line, thereby greatly reducing the effect of the skew between surfaces caused by interchangeable disk drives and disk packs. The half-duplex double frequency transmission mode is used to transfer data to and from the disk drives, in order to maintain head independence all the way to primary memory.

Standard Message Port (SMP)

The SMP accommodates register to register transfers by sending the 52-bit SMP word shown in Figure 4.

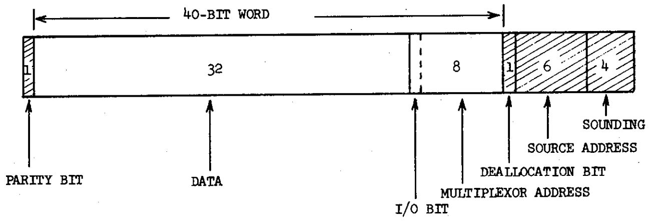

Figure 4—The 40-bit SMP word and 12-bit appendage

As with the BTP, similar considerations led to a 2-bit transfer path for the SMP. Information is transmitted bit serially on one line, using double frequency encoding. The other line is used to receive synchronization signals or messages from the SMP at the other end.

The 40-bit word corresponds to the 40-bit parallel path of an interface to a SMP. The implementation of the META 4 makes 40 bits convenient, although other word lengths would be acceptable. This word includes a data field and a multiplexor address field which suggests the general structure of an interface to the EAN. Terminal nodes are attached to multiplexors which channel SMP messages to addressable registers of the same or of different devices. In effect, the multiplexor address is the address of a register interfaced to a SMP. Registers controlled by fixed sequential circuits can recognize or generate only their own addresses. Registers controlled by processors can deal with any address. The I/O bit of this address is separably distinguishable. It specifies whether the addressed register is an input or an output register. Therefore, the sending SMP can expect a response message within a fixed time duration if the message is addressed to an output register. This feature was added to the SMP for efficiency. Some other timing source would work as well, but more processor time and control storage would be required. The lack of a response is a detectable failure mode.

One of the main concepts involved in the design of the SMP is transparency of the network. This concept is reflected in the fact that anything relevant happening at one port is reported in some way to the other port. This includes synchronization as well as error detection. The shaded fields shown in Figure 4 are generated and used by the EAN for that purpose.

The sounding field precedes the message and is used to alert and synchronize the receiving SMP. An error is detected if the receiving SMP is in transmitting mode. A message received error free causes a signal to be sent back to the transmitter. Another signal is returned to the transmitter when the addressed device picks up the message. The absence of either signal is detected as an error. All errors detected by the SMP of a processor node are reported to the processor as a standard 40-bit message having a special multiplexor address which identifies error messages. All errors detected by the SMP of a device node are transmitted to the SMP of the processor node where they are reported in a similar fashion. Therefore the loss of messages by collision or overlapping is either avoided or reported as a failure mode.

A parity bit is appended by the transmitting SMP and checked by the receiving SMP. In addition, the receiving SMP checks the format of the bit stream (number of clock pulses and time interval between them). These two simple checks, with double frequency encoding, detect a larger class of errors than without double frequency encoding. The probability is extremely small that error bursts will complement an even number of data bits without effecting intervening clock pulses. The failure of any of these checks is reported as an error. It should be noted that we chose to provide checks on a message basis. Longer messages which are made up from several SMP words may require other checks at the process level (like checksums) to guarantee the contents of the total message.

The error mechanisms described above prevent loss of information by distortion of message contents or by message loss. Another mechanism has been introduced to protect against transmission of messages to the wrong terminal node. The integrity of a link through the EAN is ensured by two addresses available at the terminal nodes. Each SMP has its own unique wired-in source address which is appended to each transmitted message. In addition, each SMP has a Source Comparison Register which is loaded as part of the protocol used to establish a link. It contains the source address of the SMP located at the other end of the link. The source address of an incoming message is checked against the contents of this register. A mismatch causes the message to be ignored and an error to be reported.

The Source Comparison Register is cleared by an incoming message having the deallocation bit on. Only the Control Processor can substitute a zero source address for the wired-in source address of the SMP to which it is attached. Thus the clearing of the Source Comparison Register returns the usage of the terminal node exclusively to the Control Processor. The loading of the Source Comparison Register of a device node is possible only with a zero source address message. Therefore the protocol to establish a link between a processor node and a device node requires the intervention of the Control Processor. This mechanism allows the Control Processor to retain control of the EAN and to check that the Problem Processors make correct connections. By the time a Problem Processor is allocated to a subsystem, all of its nodes have selected the non-existent switch node, thereby having disconnected the Problem Processor from the EAN. Thus, a similar loading procedure cannot be used to set the Source Comparison Register of a processor node. Each Problem Processor must load its own register. It does so, through the CCP, as part of the switch node selection operation. In addition, the cleared state of the Source Comparison Register is indicated by a SMP signal which is made available to the device controller. Any controller can have special checking features which distinguish between the Control Processor and Problem Processors.

EAN CONTROL SEQUENCES

A presentation of all EAN control sequences is beyond the scope of this paper. The examples represent typical communications within one subsystem, and between different subsystems. They are simplified by the elimination of steps that are required for higher level system control, but not for EAN control. For simplicity, SMP is not distinguished from the device to which it is attached. Therefore each Problem Processor, PP, has a source address p; a device, D, is identified by its source address d; and the Control Processor, CP, has source address 0.

The first example allocates a device to a subsystem. The Source Comparison Register of a free device is assumed to hold the zero source address reserved to the CP. A device is considered to be allocated whenever its Source Comparison Register holds the source address of a PP.

Allocation of a free device D to a PP:

1—CP connects itself to D.

2—CP loads the address p into the Source Comparison Register of D with a zero source address message.

3—CP receives an acknowledgment from the SMP of D to verify that the Source Comparison Register has been loaded correctly.

4—CP disconnects from D.

5—Eventually, by means of a processor to processor communication, CP instructs PP to connect to D.

6—PP connects to D and loads its own Source Comparison Register with d.

A path between D and PP is now established, and the transmission of messages can begin. The validity of the path is checked by PP with the first message it sends to D. If the terminal nodes of D and PP have a BTP, then transfers to or from primary memory can also be initiated. The form of communication necessary for initializing BTP transfers is generally a one-way stream of messages from PP to D. The memory channel of PP must be independently instructed by PP micro-code.

The next example is a control sequence which establishes a link between CP and PP by request of PP. Two assumptions have been made. First, one free switch node (N) is dedicated to interprocessor communications. (Consequently, only one pair of processors can be in communication at any time.) Second, there is an interrupt channel (I), separate from the EAN, which can be used by any processor to interrupt any other processor.

Initiation of communications by PP:

1—PP interrupts CP through I. This is a request for communication. If possible, PP then continues to run its task while waiting for CP to satisfy its request.

2—When CP is willing to communicate with PP, it connects itself to the switch node N and loads its own Source Comparison Register with p.

3—CP interrupts PP through I.

4—PP then connects immediately to N and loads its own Source Comparison Register with zero.

5—PP sends the first word of the message to CP, thereby notifying CP that the link has been made.

SUMMARY

The PRIME system can be viewed as a spacially small computer network for which the EAN serves two purposes: to interconnect subsystems, and to interconnect devices within subsystems. The architectural approach represented by PRIME is reflected in availability, data security, evolvability, and economic features of the EAN. As a result, the EAN has both similarities and dissimilarities with other networks.

Communications with subsystems are made possible by very high channel capacities, a feature which distinguishes the EAN from spacially large networks. Data security is accommodated by providing for subsystem to subsystem communications through the EAN, instead of through primary memory, and by detecting failure modes which might lead to penetration of subsystem boundaries. Availability considerations, as well as data security requirements, lead to various error detecting and reporting mechanisms which are built into the SMP. Other availability features are the ability of the EAN to exclude faulty modules by reconfiguring subsystems, the ability to redesignate any Problem Processor as the Control Processor, the limitation of the effect of failures, and the network transparency which considerably eases fault diagnosis. Economy considerations lead to the construction of terminal nodes from three types of ports, the provisions for distributed controllers, the simplicity of the SMP interfacing, and the simplicity of the EAN structure. Finally, evolvability is served by plug-in expansion to 24 processor nodes and 31 device nodes, and by the multiplexor address field which permits fan-out from each terminal node.

ACKNOWLEDGMENTS

The authors would like to thank R. S. Fabry, C. V. Ravi, and particularly B. R. Borgerson for numerous discussions and ideas which significantly influenced the design of the EAN.

An over-the-shoulder look at discrete simulation languages

by IRA M. KAY

Southern Simulation Service, Inc.

The past of simulation languages resembles any other history of a subject. For those interested in computers, it presents an absorbing story with moments of outstanding achievement. When Shakespeare said "The Past is the Prologue" he preceded the age of the computer, but he recognized that, regardless of the field, the history, the habits and the education of those engaged in any enterprise shape the way the future will be. Accepting this hypothesis, it then behooves us to look to the past if we are to see what the future holds in digital discrete simulation.

Any practitioner of the art of simulation for a number of years can truthfully say that the past ten years have been both fruitful and full. The term "fruitful" is used in the sense that a relatively new art has been applied to such a wide range of subjects. Mr. Stanley Reed of IBM, in describing the applications to the attendees of the First Annual Simulation Symposium in Tampa, Florida in January 1968 gave a list of applications, and they are repeated here as Appendix I. Any art that can serve this many fields must certainly be classified as fruitful! "Full" is used in the sense that simulation languages have proliferated as tools to serve the researcher. The author, in an invited paper for the Fifth Annual Simulation Symposium provided an inventory of general purpose digital discrete simulation languages. After excluding any special purpose languages, and of course, any digital continuous languages, there were thirty-five inventoried and described. An alphabetical list of the languages (augmented by later additions) is contained in Appendix II, and demonstrates the "fullness" of our past ten years.

One might ask why so many languages have appeared on the scene, and wonder about their availability today. The "why" is hard to explain, other than to say that in many cases pride of authorship kept many going when common sense should have indicated that other available languages would fulfill the needs. In other cases, a simulation compiler was required for a specific computer, and the authors proceeded with what they felt met the needs of the user and thus produced a new language.

Regardless of the numbers, however, there is truly no difference to the philosophy of how the languages work for modeling and simulation. The basic alikeness of all simulation problems is what provides a fertile field for simulation languages. Each in its own manner has a timing routine which keeps scheduled future occurrences in chronological order, each advances a system held variable representing the current time consistent with the occurrences as their scheduled time is reached, and each provides for the gathering of statistics concerning the specific variables (values) the researcher might wish to evaluate. Examination of the languages produced reveals that there were three basic approaches to providing the simulation languages and almost all the languages fit into one of these three styles, or "families".

First, the authors took an existing scientific language like FORTRAN or ALGOL and prepared sub-routines to provide the user with the special requirements of simulation languages, i.e., timing, set manipulation, random deviate generation, statistical summary and input-output. Then the user is able to write in the "host" scientific language, calling the furnished subroutines for the special actions desired. This is a direct method of getting the new user quickly into using simulation languages, in fact, we can almost call it the painless approach, and this ease of transition is the strongest argument for using languages of this type. This writer chooses to name this the GASP family, after the best known of that type language. A "family portrait" of these languages is:

GASP FAMILY

ESP (The **E**lliott **S**imulation **P**ackage)
FORSIM IV
GASP (**G**eneral **A**ctivity **S**imulation **P**rogram)
HOCUS (**H**and **o**r **C**omputer **U**niversal **S**imulation)

JASP (JOSS Conversational Simulation Program)
PA3
PROSIM (**Pro**gram System for **Sim**ulation)
QUICKSCRIPT
SIMON
SIMQUEUE
SPURT (A **S**imulation **P**ackage for **U**niversity **Re**search)
UNS
UNISIM

The second family of languages uses a logical block design for describing the model to be simulated. This means that blocks of certain shapes and identifiers call for designated actions on the part of the computer. Almost in a sign language then, a researcher can portray his model, calling for the generation of transactions, their path through a complex world, the capacities and capabilities of the world through which it must pass, the alternate solutions under blocked overloaded or changed conditions, and still without, or with most minor computer programming capability, the researcher can simulate the world of his model. The compiler interprets the logical design and produces an operational program, adding without demand a wide range of statistical summarizations concerning the period of simulation. This type of family must be called the GPSS family, after the best known and most copied language of all. A "group photograph" follows:

GPSS FAMILY

BOSS (**B**urroughs **O**perational **S**ystem **S**imulator)
EGPS (**E**xtended **G**eneral **P**urpose **S**imulator)
FLOW SIMULATOR
GESIM (**G**eneral **P**urpose **D**iscrete **Sim**ulator)
GPDS (**G**eneral **P**urpose **D**iscrete **S**imulator)
GPS (**G**eneral **P**urpose **S**imulator)
GPS K (**G**eneral **P**urpose **S**imulation **K**)
GPSS (**G**eneral **P**urpose **S**imulation **S**ystem)
GPSS/NORDEN
QUICKSIM

The last family of languages are those which provide a syntax of their own and have the necessary compiler capability to react to the simulation demands of the user for all the aforementioned prerequisites of a simulation language. These type of languages require a programming expertise on the part of the user, but in turn permit him the widest range of operation in dealing with complex problems, and the most ability to tailor his program to fit a particular problem. They are also the most parsimonious in memory use and least costly in running time. This group is called the SIMSCRIPT family after the best known and most widely used of that type. They include:

SIMSCRIPT FAMILY

CLP (**C**ornell **L**ist **P**rocessor)
CSL (**C**ontrol and **S**imulation **L**anguage)
GEMS (**G**eneral **E**lectric **M**arketing **S**ystem)
GSP (**G**eneral **S**imulation **P**rogram, Mark II)
MILITRAN
MONTECODE (**Monte** Carlo **Code**d Simulations)
OPS-3
SEAL (**S**imulation, **E**valuation and **A**nalysis **L**anguage)
SIMPAC
SIMSCRIPT
SIMTRAN
SIMULA
SOL
SOLPASS
SPS-1

All sorts of attempts have been made to "rank" these languages, or to try to advise a reader that one language would provide more capability than another. Other papers have been written which provided detailed comparisons of several of the languages. Presumably, in the latter case, the reader was to be in a better position to make a choice. In the opinion of this writer, all of such effort is futile. First, the choice of a language depends on an expert choosing among them, if all other factors are equal, which rarely occurs. Next, the choice depends upon the language in which the researcher can program. There is no virtue in a choice which cannot be utilized by the programmer, or at least, acquired by him within a reasonable time. Last, there is the question of compiler availability. Given a choice of one language over others, and given that the researcher is capable in that language, what earthly purpose is served if a compiler for that language is not available within a reasonable range of the intended user?

It has been the sad experience of the author, in which he is as much the culprit as the observer, that those who discuss several languages are rarely expert in more than one and never in more than two. However, with great pomposity, the "experts" discuss what each of several languages can, and cannot do, displaying, by their errors easily discernible by a real expert in any one language, that they have no real right to qualify or quantify that language. If several "single language" experts could objectively discuss any one paper which rates or ranks languages, it is forecast that much air could be released from the balloon.

To view these languages in retrospect has, in most cases, a nostalgic charm. It is even more important to now identify those which are still "active". With all due respect to second generation computers that are living a graceful old age in obscure universities, only those languages with compilers available on third generation machines are listed.

Arranged by families, the current list is:

GASP Family	*GPSS Family*	*SIMSCRIPT Family*
GASP	BOSS	CSL
HOCUS	EGPS	SEAL
PROSIM	FLOW SIMULATOR	SIMSCRIPT
SIMON	GESIM	SIMULA
SIMQUEUE	GPS	SOL
SPURT	GPS K	
UNS	GPSS	
	GPSS/NORDEN	

With a backward glance over our shoulder then, we have every right to look to the future with confidence. Any discipline which can invent at this prolific rate cannot but move forward with equal ability to formulate tools for the future work.

APPENDIX I

1. *Advertising*
   A. Media selection
   B. Impact on sales
   C. Campaign strategy evaluation
   D. Sales contests
   E. Customer contests
2. *Airlines*
   A. Runway utilization
   B. Terminal facility planning
   C. Crew scheduling
   D. Reservation system modeling
   E. Airliner seating and freight configurations
   F. Spare parts inventory
   G. Scheduling of service and maintenance facilities
   H. Time tables
   I. "Stack" modeling
   J. Cargo handling
   K. New airport facilities and locations
3. *Banking*
   A. Operation of bank floor (teller model)
   B. Behavior of on-line system
   C. Check transit model:
      1. Collection routes
      2. Centralized vs. decentralized processing
      3. Schedule arrival of inscriber operators
      4. Breakpoint for specially handled items
   D. Interest rate and other policy studies
   E. Special service studies (credit card, payroll, etc.)
4. *City Planning and Urban Renewal*
   A. Transportation networks
   B. Planning for services, facilities, etc.
   C. Welfare studies
   D. Crime and law enforcement studies
   E. Budget planning
   F. Information systems and record planning
5. *Communications*
   A. Information flow in networks
   B. Adaptive routing
   C. Study polling disciplines, concentrators, buffering, etc.
   D. Intercept and rating systems
   E. Evaluate telephone information system
   F. Maintenance and service facilities planning
   G. Studies of future growth needs
6. *Data Processing Systems*
   A. Response time, throughput analysis for real-time systems
   B. Organization of direct-access files
   C. Study queuing disciplines
   D. Storage allocation and buffering
   E. Study degraded performance
   F. Study operating system behavior
   G. Flow of jobs through a computer "shop"
   H. Priority assessments
   I. Equipment add-on effects
   J. Personnel and organization studies
7. *Distribution*
   A. Truck routing
   B. Optimization of distribution networks
   C. Number and location of warehouses
   D. Warehouse automation procedures
   E. Inventory management
   F. Schedule work crews
   G. Design truck docking facilities
   H. Design packaging facilities
   I. Information systems design
8. *Elevator Operation*
   A. Number of elevators
   B. Dispatching rules
9. *Enterprise Models*
   A. Flow of material, men, money, information. Evaluate all-over behavior—design for maximum profit. Policy studies at corporate levels
   B. Effect of reducing delays (such as installation of management information system)
   C. Personnel rules
   D. Advertising allocation
   E. Capital investment
   F. Diversification, merger and risk studies
10. *Gaming (other than war games)*
    A. Management games
    B. Purchasing games
    C. Creation of sporting events ("dream world series")
    D. Training models
11. *Insurance*
    A. Policy administration and accounting
    B. Investment studies
    C. Information and retrieval systems design

D. Statistical aging
E. New policy plans

12. *Job Shop Simulation*
A. Bottleneck elimination
B. Capacity-production studies (order backlog)
C. Work rules
D. Equipment evaluation and layout
E. Quality control

13. *Manufacturing*
A. Facilities planning
B. Assembly line balancing
C. Scheduling
D. Manpower allocation
E. Inventory management
F. Quality control
G. Information systems
H. Equipment maintenance
I. Subcontracting policies and schedules
J. Raw material acquisition
K. Plant location
L. Labor studies

14. *Marketing*
A. Pricing
B. Advertising
C. Sales force allocation
D. Product installation and acceptance
E. Competitive strategy
F. Product introduction studies
G. New product requirements

15. *Medical*
A. Behavior of real-time information system
B. Blood bank inventory
C. Admission/discharge policies
D. Hospital bed and patient scheduling
E. Scheduling of staff
F. Scheduling nurse activities

16. *Metal Processing*
A. Facility planning and scheduling
B. Warehousing
C. Ordering policies
D. Open pit mine design

17. *Monte Carlo simulation of complex deterministic problems*

18. *Paperwork Flow*

19. *Personnel Policies*
A. Hiring and promotion rules
B. Allocation, distribution, and movement of personnel

INTRODUCTION

The need for evaluating the performance of contemporary computer systems is well recognized by the manufacturers as well as the users of these systems. The evaluation is difficult because of the complexities and sophistication of the computer hardware and software system design. The computer manufacturers have produced an abundance of literature encompassing somewhat subjective evaluations of their products. Unfortunately, relatively little effort has been directed by the manufacturer toward the development of generalizable scientific tools for the purpose of a quantified evaluation of the performance of computer systems operating in a specified environment. The need for such generalizable scientific tools for studying the behavior of a given computer system in a specified environment can hardly be over-emphasized.

Contemporary computer systems are, in general, architectured from organized semi-independent processing modules which share a finite set of modular resources. The performance characteristics of a computer system are partly governed by the characteristics of the various modules and partly by the interactions and interrelationships among these modules. A performance evaluation instrument for these systems should provide an insight into the dynamics of the interactions among the various components of the system. This hypothesis strongly suggests simulation techniques for investigating the behavior of computer systems.

Simulation, by definition, is a process of conducting experiments on a model representing an abstraction of the system. Simulation may take place only if a model of the system under investigation is available.

As previously hypothesized, computer systems may be represented in terms of components, variables, parameters in conjunction with algorithms which describe corresponding logical and functional relationships. However, the dynamic complexity of these systems coupled with the desired level of detail, does not facilitate the translation of these models into a set of equations which are analytically tractable. Nonetheless, it is possible to apply the description of the computer system (model) to a given set of input to the system. The manner in which the model reacts to this input may be summarized in terms of the variables of interest such as the time consumed by the management functions and the fraction of the time the various system components are busy. By varying the input and/or varying the model, an investigator can observe the variables of interest and make appropriate decisions. The enormity of computations and the volume of data involved, in investigating systems in this manner, can be handled effectively if the model is translated into a computer program. The validity of this approach is evidenced by the simulation studies conducted by Nielsen,[16,17] Katz,[6] Scherr,[22] and Rehman and Gangware[19] among others. These simulation studies were reported to be successful. The building of simulation models requires specialized skills and time. These requirements act as deterrents for conducting generalized simulation studies of computer systems.

There is a need in several areas for a mechanism that enables the construction of working simulation models (at several levels of detail) in relatively short periods

* Some of the work leading to this paper was supported in part by ONR-THEMIS Contract N00014-68-A-0151

of time. Such a mechanism would not only be useful to the designers and users of the computer systems as a "quick-look" mechanism but would also have a significant pedagogical value. Students of operating systems could gain in-depth knowledge through designing and observing operating systems by the use of such a mechanism.

In the development of the OSSL language and simulator an effort has been made to provide the user with the capability to represent all components of a computer system including memories, processors, and input-output systems in both an associative and a hierarchical relationship. The OSSL language has not been written for usage in areas other than computer systems simulation and is intended to be limited to this area of application. The known limitations of the language lie in the representation of detailed discrete phenomena such as a particular memory mapping algorithm, a hybrid input-output algorithm, etc., although most, if not all, of these cases can be represented stochastically in considerable detail. A similar effort has been made in OSSL to enable the representation of software processors and task sequences, stochastically, in sufficient detail and accuracy to provide for the simulation of any specific computer system work load.

THE SIMULATION LANGUAGE

This paper presents an overview of a language developed for structuring simulation models of computer systems. A more detailed description of the OSSL Language and its use is presented in a User's Guide.[25] The various language elements reflect the phraseology in use by those involved in the implementation of computer systems. The format-free language has been implemented in a subset of the FORTRAN IV language for the following reasons:

(a) FORTRAN IV is available on almost all medium- to large-scale computer systems. Special features of the language were purposely avoided in the coding process to facilitate usability on a variety of implemented systems.
(b) FORTRAN IV has the potential to accommodate the flow oriented structure of GPSS, and also the entity, attribute, set, state, and event concepts of SIMSCRIPT.
(c) FORTRAN IV provides the facility to construct adequate specialized data structures needed for simulating computer systems.
(d) Implementation of the language interpreter is much easier in a general purpose language like FORTRAN, than in the special purpose simulation languages like GPSS, SIMSCRIPT, SIMULA, etc.
(e) The simulator and the language interface have been coded in FORTRAN IV in order to provide user modularity. The various OSSL segments have been represented via FORTRAN subroutines which are as accessible as provided for by the particular FORTRAN compiler.

A simulation model for a given computer system consists of components representing

(a) the hardware characteristics and system configuration,
(b) the operational philosophy of the system, and
(c) the environment in which the system is to function.

The simulator employs the asynchronous timing technique for advancing the model through the simulated time. This implies that the state of the system is updated upon the occurrence of events. An event may be the start of a new job, initiation/completion of data transmission, interruption of a running program to provide CPU service relative to a different user job, etc. All the processes to be simulated are viewed as a series of events. The updating of the state of the system consists in changing the simulation parameters as well as the scheduling of future events induced by the event causing the update. All future events thus scheduled are filed in a threaded list. The events are retrieved from the list in the order of their scheduled occurrence of time for updating the state of the system. Such a scheme positions events on the time line and the updating mechanism relates the events to their respective processes, thereby enabling the handling of concurrent operation of the various processes.

The language described herein allows for a modular construction of simulation models representing these components. Each of the components may consist of one or more segments provided by the language. The three components of the model may be structured as follows:

HARDWARE CHARACTERISTICS AND SYSTEM CONFIGURATION

This component may be defined through the following two segments of the language:

Central processing units (CPUs)

The CPUs are considered to be interruptible entities capable of executing instructions related to a single request at any instant of time. All requests for CPU service have an associated priority level. The language allows for the definition of up to 15 CPUs in the system.

```
              CPU DATA
CPU  1
     QUEUE 7
     UNINTERRUPTIBLE LEVEL 45
     TIME QUANTUM .050
     INSTRUCTION TIMES .00001 .000015 .00005
     TABULATE BUSY TABL
        END OF CPU DATA
```

Figure 1

Figure 1 shows an example of the CPU definition segment. CPU numbered 1 is being defined. Requests for CPU service are entered in the queue number 7 if they cannot be met immediately.

The CPU goes into an uninterruptible state if the request being executed has a priority level of 45 or higher. The time quantum is specified to be .05 units of time. The CPU can execute one instruction each of class 1, 2 and 3 in .00001, .000015 and .00005 units of time respectively. The language allows for up to 10 classes of instructions. The time required for instructions belonging to classes 3-10 is specified to be zero. The continuously busy spans of the CPU are to be tabulated in the frequency table labelled TABL.

Devices and channels

Characteristics of the peripheral devices like the card-readers, card-punch equipment, teletypes, CRT units, etc., are defined in this segment. The system configuration is implied through the definition of each device. Multiplexor channels are not to be included since these are transparent to the simulation model. This is because a multiplexor channel is always available to the device controllers attached to it.

Figure 2 shows a sample definition of the segment. The system configuration implied is shown in figure 3. The characteristics of the CPU would be defined in the CPU segment.

The segment, as defined, specifies one card-reader, one line printer, one card-punch and two discs. The strings TCR, TCP, T1, T2, T3 and T4 are the labels assigned to the user defined distribution functions. Requests for the selector channel are to be entered in queue 5 if they cannot be attended to immediately. Similarly, requests for disc number 2 are to be entered in queue number 3 if they cannot be attended to immediately.

THE OPERATIONAL PHILOSOPHY

This component of the simulation model embodies the manner in which the user jobs flow through the system. The flow of jobs involves movement of data among the system components, allocation of primary memory, scheduling of jobs for execution and file management functions. The manner in which these

```

```

Figure 2

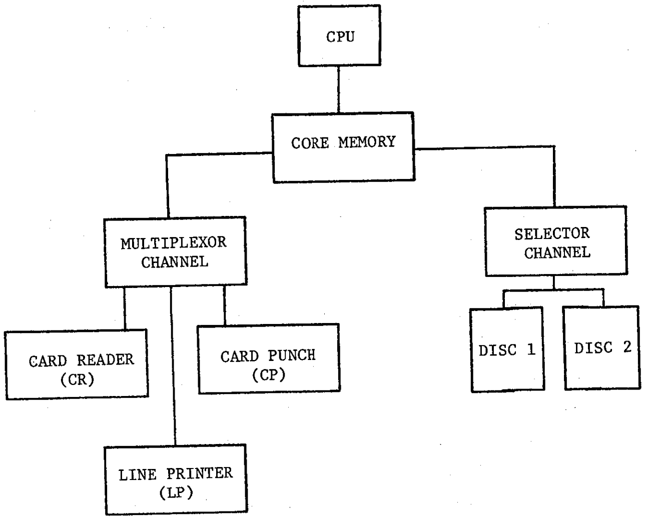

Figure 3

activities are to be performed are defined by the following segments:

Bufferpools

The language allows for the operation of up to twenty bufferpools numbered 1 to 20. A request for space in the bufferpool is disposed of in the following manner:

(a) User defined criterion are applied to the request to determine if the request is to be met.
(b) Number of instructions (say n) to be executed for applying the criterion are generated in accordance with the user specified distribution function.
(c) If the request is to be met, the number of instructions to be executed (say m) for the assignment of space are generated in accordance with the user specified distribution function.
(d) If the request is not to be met immediately, the number of instructions (say m) to be executed to enter a specified queue are generated in accordance with the user specified distribution function.
(e) A CPU from the specified list is selected to execute $n+m$ instructions.
(f) The request is either met or placed in a queue upon execution of $n+m$ instructions.

Figure 4 shows a sample definition of the bufferpool segment. Bufferpool numbered as 1 containing 100 buffers of a unit space each is being defined. The number of instructions for decision, assign, refusal and release activities follow the user defined distribution functions labelled DISA, DISB, DISC, DISD. Requests for bufferspace are to be placed in queue number 10 if they cannot be met. MXA and MB are the labels assigned to the proportion of the various classes of instructions to be executed by the CPU number 1. The priority level for the CPU service associated with the assignment and release of bufferspace has been specified as 92.

     END OF BUFFERPOOL DEFINITION
```

Figure 4

The request for bufferspace is to be met if the file requesting space is using less than 3 buffers or at least 1 buffer is available for each file attached to the bufferpool.

Movement of data

Movement of data in the system is described via the definition of one or more PROCEDURES. An example of a procedure is the set of activities associated with the input of a job in a batch-processing system like the XDS system SIGMA 7 symbiont and the IBM System/360 SPOOL (DOS/360 POWER and OS/360 HASP).

The input procedure may consist in the movement of the source statements from a card reader on to the disc. This movement of data would involve various activities like the request and assignment of bufferspace, activation of the card-reader, deposition of the card image into a buffer, emptying of the buffer onto the disc, release of the bufferspace, and update of the various tables.

The various tasks being performed by a computer system under the direct control of its operating system may be grouped into procedures. These procedures are activated by the services requested by a user's job. A procedure consists of an ordered list of statements and thus are flow oriented. The language provides 38 different statements for defining procedures. There are statements to request system services like the movement of data, request/release of bufferspace, request for CPU service via an interrupt, etc. Statements have also been provided for the management of records in files and interrogation of the attributes of files. The language also provides statements for controlling the flow within a procedure. The procedures defined by the user are assigned unique labels. Individual statements comprising the procedure may be assigned a label. Some examples of the statements available are as follows:

Statement:

MOVE TO DISC 2

Execution of this statement causes data to be moved to Disc 2.

Statement:

INTERRUPT CPU 1 PRIORITY 95 QUANTITY A MIX MX

This statement generates a random value, say *n*, from the user defined distribution function labelled A. A request with a priority level of 95 is placed on CPU 1 to execute *n* instructions of the mix labelled as MX.

Statement:

REQUEST 1 FROM BUFFERPOOL 2

A request for space from the bufferpool number 2 is generated and disposed of as prescribed by the user in the BUFFERPOOL segment.

Statement:

ASSIGN FILE 6

The statement creates file 6 for the job being handled by the procedure.

Statement:

ATTACH FILE 8 TO BUFFERPOOL 1

This statement attaches file 8 belonging to the job to the bufferpool 1.

Statement:

CHECK IF RECORD READY

The statement gets executed only if a record is available for reading.

Statement:

CHECK IF RECORD IN FILE , ET

The flow is transferred to the statement labelled ET if the file is empty, otherwise the flow reaches the next sequential statement.

Statement:

INCREMENT DATA IN FILE 6 BY 2

This statement increases the number of records in file 6 by 2.

Statement:

REQUEST CHANNEL 1 2

This statement is considered executed only when either the selector channel 1 or the selector channel 2 is made available to the procedure.

A sample procedure to mode input from a teletype into the system is shown in Figure 5.

```

```

Figure 6

Job scheduler

Assignment of CPU for executing the code specified by the user's job is handled by the job scheduler. The model provides for the simulation of batch-processing, time-sharing and multiprogramming computer systems by an appropriate definition of scheduler. Figure 6 shows a sample definition of the scheduler. A time-slicing system is specified. Jobs awaiting CPU assignment for the execution of code are placed in queue number 7. CPU number 1 is to be used for executing the code. The number of jobs under paging at any time may not exceed 5.

Memory management

This segment is for the purpose of defining the various parameters as well as the decision rules to be used for allocating primary memory to the various jobs. A sample definition of the memory management functions is shown in Figure 7. The primary memory consists of a single partition containing 512 pages. All the user specified code is relocatable. Pages not in use are used for meeting page demands. If no such page is available, a set of pages is generated. The pages belonging to this set have been accessed at least once and do not belong to the job demanding the page. The page that has been in residence the longest among the members of the generated set is selected for meeting the demand. A page is swapped only if it has been modified. The rolling-in and rolling-out of pages are in accordance with the user defined procedures labelled RIN and ROUT respectively.

```

INTERRUPT LEVEL FOR CLOSING FILES 97
INTERRUPT LEVEL FOR ATTACH/UNATTACH FILES 97
END OF FILE MANAGEMENT DEFINITION
```

Figure 8

THE ENVIRONMENT

This component of the simulation model embodies the services that the system is called upon to perform. The language provides for structuring the environment in terms of jobs. Since the jobs require a variety of system services, the language allows for the classification of jobs into numbered types. All the jobs belonging to a particular type demand the same system services in the same order. However, the amount of service demanded by jobs of the same type may be different. The services demanded by the job may be classified into three categories, viz., entry of the job into the system, computations as specified by the job and the delivery of the computational results by the system. Entry of the job, the delivery of the computational results and the manner in which the computations are executed is fixed by the design of the system (as represented via the hardware configuration and the operational philosophy) and is described by specifying job steps relative to each type of job.

Code

The computations to be performed are represented by the code to be executed. The code may pertain to the compiling, loading, and the job itself. The language provides the facilities to specify the code to be executed. The language allows for the structuring of the various software processors from the user defined code.

The software representation is at a macroscopic level. A software program to be represented is divided into one or more "blocks." Each of these blocks contains the instructions to be executed, the specific pages needed in core for the execution of the block. In addition, the block may also contain specifications on the pages modified and the frequency with which the various pages are accessed during the execution of the code contained in the block.

A block is assigned a unique label so that a reference may be made to it for the purposes of structuring software processors, specification of code for the user's jobs and transfer of control during execution.

Figure 9 shows a sample definition of the code. Three blocks of code labeled EX, ST, AND EX2 have been defined. A brief explanation of the code contained in the block labelled EX is as follows:

Pages 1, 3, 7, and 9, relative to the job are needed in core before the code may be executed. Pages 3 and 7 will be modified as a result of the execution of the code.

The statement

INITIATE READ 1 IC 3

implies that the procedure associated with the type 1 read is to be invoked. The number of records to be read follow the distribution labelled IC and the file number 3 is involved in the read statement. Control is transferred to the next statement without awaiting the completion of the read.

The statement

E READ 2 RDZ 5 ST

specifies that records from file 5 are to be read from file 5 in a manner defined by the procedure associated with the type 2 read. The number of records to be read is to be randomly generated in accordance with the distribution function labelled RD2. In case file 5 is empty, control is transferred to the block labelled ST. Control is transferred to the next statement only after the read statement has been completed. E is the label assigned to this statement.

The statement

COMPUTE COM MX

specifies that the CPU is to be requested to execute instructions of a mix defined by the label MX. The number of instructions to be executed are randomly generated from the distribution function labelled COM.

The statement

WRITE 2 WT1 7

specifies that a number of records, randomly generated from the distribution function labelled WT1, be written into file 7. The manner in which the records are to be written into file 7 is specified via the procedure associated with type 2 write. Control is transferred to the next statement only after the write operation has been completed.

The statement

```
LOOP LE E
```

specifies that the statements starting with the one labelled E and ending with the one before the LOOP statement are to be executed a number of times randomly generated from the distribution function labelled LE.

```
         CODE DEFINITION
EX       BLOCK
         PAGES NEEDED 1 3 7 9
         PAGES MODIFIED 3 7
         INITIATE READ 1 IC 3
E        READ 2 RD2 5 ST
         COMPUTE COM MX
         WRITE 2 WT1 7
         LOOP LE E
         TRANSFER .4 EX 2
         WRITE 2 WT2 7
ST       BLOCK
         STOP
EX2      BLOCK
         PAGES NEEDED 2 4 5 6 8 9 10
         PAGES MODIFIED 4 8
E        READ 2 RD 6 ST
         COMPUTE CA MP
         WRITE 4 WT 8
         JUMP .8 E
         STOP
      END OF CODE DEFINITION
```

Figure 9

The statement

```
TRANSFER .4 EX2
```

would result in the generation of a random value from the uniform distribution over the interval (0., 1.). If the value of the number generated is less than or equal to .4, the control is transferred to the block labelled EX2, otherwise the control reaches the next sequential statement.

Input/output

The procedures associated with the different types of reads/writes are declared as shown in Figure 10. RDA, RDB, AD, W, AND RITE are the labels of the user defined procedures.

```
     INPUT/OUTPUT PROCEDURES
      READ 1  PROCEDURE RDA
      READ 2  PROCEDURE RDB
      READ 3  PROCEDURE AD
      WRITE 1 PROCEDURE W
      WRITE 2 PROCEDURE RITE
  END OF INPUT/OUTPUT DEFINITION
```

Figure 10

Software processors

Software processors may be defined from the specified code. A sample definition of a software processor named FORT consisting of 31 pages is shown in Figure 11. EXE is the label of a block of code.

```
      SOFTWARE PROCESSOR
       PROCESSOR FORT
          STARTS AT EXE PAGES 31
  END OF SOFTWARE PROCESSOR
           DEFINITION
```

Figure 11

Code specifications for the jobs

The number of pages and the code of a job arriving in the system is specified in the job list segment. Each entry in the list contains the number of pages and the reference to a label of a block of code. The job list is subdivided. Each sub-list belongs to a different job type. The sub-lists are circular and hence endless. Each of the sub-lists has a pointer indicating the entry to be used for assigning the number of pages and the code to a job arriving in the system. The pointer moves to the next entry after the current entry has been used. Figure 12 shows a sample job list.

```
                 JOB LIST
Type 1
   PAGES 143  STARTS AT BLOCK C1
   PAGES  78  STARTS AT BLOCK LA
Type 2
   PAGES  47  STARTS AT BLOCK LB
   PAGES  43  STARTS AT BLOCK CN
          END OF JOB LIST
```

Figure 12

Job description

The job type is characterized by the specification of the relationship between the various procedures and processors. A job type is specified in terms of steps to be executed sequentially. Each step consists in either the execution of a procedure or the execution of code. Figure 13 shows a sample job description.

```
    JOB DESCRIPTION DEFINITION

  Type 1

     JOB STEPS ARE AS FOLLOWS:
         PROCEDURE IN FILE 7 DEVICE 2
         EXECUTE FO
         EXECUTE LO
         EXECUTE JOB
         PROCEDURE OUT FILE 8
       END OF JOB DESCRIPTION
```

Figure 13

IN and OUT are the labels of the user defined procedures, whereas FO and LO are the labels of the user defined software processors.

The language embodies other elements for defining:

(a) the various distribution functions,
(b) the various frequency tables,
(c) the various cumulative distribution functions for generating the job types,
(d) queue disciplines,
(e) initial conditions,
(f) limits on the number of jobs in the system at any instant of time, and
(g) other simulation parameters like the seed for generating random numbers, length of a simulation run and the number of reports to be generated.

USE OF THE MODEL

Several simulation studies have been carried out to check the operation of the generalized model. One such case is included to serve as an example for demonstration of some of the uses of the generalized model. The particular simulation study concerns an on-line enquiry system as described on page 79 of the *General Purpose Simulation System*/360: *Introductory User's Manual*, IBM Inc., Form GH20-0304-4. A GPSS construct of the enquiry system appears on pages 82-83 of the referenced material. The on-line enquiry system was selected for simulation due to its relative simplicity and because of the availability of published results for comparison purposes.

The experiment consisted of processing the OSSL version of the basic GPSS model in order to verify the similarity of the results. The OSSL model was constructed using as nearly as possible identical parametric information to that assumed for the GPSS representation of the five teletype computer enquiry system. The basic OSSL model is shown in Figures 14a, 14b, and 14c.

An explanation of various statement types may be found in Reference number 25 (Wyatt & Dewan, 1971).

All the jobs arriving in the system require the same set of services from the system. The only distinction between jobs is the teletype number from which they originate. This distinction was used to build the five types of jobs that the model services. Jobs belonging to type *n* implies that they originated from the teletype number *n*. Thus a job type 3 implies that the job originates from the teletype number 3.

The job description segment defines the job steps associated with each of the five job types. Each of the five job types consists of a single step, viz., execution of the procedure labelled ENQY. The specifications imply that a job arriving in the system would cause the activation of the procedure ENQY relative to this job. The file associated with the procedure will be 0. The device number associated with ENQY would depend on the type of the job. Thus if the arriving job is of type 2 the device number 2 would be associated with ENQY. The priority associated with jobs is set to 101 due to lack of specifications.

The Bufferpool Definition segment specifies that the system is to contain a bufferpool numbered as 1. All the buffers in this pool are of a fixed size. The total space in the pool is 10 units divided amongst 10 buffers. Requests for bufferspace are to be placed in queue 7 if they cannot be satisfied immediately. Number of instructions to be executed by the CPU for the assignment and release of bufferspace is specified as zero (by default). Lack of decision rules specifications for the assignment of bufferspace imply that the requests for bufferspace are to be met if bufferspace is available.

The Initial Condition segment specifies that at simulated time zero one job is to arrive in the system. The type of this job is to be determined by the cumulative distribution function labelled J1.

The Simulated Time Specification segment specifies that the model is to be operated for 1020000 units of simulated time after which a report is to be generated. Lack of the random number seed specification implies that the system is to use the built-in random number seed during the simulation process.

The output generated by the generalized model is in the form of a report shown in Figures 15a, 15b, and 15c. The report contains the various statistics concerning the teletypes, CPU, the selector channels, the bufferpools and the various queues.

It may be pointed out that the CPU service related to interrupts is considered as overhead. Since all the CPU services in the simulated system were represented by interrupts, the generalized model reports that all the CPU utilization was for overhead.

TABLE I

EQUIPMENT		AVERAGE UTILIZATION	
GPSS Model	Generalized Model	GPSS Model	Generalized Model
TERM1	TTYP 1	.242	.2506
TERM2	TTYP 2	.231	.2512
TERM3	TTYP 3	.251	.2568
TERM4	TTYP 4	.266	.2517
TERM5	TTYP 5	.260	.2510
CHANI	CHAN 1	.118	.1192
CPU	PROCESSING UNIT 1	.645	.6385
CHANO	CHAN 2	.177	.1782
CORE	BUFFERPOOL 1	.099	.1010

TABLE II—Message Transit Time Distribution

Interval	Percent of Total	
	GPSS Model	Generalized Model
0-400	10.89	13.026
400-500	16.14	17.385
500-600	20.04	18.722
600-700	11.69	9.807
700-800	9.34	8.370
800-900	7.79	6.984
900-1000	6.04	6.043
1000-1500	12.75	12.927
1500-2000	3.35	4.160
2000-2500	1.30	1.535
2500-3000	.21	.545
3000-3500	.00	.347
3500-4000	.04	.149
over 4000	.00	.000

The results obtained by the generalized model are essentially the same as those obtained by the GPSS model. The equipment utilization as reported by the two models is shown in Table I.

The total transit time distribution of the messages as obtained by the two models is shown in Table II. The differences in results obtained by the two models may be attributed to sampling error.

Figure 15c—Results of experiment 1

In developing the OSSL version of the GPSS model, the following advantages of the OSSL language over the GPSS language for computer system simulation were noted:

1. There is a more direct correspondence between the various components of a computer system and the available OSSL language segments. This feature practically eliminates the translation of the computer system operation concepts into simulation concepts as contained in GPSS or any other general purpose simulation package.
2. The OSSL language elements reflect the terminology used by the designers and implementors of computer systems. This feature goes a long way in reducing the time required for structuring and debugging of a simulation model. A side benefit is expected to be the ability to involve interested people who do not know the simulation techniques.
3. The OSSL language is self documenting and thus considerably reduces the need for lengthy explanations for communicating the model being simulated.
4. The OSSL simulator is capable in dealing with fractions of unit time, whereas GPSS deals in integral values for time. This feature eliminates the scaling of the time specifications by the user.
5. The OSSL language provides the user the ability to define the various distribution functions in terms of their parameters rather than via a table.
6. The OSSL language provides for free-format input as opposed to the fixed-field format of GPSS.
7. The modularity of a particular simulation model expressed in the OSSL language will allow for several persons to contribute to a simulation study much more easily than the GPSS language.

CONCLUSIONS

The OSSL language, developed for simulating computer systems, seriously attempts to reflect the terminology used by the designers and implementers of computer systems. This semantic structure should allow the use of the language even by those who are not particularly well-versed in the art (and science) of simulation. The free-format syntax of the language should also encourage its use. The OSSL simulator is also inexpensive to use. The simulation run relative to the on-line inquiry system consumed 30 seconds on the UNIVAC 1108 computer system. Other, more complex systems have been simulated in from approximately one to five minutes (CPU time) on the UNIVAC 1108. The ratio of simulated time to real time is not readily generalizable since it depends heavily on the complexity and number of concurrent processes being simulated.

A simulation model structured by the use of the language consists of several interrelatable but modular segments. This modularity makes it easy to effect changes in the model. Moreover, it enables several persons to contribute to the simulation study. In addition to providing simulation capability, the generalized model provides a tool to document computer systems in a relatively unambiguous manner as demonstrated in the examples. This capability, hopefully, will raise the level of communications between personnel dealing with the different aspects of computer systems.

The language may also be used as a pedagogical device in the area of computer operating systems. Modelling of operating systems has the potential of providing to students invaluable insight into the dynamic relationships of various elements of an operating system. For example, the OSSL language is being used in a graduate course in computer operating systems design and in graduate research at the University of Houston. The ability of students without formal training in simulation to grasp, learn, and use the OSSL language in computer systems simulation based on this limited experience has been very gratifying. With the OSSL User's Guide[25] as a reference, students with a strong background in computer operating systems are able to have simple models developed and executing in a matter of days. Relatively complex models have been developed and experiments implemented by a different group of similarly prepared students within a matter of three to four weeks. A more complete analysis of the results of the usage of OSSL in the tracking of computer operating systems topics is being prepared for a future paper.

During the brief but intensive period of usage of OSSL since June of 1971, a list of improvements and modifications is being compiled and some such changes are being implemented as time permits. A partial list of these improvements is as follows:

1. Introduction of dynamic storage allocation for storage relative to model parameters during execution.
2. Provision for more extensive and specific error messages for both compile time and execution time errors.
3. Provision of recursive "Subroutine-like" capa-

bility for procedures written in the OSSL language.

4. Expansion of memory management and processor simulation capabilities to allow for user representation of more "exotic" computer system architectures.

It is recognized that the language may not be able to simulate all computer systems, primarily due to the current weakness of the language in the area of "unconventional" memory management strategies and intraprocessor scheduling algorithms. This weakness suggests that more research needs to be done in this area. To this end, the language has been implemented with an open-ended structure, which will hopefully allow for the inclusion of these and other developments with minimum difficulty.

It is hoped that the language will be used extensively to establish its usefulness as well as its limitations.

Discrete computer simulation—Technology and applications—The next ten years

by JOHN NORRIS MAGUIRE

Consultant
Reston, Virginia

Digital computer simulation is an effective method of pretesting proposed systems, plans or policies prior to the development of expensive prototypes, field tests or actual implementations. In simulation analysis the computer traces out in detail the implications and consequences of a proposed system or course of action. Compared with other forms of analysis, simulation is more realistic, more easily understood and more conclusive. Because the results are easier to understand, the conclusions receive wider acceptance.

As an aid in making important decisions, the use of computer simulation is growing at an astonishing rate. A decade ago it was used occasionally in manufacturing, military, nuclear, and a few other pioneering applications. In more recent years its use has expanded exponentially, both through increased coverage of old areas and in application to new areas. The growing list of successful uses includes the simulation of proposed information systems and manufacturing facilities; proposed inventory control systems; war games such as air battles, tank battles, and amphibious operations; hydroelectric, transportation, and communication systems; and many more.

Five factors have triggered this growth in the past and will continue to do so in the future. The first is the increasingly widespread recognition of simulation's role in careful planning. It pretests proposals under alternate contingencies prior to implementation. To a certain extent, it provides hindsight in advance.

The second factor contributing to the growing use of simulation is the advancement in techniques for producing simulation models and programs.

The third factor is the increasing availability and use of generalized models which focus on particular problem areas. The most notable successes here have been in the information systems area, but the development and use of generalized models have been spreading rapidly into other areas such as inventory, transportation, logistics, financial and management planning systems.

The fourth factor contributing to the increased use of simulation is the application and acceptance of more scientific techniques to the experimental design aspects of simulation experiments. Coupled with this has been the development of automated analysis techniques for simulation models.

The fifth factor is the increasing availability of data vital to the formulation of models. Naturally, this change has come about mostly in the areas which have been susceptible to a high degree of automation, e.g., computerized information, inventory, financial and manufacturing systems. Successes in these areas have accelerated simulation research and applications in areas such as marketing, social, biomedical, oceanography and environment/ecological systems where the data is more sparse, but growing rapidly.

These statements are generally true for all types of modelling. It is convenient to classify simulation models into two major types: continuous change models and discrete change (or discrete event) models. Some models are clearly best described by one type or the other; for a few problems, either type may be used. Many of the comments to follow on technological developments and trends will be applicable to both kinds of modelling, but the discussion will concentrate on discrete event modelling.

THE SIMULATION PROCESS

A brief review of the simulation process itself is appropriate prior to discussing the recent and likely future technological changes in this process. One view of the simulation process suggests that there are ten steps as illustrated in Figure 1.

1. *Formulate the Problem* This includes a definition of the general objectives of the study; specification of the questions to be answered; and a description of decision criteria and processes.

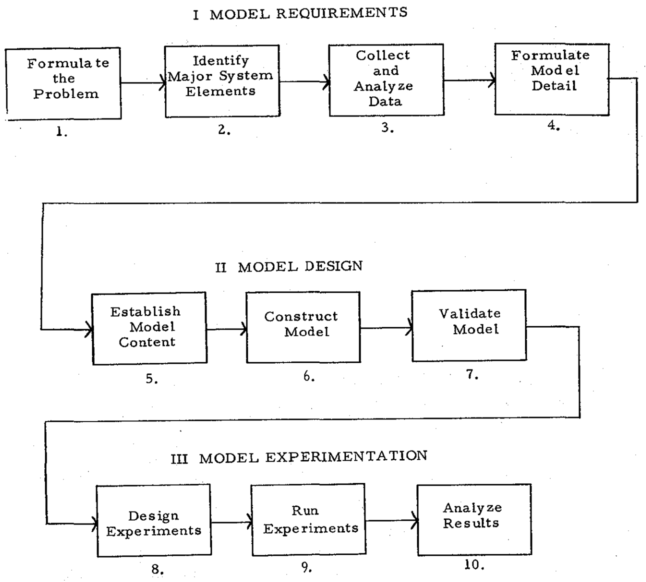

Figure 1—Modelling tasks

2. *Identify Major System Elements* A description of the major system components and features has to be developed; explaining functional dependencies and interrelationships. Also, the "domain" of the system under study should be defined in terms of exogenous and endogenous phenomena.
3. *Collect and Analyze Data* This involves the classification and identification of relevant data sources. Procedures/data collection forms/computer programs/devices may be used in the collection of this data.
4. *Formulate Model Detail* Create the design specifications defining basic elements and their characteristics coupled with a verbal description of model operation.
5. *Establish Model Content* Specify the degree to which phenomena will be enacted. Establish control and experiment parameters along with system performance measures.
6. *Construct Model* Evaluate alternative modelling techniques; flow chart, code and de-bug the model.
7. *Validate Model* Compare simulated data with hypothesized, actual, and/or historic data; and perform sensitivity analysis.
8. *Design Experiments* Evaluate alternative experimental design techniques and compare with SimOptimization* procedure; make decision and set up experiments.
9. *Run Experiments* Implement model initialization and operating procedure and perform experiments.
10. *Analyze Results* Relate the results back to the real phenomena; decide if further experimentation is required; and document results.

Of these ten steps of specified simulation activity, step Number 6, Model Construction, is the one that has seen the most dramatic change in the past decade through the development of high level simulation languages and generalized models. Changes will continue to take place in this area and these will be discussed in a later section of this paper.

Significant changes have also taken place in the following steps:

3. Data Collection
8. Experiment Design
10. Analysis

It is in these three areas where some substantial changes may be expected to occur in the coming decade.

Again, the five factors which seem to have brought about an expotential increase in the use of simulation are:

1. Recognition of simulation's advantages.
2. Advancements in techniques for producing models.
3. Increased availability of generalized models.
4. Increased application of experimental design and automated analysis techniques.
5. Increased availability of relevant model data.

Trends in these five areas can be discussed and extrapolated with a reasonable degree of confidence for the next decade. Other positive factors will also influence the growing use of simulation. These factors include:

- Larger numbers of students leaving the campus trained in simulation techniques.
- Successes with simulation in new application areas.
- Reduction in the cost of using computer simulation, especially for machine time as we enter the "no-cost processor" era in the 1980's.

The major factor on the negative side which might tend to inhibit the growing use of simulation in a particular functional area or organization is either the misapplication of the technique or low quality work performed by an over zealous, ill equipped individual or group. This will happen, as it has in the past, as a field turns from more of an "art" to more of a "science." Examples of this type appear in every new field, be it process control computers or heart transplants, but it is

* SimOptimization is a Trademark and Service Mark of Consolidated Analysis Centers Inc.

not expected to be a significant deterrent to increased use of computer simulation.

1. Recognition of Simulation's Advantages

One indicator that this has occurred is simply the vast sums of money and resources being expended in the area and the trend is clearly up—after possibly a leveling off during the recent recession. One measure of this effort is the published computer simulation papers and conferences devoted solely to the subject. In addition to many simulation papers presented as parts of many conferences such as this Spring Joint Computer Conference during the past five years, new annual simulation conferences include:

- Summer Computer Simulation Conference (1970 Denver, Colorado—1971 Boston, Massachusetts)
- Applications of Simulation (Usually New York)
- Annual Simulation Symposium (Tampa, Florida)

Attendance at these conferences has been growing and the proceedings from the 1971 SCSC ran 1,323 pages. Various organizations and societies have co-sponsored one or more of the above conferences. These societies include:

- American Institute of Aeronautics and Astronautics (AIAA)
- American Institute of Chemical Engineers (AIChE)
- American Institute of Industrial Engineers (AIIE)
- American Meteorological Society (AMS)
- Association for Computing Machinery (ACM)
- Board of Simulation Conferences (BSC)
- Institute of Electrical and Electronics Engineers (IEEE)
- Instrument Society of America (ISA)
- Simulation Councils, Inc. (SCi)
- SHARE—IBM User Group
- The Institute of Management Science (TIMS)

While there is a way to go before operating personnel use, or at least endorse simulation techniques, the previous paragraphs do indicate that general acceptance of the technique has occurred among professionals working in a variety of fields.

2. Advancements in Techniques for Producing Models

These techniques have centered around the development of high level simulation languages. A detailed discussion of these languages is presented in Mr. Ira Kay's paper for this session.

The two most widely used discrete event simulation languages are SIMSCRIPT[1,2,3] and GPSS.[4] A recent development has been the availability of the HOCUS modelling method.[5] With simulation techniques and languages, as with most other tools, there is a trade-off between performance and simplicity of design. The HOCUS approach occupies a particular point on the trade-off curve. SIMSCRIPT and GPSS represent two other distinct trade-off points. Each of the three systems fulfills an important need not fully met by the other two, even though the basic principles underlying all three systems are essentially the same.

The extreme simplicity of HOCUS gives it many important practical advantages over other methods, including quick model formulation, the ability to operate the model by hand, and easy transfer to a computer. On the other hand, some simulation models cannot be forced into the limited HOCUS framework.

At the other extreme, SIMSCRIPT is the most general and powerful of the three techniques. It demands highly skilled simulation analysts or programmers, but its great power and generality are sometimes indispensable. GPSS falls between HOCUS and SIMSCRIPT (Reference No. 6 details an evaluation of major simulation languages—although published in 1966, the study is still reasonably valid). Some systems can be classified as a restricted language or a generalized model depending upon your viewpoint. An example of this is ECSS (see: Kosy, D. W., "Experience with the Extendable Computer System Simulator," RAND No. R-560-NASA/PR, December, 1970).

The main point is that the programming "bottleneck" in the development of simulation models has, for the most part, been solved. Refinements will continue in the simulation language field. Two of the most promising developments are interactive modelling and simulation oriented graphics.

The best known interactive simulation language is OPS-3.[7] This language was designed and implemented at M.I.T. and used successfully to demonstrate the feasibility of interactive modelling. Operating in a time-shared environment under the M.I.T. Compatible Time Sharing System (CTSS), OPS-3 provides a user with on-line interactive communication between himself and a programming system. Using it, one can, in a single sitting, compose a program, test and modify it, expand and embellish it, and prepare it for subsequent production use.

A considerable amount of simulation-oriented graphics research is going on right now. At the Norden Division of United Aircraft, an IBM 2250 is used to modify source language GPSS programs and view their output in graphical form.[8] At the RAND Corporation, the Grail system and the RAND Tablet are used to construct GPSS programs on-line from hand-drawn flowcharts.[9] At M.I.T., the SIMPLE project is using graphics for man-computer interaction during modelling and experimentation. Papers have been written on the use of graphics in simulation modelling and the use of existing graphics packages for analyzing simulation-generated output.[10]

There is little doubt that interactive modelling is carried out better with a CRT device than with a typewriter or line printer. When designing programs, flow-charts and other symbolic notation can be displayed. For analyzing performance data, graphs provide more insight than do lists of numbers. The growing use of line-printer plotting simulators testifies to the utility of graphic output.

Also, we will see during the next decade extensions of a few simulation languages that will include mass storage random access data handling capabilities. There already exists a design and a tested prototype for this in SIMSCRIPT. The model builder will be able to use the simulation language itself to acquire most, if not all, of the data he requires for model formulation and testing.

3. Increased Availability of Generalized Models

During the early 1960's, a few simulators for discrete, dynamic models of manufacturing, inventory and EDP systems appeared and were parameterized and relatively easy to use, but had a narrow range of application. The alternative programming solution for a computer model was frequently machine language or a language such as FORTRAN or ALGOL which typically consumed a large amount of time for implementation. After that period, there emerged a number of simulation languages that attempted to provide the flexibility of machine language with the power of a generalized model. In parallel with these developments, a number of generalized models became available. SCERT,[11] CASE,[12] S.A.M.,[13] LOMUSS,[14] and ECSS[15] are examples of generalized models of EDP systems. These models possess the advantage of "ease of use" if their structure happens to fit your EDP modelling problem. Examples of their general use are numerous,[16,17] and growing rapidly. Successful simulation applications of generalized models have helped to determine EDP design answers such as machine core size, secondary storage assignments, peripheral terminal configuration, operating system procedures and allocation rules. Similar successful use of generalized models in other problem areas insure their increased use, because of the rapid implementation and low cost usually experienced with each application of a generalized model.

4. Increased Application of Experimental Design and Automated Analysis Techniques

Much has been written about the use of computer simulation experiments for the study and design of systems.[18] For the most part, the literature has emphasized the "model building" aspects rather than the experimental design aspects of simulation experiments. It may be that by the time the typical model-builder has gone through all the steps of implementing a model, he has run out of time and frantically makes a series of computer runs changing parameters here and there on a "gut-feeling" basis. He then culls through stacks of computer output trying to perform analysis. Other factors presently associated with this situation of not using more sophisticated techniques may be *cost* (these techniques tend to require more labor and computer time) and training prerequisites (A strong mathematical and/or statistical background is required.) Nevertheless, increasing use of more analytical techniques for simulation of systems is a near certainty.

In a well-designed experiment, consideration must be given to methods of analyzing the data once it is obtained. Most of the classical experimental design techniques described in the literature (e.g., 19, 20) are used in the expectation that the data will be analyzed by one or both of the following two methods: analysis of variance and regression analysis. Recently, however, several other techniques have been proposed for analyzing data generated by computer simulation models including multiple ranking procedures, sequential sampling plans and time series analysis. Also, a technique called "SimOptimization" shows promise for automating and minimizing the number of simulation runs required.

Analysis of variance

The analysis of variance is a collection of techniques for data analysis which are appropriate when qualitative factors are present, although quantitative factors are not excluded. An example of a qualitative factor would be the testing of different decision rules in a simulation model. Regression analysis is a collection of techniques for data analysis which utilizes the numerical properties of the levels of quantitative factors. The parameters chosen for describing probability distributions are quantitative factors, but the type of probability distribution (e.g., exponential or normal) would be a qualitative factor. From a mathematical point of view the distinction between regression and analysis of variance is somewhat artificial. For example, an analysis of variance can be performed as a regression analysis using dummy variables which can assume only the values of zero or one. A treatment of the relationship between regression and the analysis of variance can be found in the book by Graybill.[21]

Multiple ranking procedures

Conway[22] and others have pointed out that analysis of variance techniques frequently do not supply the kind of information that the experimenter seeks. Referring specifically to the design of computer simulation experiments, Conway has stated that:

> *the analysis of variance seems a completely inappropriate approach to these problems. It is centered upon the test of the hypothesis that all of the alternatives are equivalent. Yet the alternatives are actually different and it is reasonable to expect some differences in performances, however slight. Thus the failure to reject the null hypothesis only indicates that the test was not sufficiently powerful to detect the difference—e.g., a longer run would have been employed. Moreover, even when the investigator rejects the hypothesis, it is highly likely that he is more interested in identifying the best alternative than in simply concluding that the alternatives are not equivalent. Recently proposed ranking . . . seem more appropriate to the problem than the conventional analysis of variance techniques, but the investigator is still going to have difficulty satisfying the assumptions (normality, common variance, independence) that the statistician will require.*[22(p. 53)]

Bechhofer's procedure for ranking means of normal populations with known variances[23,24] and Bechhofer and Sobel's procedure for ranking variances of normal populations[25] are examples of multiple ranking procedures which seem appropriate to the design of computer simulation experiments.

Sequential sampling plans

Experimental designs which use analysis of variance as a technique of data analysis are based upon the assumption of fixed sample size. However, with certain kinds of experiments conducted on an "accumulation-of-information" basis, sequential sampling methods can be utilized which may lead to significant reductions in sample size. Since we are using computers on an accumulation-of-information basis and not planting plots of beans that will mature next year, we may want to take advantage of the savings (in terms of computer time) sequential experiments offer. Sequential sampling methods were designed for testing hypotheses or estimating parameters "when the sample size is not fixed in advance but is determined during the course of the experiment by criteria which depend on the observations as they occur."[26(p.365)]

In testing a hypothesis with a computer model, the sequential method yields a rule for making one of the following three decisions at each stage of the simulation experiment:[27(p.271)] (1) Accept the null hypothesis; (2) Reject the null hypothesis; (3) Continue the simulation experiment by generating additional data.

Although Wald's *Sequential Analysis*[28] is probably the best known reference on sequential sampling procedures, the optimization procedures developed by Dvoretzky, Kiefer and Wolfowitz[29(pp.51–55)] appear to offer promise in analyzing data generated by computer models. Chernoff's[30] article entitled, "Sequential Design of Experiments" considers a number of important aspects of sequential designs also.

Spectral analysis

Spectral Analysis[31] is a statistical technique widely used in the physical sciences to analyze time-dependent physical processes. There are at least two reasons why one may want to consider spectral analysis as a technique for analyzing data generated by computer simulation models. First, data generated by computer simulation experiments are usually highly autocorrelated. Yet classical statistical theory of the design of experiments (analysis of variance) is based on the assumption that component observations or experimental outcomes are independently distributed. In simulation experiments involving autocorrelated data, classical statistical theory must be replaced by a sampling theory such as spectral analysis in which the probabilities of component outcomes in a series depend on other outcomes at other time points in the series. Second, as one becomes more sophisticated in the analysis of computer simulation data, he may become interested in analyzing more than expected values and variances. "When one studies a stochastic process, he is interested in the average level of activity, deviations from this level, and how long these deviations last, once they occur. Spectral analysis provides us with this kind of information. Spectral analysis studies the salient time properties of a process and presents them in an easily interpretable fashion for descriptive and comparative purposes."[32]

Fishman and Kiviat[32] have written a survey article on the use of spectral analysis in analyzing data generated by computer simulation models. Tukey[33] has written an article in which spectral analysis and the analysis of variance are compared in detail.

SimOptimization

SimOptimization[34,35,36] is a set of optimum-seeking techniques embedded in an automatic cycle of simulation-analysis-simulation. These procedures quickly locate improved policies and computer system configurations in simulation models. Their use greatly increases the value of simulation analysis.

While simulation is more realistic and easier to understand than mathematical optimization, it has the disadvantage of being somewhat clumsy to use. A typical simulation model has an enormous parameter space in which the desired optimum solution is concealed. Finding this solution can be difficult.

Fortunately, a good analyst, using his judgment and intuition can find improved solutions by studying the results of a limited number of simulation runs. Even so, the process of making a few runs, studying them, deciding what runs to make next, then repeating this procedure, is a time consuming and costly way to grope for a good solution. By using SimOptimization, the preferred solution for most models can likely be determined in a single computer run consisting of from two to four simulation and analysis phases.

In most simulation models, optimality cannot, of course, be proven rigorously. However, SimOptimization solutions are at or very close to the "apparent" optimum. In every case, a "good" solution to a realistic model is preferable to an "optimal" solution to an unrealistic model.

While SimOptimization is still new, all of its applications have been highly successful. Judging from this empirical experience, SimOptimization seems to offer the best of two worlds, namely the realism of digital simulation combined with the convenience of automatic analytical solutions.

5. Increased Availability of Relevant Model Data

The technological changes taking place today in data collection in information processing, or "EDP Systems" is taking place in parallel with other areas such as finance and manufacturing and portends what is going to happen in the future in other areas susceptible to simulation. A detailed discussion follows covering the trends in EDP System data collection. Within the next decade we will see similar changes in other areas where data is now laboriously collected only on an *ad hoc* basis for a simulation study.

A key step in the process of constructing an EDP system model is the collection of data characterizing the work load. Of course, if we are hypothesizing a new system in a new environment, it doesn't pose much of a problem. But, typically, the model builder is studying possible hardware and software changes to an existing system. Therefore, he must represent as accurately as possible the complete system. In the past, this meant collecting some data on the work load and the computer system. Job data was (and still is) frequently obtained from an accounting file generated by the operating system. The characteristics of the hardware are obtained from the technical manuals.* This is the procedure used in applications, of which the study by Hutchinson and Maguire[17] is an example.

But computer system complexity has increased faster than our ability to characterize these systems. Today, the complex interactions between the work load, hardware and software of computer systems make the batch-processing systems of the second generation appear very simple, indeed. The difficulty today of even intuitively being able to predict the performances of some of these systems creates a situation where simulation for EDP systems is in more demand than ever. The recent development of EDP System Hardware and Software monitors offers a solution to this problem. As will be shown, use of these monitors can help solve operating problems and increase efficiency in the short run, but an even greater value may be in their use for generating data for EDP system models for pretesting system changes.

Hardware monitors

A hardware monitor consists of sensors, control logic, accumulators, and a recording unit. The sensors are attached on the back panels of the computer system components—CPU, channels, disks, etc. The signals from registers, indicators and activity lines picked up by the sensors can be logically combined or entire registers can be compared at the control panel and then be routed to the accumulators for combining or timing events, e.g., CPU active, any channel busy, disk seek counts and times, etc. Typically the contents of the accumulators are written periodically to a magnetic tape unit. The magnetic tape is batch-processed by a data analysis program to produce a series of analysis, summary and graphic reports. Figure 2 shows a hardware monitoring system.

* Some generalized models such as SCERT and CASE maintain this data on tape for convenience in processing.

Table I lists some hardware monitors presently on the market.

Figure 3 illustrates some typical output from a data analysis program run against a monitor tape.[37]

Two examples of how hardware monitors are used to improve system performance are:

1. Channel Imbalance

If the channel utilization is high, but the channel load is not balanced, the device activity needs to be measured to determine device rearranging. A new system performance profile should be measured to verify the results.

Low channel utilization would indicate that all the work can be placed on one channel with little effect on the system throughput.

2. Multi-programming Effectiveness

A large CPU ACTIVE ONLY time coupled with a low CPU-CHANNEL OVERLAP indicates that the benefits of multi-programming are not being obtained. Possible reasons are poor job scheduling (a balance is needed between CPU and I/O bound jobs); poor data set allocation (data sets should be on different channels so they do not have to be retrieved sequentially), or inefficiently written programs. Several of the production jobs which use a large part of the system resources should be selected and run stand alone in the system to create an individual job profile. These profiles show data set usage to make data set placement changes and processing phases which are CPU or I/O bound to enable efficient job scheduling. This will increase CPU utilization and system throughput.

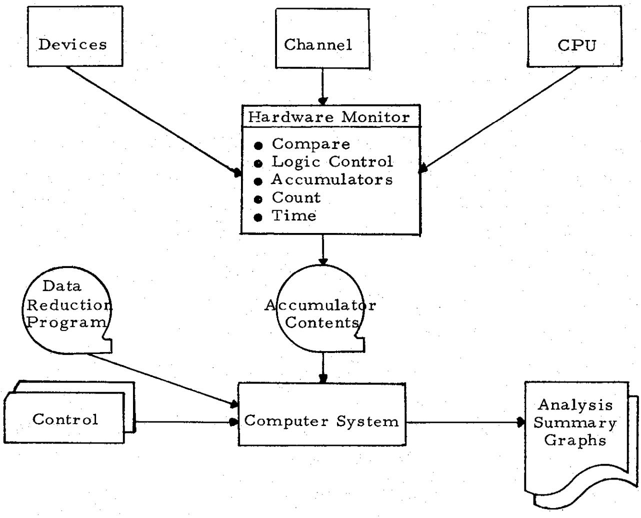

Figure 2—Hardware monitor system

TABLE I—Computer Hardware Monitors—A Sampling*

Supplier	Hardware Monitor	Price
Allied Computer Technology, Inc. 1610 26th Street Santa Monica, California 90404	CPM II	$35,000 to $80,000
Telephone: (213) 828–7471	CPM III	$14,700 to $24,000
Computer Learning & Systems Corp. 5530 Wisconsin Avenue Suite 1600 Chevy Chase, Maryland 20015 Telephone: (301) 652–9220	X-RAY	$2,350/month or $50,0000 purchase
Computer Synectics, Inc. 328 Martin Avenue Santa Clara, California 95050 Telephone: (408) 247–0200	SUM	Starts at $1,750/ month for one year lease or $34,000 purchase
COMRESS 2 Rockville Court Rockville, Maryland 20850 Telephone: (301) 948–8000	Dynaprobe	$4,000/month—lease $34,000—typical purchase price
IBM Corporation 112 E. Post Road White Plains, New York 10601 Telephone: (914) 696–1900	SMIS	$1,800 for basic service contract

While the data derived from the hardware monitor is useful for immediately improving system performance, it can also be very valuable to the model builder contemplating major changes or new systems. This data serves as:

- Input to development of the model.
- A validation "check point" for model testing.

The hardware monitor does not degrade or interfere with the system it is measuring and requires no system overhead. A software monitor, on the other hand, is a

Figure 3—Histogram of CPU active

program itself, uses system resources, and adds to system overhead. Both have their merits. A software monitor costs less than a hardware monitor and does a better job of getting a "fix" on the system workload.

Software monitors

The important variables in a computer system can be classed as either quantitative variables or qualitative variables. Quantitative variables are concerned with the magnitude of some quantity such as cpu active time. Qualitative variables identify which, of a perhaps very large number of different system elements, are being considered. For example, when measuring the work performed by a given program (i.e., the percent of available cpu cycles being utilized), it is necessary to identify each module and overlay segment individually and to show the cpu activity requirements of each. The module and segment names are the qualitative or descriptive variables, the cpu activity associated with each is the quantitative variable.

Qualitative and quantitative variables must be combined to present a usable set of measurements. One of the advantages of software monitors is their ability to obtain both from the system itself. This eliminates the necessity for using manual techniques to obtain or correlate information on what elements were active during the data collection process. When the descriptive data required is not available through console logs or other means, then either a pure software approach must be used or special software supplied to obtain the needed descriptors in a manner which permits proper correlation.

How a software monitor extracts variables from memory is conditioned on the timing and form in which such variables are retrieved in memory, which in turn tends to be a function of the structure of the operating system, compilers, etc. Thus, software monitors are at least operating systems dependent and can be compiler dependent or even problem program dependent.

Ideally, the act of taking a measurement should not alter the system being measured nor require the system to be altered beforehand. This is not perfectly achievable in software monitors. A good software monitor extracts data from the system without *significantly* altering the run characteristics of the system. This involves three parameters: cpu cycle requirements, I/O activity, and core usage. The first two quantitative variables can be expressed as a percentage of some total time, rather than an absolute count. Thus classical sampling techniques can be used instead of activating special codes or going to the techniques of trace routines. Furthermore, if the frequency of sampling is less than the minimum time in which some event can occur, then other measures of interest can also be supplied. Thus, even though the sampling techniques are used, software monitors can obtain the cylinder addresses of successive head movements on discs by using a sample interval less than the minimum positioning time.

The third design parameter—core usage—is resolved typically by the simple expedient of separating the data extractor mechanism from the data analysis function. As an example, Figure 4 illustrates this structure for the Boole and Babbage program evaluator (PPE).[38]

Application examples are given in References 39 and 42 using PPE[40] and another software monitor called CUE.[41]

This has several other important benefits, such as the ability to combine and/or reanalyze raw data in various ways. While some software measurement tools have been built with the extraction and the data reduction mechanisms combined, experience with them has tended to further strengthen the case for separation of these two functions. Table II lists some software monitors presently available.

The techniques of sampling as used in software monitors are based on relatively straightforward mathematical concepts. Assuming randomness (viz. absence of synchronization) of observation with respect to the events being sampled, the accuracy of the data obtained is a function of the number of samples taken, *not* the frequency of sampling. For example, monitoring a one-hour program with a sample frequency of one-half second, for a total of 7,200 samples, results in data accurate to within 1.5 percent with a confidence level of 99 percent. The cpu cycle needs of an extraction mechanism would be much less than 1 percent in this instance. On the other hand, the "overhead" can run as high as 20 percent with a sample frequency as small as 16 milliseconds.

Figure 5—Partial sample of code activity histogram

An example of software monitor output is illustrated in Figure 5.[38]

These monitors are most useful when used on a job mix containing programs which are either run frequently or which take a long time when run. The most effective technique is to maintain a list of the top ten "cpu cycle using" programs, and to continuously work on these to reduce their cpu cycle time requirements. As improvements are made on one, other programs usually then move up the list for rework. This activity coupled with configuration improvements can result in very significant improvements to system throughput rate.

FUTURE TRENDS

The practical application of hardware and software monitors for improving EDP system efficiency has been amply demonstrated in the past year or so. These monitors provide a wide spectrum of detailed information on EDP systems, their workload and the interactions between hardware, software (operating system), and user programs. The potential for using this information for the construction, validation and use of EDP system models has not been realized. There appears to be a need for EDP models for planning purposes or for pretesting system changes suggested by intuition or monitor use. The monitors by themselves have limitations for planning future EDP systems. There are a few indications that the "monitor people" will add some simulation capability to their monitors. For example:

> *Software adds important new capabilities to the hardware monitor, significantly increasing the usefulness, power and flexibility of such systems. The first software specifically designed to simulate hardware changes based on actual measurements made by hardware monitors has just been announced by Computer Synectics, and deserves mention. In addition to the 16 hardware accumulators provided by the hardware monitor, this software provides 19 pseudo-accumulators and time of day. A powerful set of operators is provided to manipulate these pseudo-accumulators. Virtual simulation of a wide range of possible hardware and software alternatives is thus made feasible, which can give rise to marked improvements in overall system performance, but based on recorded data about the user's actual job mix and working environment rather than on theoretical factors alone, and before equipment is physically changed or installed. And these advances are achieved without the inclusion of a minicomputer in the hardware monitor.*[43]

Recent research work by Noetzel[44] conceptualizes a design where a "meta-system" automates most of the simulation functions for a system designer. This concept is illustrated in Figure 6.

The concept for such a system has been fairly well

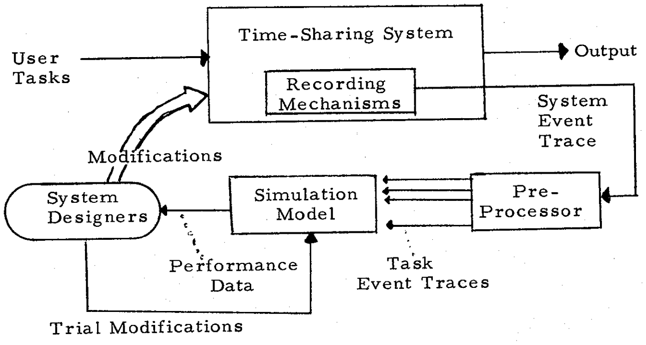

Figure 6—META system design

detailed; the operational demonstration of such a system has yet to be shown; and the economic feasibility of such a system remains dubious.

It appears that the next major step in EDP system design methodology will be widespread use of EDP hardware and software monitors (in addition to their normal operational use) as valuable sources of data for EDP model construction and use. These models will typically be implemented through use of generalized EDP models such as SCERT or CASE, or through use of high level software such as SIMSCRIPT, GPSS, or HOCUS for customized models.

From a simulation viewpoint, these technological changes taking place in the EDP system design area are examples of what is being experienced in other "hard" data areas such as finance, logistics and manufacturing. One can expect similar changes in the "soft" data areas such as marketing, social, and oceanography within the next decade.

In the coming decade, management personnel will be increasingly involved in the development of simulation models to *assist* them in making management decisions at all levels. In the past, the false promise of the computer automating management decision making disillusioned many management personnel who have again relegated the computer to routine data processing.

A pre-determined simple mathematical statement to be minimized or maximized by a mathematical procedure inside a computer has, so far, turned out to be a very poor substitute for the shifting sensitivity of a good business executive to the implications of a decision for many groups. There seems to be no alternative to discussions with a variety of people in order both to consider the trade-offs between various goals of the organization and to get from the various parties the commitment which is essential to the successful implementation of the decision.

But, as standard optimizing procedures, such as linear programming, have been losing favor with management, simulation concepts have been attracting more and more interest—and will continue to do so. The judgment of the manager plays a crucial role in the formulation of most management-oriented models. Many model interrelationships and variables depend upon the intuition, experience and judgment of management. With the growing participation of management in model development and use, further acceptance of the technique and implementation of models at higher levels in organizations is likely to follow.

This trend will be accelerated by an increasing number of models which will be implemented via a terminal into a time-sharing computer system. Often, this terminal will consist of a CRT device with associated software for the display of model output data in graphical forms. These technical innovations will facilitate the direct participation of management in model execution and modification. The next ten years will be an exciting and productive era for simulation techniques.

HISTORY

By 1970 some users had regained control of the computer. This occurred because an operational mode had come into existence that permitted the man and the computer to simultaneously attain the productive heights that each had previously, but separately, achieved. The installation of this mode was prompted by the results of analyzing the computing environment of the late 1950's and early 1960's.

Scientific computer installations circa 1960 operated in an environment in which computer runs, or "shots", were pre-scheduled, making the total system responsive to the individual who had "hands on" control of the machine. He was permitted to stop processor execution at some pre-set memory or instruction cycle, insert changes via the console, manually position tapes, take and immediately print snapshot dumps, relocate I/O channels, and isolate hardware failures. The total resources of the installation were provided to achieve this mode of man and machine interaction that resulted in high user productivity.

Business oriented installations had a less personal environment because of the production, rather than developmental nature of their work. However, production runs did require manual intervention because the processing cycle generally consisted of a progressing chain of separate events. Consequently, in both situations, operators were designated to service the printer, punch, reader, and other peripherals; keypunch facilities were provided inside the computer room; scratch tapes were immediately available; and engineers were assigned to maintain the hardware.

As computers grew in capability and cost, the opportunity for individual control lessened. The price of user convenience became too high. A way was sought to increase the productivity of the computer. Uncorrelated service routines such as memory dumps, loaders, compilers and assemblers were brought together under one supervisory program. By the early sixties supervisory programs were gaining control of the operational environment of the computer, causing the activities once manually performed in the "hands-on" mode to now be performed "hands off." System utilization increased, and by superficial measurement, increased systems productivity claimed. However, user productivity suffered. Runs frequently were aborted due to an improper monitor control statement, user awareness of the event following hours after its occurrence. Large and frequent core dumps, whose processing consumed equipment and increased turnaround, were taken in order to trap in print much of what once had been observed by eye. These and similar events discouraged the installation manager because, in spite of a highly efficient operation, his stated goal—increased overall productivity—was missed.

Multi-programming and rotating machinery, i.e., drums, discs, etc., offered some relief to what had become an intolerable situation. Processing files from drums and discs reduced tape utilization, and improved channel usage between main and auxiliary storage. Multi-programming systems provided for a more efficient use of the processor to process data and to service peripherals. Multi-processing held out the promise of lower cost through peripheral sharing, processor backup, and abundant capacity for special processing requirements. Extremely high system utilization was achieved, but the user was still forced to negotiate with the computer in a "hands-off" mode. This meant (1) he was unable to address the system except by those devices resident within the computer room; (2) he was forced to predict and prepare for all possible events that could occur during the execution of his program; and (3) his employment of the computer was through a manual operations procedure not under his control.

THE UTILITY

Early form

The effort that surmounted this impeditive mode was the imaginative coupling of software, hardware and communications capabilities into systems designed to accommodate remote access and user interaction and to remove manual intervention. The card reader, printer, and keyboard, in becoming terminals, offered to bring the computer to the user. Simplified and well-designed control languages and file editors made access to processor and files more convenient and approachable. A teleprinter became an on-line keypunch as well as an input and output station; card readers and high speed printers were available when needed, and no one intervened. The user at his terminal was regaining the position of control he had enjoyed previously when he processed from within the computer room. A computer could now be utilized in a convenient and productive manner from wherever its many concurrent users were located.[1] The utility had its beginning.

Operational problems

Initially, this new operation mode was accompanied by new operational problems. Field maintenance, essential for terminal up-time, was poor. Existing tape library management was inappropriate because run request forms no longer existed. Operator console messages were frequent, untimely and ambiguous. Data communications were unreliable, undocumented and without established operational procedures. Central site hardware maintenance was difficult to schedule, because output remaining to be transmitted was resident to and controlled by the central processor. Errors were difficult to trap because of the urgency in continuing on-line communications. Recreating errors was impractical because the dynamic status of the environment at the time of failure was unknown. Changes to the monitor system were difficult to test because of the lack of experience about the environment in which they would exist. Preparation, distribution and user notification of changes was nightmarish.

Central site power was increasingly consumed by terminal devices whose individual throughput was less than the central site devices they replaced. Early experience demonstrated a dramatic mis-match between terminal speed, line speed and processor speed. The processor became output bound, precluding any computational activity or the acceptance of any additional input requests. The first action taken to alleviate this problem was to add additional storage capacity for I/O buffering. This solution did not accelerate the throughput of the system but merely delayed the point at which the system again became output bound, causing another calamity—delay in turnaround time. In addition, timely communication between the remote terminal operator and the central site operator, essential, for example, in order to suspend output to replenish printer paper, make forms changes, or correct terminal malfunction, was non-existent. Numerous tape mounts caused severe operator intervention, adding to central processor idle time. Queueing was primitive and a run requiring seconds of execution could find itself behind a half-hour run, and/or its output stacked behind three hours of printing. Adding to the upset was the absence of data security and privacy that contributed to lost and misdirected files.

Solutions

The introduction of communications subsystems solved some of these problems. The communications subsystem consisted of a small processor especially programmed to manage the communication between the central computer and the remote terminals. Data compression, site verification and operator communication were among the tasks well performed by this subsystem. Communications handling was thus removed from the central processor.

Separate queues were established in the central processor for tape and non-tape runs, as well as for long and short runs. Tapes were pre-mounted before run execution and short non-tape runs were executed on a regularly scheduled interrupt basis. I/O files were site code identified and terminal verification was established before data transmission began. Notice of changes to the system was included in the transmission to each terminal site. Hardware selection centered around the computational and the communications processors. The computational processor was selected according to maintainability, reliability, instruction repertoire, execution speed, and other historically accepted criteria. The communications processor, in addition to the above, was selected on its ability to easily handle multiple and dynamically switched priorities, to accommodate various speeds and dissimilar modems, as well as readily interface with multimedia mass storage devices.

Measurement

Instrumentation was installed to measure system productivity and to determine the profile of the most avid, and therefore, perhaps most productive user. Among the data collected were (1) execution time vs. output volume, (2) tape vs. no-tape runs, (3) average number of tapes per tape run, (4) terminal media by which runs were submitted, (5) time of day for heaviest traffic, (6) connect time vs. execution time, and many other criteria independent of and integrated with these.

The analysis of these data revealed that more efficient utilization of the system was achieved. There was less idle central processor time, faster response to more users, timely operator communication with the terminal site, and much improved tape procedures. The analysis also suggested that the configuration of a computing system could be optimally adapted to a given job mix. The utility's most productive user worked in an engineering discipline, demanded minimal input/output, was remote batch oriented, executed his own applications, and was substantially independent of operations personnel. This user regained hands-on posture, essentially because he was *autonomous* in his operating mode. From his terminal he initiated and resubmitted runs, made his own corrections at his own pace, and therefore bypassed the impeding nature of a manual operations procedure. He worked in his habitat and he shared with and solicited comments from those with whom he worked. His need for printed output, especially during debugging, diminished as did his need for punched card files.

Extending the service

Enthusiasm within the utility community grew as more operational problems were resolved. This enthusiasm attracted another class of users who had an opposite profile to the earlier class. This new user required numerous tape files, voluminous print files, forms changes, reprints, punched card output, and other services requiring manual intervention. This user executed runs that had a much higher ratio between I/O and processor time (e.g., 40:1 compared to 8:1), and he represented a group whose computing dollar expenditure was greater than 90 percent of the total expenditure of the computing community.

This business data processing user could only partially capitalize on the increased productivity offered by the computer utility because of the above stated characteristics of his work profile. The design legacy bequeathed his program, many of which could trace their roots back to the single function, manual step mode of unit record equipment, contributed significantly to this profile. Much of the manual processing flavor of these systems remained when conversion occurred. Operational compatability for some of these systems during their conversion from unit record machines to computers was, in fact, a major consideration. Furthermore, indeterminate output delay, due to a data communications failure, was sufficient cause to create a sense of real time urgency in payroll departments, and the possibility that company data could be compromised without detection was intolerable. Continuing investigation to understand these problems brought the utility user's profile into sharper focus. For example, a geologist programmer required multi-media output and the data he processed was, to him, urgent and private. Business programmers also did "compile-and-go" testing. Thus it became apparent that this was not the case of the engineering vs. business user, but rather the case of the *autonomous* vs. the *non-autonomous* user.

Work began in two areas to provide for the inclusion of the non-autonomous user. At the central site additional file processing schemes were installed. Print files were spilled over from drum to tape in background mode for subsequent low traffic distribution. Store and forward service was introduced permitting daytime transmission and nighttime execution of the run, or vice versa. Rotating machinery for additional buffering, as well as higher speed and full duplex lines for more rapid transmission, were added to the communications subsystem. Terminal site soft-ware was modified to facilitate additional operator communications and to service the equipment needed for local peripheral processing.

CURRENT STATUS

By now, computer installations operating in a utility mode employ several million miles of communications lines serving over 200,000 keyboard terminals, and over 20,000 high speed card reader/printer terminals. User productivity was the objective of the early installations. The growth in the number of computer utilities is attributable to that objective being met, to increased user sophistication, and to realized additional value by the installation manager.

Users continue to become more aware of the computer's value and less concerned with the computer. The utility provides a means by which the user can gain convenient access to the maximum contemporary computer power he requires. Company or department size may have little relation to the size of the computing problem at hand. With the commercial utility, a small firm has access to a resource similar to that available to the large corporation. With the in-house utility, all users within the organization have the opportunity to capitalize on the total computing resources available.

There are several values realized by the installation manager. First, there is the reduction in shake-down time of new systems software and a manpower savings due to centralized software maintenance. Centralized usage being at least equal to the sum of the usage of previously individual sites causes bugs to show up sooner, and when the bug is fixed, it is fixed for everyone simultaneously. Second, there is a low cost opportunity for expansion. Additional capacity can be added to a utility operation on a cost basis distributed throughout the user network. And, this expansion provides a low cost opportunity for back-up heretofore denied individual sites. In addition, there are savings in the overhead costs such as physical plant, hardware maintenance, site security, and parts inventories.

And, finally, there is the opportunity to focus resources on the challenges of the future. Among these are (1) low cost reliable data communications, (2) simpler user file processing procedures, (3) more efficient on-line mass storage, (4) pricing, (5) data privacy and security, and (6) effective I/O file processing.

SOLUTIONS IN PROCESS

Items (1), (2) and (3) of the preceding paragraph are receiving abundant attention. However, pricing remains as much a challenge to explain as to accomplish. Clearly, a utility user's job consumes time and space within the processor and the communications subsystem, space on peripheral storage devices, channel time to move data to and fro, communications lines and terminal devices. Further, there is the question of continuous operation and priority requests for critical needs. A multi-environment (user/processor) exists that precludes use of the historical time quantum and storage allocation pricing scheme. Determining the profile of the utility user and the effect this profile has on the total system is necessary in order to achieve efficient operations and precision pricing. A unit of cost based on user value discernible prior to execution and consistent within reasonable tolerance seems to be in the offing.[2]

Data privacy is in its own right an emerging industry being prodded into existence because of the sheer dollar value at risk. Corporation data and computer programs are assets with high determinable value. Schemes and procedures for the protection of these assets are, for many installations, non-existent and, often where present, inadequate. The installation manager faces a severe challenge in finding the procedure to achieve data privacy and security. Within this procedure must be the means to prevent accidental and deliberate acts that destroy or jeopardize the storage, processing and retrieval of data.[3] And this protection, this electronic lock[4] that may include cryptographic enciphering of files, must be installed without restricting or encumbering authorized user access. The security procedure must control physical access to the computer room, tape library and card file room, audit installation transactions and encourage a general security consciousness in installation personnel.

Speedy I/O handling is as critical as the processing of the data. Transmission queueing and intermediate storage of the terminal I/O files are among the significant factors contributing to the complexity of the developing I/O processing solution.

SUMMARY

As the past has demonstrated, solutions to processing problems will be found and, in turn, will provoke imaginative new ways to consume the power of the computer. This being the case, the installation manager will continue to face the decision of what operational mode his installation should employ. The utility makes access to contemporary and consummate computer technology simple and convenient, removes the geographical limitation of those working in cooperative efforts, and frees talent for creative activities by automating clerical procedures.

The economic value concomitant with these achievements, whether it be yield on the utility investment or quality of the final product resulting from the availability thereof, will be left to the determination of the reader.

The utility has emerged. As it matures it will move closer to the realization of its potential which is to bring the value of the computer to all who request it wherever and whenever they desire.

Installation management—The next ten years

by RONALD M. RUTLEDGE

Carnegie-Mellon University
Pittsburgh, Pennsylvania

INTRODUCTION

In this paper we will give our extrapolation of the exciting challenges facing installation managers in the coming years and how we expect to react to these challenges. We view the evolution to the present stage as having gone through three generations of installation management. The first generation was marked by the early computers with small memories and relatively crude input devices in which the operation of the computer was done mainly by the person using the computer. In this early generation the computer installation manager had the hardy pioneer spirit and knew most of his customers by first name. One of his main worries was how fast he could get the next model of the computer.

The second generation was marked by the introduction of tape operating systems and some primitive disc systems which required that the person operating the computer be very nimble and able to react quickly to the need for changing tapes so that computer utilization would not drop. In that generation the customer moved away from being in direct contact with the computer but there were still many customers who used the computer directly. Input and output were becoming a problem. The installation manager now had to start worrying about planning the layout of the I/O area carefully and was looking forward to the coming generation for order of magnitude improvements.

In the third generation we found the introduction of multiprogramming facilities through the use of primitive drums and improved disc facilities. And here, as in the second generation, the need for competent operation of the equipment became of increasing importance. One then had many jobs requiring tapes and discs running at the same time. The I/O problem increased even further and the great hope of eliminating it through terminal access was dismally smashed. The utilization of remote job entry stations did finally ease the problem in the latter part of this generation. By using remote job entry stations, most customers no longer required their own computer nearby to get adequate computing service. In this generation the installation manager had to face up to the full problems of being a production specialist, a resource accountant, a businessman and a technocrat.

In what we now view as the fourth and present generation at Carnegie-Mellon University the distinction between the generations becomes hazier. We will list the main characteristics of this generation. Awareness that computers cost large sums of money and that poor utilization is not uncommon here become permanent issues with the economic decline. The possibility of inexpensive mass secondary storage is becoming very real and in some cases is almost here. At times our complex systems appear to be working stably. Computer installations are no longer simple one machine, one vendor sites.

Telecommunication is now as big a problem as the computers and people are asking what they are getting for their dollar rather than how fast they can get the next piece of equipment.

The fifth generation we project will be characterized by low cost mass secondary storage, so inexpensive and efficient that tape drives will become uneconomical to use in many cases. Telecommunications will be reliable and economical, so that we will not hesitate to use a computer at the opposite end of the country. Time-sharing systems will actually work reliably. No one will take note of using the system with several hundred people on it. Computer installations will become rather amorphous entities consisting of complex inner connections of many different CPUs' memories, and various storage devices.

In the fifth generation, management information systems will become paramount. Low-cost mass storage will make implementation easy and the interconnections of networks will make distributive data bases a reality. The challenges in the coming years are put into the reference framework of cost effectiveness. Cost effectiveness is the main theme of our management's interest and it should be and probably will be the main theme for the foreseeable future.

By meeting some of the challenges mentioned, Carnegie-Mellon University (CMU) was able to cut its Computation Center costs by 40 percent and at the same time improve service, deliver more computing power, and increase customer satisfaction in a short period of a few months. Some details of this accomplishment have been covered elsewhere.[1] In our experience, innovation and implementation of automation is not an easy straightforward process, but the challenges can be met.

PERSONNEL AND ORGANIZATION

One of the largest voids in today's information processing technology is the lack of qualified educators to train the personnel we need. The ACM Curriculum Committee on Computer Education has presented reports[2,3] which will probably form the foundation of many curricula for training our future personnel.

The increasing complexity of the computer installation requires a shift to more technically competent personnel for daily operations. Unfortunately this shift in general has been too slow and many present installations suffer with reduced productivity due to less than optimally trained personnel.

Several years ago there were studies[4–7] which revealed that the difference in the productivity of programmers can be an order of magnitude.*

Unfortunately, evaluating programmers[3] remains in a state of witchcraft. We cannot hire enough experienced programmers, and we are willing to train or hire inexperienced persons. Hopefully, by evaluating them over a period of employment, we can get a few very good ones from the crop. CMU receives big dividends in minimizing the actual number of personnel while maximizing on the competence of individuals. In other words, the incremental cost of properly compensating the excellent programmer is well worth the price if we are lucky enough to have him.

The actual organization of a computation center is not so important since the organization should reflect an attempt to optimize the contributions of the individuals and inter-personal relationships with respect to the objective function of the group. Therefore, one would reasonably expect the organization to change in time as the different members of the team come and go. Though the usual organizations are somewhat reluctant to be highly dynamic, the rapid change in the advancement of information processing technology presently allows one to have a flexible organization without having the appearance of a continual card shuffle.

At CMU the shift to better qualified personnel has taken the route of the control center concept[1] with the elimination of the usual operations groups. The computation center staff sections are hardware, information, and software systems and with few exceptions every professional takes his turn being in charge of the control center. The programmer in charge of the control center may have as many assistants as the load requires. This approach is parallel with more automated operations requiring more technical skill and has significantly reduced operating costs. Better service and a more stable system result because of the increased technical ability of the personnel in charge to answer inquiries and react to contingencies.

Personnel are the only important resource. Whatever machine we have today will certainly be outdated in five years whereas our personnel will be more valuable in five years if we give them the proper motivation to keep abreast of our challenging field.

THE EXECUTIVE GAP

Most computer installations are a part of a greater organization which the installation serves. With the increasing utilization of computing resources the importance of the installation to the parent organization is increasing. The rising costs of these computing resources to the parent have forced many organizations to recognize the need for an executive position with the responsibility for coordinating and integrating the organization's computing resources. This executive must be technically and administratively competent.

In most organizations today there is not an executive position with adequate technical competence for the magnitude of importance of the organization's computing resources. One or more installation's managers have been given default technical responsibility without proper administrative authority for effectively handling the responsibility. One common symptom of this executive gap is separate computer installations for "administrative" and "scientific" computing. The managers and their organizations who recognize and react to this common gap in their executive structure have much to gain in better utilization and reduced total costs.

* These studies were attempts to evaluate the relative merits of time-sharing versus batch processing as a means of programming. Although the intended results were inconclusive, the wide range in programmer productivities was repeatedly demonstrated.

Until the executive gap is filled the installation managers must understand the requirements of the organizations they serve as well as keep abreast of computer technology if their service is to be efficient. This requirement of having an executive position which must be alert to developments in the rapidly changing computer technology is one of the toughest challenges to be met if our organizations are to receive the proper benefits of our technology.

CONFIGURATIONS

Will the small computer installation disappear and be absorbed by the giant emerging ones or will a small computer installation have a place in the future? The answer to this question obviously depends on the circumstances. Just as a small switchboard has a place in our present day telephone system, there are many circumstances where the small switchboard doesn't belong. In our projection it will be more than ten years before the small computer installation is really threatened in the same way as a small telephone switchboard. Certainly the installations that will exist over the next few years will become more amorphous entities rather than one single CPU or one single manufacturer. Reliability will be markedly improved[9] through new circuitry,[10] improved hardware technology,[11] and better software.[12,13] Emerging large mass storage systems[14,15] will permit a greater degree of automation and accommodate the developing management information systems. The general population is beginning to understand the basic principles[16] of machine configurations. We now have our first book characterizing in a systematic way the various computer structures.[17] The minicomputers won't replace the large CPU's but they will certainly supplement and complement them. Every large CPU probably will have numerous minis around in various functions for which the larger CPU is less cost effective.[18]

NETWORKS

Computer networks[19] are another area in which the small computer installation is threatened by replacement with a remote job entry facility or a few terminals. This will eventually happen, but we certainly do not think it will be in the next few years. It is, however, definitely a possibility in five to ten years. Communication[20,21] problems have held the development of networks back many years. However, the great thrust provided by the underwriting of the ARPA Network has provided the enthusiasm for exploring the present potential of networks.[27]

Actually there will be two forms of networks, the local network and nonlocal or long distance network. There are many advantages to local networks which haven't been properly realized by the installation manager. Many installations have various computers with duplicated hardware and software facilities.

The linking of local computers and the reduction of redundant facilities will result in the elimination of duplicate costs and also in increasing cost effectiveness because jobs will be easy to run on the appropriate machine. This was successfully accomplished recently at CMU with sizable cost saving (capital and operational), increased effectiveness, and added functional capability for the customers which formerly used each system as an independent entity.[1]

Also the reliability of the total installation will be improved since one can transfer a job more easily from one machine to another. The non-local or long distance networks will satisfy peak load demands and actually permit installations to run at a greater average capacity because they will not have to have an excess capacity to satisfy peak loads. The result will also be an increased cost effectiveness. The non-local networks will allow each installation to give one stop service to a broad spectrum of functions which will be available through the networks to which it is connected.

RESOURCE ACCOUNTING AND CONTROL

The measurement of computer systems has now come of age with the first annual workshop on software system performance evaluation held last year[28] and installations are developing their own means of implementing primitive measurement facilities. In the coming years manufacturers may actually supply measurement facilities as parts of the standard system. We should not have to buy a computer as though it were a car without a speedometer or gas gauge or odometer. The question of pricing,[29] cost accounting, and the administration of computer resources* is now considered an integral part of the resource accounting and control schemes.[30,31] The marketplace will demand the facilities to measure and record utilization. Whether one should lease or buy and how and why one should write off purchased equipment is a commonly discussed issue. The marketplace will discover that

* With proper accounting and pricing sometime during the coming years we will stop referring to our customers as 'users.' The label 'user' has adverse psychological effects for the 'user' and the ones 'used.'

purchasing equipment and using some sort of declining balance depreciation is the proper and logical way to cost account for equipment resources of a changing technology.

HARDWARE PROJECTS AND MAINTENANCE

This area is becoming a challenge due to the increased in-house capability of installations not only to maintain but also to fabricate and enhance their equipment. The recent emergence of the 'Brand X' peripherals has created a problem in many installations with multi-vendors. Now the installation requires at least one person competent in hardware logic to minimize the potential conflicts between various vendors. For those with the capability, a potential savings of some magnitude exists for in-house maintenance of equipment.[1] But for those who do not prefer this route there are third party vendors who will furnish maintenance for various manufacturers' equipment.

SOFTWARE PROJECTS AND MAINTENANCE

Software still continues to be one of the biggest challenges. The Third ACM Symposium on Operating Systems[32] last year gave us the impression that perhaps operating systems were now being comprehended.

In general we are beginning to see logical structures and approaches to putting systems together. Three annual conferences have been held on software engineering. Their accompanying proceedings[33–35] project that an emerging profession is developing in software engineering. In the next few years we will even be getting the handbooks or cookbooks which will tell our software engineers what pieces to use for the type of system we want to put together. The education, training, and development of programmers and operators is still somewhat of a controversial subject.[36] Some curricula are becoming standardized and our first book on management of computer programming was recently published.[37] Perhaps people have not learned that we still have to develop the art of managing a large software project. It has been our experience that the project employing more than three programmers is likely to have serious problems without careful structuring of the project[38] and software.[39] With the continual unbundling that is occurring perhaps the vendor software groups will have to stand on their own or face up to competition from the outside. Then the quality of the vendor software will be improved or the purchaser will not opt to take it. This will hopefully create more competition where installations can go to third party for maintenance of their standard operating system and have more options to buy software packages built to order for them.

CONTRACTS AND LAW

Contracts[40] and law unfortunately tend not to be recognized as the challenge they are, although many of us have recognized this the hard way. Monopolistic tendencies of the various competitors in the marketplace require the installation manager to have an understanding of the Antitrust Laws.[41] The field of law is also now becoming aware[42] of the particular requirements of the computing technology.

STANDARDS

An old and difficult challenge is still with us. The emergence of the networks has shown that if the networks are going to work, which they surely are, people will be forced to use standards.[43] The developing of microprogramming[44] capabilities hopefully will allow not only better standards but also allow a standard operating system which would run on most computers and still allow the computer to have its own unique capabilities.

COMPETITION IN THE MARKETPLACE

Do you really have competition in the marketplace? With the folding of RCA Commercial Computer Division and with GE electing to get out of the field, some think that competition is decreasing rapidly to zero. Of the many and various extreme views on this subject one of the more moderate was expressed by Larsen.[45] He said, "Hurting IBM is easy; solving national problems is tough and difficult. A good solution requires all of the business and technical skill at the industry's disposal. It also requires that we care—not about IBM, but about the United States, if we are to keep the United States in its lead of the computer technology." Larsen, unfortunately, did not cover the case of an international monopoly.

The real question is whether or not our workable but competitive system gives the marketplace a fairly priced and up-to-date product. If one company spends more on research and development than most of its "competitors" gross[46] is it possible to compete rather than just trail behind and subsist on leftovers? Could Fortran and OS/360 have survived in a free and knowledgeable marketplace? How many installations have computing contracts tailored to their requirements and explicitly hold their vendors liable for failure to deliver as promised rather than the "standard" contract loaded with the "come hell or high water the installation will pay the vendor" clauses? Does the installation have the engineering specifications for equipment worth millions? What can the installation do if its equipment is not maintained properly? Go to another company for maintenance? We must decide if the answers to these and many other such questions are satisfactory. If the answers are not satisfactory then one of the most difficult and important challenges facing us is what to do to obtain a marketplace where the competition benefits the customers.[47]

The motivation behind present day monopolies is not usually the hungry greed of the communist's stereotyped capitalist, but rather nothing more than the desire for the easy life (i.e., a secure well-paying job). To quote Judge Wyzanski,[48] "Some truth lurks in the cynical remark that not high profit but a quiet life is the chief reward of monopoly power. And even if a particular enterprise seeks growth and not repose, an increased rate in the growth of ideas does not follow from an increased concentration of power." This understandable motivation permeates the bureaucracy of the monopolistic organizations with the result that the monopoly power is not overtly exercised by any one individual but by a collective effect sometimes expressed as, "It is our policy", "We must treat everybody the same", or "We can't make exceptions". The salesman representing the monopoly, though benefiting from the monopoly, is quite helpless at combating his company's policy. This indirect collective effect can only be effectively changed by collective effort. Why can't the customer groups make their own standard contracts?

The Justice Department has historically acted very slowly on monopoly power. The large organizations with power to act do not want to "cast the first stone." The small installation cannot afford the time and money, and may times is justifiably afraid to fight. A giant organization is a fierce and ruthless opponent[49] but our obligation to society demands that if we decide detrimental monopolies exist, then we must face the challenges.

MANAGEMENT INFORMATION SYSTEMS

Corporations and private communities are recognizing the need for and the potential benefits of being able to make more informed decisions through the use of computers. Unfortunately these areas perhaps have been the hardest to penetrate due to the classical conservatism of the management[50] which will use these systems. Operating systems have not been outstanding successes in delivering past promises, but now that operating systems have become reliable, many different management information systems exist. Businesses are demanding the implementation of systems.[51,52] In fact the Government[53] feels they are absolutely essential to the future of the congressional operation.

INNOVATION AND AUTOMATION

Innovative operations through automation should be the theme of the installation manager. He has at his disposal the machines which represent enormous advances made in automated processes and which, by means of information systems, have furnished us the ability to make informed decisions.

Why hasn't the installation been able to exemplify the pinnacle of automation and innovation by allowing the machine to control the routine operations? With our society's becoming suspicious of computers[54] and their encroachment upon privacy, installation managers will have to be innovative to impress society[55] that the powerful facilities are in competent hands. In the post-industrial[56] era, with information doubling every 12 years,[57] the challenge of keeping track of one's own installation will continue and should be met with our own technology.

SUMMARY

Innovation and automation: with this as the theme of our coming years, the installation manager should set the goal of making his installation the pinnacle of innovation and automation. He will have to be prepared to justify to management not only that his present equipment is cost effective but that what he proposes to get in the future will improve the installation's cost effectiveness. Management is forced to recognize the large cost that information processing technology is now starting to represent with respect to the organizations' total budget. We are all very lucky to be a part of this exciting era but we must not make the mistake of leaning so much on our lessons of the past to extrapolate our actions into a very innovative and challenging era which may be totally different from our past experience.

ACKNOWLEDGMENTS

Although the director prepared this paper, the Computation Center Staff originated many of the ideas

presented here, and their exceptional competence and exemplary dedication made possible this exploration and the actual utilization of some of these ideas.

A set of goals and approaches for education in computer science

by SAUL AMAREL

Rutgers University
New Brunswick, New Jersey

INTRODUCTION

In order to evaluate and plan educational programs in computer science it is important to have a clear conception of the internal structure and content of the discipline, and also of its relationships with other disciplines. It is also important to have a clear set of goals, values, and priorities in the light of which given programs can be evaluated, and new approaches can be developed.

In this paper I will discuss a specific set of goals and approaches for educational planning in computer science. Much of our planning at Rutgers reflects the viewpoints that I am presenting here.

THE STRUCTURE OF COMPUTER SCIENCE

In Reference 1 I have presented a framework for curriculum planning in computer science which combines a global view of the discipline and a local view. The global view is concerned with the kinds of objects, phenomena, and concepts that form the domain of discourse in computer science, and also with the pattern of relationships between this domain and other domains of study. The local view focuses on a structured description of the knowledge, problems, and activities within the discipline.

In developing the local view of the field, I find it useful to distinguish between two broad categories of activities: (1) activities concerned with problems, methods of solution and programming; and (2) activities concerned with representations, languages, schemes of processing, and system designs. They correspond roughly to *computer applications* and to *systems*. Within each of these two categories there is a broad spectrum of types of activities: development of formal systems and formulation of theories; search for fundamental principles; invention and exploration of new schemes; design and construction of new systems; and experimentation with existing systems. The range extends from purely theoretical work to practical work within the state of the art.

Theory and practice

I think that it is important to maintain a view of the field which helps to *minimize the distance between theoretical and practical work.* Computer Science is concerned with analysis and synthesis aspects of various types of computer applications and systems. A continuous interaction between theoretical and design/experimental work is needed for a vigorous rate of progress in the field. Theoretical work in a rich applied environment is likely to receive stimulation along lines of 'relevant' models and theories. Design and experimental work in a good theoretical environment promises to lead to more efficient and powerful systems and applications.

An important reason for maintaining a strong coupling between theory and practice in academic computer science is our responsibility for guiding the growth of the discipline toward the dual goals of intellectual depth and coherence, and also of pragmatic significance for the real world of computing. Because of the phenomenal growth of the computer field, we are witnessing a rapid accumulation of vast amounts of unstructured information: specifications of many diverse hardware and software systems, records of a variety of operating experiences, discussions of different principles, techniques, and empirical advice, and many fragments of knowledge only weakly related to each other. In order to be able to build on top of what has been done in the past, and in order to understand and effectively use new developments, we must plan computer science programs in accordance with the following: (a) exposure to what is being done in the real world of computing, (b) study of ways for bringing order into what is being done, through an active search for unifying principles, general methods and theories, and (c) exploration of new computer designs and applications in the light of new concepts and theories.

Clearly any structural description of the subject matter of computer science reflects certain points of view and values about what we ought to teach and how. By not using a separate category for 'Theory' or 'Formal Systems' in a broad structuring of the field I am injecting a specific viewpoint into curriculum planning which favors 'rapprochement' between theory and practice in computer science programs.

Systems and applications

Our academic planning at Rutgers is based on further substructuring of the two categories 'Systems' and 'Applications' into the four parts 'Hardware Systems' 'Software Systems', 'Numerical Applications', and 'Nonnumerical Applications'.[2,3,4] The 'Hardware Systems' part covers mainly machine organization, digital subsystems, operating systems, and design processes. The emphasis in the 'Software Systems' part is on machine level representation and programming, operating systems and language systems. The 'Numerical Applications' area is mainly concerned with problems and procedures where numerical data are dominant, such as problems in numerical analysis and in statistical processing, optimization and mathematical programming, and certain classes of modeling and simulation problems. The 'Nonnumerical Applications' area is primarily concerned with processes involving nonnumerical data. Examples of such data are: representations of problems, situations and programs; symbolic expressions; language text; abstract structures; and graphic objects. In addition, each of the application oriented areas is concerned with relevant studies in high level languages, schemes for representing problems, data bases and procedures, and related theoretical subjects.

Each of the four parts described above provides a basis for a "topic of study", which may be chosen by a student as an area of concentration. The partition into the four areas reflects an attitude to curricular design which is widely accepted at present. It has a fairly sound conceptual basis, and it leads to an implementable program which can now be supported by considerable experience and a growing literature. The conceptual basis is essentially *reductionist*: computer systems are decomposed in terms of different types of structural components (structural properties determine possible modes of computation), and computer applications are differentiated in accordance with major types of data structures (properties of data structures determine types of information processes). This reductionist attitude will probably change in the next few years, as it will become increasingly desirable (and feasible) to treat hardware and software designs in a unified manner, and as the emphasis in application areas will be on broad problem types where both numerical and nonnumerical processes will play essential roles (e.g., modeling and decision making in medicine, large design and optimization problems). The changes are likely to come first in advanced parts of graduate programs, and they will gradually move toward undergraduate programs. I expect the changes to be relatively slow, not only because of the conceptual issues involved in restructuring the field, but also because of the natural inertia of educational systems where required courses, supporting texts, and other relevant resources, cannot change overnight.

A structured description of the field is an important input for planning an educational program, and it already reflects a specific set of viewpoints and decisions on priorities. We need, in addition, further clarification of priorities in order to determine (a) the relative emphasis that the program should place on different parts of the field, and (b) the way in which individual students should be guided through the program.

Our emphasis at Rutgers is on the *relationship and mutual impact of application areas and computer systems.* This implies a fairly balanced set of activities in applications and systems, with major effort in problem solving methods, computer procedures, languages, systems software, and associated theories. This approach is consistent with our view that studies of computation mechanisms and system designs should grow in an environment which is rich with significant and challenging computer applications.

COMPUTER APPLICATIONS

I believe that serious work on new types of computer applications is essential for the healthy development of computer science. The challenges presented by new applications and the constructive attempts to meet them will continue to be key factors in the evolution of computer systems and in the conceptual maturation of the field. Work on new applications will lead to increasing collaborative ties with people in other disciplines; this will increase the 'surface of contact' between computer science and other areas, to the benefit of all involved. In this context, computer science could provide an academic home for certain important activities associated with *applied mathematics*: the formulation and study of models, the development of methodologies for bridging the gap between a real life problem and its representation within a system wherein the problem can be solved, and the study of broad approaches to problem solving.

In our programs at Rutgers, computer applications are studied at various levels. A freshman-level introduction to computing is oriented to hands-on experience with computer problem solving, using BASIC on a time sharing mode. Sophomore-level courses in computer problem solving focus on a variety of problem types (numerical and nonnumerical) and on the use of several high-level languages—FORTRAN, PL/I, SNOBOL. Thus computer languages and their features are introduced in the context of their *use* for formulating computer procedures of different types in a variety of problem areas. The study of computer organization, machine level programming, and systems software follows the courses where problem solving is the dominant theme. Thus, a student is first exposed to *what* kinds of things computers do and how can they be *used*, and then he is led to consider *how* computer systems operate, how they are structured and how they can be *designed*.

The study of computer applications continues in our upper level undergraduate classes with courses in numerical methods, data processing methods and nonnumerical algorithms. At the graduate level, two introductory (and required) courses on numerical analysis and nonnumerical algorithms are followed by a collection of courses and seminars which explore in different degrees of depth a variety of application areas, procedures, and approaches to problem solving.

Recently we established an (NIH supported) research resource on *computers in biomedicine*. This provides a focus for collaborative activities with people in medicine, bioengineering, psychology and ecology on a broad range of problems that involve the use of computers in biomedical inquiry. This type of research activity is an extremely important environment for advanced graduate work and for faculty research in various aspects of advanced computer applications.

Nonnumerical applications

The study of nonnumerical applications is of central importance in a computer science program. It provides insight into the broad notion of computers as symbol manipulators, and it permits a clear view of many key information processing concepts that become obscured when presented only in the context of mathematical algorithms for numerical problems. Also, the domain of nonnumerical applications is extremely large, and it contains a great variety of significant problems in the field. In addition to the broad spectrum of problems from elementary data processing to complex decision and problem solving in artificial intelligence, the entire area of systems software (languages and operating systems) is mainly founded on nonnumerical processes and techniques.

Artificial intelligence

Work in artificial intelligence problems provides an excellent opportunity for the study of nonnumerical processes and for the clarification of certain basic issues in software design. It is important to work toward the development of closer links between artificial intelligence studies and other studies in the mainstream of computer applications and of systems design. I believe that this will be of benefit to computer science education, and in general, it will stimulate new, significant developments in the computer field.

It is becoming increasingly clear that there is no sharp dividing line between the problem solving procedures of artificial intelligence and the procedures of today's 'conventional' software.[5] It is useful to think that computer procedures lie in some sort of continuum, and each procedure in the continuum is characterized by the relative amount of systematic versus heuristic knowledge available to it, as well as the degree to which this knowledge can be efficiently exploited by the procedure for the solution of specific problems in its domain. At the one end of the continuum, where systematic knowledge is dominant and its mode of utilization is highly efficient, we have the customized procedures and the formally validated algorithms of the well developed computer application areas. At the other end, where amount of systematic knowledge is low, we have the general, flexible, goal directed procedures of artificial intelligence, where a set of relatively weak problem-specific principles are combined with heuristic methods for the control of processes that search for solutions. In between, we have the bulk of procedures that run on computers at present—including procedures that manipulate computer languages, and those that control computer operations.

The notion of a procedure continuum, where the emphasis is on types of information processes and on types of knowledge associated with them, promises to provide a fruitful conceptual framework for education in computer science. It would be interesting to explore it further in the context of future curriculum designs.

Numerical applications

Numerical analysis and several other subjects in the general area of numerical applications are among the best developed in the field in terms of systematic knowledge available and theoretical treatment of algorithms. I think that these subjects have an important place in a computer science curriculum, not only because of their great significance for many computer applications, but also because they provide models of 'high quality' procedures and of successful theoretical approaches to their study. Such models are needed for progress in other, less developed areas of the field.

INTERACTION WITH MATHEMATICS

The study of numerical applications is closely related to mathematical studies. A strong mathematical background (especially in calculus and linear algebra) is needed for work in most numerical applications. Conversely, numerical applications are in themselves significant topics of study in mathematics.

The question of *mathematical preparation* for work in computer science must receive careful consideration in the development of computer science programs. Theoretical work in computer science relies on several branches of mathematics and logic. In addition to the formal background needed for numerical applications, various topics in abstract algebras, in logic and foundations, in combinatorial analysis, in graph theory and in probability theory are needed for work in well developed areas of nonnumerical applications and of computer system design.

A problem aiises when we consider the training of people who are oriented to the bulk of design and application activities in the field. For the most, these activities are in areas where relevant theoretical knowledge is poor. There is considerable consensus among computer science educators that people working in these areas must have at least a certain level of 'mathematical maturity.' This does not imply necessarily the knowledge of specific mathematical facts and methods. What is meant usually is training in disciplined modes of thought, in the manipulation of abstractions, and in the development and use of methods that can apply in a great variety of situations. To obtain this type of training, we have several approaches: (a) provide sufficient exposure to offerings in regular mathematics curriculi, (b) restructure some mathematical offerings to attain within a limited time, both the 'maturity' objective and the objective of education in mathematical topics of special relevance to work in the computer field, and (c) develop computer-based courses that address themselves directly to the underlying cognitive skills implied by 'mathematical maturity,' without using conventional mathematical material. These approaches are not mutually exclusive. I believe that it is an important challenge for computer science education to develop the approach (c). In parallel, I would place considerable stress on the approach (b). I am basing this on the conviction that even those who graduate at present from a computer science program and expect to take a programming job which does not require an immediate specific knowledge of mathematics, must be equipped against rapid obsolescence in a field which is extremely dynamic and which requires continuous learning and adaptation to new concepts and techniques. As theoretical knowledge grows in their area of activity, they must be prepared to understand it and to use it. Formal approaches will continue to develop in computer application areas; they are likely to penetrate more and more in systems design areas as concern with quality and *efficiency of designs* will continue to grow, and as methods of system analysis and evaluation will become increasingly available.

Wallace Feurzeig and his colleagues at Bolt Beranek and Newman have started to design courses where computer programming is being used as a key to the development of certain basic mathematical ideas and of skills for abstract reasoning.[6] This work has been oriented so far to pre-college instruction. It would be extremely interesting to develop courses of this type for introductory college instruction. In addition to their effectiveness for the development of 'mathematical maturity,' such courses would be exceptionally well suited for the introduction of computers to a large number of college students who, because of their 'fear of math,' hesitate to take introductory computing courses in their present form (which is commonly biased toward mathematical calculations).

INTRODUCTION TO COMPUTING AND TO GENERAL EDUCATION ABOUT COMPUTERS

Computer science departments have an important responsibility to provide broad *introductory computing courses* to the entire College population. In order to reach a very wide group of students, with a great possible variety of backgrounds and orientations, it is important to develop courses with no special mathematics requirements and with the main emphasis on the essentials of information processing and on hands-on problem solving experience with computers. The design of such courses is of considerable value for computer science as a new discipline, since it forces attention on fundamental concepts in the field and on imaginative ways of communicating them.

One of the most promising areas for the use of CAI in a college curriculum is in introductory courses in computer science and in mathematics. It would be highly desirable to stimulate the development of such computer-based courses in computer science departments; this would be a valuable activity for both faculty and students.

In our program at Rutgers we have had some experience with an introductory course where the emphasis was on uses of computers and on their *impact on society*. We found that students at the freshman level were much more interested in what computers are and how they can be used, rather than in general questions about the impact of computers on society and the broad significance of a growing computer culture on people. I think that it is profitable and important to discuss these issues in a senior seminar; at that level, students have more knowledge (of computers and of other things), and more maturity and motivation to study relationships between computers, man, and society.

SUGGESTED APPROACHES TO LONG RANGE EDUCATIONAL PLANNING IN COMPUTER SCIENCE

The question of *educational breadth* versus *specialization* is central to long range academic planning in computer science. As the computer field grows, there is an increasing demand for in-depth training of a variety of specialists. If the rate of generation of general principles and methods in the field will continue to lag behind the rate of production of specific computer systems and specific application packages, then there will be a tendency for computer science curriculi to be overwhelmed by a variety of fragments of detailed, specialized material—and for students of computer science to have negligible opportunity of being exposed to other disciplines, and to areas of intellectual activity where computers do not necessarily play major roles. On the other hand, it is essential for computer science not to grow in isolation, but to actively seek and strengthen intellectual bonds and working contacts with other disciplines. Accordingly, future contributors in the field must develop the ability to communicate and collaborate with people in other areas, and to be sensitive to ideas and concerns outside their discipline. This implies the need for balance between activities within the discipline and outside it. Also, the nature of studies in computer science should reflect the *dynamic character of the field*, and the need to develop in students a capacity for independent learning and growth.

The following set of approaches are suggested in response to the requirements for educational balance and for adaptability to fast changes in the field:

(a) The core of computer science courses that are needed for an undergraduate major should be limited to between a third and a half of the total courses needed for an undergraduate degree. These ratios will be much higher at the graduate level. In any event, students at all levels should be encouraged to take courses in other areas.

(b) An important part of academic planning is to develop (in some detail) options for *combined studies* involving computer science and other disciplines. Undergraduate areas of specialization should be created by combining the computer science core courses with courses in other appropriate disciplines (in particular, with Mathematics, Electrical Engineering, and Management Sciences/Business Administration). This implies a limited core curriculum offered by the computer science unit, and *close curriculum coordination* with the other academic units. Similar curriculum coordination should develop in graduate programs. One of the most effective ways of stimulating contact with other disciplines at the graduate level is to facilitate/induce projects and research which are directly related to advanced computer applications in these disciplines.

(c) An appropriate balance (and coordination) should be established between the lecture courses, the seminars, and the project-oriented courses that are components of a program. Lecture courses should concentrate on fundamentals, on structured presentations of parts of the field, and on general guidance to independent study of the growing body of 'raw data' concerning specific computer systems, languages, and applications. Seminars should focus on specific new developments in the field (exploratory current research, attempts to develop principles and theories) and on discussions of broad issues (e.g., computers and society). Project-oriented courses should provide opportunities for synthesis of information obtained from various sources, for collaboration (with people in the field, as well as with others), and for extensive practical work within the state of the art. An important project course would be an undergraduate, upper-level "*design studio*" where students would work on substantial software designs of operating systems, language processors, interfaces, etc.

(d) The interface between undergraduate and graduate programs in computer science should be flexible—with students moving relatively freely both ways, and courses moving steadily from the graduate to the undergraduate program. This movement of courses does not mean an increase in the number of undergraduate courses, but a restructuring, updating and general strengthening of the undergraduate program—whose overall size should remain relatively stable. One of the reasons for a flexible undergraduate-graduate interface is the fact that most students entering graduate computer science programs still come from different academic disciplines, and their knowledge of computer science varies widely. As undergraduate computer science becomes more widespread, the nature of Masters-level programs will change, and prerequisites for graduate admissions are likely to become more demanding in areas of computer systems and applications. In the meantime, criteria for graduate admissions should remain more flexible on questions of specific subject matter; the emphasis should continue to be on overall undergraduate academic performance (especially in mathematical sciences), personal characteristics such as initiative and inventiveness, and motivation to work in computer science. Because of the dynamic character of the computer field, I expect that we will have for some time a process of curricular changes where the Masters program of today will be essentially included in the Bachelors program of tomorrow. In general, a terminal Masters program in computer science will continue to provide the training needed for advanced professionals in the computer field. Increasingly, Bachelor programs in computer science will also train many of the professionals in the field.

(e) A major part of advanced graduate work in computer science should be devoted to exploratory projects and to *research*. A good research environment is essential. This means an appropriate intellectual climate, good communications, and easy access to computer resources. An important goal, both for faculty and for graduate students, would be to introduce order and cohesiveness in the field, to search for basic principles and general methods, and to design better academic programs in computer science. As part of these activities, new courses should be developed, with the emphasis on fundamentals and also on ways of using computers as integral parts of the preparation and administration of the courses. It would be desirable to have doctoral research develop in the context of such educational projects.

In general, we should recognize that systematization of fundamentals in the computer field, and design of appropriate academic programs is a key responsibility of computer science educators. These activities constitute a process of *continuous self-improvement* of computer science programs. Such a process is an essential part of any academic program; it is of special significance in computer science. Efforts toward academic planning and program improvement should receive support and recognition—the same as direct teaching and other types of research and development. Contributions in these areas will have important implications both for the effectiveness of computer science education, and also for the overall quality and efficiency of work in the computer field.

Computer science education—The need for interaction

by M. STUART LYNN

Rice University
Houston, Texas

I would suggest that one of the central problems of computer science today is understanding what it's for. As a consequence, given this hypothesis, from an educational standpoint it is not clear what students are expected to represent when they graduate with degrees in computer science. To the potential employer, the situation becomes even more confused when (in better times) he believes he is recruiting one thing and finds that he has hired something else.

This lack of understanding and eventual misrepresentation is not surprising in a young discipline. Perhaps one of the difficulties faced by computer science is what may be an over-eager attempt to formalize its content and boundaries, and in so doing discouraging the growth, change and vitality which have characterized the last decade. Perhaps, also, there is an increasing role being played by what may be (but should not be) an underlying conflict between the systematic and formalizing demands of science, and the engineering demands by which concepts are made useful to man; this conflict underlies much recent uncertainty in education in other disciplines, and it should not be surprising that it is becoming increasingly present where computing is concerned.

An example, in the Curriculum 68 Report,[1] of where potentially harmful boundaries exist lies in the treatment of numerical analysis. On the one hand, insufficient priority is given to this area, insofar as the proposed course contents are only suggestive of the field and give no insight as to the relationship of numerical analysis to the domain of computer science or to the domain of uses of numerical analysis in computer applications. On the other hand, excessive priority is given to numerical analysis when compared with other uses of mathematical analysis in computer applications: statistics, signal analysis, pattern recognition, control theory, mathematical programming, operations research and others. The proper role of each of these and related areas, and of their interrelationships, needs to be determined by examining the ways in which they are put to use in computer applications, with what priority, and then working backwards to define the appropriate educational structure. It is not clear that the existence of numerical analysis in the computer science curriculum should be an end in itself.

Perhaps too much of computer science has been concerned with formalization. To a degree, such concern is proper; there is clearly a need to develop and understand, systematically, fundamental principles and the interaction of these principles with each other; and a further need to educate in such a way as to encourage growth based upon a formalized body of knowledge. This should not, however, be the end in itself, as appears to be the trend.

This trend, if it exists, is not directly the fault of the Curriculum 68 Report.[1] It occurs partly perhaps because Curriculum 68 is too comprehensive, or too ambitious; and since in practice limited budgets may dictate that only selected parts are implemented, an unbalanced educational structure may be achieved.[2] Perhaps, too, Curriculum 68 is guilty of leaving to chance (see p. 155) what may be the most difficult question of all; how to effect the interaction with other disciplines which is so essential to the vital development of computer science. Amarel[3] has separated computer science activity into its *synthetic* and *analytic* components, the former having a "pragmatic flavor largely responsible for major advances in computers and for great diversity of areas in which computers are being applied", and the latter ". . . providing conceptual guidelines". He advocates a continuous interaction between these two components as essential to a vigorous rate of progress in the field. I would suggest that education in computer science, as structured in Curriculum 68, may be guilty of inhibiting that interaction, not encouraging it.

More positive steps need to be taken to encourage this interaction between the science of computing and the uses of computers. I am not suggesting interaction does not exist, only that it has received decreasing emphasis in recent years. Perhaps such encouragement cannot be achieved solely within the definition of computer science education itself, but requires closer examination of the administrative structures within which computer science operates.

It is likely that the industrial employer will become increasingly selective in its recruiting at all levels. This will be dictated not only by short-term considerations, such as the current state of the economy, but also because he will primarily be looking for graduates who have the breadth to be able to understand and deal with a wide spectrum of his problems, graduates who have the flexibility to modify their areas of interest as needs and priorities change. To the extent that education in computer science prepares students for their future, and for a considerable number this may mean industrial employment, Curriculum 68 needs careful reexamination, since it is not clear that it contributes substantially to this requirement.

A mathematician has been defined as one who, given a problem to solve, solves a whole class of problems of which the original is not a member. It can be argued that there has been a breakdown in the lengthy communication channels between mathematics and the environment in which it operates: whether this is good or bad for mathematics is a matter of point of view. It would, however, be bad for computer science. If students are to be prepared for what may be ahead, they must be given perspective, and a realistic insight into how computer science fits into and relates to the world around it. They should not, to reverse Oscar Wilde's definition of a cynic, be encouraged to know the value of everything and the price of nothing.

Operating systems principles and undergraduate computer science curricula*

by PETER J. DENNING

Princeton, University
Princeton, New Jersey

INTRODUCTION

In the years since 1969, the study of computer systems has assumed a role nearly equal in importance to "theory of computation" and "programming" in computer science curricula. In contrast, computer systems was regarded as recently as 1965 as being inferior in importance to these two more traditional areas of study. This is a significant change in attitude. The harbingers of the change appear in ACM's Curriculum 68,[1] and the speed of its development is demonstrated in the report of Task Force VIII of the COSINE (Computer Science in Electrical Engineering) committee of the Commission on Education of the National Academy of Engineering, entitled "An Undergraduate Course on Operating Systems Principles."[2]

The reasons for this change, the nature of computer-system studies, and the potential impact on future developments will be analyzed in this paper. I shall begin with a brief overview of computer science itself, in order to place the study of operating systems in perspective; I shall then discuss the general need in the computer industry for principles, many of which relate to computer and operating systems; finally, I shall discuss how an operating systems principles course may be organized.

ON COMPUTER SCIENCE

Computer science is the study of the design, analysis, implementation, and application of information-processing procedures.[1,3,4,5,6] In their writings, our educational leaders have consistently stressed the importance of *concepts* and *first principles* in studying the material of computer science. All proposals for computer science curricula—especially undergraduate curricula—have distinguished carefully between courses dealing with first principles and courses dealing with applications. Courses of the former type tend to be considered as "core curriculum" courses, but not courses of the latter type. (It is interesting to note that courses on operating systems were, until very recently, considered as being of the latter type. Even as it has been discovered that operating systems has a set of first principles independent of details depending on the technology, this subject matter has increasingly been considered as worthy core material.)

Courses offered in computer science curricula can be classified (roughly) into four categories: formal systems, programming systems, computer systems, and applications. The distribution of courses among the four areas will depend on the objectives of a given institution. (I believe they should be of equal importance.) *Formal systems* deals with the various mathematical systems for studying computation itself. Some of the topics taught in courses of this category include: the theory of automata, the theory of formal languages, the theory of computability, the theory of complexity of computations, and the theory of numerical computations and error propagation. *Programming systems* deals with the algorithms that perform computations on a practical level. The topics taught in courses of this category include both the concepts of programming languages and the problems of implementing algorithms. Programming language concepts encompass topics like programming language control structures (e.g., sequencing, iteration, conditional transfers, assignments), representing data, use of recursion, use of subroutines, parsing, compilation, and assembly techniques. The study of algorithms includes topics like language-independent algorithm specification, data representation, analysis of algorithms and data structures, proving *a priori* the correctness of algorithms, algorithms for searching and sorting, algorithms for

* Work reported herein was supported in part by NSF Grant GY-6586.

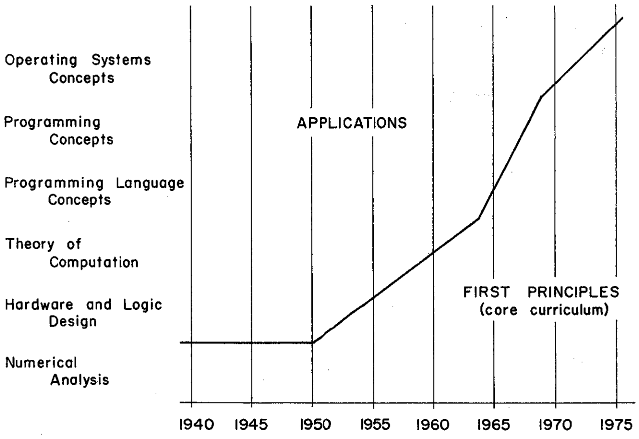

Figure 1—Evolution of first principles

dynamic storage allocation, and heuristic algorithms. *Computer systems* deals with the problems arising when algorithms are implemented on physical devices. Some of the topics taught in courses of this category include design of hardware and logic circuits, organization and design of standard equipment (e.g., processors, memories, peripherals), design of software systems, design of complex systems, control of parallelism and concurrency, control of processor and memory and other resources, analysis of system behavior, modeling the behavior of computing processes. As will be discussed shortly, these three categories deal with what I call the "first principles" of computer science. Topics which are dependent on the present-day technology, or are likely to be of little interest in more than, say, five years, are the subject of courses in the *applications* category; these include discussions of particular languages or particular machines or particular operating systems, systems programming techniques, specialized programming techniques, business data processing, and information retrieval.

The reader will note that Artificial Intelligence has not been mentioned in the above. In many respects, it cuts across all the categories. In many respects, it is an entirely different approach to computer science than the one I have outlined. Many computer science departments offer Artificial Intelligence courses on an elective basis and do not consider them as part of the core curriculum.

When I use the term "operating systems principles," I mean the software, control, modeling, and analysis aspects of the computer-systems part of computer science.

Figure 1 is a very idealized overview of the evolution of the first principles of computer science. Topics are listed along the vertical axis, time along the horizontal; those topics below the curve at a given time are considered as core-curriculum topics at that time. Conceptual approaches to numerical analysis have been with us since the beginning of electronic computing, since these were the primary purposes to which Burks, Eckert, Goldstine, Mauchly, von Neumann and their contemporaries envisioned their machines being applied. Although hardware and combinational logic design concepts using Boolean algebra to describe switching functions had been proposed by Shannon before 1945, this area received a strong impetus from the sequential machine work of Huffman, Mealy, and Moore during the early 1950's. The modern approach to the theory of computation, which emphasizes the relations among abstract machines and abstract languages and computational complexity did not evolve until the mid 1960's and the first texts in this area did not appear until the later 1960's.[7,8] Programming languages were introduced in the later 1950's (FORTRAN in 1956, ALGOL in 1958) but the concepts underlying them were not put down in systematic, textbook form until the mid-1960's.[9] Concepts about algorithms themselves, concepts more or less independent of programming languages, did not become systematized until the late 1960's.[10] And finally, the concepts of computer systems are only recently being put in text form at a graduate level[11] and nothing save a report exists describing them at an undergraduate level.[2] Thus it is evident that the development of a wide range of core material—the first principles of computer science—is quite recent in the era of electronic computing. Since much of the material of major interest to the industry itself—programming and system concepts—has just recently entered the "core area", it is no surprise that the industry has long regarded computer science as being somewhat irrelevant. I do think we can expect a change in this attitude.

On the basis of Figure 1, one can see why the majority of computer science departments were not established until after 1965. Academia has always been reluctant to establish degree programs in subject areas with no discernible broad base of first principles.

ON THE NEED FOR PRINCIPLES TO BE APPLIED IN THE COMPUTER INDUSTRY

As mentioned, Figure 1 illustrates why the industry has tended to hold computer science education in disregard, i.e., because the topics of interest to it (concepts of programming and design of systems) have not been treated on a sound conceptual basis in curricula. Looking at Figure 1 from a different perspective turns up another interesting observation: For some twenty years, the leaders of industry (management) have had to proceed without a set of first principles in the areas of major interest to them. This perhaps explains (in part) why so much difficulty has been experienced in getting "third generation" computer systems operational: There had been no systematic set of concepts according to which designers and programmers could be guided. This had left the industry in the rather uncomfortable situation of being accused in the public media of misusing, or condoning the misuse of, computers. Witness, for example, the great public outcry with respect to privacy and protection of information.

In many respects, then, the allegations that the computing industry is "adrift" and "unprincipled" have some basis in fact. The allegations that computer science education has not been of much help to the industry likewise have some basis in fact. We cannot, however, afford to wait ten or twenty years for the present crop of computer science students to move into the leadership positions of industry. Those presently in the leadership positions must not only be made aware of the existence of principles, but they must be made aware of the principles themselves.

In a recent statement,[12] ACM President Walter Carlson recognized this problem, saying "... There is too little systematic codification of fundamentals (i.e., first principles). There is almost no communication between the research people and system designers or operators. There is a widening sense of frustration among academics over misuse (or lack of use) of proven computer technology in practical operations." Figure 1 demonstrates that at least a basis exists for reversing the trend addressed by Carlson's first point.

To illustrate Carlson's third point, let me discuss three examples of common misconceptions attributable to a lack of understanding of the first principles of computer science: (1) The "software problem," i.e., the increasingly high costs of software development and lack of quality control over software packages, is a long way from being solved. (2) The "protection problem," i.e., that of guaranteeing the privacy, security, and integrity of information, is yet to be solved adequately. (3) The "computer utility" was a fad which, thankfully, is dead. It would astonish some managers to know the facts: Solutions to the software and protection problem exist now—and have existed, in computer utility research projects, since at least 1965! (I will elaborate below.) While much work remains to be done, I think it is safe to say that these solutions are adequate for present-day purposes. The solutions to these problems evolved in the design and use of such systems as the CTSS (Compatible Time Sharing System) and its successor MULTICS (Multiplexed Information and Computing Service) at MIT. Both these systems are regarded as first steps in the evolution of the computer utility, and rely on the computer-utility environment for their viability; thus, the attitude that the computer utility was a fad is in fact an attitude hostile to the solutions of the two problems. That so many who hold leadership positions in the computer industry have failed to recognize that CTSS and MULTICS implement solutions to these problems—even as undergraduate students exposed to an operating systems principles course seem to have no such difficulty—further reinforces my conviction that the first principles of computer science are not widely disseminated or appreciated.

The solution to the software problem in CTSS and MULTICS is based on the concepts of *programming modularity* and *sharing of information;* the requisite mechanism took the forms of the CTSS file system and the MULTICS virtual memory.* The solution to the protection problem in MULTICS is based on the concepts *protection rings* (or "domains") and on *controlled access to information.*** An important aspect of these two solutions is, neither can be accommodated on most systems presently on the market without major alterations in hardware and software architecture. It is the failure of management to understand the principles on which the solutions are based that has made them unable to recognize that CTSS and MULTICS solve these problems, and has led them to market systems in which technically sound solutions to the software and protection problems are not possible.

The foregoing criticisms of management are meant to be constructive in the sense that managers (and other elements of the computing profession as well) cannot play their roles to perfection without a thorough understanding of the principles of computer science. And, because it is only recently that the first principles have become systematized, it is difficult to expect managers to interpret new developments in the light of guiding principles.

ON THE IMPORTANCE OF COMPUTER SYSTEMS CONCEPTS

I have devoted a considerable amount of space to emphasizing the first principles of computer science and

* A description of the CTSS file system can be found in Wilkes' remarkably concise 96-page book,[13] a description of the MULTICS virtual memory can be found in the paper by Bensoussan, Clingen, and Daley.[14] Both these descriptions make it adequately clear that these systems, in their own contexts, have solved the software problem.

** The concepts of protection systems are discussed by Lampson,[15] and by Graham and Denning;[16] systems implications of protection are discussed by Wilkes[13] and by Schroeder and Saltzer.[17]

analyzing the effects in the computer industry of having no first principles. I have done this to emphasize how the first principles of computer systems have a natural place in computer science. Aside from these larger considerations, there are several reasons why a systematic presentation of the first principles of computer systems is important in and of itself.

First, the so-called case-study approach to teaching computer systems has been more or less unsuccessful wherever it has been tried: The student becomes so immersed in the particulars of the given system that he cannot distinguish important principle from irrelevant detail. In my limited experience, I have met only with success using the "modeling and analysis" approach. Thus, computer system principles are useful in the practical task of teaching others about computer systems.

Second, it is increasingly evident throughout the computer industry that we literally can no longer afford to develop ever larger, ever more complex systems without solid notions of how they are to be structured or how they are to behave. We can no longer afford to put together systems which are extremely wasteful of their own resources. We can no longer afford *not* to apply the concepts and principles in practice.

Third, for some inexplicable reason, the design of complex software and hardware systems has been considered traditionally as an "application" problem, a "technology-dependent" problem. In contrast, it is now being realized that designing complex systems—systems which operate as intended, whose correctness and behavior can be established *a priori*, whose performance can be monitored easily—is an intellectual task worthy of our best minds. (In other words, the computer-systems area has inherited one of the most important problem areas of computer science.) This realization has stimulated increasing amounts of research in computer system modeling and analysis, a principal result of which has been the emergence of a teachable, comprehendable body of operating systems principles. Much of "computer system theory" is concerned in one way or another both with managing complexity in software and hardware systems and with complex algorithms involving parallel processes, so that it is relevant to many practical problems now facing the industry.

Fourth, and perhaps of the most long-term significance, there is an ever widening appreciation of the view that our world has become a vast real-time system whose complexity is beyond the reach of the unaided human mind to understand. It is not difficult to identify the essential elements of information systems in business systems, economic systems, urban systems, and even social systems. Again and again we see decisions being taken to regulate such systems as these which, despite the best of intentions, often turn out to have the opposite of the intended effect. Jay Forrester has called this phenomenon the "counterintuitive behavior" of complex systems.[18] It is explained by the inability of the unaided mind fully to grasp why the long-term effect of a policy is often the opposite of its short-term effect, or fully to comprehend the complexities of, and interrelations among, the various parameters that influence a system. Forrester's simulation experiments of urban and business systems show that the intended result may normally be obtained only when *all* the controllable parameters of a system are governed by a single policy, not when each such parameter is controlled individually. This type of phenomenon is hardly new in the experience of computer system designers. As computer system "theorists" axiomatize information systems, developing systematic approaches both for managing complexity and for guaranteeing *a priori* that a system will operate as intended, the results of their efforts should be applicable to the solutions of problems in social, urban and other noncomputer information systems.

ON THE APPROACH

As I have stated, I call this the modeling-and-analysis approach to studying operating systems, to distinguish it from the case-study approach. The material can be organized and presented as a sequence of abstractions together with examples of their applications, each abstraction being a principle from which most implementations can be deduced. The concept-areas (in which teachable abstractions exist) are:

procedure implementation
concurrent processes
memory management
name management
resource allocation
protection

Experience shows that the most coherent treatment is obtained if the topics are organized according to this list of concept-areas.

The COSINE report[2] goes into some detail instructing instructors how to present these abstractions; a COMPUTING SURVEYS paper[19] explores them in some detail from a student's viewpoint, the Coffman-Denning text[11] treats the mathematical analysis related to them. Accordingly, I shall restrict myself here to outlining their content.

The background required of students undertaking this type of course should include: a working knowledge of programming language features; an elementary understanding of compilation and loading processes; processor organization and operation, including interrupts; memory organization and operation; and data structures such as stacks, queues, arrays, and hash tables. This background could be obtained from a course on programming languages (e.g., ACM's Course I-2)[1] and a course on computer organization (e.g., ACM's Course I-3).[1] A data structures course (e.g., ACM's Course I-1)[1] is helpful but not necessary.

The course itself is related to ACM's systems programming course (ACM Course I-4)[1] but differs in at least two significant ways. First, the ACM outline suggests a "descriptive," case-study approach whereas this course is organized along conceptual lines. Second, ACM's course emphasizes techniques of systems programming whereas this course emphasizes the principles of system organization and operation. This shift in emphasis is made possible by new developments, since the ACM report predates the appearance of much of the modeling and analysis material on which this course is based.

The instructor of this course will find it useful to introduce the subject by pointing out how, despite the wide range of operating systems types and capabilities, there is a set of characteristics common to these systems. These characteristics include: (1) *concurrency*, i.e., many activities proceeding simultaneously, (2) *sharing of resources* and the existence of a centralized resource allocation mechanism, (3) *sharing of information*, (4) *protection* for information, (5) *long-term storage* of information, (6) *multiplexing*, i.e., the technique of switching a resource (rapidly) among many requestors so that it is assigned to at most one at a time, (7) *remote conversational access*, (8) *nondeterminacy*, i.e., unpredictability of the order in which events will occur, and (9) *modularity* in design and operation of systems. It is important to point out that, for pedagogic reasons, the course material is presented (more compactly) according to the six concept-areas stated earlier, and not directly among the lines of these nine common characteristics.

The area of procedure implementation is important because the reason computer systems exist at all is to provide an efficient environment for executing programs. The notion of procedure is important because of its close relation to programming modularity. The basic concepts—pure procedure, procedure activations and activation records, parameters, local and nonlocal references—should be presented first. Then the main concept, "procedure in execution" (i.e., a procedure which has been called but has not yet returned) and its implementations, is presented. An abstract description of "procedure in execution" is a pair of pointers (i, r) where i is an instruction pointer and r an activation-record pointer (local environment pointer). Every implementation must solve three problems: (1) allocating and freeing storage on procedure call and return, (2) interpreting local references, i.e., those to objects in the activation record, and (3) interpreting nonlocal references, i.e., those to objects in other activation records. The implementations of "procedure in execution" in languages like FORTRAN, ALGOL, or PL/I can be deduced from these concepts by considering the restrictions imposed by these languages.

The area of concurrent (parallel) processes is important because one of the purposes of an operating system is controlling many, independently-timed activities. A "process" can be regarded as a "program in execution" and has an abstract description much like "procedure in execution." "Parallel Processes" is the notion that, at any given time, more than one program will be observed to be somewhere between its initiation and termination points. There are four process control problems of principal concern: (1) *determinacy*, i.e., the property that the result of a computation by cooperating processes on common memory cells is independent of their relative speeds, (2) *freedom from deadlock*, i.e., the property that allocation of resources is controlled so that at no time does there exist a set of processes, each holding some resources and requesting additional resources, such that no process's request can be satisfied from the available resources, (3) *mutual exclusion*, i.e., the property that, of a given set of processes, at most one is executing a given set of instructions at any time, and (4) *synchronization*, i.e., the property that a process, whose progress past a given point depends on receiving a signal from another, is stopped at that point until the signal arrives.

The area of memory management is important because every practical computer system incorporates a hierarchy of storage media characterized by various compromises among access time, capacity, and cost; a set of policies and mechanisms is required to increase system efficiency by arranging that the most frequently accessed information resides in fast access memory. The abstractions used here are those of "virtual memory": address space, memory space, and address map. The common implementations of virtual memory (e.g., paging, segmentation) can be deduced from these abstractions by considering factors such as efficiency of mapping operations and efficiency of storage utilization. Once the implementations have been studied, one can study the policies for managing them. Finally, it is straightforward to generalize the discussion to the implementations and policies of multiprogramming and of auxiliary memory problems. The foregoing development will lead to a computational storage system (i.e., that part of the memory system in which references are interpreted by the hardware) which presents to each programmer a large, linear address space.

The area of name management is important because a linear address space such as provided by the preceding development has inherent limitations from the standpoint of programmers and system users. It cannot handle growing or shrinking objects, provide different contexts in which processes may operate, allow for sharing or protecting objects, or implement a long-term storage system in which objects may reside independently of any context. In other words, linear address space cannot support modular programming to the extent required by today's system objectives. These limitations can be overcome by extending the memory system to allow programmers to define objects of variable size, assign names and (variable) contexts to these objects, allow shared access to objects, and specify dynamically which subset of a universe of objects should participate in a computation. That part of the memory system which implements these new objectives is called the "long-term storage system"; it may be distinct from the computational storage system or it may be one and the same. Computers implementing a virtual memory and a file system are examples of the former, computers implementing segmentation are examples of the latter. In either case, a global (system-wide) scheme for naming objects must be devised (in order to allow sharing), the (directory) tree hierarchy with "pathnames" being most common (in this case the long-term storage system provides a tree-structured space of objects in addition to the linear space or spaces provided by the computational storage system).

The area of resource allocation is important partly because the complexities of the interactions among all the processes in the system dictate that a central policy regulate resource usage to optimize performance, and partly because one effect of implementing the previous abstractions is to hide machine details from users, placing the burden of allocation decisions squarely on the system. One can distinguish long-term from short-term policies, the latter being of primary concern here. One can model a process (from a resource-allocation view) as cycling among the "demand-states" ready, running, blocked; correspondingly one finds a network of queues with feedback in the computer system. Processes are distributed among the queues according to demand-states, and change queues according to changes in demand-state. In terms of this, one can study specific queueing policies and overall network control policies; one can study the meaning of concepts like "system balance" and "thrashing"; and one can study what evaluation techniques are applicable. Models of program behavior and the use of statistical analysis are important to an understanding of resource allocation and are used throughout.

The area of protection is important in any system where there may reside procedure and data belonging to more than one individual. It must not be possible for one process to disrupt or corrupt service to others, and access to information (especially if confidential or proprietary) must be permitted only under appropriate authorization. The abstract model of a protection system includes: (1) a set of "domains" or "protection contexts," i.e., sets of constraints according to which a process may access objects, (2) a set of "objects," i.e., everything to which access must be protected or controlled (including the domains), and (3) a mechanism that both specifies and enforces access rules by processes to objects, the type of access depending on the domain with which the process is associated. The mechanism can be specified in the form of an "access matrix" (e.g., if A is the access matrix, $A[d, x]$ specifies the types of access a process associated with domain d has to object x). Most of the implementations of protection found in practice can be deduced from this model.

There remain certain issues that have not been treated definitively in the literature but which nonetheless are of central importance in computer system operation and design. These include: reliability, performance evaluation, design methodologies, and implementation strategies. They must, unfortunately, be relegated to a pedagogically inferior position at the end of the course. I should emphasize that this reflects the absence of teachable material, not the importance of the issues. As viable abstractions in these areas are evolved, they will be welcome additions to the course.

CONCLUSIONS

Operating systems principles can be regarded as the study of complex algorithms comprising parallel activities. This paper has reviewed and analyzed the importance of a significant change in attitude: The assumption of computer operating systems principles into the core of computer science. The analysis of this change was done in the light of the evolution of the "first principles" of computer science, of the need for these principles to be applied in the computer industry, and of the increasing need for systematic ways of dealing with complex, real-time information systems. An outline for a course on operating systems principles was described, the concepts being chosen for inclusion in the course on the basis both of demonstrated utility in practice and of their being straightforward generalizations of widely accepted viewpoints.

The first twenty-five years of the computer industry, years of remarkable achievement, have not been without their problems. Now that computer science education is maturing, we should be able to expect closer cooperation between universities and industry in solving these problems.

Theory of computing in computer science education

by PATRICK C. FISCHER

University of Waterloo
Waterloo, Ontario, Canada

INTRODUCTION

Theory of computing means the abstract study of the nature of computation and computing devices. By convention, the terminology is usually applied in a narrower sense to exclude numerical analysis. Thus, theory of computing includes the theory of finite automata, formal languages, computability, computational complexity, and some aspects of switching circuit theory and logical design. The deviation from the literal meaning of the term may have occurred because numerical analysis was already a well-established subject when the other components of this area were in their infancy. On the other hand, it may be a reflection of the emphasis on discrete mathematics by workers in theory of computing, in contrast to the preponderance of continuous methods in numerical analysis.

In *Curriculum 68*, theory of computing was represented by the following courses.*

B3	Discrete Structures
I6	Switching Theory
I7	Sequential Machines (Automata Theory)
A1	Formal Languages and Syntactic Analysis
A7	Theory of Computability

CURRICULUM TRENDS

Lower-level courses

The courses B3, I6 and I7 above have been remarkably stable, perhaps because of the relative distance of their content from the frontiers of research. Perhaps some minor changes might be considered: Course B3 could include some material on the first-order predicate calculus rather than just the propositional calculus, and Course I7 still lacks a textbook which is teachable and has a good balance between intuition and rigor. Nevertheless, the 1968 descriptions for these courses are still a very good approximation to current course offerings in a number of university and college departments of computer science.

Formal languages

Turning now to the advanced-level courses, one finds more updating needed. Developments in formal language theory have taken place in both the area of parsing methods and the study of abstract families of languages. An updated course A1 would probably do well to assimilate a greater proportion of the new material in the former area, thus shifting the overall orientation of the course more toward the practical side. In order to make room for this recent material, a few lectures worth of the most basic material, e.g., the notion of a formal grammar as a generator of a language and some of the equivalent interpretations in terms of abstract machines, could be introduced earlier as part of the course I-X proposed below.

Theory of computability

A considerable amount of activity has taken place within the area covered by Course A7, and much of the new material is already entering the computer science course offerings of several universities. The new material lies principally in three areas:

1. computational complexity,
2. analysis of algorithms,
3. program schemata.

We will discuss these areas briefly in order to define their scopes, but will not attempt a survey of the many interesting results which have been obtained.

* *Comm. ACM 11*, 3 (March, 1968), pp. 151–197.

Computational complexity

The first of these areas dates back to 1960 when M. Rabin suggested that one could study the classification of computable functions according to the degree of difficulty of computing them.^{B28} (Until then, the main efforts in computability theory were, in fact, directed toward understanding and classifying the uncomputable functions in order to gain insight into the foundations of mathematics.) Thus, this area is the oldest of the three and was the first to split off from the traditional computability theory (often called recursive function theory), which began in the 1930's.

In computational complexity studies, the most common overall approach is to consider programs which are "efficient" in the sense that they either do not exceed a bound on resources available at execution time or do not exceed a bound on those available at compile time. Thus, one either considers all programs which are sufficiently "fast" or sufficiently "small" and determines which functions can be computed by such programs. The classes of functions obtained relative to a given resource bound are called "complexity classes," and one principal aim of this area is to study their mathematical properties. Examples of resources related to execution of a program which have been studied are: number of steps on a Turing machine, memory cycles on a random-access machine, total memory space needed on a typical computer, number of bitwise operations on any computer. Examples of resources related to compilation of a program are: program size (in bits), depth of nesting of DO loops in a FORTRAN-like language, number of blocks in a program.

In addition, the features of all computations with resource bounds have been axiomatized by M. Blum, and a number of machine-independent results have been proved. Thus, mathematical rigor has reinforced the programmer's intuition in verifying that for any computable function there are arbitrarily bad (e.g., slow or huge) programs which do, in fact, compute the function. On the other hand, the "best" programs for a function cannot always be effectively found. Furthermore, some functions simply have no best programs.

The notion of "time-space trade off" is beginning to be the object of study via the consideration of complexity of finite functions (i.e., functions which need to be evaluated for only a finite number of inputs). Until recently, finite functions had been dismissed as trivial, since all finite functions can be computed quickly via programs with large tables built into them. By taking program size into account, a rich enough structure is available to permit the investigations of this subarea. Another related concept is that of randomness, since a sequence can be considered to be essentially random if a program to print it involves the equivalent of storing the entire sequence in the program. Conversely, a non-random sequence is one which can be predicted and therefore computed by a relatively short program.

The techniques used to prove theorems in computational complexity theory tend to be closely related to techniques used in automata theory and recursive function theory. Thus, proofs may involve diagonal constructions, counting arguments or analysis of rate-of-growth of resource needs. The results in this area have had relatively little direct practical application in the sense that the algorithms produced generally compute functions of only theoretical interest. However, a great deal of understanding about the nature of computation and the relationship between machine organization and computational efficiency is being obtained.

Analysis of algorithms

This area has evolved as a branch of computational complexity but has recently acquired its own distinctive character as well as a sizable group of converts. (It is still new enough to have no standard name; other names include "efficient algorithms," "optimal algorithms," and "concrete computational complexity.") Again, interest is in the degree of difficulty of computing functions. However, one now tends to focus on a given function (or a relatively small class of functions) and to attempt to determine the complexity of the best algorithms for computing it, if such exist and can be found. If optimal algorithms are not known, lower bounds on complexity measures are investigated and near-optimal algorithms sought. Examples of functions or procedures considered include: sorting, determination of the median of a sample, polynomial evaluation, matrix multiplication, checking graph isomorphism.

In analysis of algorithms, the measures of complexity are all oriented toward execution efficiency rather than program structure. Examples of measures commonly used are: the number of multiplications and/or divisions executed, number of all arithmetic operations, number of data references, number of data comparisons. The measures thus involve quantities which are basic in most programming systems. Furthermore, by considering only programs which compute a given function, rather than studying all programs possessing a certain degree of efficiency (regardless of what they compute efficiently), one limits himself to programs computing functions of practical interest, and his search for an algorithm which is both efficient and useful follows more closely that of the programmer than the theoretician. For these reasons, analysis of algorithms has a considerably more practical flavor than (other) computational complexity theory.

(Some of this aura of practicality is, of course illusory. Minimizing the number of multiplications may not minimize cost, when eliminating one multiplication adds 10 addition operations. Furthermore, simply counting the number of arithmetic operations tacitly assumes, for example, that addition of very long numbers costs no more than addition of short numbers. Such assumptions are just as idealistic as assuming that minimizing steps on a multitape Turing machine will minimize cost on a real computer, but they have more popular appeal since they do not limit one to hardware with a very low market penetration.)

The methods used in analysis of algorithms tend at times to be *ad hoc* in nature, especially when searching for new and better algorithms. The techniques for establishing lower bounds tend to come from combinatorics and numerical analysis, and a background in these areas appears to be more important for the algorithm analyst than a background in other theory of computing.

Program schemata

Research in program schemata is also on the upswing although the total activity in this area is probably not as high as in the other two. The main objects of study are programs in which the particular domain of data and the meanings of the primitive operations on that data are not specified. One example of a program schema would be a flow chart in which the contents of the various computation and decision boxes are left unspecified. One then studies the relationships between the "uninterpreted schema" (e.g., the flow chart) and the programs resulting when various functions are "plugged in" to the uninterpreted portions of the schema (e.g., the flow chart boxes).

In its purest form (most features of the model uninterpreted), the study of program schemata is closely related to work in language definition and program validation. As one builds more structure into the model, allowing some features to have fixed interpretations (e.g., a box which computes $\lambda x[2x]$) and others to be uninterpreted, this area tends to behave more like a branch of computability theory. However, instead of computable functions, one now considers computable functionals, i.e., mappings from functions to functions rather than from numbers to numbers. For example, a flow chart with two boxes in which the output of the first box becomes the argument for the second might be viewed as the functional producing composition of two functions when the functions are given as inputs. Thus, if the first box were to be interpreted as computing a function g and a second box as computing f, then the whole program would compute $\lambda x[f(g(x))]$.

The techniques for proving theorems about program schemata tend to be similar to those of classical computability theory, and the models used have their roots in common programming languages.

SUGGESTED CURRICULUM MODIFICATIONS

Basic computability theory

A few minor curriculum changes were suggested at the beginning of the previous section. However, for the course offerings in computability theory, the modifications should be more extensive. It is proposed that the more basic and machine-related material in the present Course A7 be combined with a short introduction to formal language theory and presented as a new intermediate level Course I-X. The choice of material to put into I-X was based on an assessment of relevance to computer science, estimated present development and future stability, and availability of textbook material. By teaching the material in Course I-X at the undergraduate (or first-year graduate) level, one will have more flexibility with respect to the advanced-level Course A1 on formal languages and in new courses in the previously described areas of computability theory. Fairly detailed suggestions are made below for Course I-X, following the format of *Curriculum 68*.

The remainder of the material in Course A7 included both recursive function theory and computational complexity material. However, much of the new material in analysis of algorithms and program schemata is more relevant to computer science than that in recursive function theory. To be sure, a student would still benefit from the more traditional approach since understanding the historical origins of a subject helps place the material in a proper perspective. Furthermore, the techniques traditionally used are applicable to problems in computational complexity theory and often in theory of program schemata. However, there is now much more than enough material in computational complexity, analysis of algorithms and program schemata to fill a term course, thus creating a pressure to displace the less relevant material. Therefore, the recursive function theory ought to leave the computer science curriculum recommendations. (It will still be taught in mathematics departments, of course.) It is encouraging that so much good work has been done on problems which have their roots in computer science in so short a period of time.

Course I-X: Introduction to computability theory and formal languages

Approach

This course is designed to introduce the advanced undergraduate or first-year graduate to formal systems of computation (including formal languages) and to give him a basic understanding of the nature of the unsolvability phenomena which pervade attempts to deduce correctness of programs, equivalence of algorithms, etc.

Prerequisite: Course B3 or a course in logic or algebra.

Content

1. The intuitive notion of effective computability as involving the existence of an algorithm. The Turing machine as one precise formal model for the notion. Equivalence of the computing power of the standard class of Turing machines with classes obtained by varying the control structure of the machine (e.g., Wang's single-address serial memory machines) and the data structure of the machine (e.g., more than one tape, multiheaded tapes, n-dimensional tapes, nonerasing tapes, random-access storage, etc.).

2. Universal Turing machines, i.e., the construction of an interpretive program to simulate other Turing machine programs.

3. The unsolvability of the halting problem; the effective production of counterexamples for alleged halting problem solvers. Some other unsolvable problems (blank tape halting problem, printing problem, etc.). Some solvable problems (computations on bounded space, etc.).

4. Numerical approaches to computability. Primitive recursive and recursive functions. Encodings of lists of integers into single integers (pairing functions) and encodings of computations (arithmetization).

5. Other models for digital computation: program machines, loop machines, machines with pushdown stores, stacks, counters, etc. Simulation of Turing machines by machines with only two counters.

6. Post combinatorial systems and formal grammars as a special case. Production notation for specifying grammars. Recursively enumerable, context-sensitive, context-free and finite-state grammars. Examples of languages of varying complexity, e.g., a^nb^n, $a^nb^nc^n$. Proof that $a^nb^nc^n$ is not context-free.

7. Grammars vs. abstract machines. Representations of the above in terms of Turing machines, linear bounded automata, one-pushdown machines, finite-state automata, respectively.

8. Unsolvability of the Post correspondence problem. Applications to unsolvability problems in formal languages.

References—Course I-X

The richest sources of material for this course are Minsky and Hopcroft-Ullman.[A8,A6] The former has good, readable coverage of 1-5, above, and part of 6. The latter has a more formal approach and covers 6-8 very well.

Advanced computability theory

No single solution is proposed for taking Course A7, now bereft of both basic computability theory and recursive function theory, and refurbishing it with more relevant material while retaining the computational complexity theory previously contained there. One reasonable approach would be to convert the course into a survey-in-depth of all three areas described above. The most generous answer (for devotees of computability theory) would be to convert A7 into a course on computational complexity theory and to establish new courses in both algorithm analysis and program schemata. This, in fact, is the current situation in the graduate program at Waterloo. However, graduate course offerings are obviously highly dependent upon the interests and quantity of faculty members. (Until the current academic year Waterloo offered courses equivalent to I-X and a single graduate term course in computability theory. The latter course took the survey-in-depth approach.)

Activity in analysis of algorithms has grown so rapidly that the accretion of new results and interesting algorithms has far exceeded progress in determining underlying principles. Thus, it will be difficult to keep a course in this area from becoming a collection of programming tricks. Nevertheless, courses in analysis of algorithms have already sprung up at a number of universities and are attracting respectable enrollment figures. Furthermore, the potential value of such a course for persons who think they like programming and dislike all theory outweighs the difficulties due to the roughness of the area and lack of adequate pedagogical material. Thus, it is quite likely that many schools will choose to offer a course in analysis of algorithms regardless of whether or not the computational complexity and program schemata theory are covered as well. If this turns out to be the case, the best solution for Course A7 would be to embrace both of these latter areas.

A list of topics and references in each of the three areas is given below. In view of the discussion just concluded, these are not to be interpreted as specific recommendations for courses but only as a sample of material in each of the areas.

ADVANCED TOPICS AND REFERENCES

As stated previously, the topics and references presented below are not all inclusive and are *not* suggestions for three separate courses.

Computational complexity

Topics

1. Complexity classes defined in terms of Turing machine time bounds, space bounds, and tape reversals.[B14,B18,B21,B34]

2. Models for real-time computation, Turing machines with many tapes vs. one or two tapes, Turing machines with many heads per tape vs. one head per tape.[B13,B24,B29,B32]

3. Random-access register machines, iterative arrays, n-counter machines and real-time countability, other computing devices.[B2,B9,B15,B16,B36]

4. Axiomatic approaches to machine structure, bounded action and bounded activity machines.[B10,B35]

5. Complexity classification by functional definition, primitive recursive functions, the Grzegorczyk classes, honest functions, loop program machines.[B8,B26,B30,B31]

6. Axioms for machine-dependent complexity theory, existence of arbitrarily bad programs and arbitrarily hard-to-compute functions, speed-up theorem.[B3]

7. Machine-independent complexity classes, uniform hierarchy (compression) theorem, honesty theorem, gap theorem, union theorem.[B20]

8. Complexity of finite functions, expressive power of programs, random sequences.[B4,B7,B25]

References—Computational complexity

In general, only material appearing in standard journals and written in English is given. Thus, a number of recent results and papers in foreign languages, principally Russian, containing relevant material have been omitted. Fairly comprehensive coverage of machine-independent complexity theory as well as some additional references are found in the paper by Hartmanis and Hopcroft.[B20] Two previous references are also relevant to this area.[A9,A12]

An extensive "Bibliography on computational complexity" was compiled by M. I. Irland and the author in October, 1970, but has not been published. A limited number of copies are available as Research Report CSRR 2028, Department of Computer Science, University of Waterloo.

Analysis of algorithms

Topics

1. Matrix multiplication in fewer than n^3 steps. Some lower bounds for matrix multiplication and inner product.[C3,C10,C13]

2. Polynomial evaluation. Optimality of Horner's rule in general case, preconditioning. Evaluation of a polynomial at more than one point.[C7]

3. Lower bounds for addition and multiplication of integers. Methods for multiplying in fewer than n^2 bitwise operations. Fast Fourier transforms and their application to multiplication.[C5,C8,C11,C12]

4. Sorting and searching methods. Treesort, radix sorts, polyphase sorts. Lower bounds on the number of comparisons necessary. Finding the ith largest in a set of elements. Evaluation of binary searching, AVL trees.[C2,C4,C6]

5. Graph algorithms. Planarity testing, connected components of a graph, transitive closure.

6. Miscellaneous algorithms. Matrix transposing in a paging environment, garbage collection, g.c.d. of polynomials, power of an expression, etc.[C1]

References—Analysis of algorithms

A considerable amount of current material is available only in the form of course notes or technical reports. Such items have been omitted here although courses being taught in analysis of algorithms are drawing up to half of their material from such sources. Thus, the references below serve more to give the flavor of this area than to constitute any approximation to a complete set of source material. Presumably much of the current material will appear in standard journals within a year.

Many informal working papers in this area can be found in recent Proceedings of the ACM Symposia on Theory of Computing (available from ACM) and Proceedings of the IEEE Symposia on Switching and Automata Theory (available from the IEEE or the IEEE Computer Group). Also, a "Bibliography on the analysis of algorithms" has been compiled by Professor E. M. Reingold, Department of Computer Science, University of Illinois at Urbana. As of the time of writing it has not been published.

Social science computing—1967-1972

by HUGH F. CLINE

Russell Sage Foundation
New York, New York

Social science computing continues to grow both in quantity and variety of problem applications. Increasing numbers of social scientists are using increasing amounts of computer time on an increasing array of machines. Social scientists have upgraded their competence in computing and produced a number of programming systems for use in their research and instructional activities. Each year more social science graduate students are trained in the use of computers, and more social science departments now have at least one faculty member who is competent in computing. Of course, all these developments did not occur in the past five years. Important preliminary steps were taken as early as fifteen years ago. But during the period 1967–1972, social science computing has made significant progress and is now recognized as a member of the computing community.

In addition to increasing the amount of use, the number of programming systems, and the level of competence, social scientists have also vastly improved the exchange of information among computer users. Five years ago most social scientists were completely ignorant of computing activities outside their own institution. Many graduate training centers had developed a set of standardized, second-generation computer programs for social science research, but very few of these were ever exported to other universities. This was partially due to the difficulties of producing machine-independent programs, but patriotic zeal for the "local product" also created a reluctance to learn about other programs or systems. Many of these locally developed programs became obsolete with the distribution of third-generation machines, and social scientists, who were unwilling to make the effort to redesign and reprogram, took their heads out of the sand and began to look elsewhere. The transition from the second to the third generation caused many problems for social scientists as well as others, but it did lift the self-imposed intellectual quarantine among social scientists and created the climate for effective exchange of information on computing activities.

The most notable development in this regard has been the establishment of the *SIGSOC Bulletin*, a quarterly publication of the Special Interest Group for Social and Behavioral Science Computing of the Association for Computing Machinery. Under the editorship of John Sonquist, University of California, Santa Barbara, the *SIGSOC Bulletin* has become a major source of communication among the 450 subscribers. In addition, the activities of such organizations as the Inter-University Consortium for Political Research at the University of Michigan, the Roper Public Opinion Research Center at Williams College, and the National Program Library/Central Program Inventory Service for the Social Sciences (NPL/CPIS) at the University of Wisconsin have all contributed to the production of the new social scientist computer cosmopolite.

Despite all these promising developments over the past five years, it is not correct to state that social science computing is problem free. There are a number of very serious problem areas which require concerted attention in the next five years. In order to highlight these questions, I will present some findings from a study of computer uses in the social sciences which I have undertaken for Russell Sage Foundation. The study includes a description of current social science computing activities and an examination of the influence of computing on substantive social science problems.

Before turning to the results of the study itself, it should be useful to describe briefly in what ways social scientists are using computers. I have found it convenient to distinguish among four general types of computing applications: data processing and statistical analysis; simulation; computer-controlled experimentation; and large data file management. The most common application, data processing and statistical analysis, has often been referred to as the "bread and butter" of social science computing; for it typically accounts for the bulk of social science department computing budgets. Although most such applications involve numerical data, the analysis of textual materials is increasing. Typically, the investigator first puts the raw data into machine-readable form, i.e., on punched cards or magnetic tape; and then the computer is used for error detection, correction, and data reduction. Subsequently, canned programs, i.e., previously written general-purpose programs, are used to perform the more standard techniques of statistical analyses. For the most part, these applications of computers involve procedures which previously were accomplished on punched-card equipment and desk calculators. Although other types of computer applications in social science research will undoubtedly increase in the near future, data processing and statistical analyses will continue to be the modal type of computer usage for some time to come.

Simulation, the second type of computer use, is considered by many to be the most promising. Social science simulation is the construction and manipulation of an abstract operating model of a social system or process. Physical operating models such as wind tunnels and flotation tanks are well-known in scientific research, but all social science models of systems are abstractions stated in mathematical equations. The investigator designs his model by breaking a system down into subunits and describing both the subunits and the relationships between subunits in quantitative terms in a simulation programming language. The computer is then used to provide artificial blocks of time in which the system operates and subunits interact and are modified according to the model. The investigator usually compares initial and final values describing system subunits. During the course of the research, different initial values and relationships between subunits may be tried in the model to produce a better fit to data observed from the real world. Simulations have been done on many different types of problems with varying degrees of success including such things as racial integration in suburban housing tracts, old age pension programs, federal aid to state education programs, and international relations problems. Of course, the value of a simulation depends upon the investigator's ability to break a system into its subunits and realistically state initial values and relationships between subsystems.

The third type of computer use in social science research, computer-controlled experimentation, is for the most part still limited to the discipline of psychology. Real-time computers are being used by a small number of innovators to control, monitor, and change laboratory conditions. The feeding schedules for animals, the timing and sequencing of presentation of stimuli to subjects, and the monitoring and recording of communications between subjects in experimental settings are all now being done with the assistance of computers. In contrast to the other types of social science computer use, computer-controlled experimentation usually requires a machine that is used exclusively for this purpose. These computers are usually smaller and slower, but they require special-purpose input/output devices which are often unique and expensive. Using computers to monitor, modify, and in some cases to supervise research certainly will open new areas for social science research.

The use of computers for large data file management, the fourth type of application, is a new phenomenon in social science research. Many investigators are now using very large data files, such as the one-in-a-thousand sample of the census which contains over 15 million data items. It is virtually impossible to use these files for research without the aid of computers, and the problems of manipulating large data sets in an efficient manner are gaining increasing attention. Alternate methods of formatting and storing data files to match the input requirements of the standard analysis routines and new programs for large data files are being developed. In addition, social scientists are continuing to merge copies of sample surveys for secondary analyses. The problems of storing, searching, and retrieving subsets of data from these archives are now being handled on computers.

The survey of social science computing activities was limited to academic settings. Although it is quite true that important innovations in social science computing have occurred in independent research institutes, such as The Brookings Institution, the National Bureau of Economic Research, and The RAND Corporation, as well as in the research departments of large business corporations, it was decided to restrict the study to universities; because obtaining a comprehensive list of non-academic research institutes would have been a major research undertaking itself. The survey data were collected at the midpoint of the half decade, May 1969, with a four-page questionnaire mailed to the chairmen of the 517 departments which have granted at least one Ph.D. degree since 1960 in the following disciplines: anthropology, economics, agricultural economics, political science, psychology, educational psychology, and sociology. After two follow-up mailings and telephone calls, 421 completed questionnaires were received, giving an overall response rate of 81.4 percent. Table I presents the response rates for the disciplines, which range from 75.0 percent to 92.6 percent.

The 517 departments are located on 134 campuses. At least one department responded from 130 campuses; and this means that we have some data on social science

TABLE I—Disciplines and Response Rates

Disciplines	Questionnaires Mailed	Questionnaires Returned	Response Rate
Anthropology	47	36	76.6
Economics	99	78	78.8
Agricultural Economics	27	25	92.6
Political Science	95	80	84.2
Psychology	121	97	80.2
Educational Psychology	36	27	75.0
Sociology	92	78	84.8
	517	421	81.4

computing from 97.0 percent of the universities included in this study. Although the questionnaires were mailed to the chairmen, the cover letter encouraged them to seek the advice and assistance of their colleagues in answering the questions. The data should therefore be interpreted as organizational, i.e., department responses. This is appropriate, for the items were designed to collect information on computing activities and not the opinions or attitudes of any particular individual. The questionnaire elicited information on hardware, software, instructional programs, and levels of computing competence.

Turning first to hardware, Table II shows the proportions of departments reporting access to punched-card equipment and desk calculators. The first column headed "Department" reports the proportion of departments that had such equipment available for their exclusive use, and the second column gives the proportion of departments which had access to the machines in the central university computer center.

This data indicate that keypunches, sorters, reproducers, and card printers were more widely available in university computing centers and that desk calculators and programmable calculators (Wang, Monroe, Olivetti, and Marchang) were more frequently available for exclusive departmental use. Despite the fact that departments had somewhat limited punched-card facilities, most did have access through their computer centers.

TABLE II—EAM Equipment

Machines	Departments	Computer Center
Keypunches	41.6	85.0
Counter/Sorters	24.7	82.7
Reproducers	9.7	75.1
Card Printers	3.6	67.5
Desk Calculators	87.4	35.8
Programmable Calculators	15.9	1.2

A total of 358 computers were reported available for social science research and instruction. This is an average of 2.8 computers per campus. (These figures on number of computers are combined from department responses for each campus, and machines reported by several departments are counted only once.) Table III presents the distribution of computers by manufacturers reported in the study.

IBM computers accounted for 66.5 percent of the total. Approximately 50 percent of the IBM machines were third-generation, i.e., System 360; and about half of the third-generation machines were Models 50 or larger. Digital Equipment Corporation computers were the second largest type available to social scientists, but this manufacturer and all others were far below IBM in social science computing. Of all reported computers, 16.4 percent were DEC machines; and about 60 percent of these were PDP 8's. The Control Data Corporation was the third largest manufacturer with 7.8 percent of all the computers reported, and almost half of the CDC machines were 6000 series computers. Finally, UNIVAC was the fourth largest manufacturer with 3.1 percent, and about half of these machines were UNIVAC 1108's. All other manufacturers were under 2 percent, and these included Honeywell, Burroughs, General Electric, Xerox Data Systems, RCA, and Philco.

TABLE III—Computers by Manufacturers

Manufacturer	Number of Computers	Percent
International Business Machines	238	66.5
Digital Equipment Corporation	59	16.4
Control Data Corporation	28	7.8
UNIVAC	11	3.1
Honeywell	6	1.7
Burroughs	5	1.4
General Electric	4	1.1
Xerox Data Systems	4	1.1
RCA	2	0.6
Philco	1	0.3
Total	358	100.0

Dominance of IBM in social science computing is of course no surprise. However, the fact that two-thirds of the computers available to academic social scientists were manufactured by one supplier should not be interpreted as widespread uniformity in social science computing systems. Over 22 different types of IBM

TABLE IV—IBM Computers

360/75	11	4.6
360/91	3	1.3
Total	238	100.0

machines were reported. Table IV shows the distribution of IBM machines by model.

These machines vary widely in cost, instruction sets speed of the central processing units, size of memories and available input/output devices. This variation shows very clearly why it has been extremely difficult to produce programs which can be widely used on many different types of machines.

The average number of computers per campus was 2.8. This figure is somewhat misleading, for these computers were not evenly distributed across all universities or departments. It is often the case that members of one department have access to a computer; but due to funding or administrative restrictions, members of other departments on the same campus may not have access. Table V lists the distribution of the number of computers reported available to the 421 departments.

Notice this distribution is quite uneven. The modal category of one computer includes 35.9 percent of the departments. A very small proportion, 3.8 percent, of the departments were comparatively quite wealthy, having access to six or more computers; and 28 departments, or 6.6 percent, reported they still did not have access to any computer.

In addition to the type and number of computers available, the location and administrative auspices of the machines also influence their utility for research and instruction. Almost 70 percent of the computers were located in a central university computing center. The remaining 30 percent were widely distributed among other university computer centers, research institutes, departments, commercial service bureaus, and combined social science department computing centers. Despite the many recent debates over the advisability of centralization or decentralization of university computing facilities, the data show that the pattern of centralization had not changed very much; and only in a very small proportion of cases, 5.3 percent, was there a computing facility for the exclusive use of the social scientists.

University-based scholars in many disciplines have recently expressed enthusiasm for the possible applications of time-sharing systems in their research and instruction. Some type of time-sharing system was reported at 33, or 25.4 percent, of the universities included in this study. Most of these were interactive compilers, which can be used for finding errors in programs but not for data processing and analysis. Only ten universities had fully operational time-sharing systems, which can execute programs; and most of these had severe restrictions on the size of the data files they can handle. In addition, 29 universities reported using some type of commercial time-sharing service. It is not surprising that time-sharing has not been more widely used in the social sciences, for very few of the existing systems are capable of efficiently handling large input or output files. Since many social scientists typically have medium- to large-sized data files, they find that most existing time-sharing systems simply cannot be used.

Regardless of whether a computer is used in a time-sharing or conventional manner, the hardware, including the central processing unit, the memory, and the input/output devices must be provided with the software or programs to execute the symbol manipulations the scientist requires for his problem. Although software usually refers to operating systems, compilers, assemblers, and applications programs, this study of com-

TABLE V—Number of Computers Available to Departments

Number	Percent
None	6.6
1	35.9
2	29.0
3	13.8
4	6.2
5	4.7
6+	3.8
	100.0

puter uses in the social sciences has been limited to higher-level languages and packages of programs. Table VI presents the higher-level languages most commonly reported by the departments.

FORTRAN IV comes close to being a universal language, but the fact that 98 percent of the departments with access to computers reported the availability of FORTRAN IV does not automatically produce uniformity and standardization, for there are many variations of the language. Limited instruction sets and maximum permissible program sizes are two of the major sources of variability. The languages most commonly available are those which the major manufacturers support with continuous error correction, documentation, and further development. The fact that FORTRAN and COBOL are so widely available to social scientists is for the most part a result of IBM's policy to support these two languages on most of their computer systems.

TABLE VI—Languages Available

Language	Percent
FORTRAN IV	98
COBOL	77
ALGOL	62
PL/I	51
FORTRAN II	49
WATFOR	44
SNOBOL	38
BASIC	28
OTHER	55

Over ninety different languages were reported in this study. Some of these have been developed locally at the universities, and others have been produced by small, commercial software companies. One can quite legitimately question the extent to which these languages are thoroughly debugged and documented, for very few universities or commercial software houses have the manpower and expertise necessary for the adequate support of languages.

The distribution of higher-level languages available to social scientists is more easily understood by examining the number of languages reported by each department, as shown in Table VII.

TABLE VII—Number of Languages

Number	Percent
1-2	10.5
3-4	23.6
5-6	29.9
7-8	18.9
9+	17.1
	100.0

The average number of languages reported by each department was 5.9. The typical pattern for a department was to have two or three languages maintained by the hardware supplier and several additional, special purpose languages maintained locally. It should be pointed out that these data refer to the number of languages reported *available* to social scientists. In a mail questionnaire, it was not possible to assess the extent to which these languages were used. However, on the basis of personal visits to over a dozen major social science graduate training centers, it is my clear impression that most social scientists use a subset of the available languages. Many social scientists adopt one and only one computer language, and they sing praises to this language with the same intense emotional commitment as the immigrant who extols the virtues of his new country.

Departments were also asked to report on the data processing and statistical analysis packages of programs available to the members of their departments. The distribution of the most commonly reported packages is listed in Table VIII.

The BMD Package, developed under the direction of Professor W. J. Dixon at the Health Sciences Computing Facility, University of California, Los Angeles, comes closest to being the universal social science statistical package.[1] Of the departments using computers, 76 percent report having access to the BMD Package. The various computer programs included in this package have proved useful in the past in many types of biomedical research projects at UCLA. Written in FORTRAN IV, and therefore relatively easy to export to other computer systems, the programs in this package include routines for data description and tabulation, multivariate analyses, regression analyses, time-series analyses, variance analyses, and a series of special programs for data transformation and scaling. Although

TABLE VIII—Packages Available

Package	Percent

SSP	52
SPSS	16
OSIRIS	16
Data-Text	13
Other	87

created in response to the needs of biomedical researchers, this library of programs has been more widely distributed to social scientists than any other package.

The second most widely available statistical package was the Scientific Subroutine Package (SSP).[2] It is a collection of over twenty different statistical routines maintained and distributed by IBM. Because it is written in FORTRAN IV, it is also easily exported. However, the Scientific Subroutine Package is not easily used by most social scientists. As the name implies, this package is a collection of subroutines; and the user must write a FORTRAN main or calling program for the subroutine he requires. Very few social scientists are able to write a FORTRAN program with appropriate linkages to subroutines. Despite the fact that our data show that 52 percent of the reporting departments had access to the Scientific Subroutine Package, I seriously doubt the extent to which this package is heavily used by social scientists.

The remaining three packages most commonly reported by our respondents were the Statistical Package for the Social Sciences (SPSS) developed by Norman H. Nie of the National Opinion Research Center and University of Chicago,[3] the statistical package OSIRIS developed at the Institute for Social Research at the University of Michigan, under the direction of Ralph Bisco,* and Data-Text, developed by Arthur Couch and David Armor at Harvard University. SPSS and OSIRIS are both written in FORTRAN IV and are relatively easy to export. The Data-Text Package was originally written in FAP, the assembly language of the IBM 7094, and operates only on the few remaining 7094 installations. Under Armor's direction, Data-Text was being reprogrammed in FORTRAN IV, and an expanded version was distributed in 1971.[5] Both Data-Text and SPSS implemented a user-oriented language in which job parameters are specified in a format similar to the natural language social scientists use in discussing data processing and statistical analyses. For example, one requests cross-tabulations by preparing a control card which states: COMPUTE CROSSTABS SEX BY OCCUPATION. OSIRIS has recently substituted for numerical job parameters a similar user-oriented language.

Eighty-seven percent of the departments reported packages other than the five mentioned above, and there were over 170 different packages. One can, of course, question the extent to which these are completely different packages. In many cases, universities have made minor modifications in existing packages and merely given them a local name. Nevertheless, it has become a common practice for many universities, and in some cases even for departments, to develop a set of programs which have a common input/output format. These packages are locally used and maintained. Typically the documentation is exceedingly poor. Efforts to support these programs are not well funded; and most of the programs have never been thoroughly debugged.

Despite the fact that over 170 packages were reported by the departments, the number of packages available to each department was quite small. Table IX lists the distribution of the number of packages.

The average was 3.0 packages per department, and the distribution was highly skewed in the direction of one, two, and three packages per department. Given the problems of importing, documenting, and maintaining these packages, it is not surprising that the number is quite small. Furthermore, since most of these packages include similar routines, there is very little to be gained by increasing the number of packages available.

Both the excess of locally developed packages and the small number of packages available to any given department point to some of the major problems in social science computing. Firstly, many of the packages leave a great deal to be desired in terms of accurate and efficient algorithms. Furthermore, a social scientists who develops expertise in using only local packages typically finds himself completely ignorant when he moves to another university.

Finally, and most importantly, the distribution of existing statistical packages has significant implications for substantive social science research problems. Despite the fact that most departments have access to more than one package, it is my clear impression that social scientists still prefer to use the locally developed package. Drawing from either a sense of comfort in using the package developed by someone they personally know or

TABLE IX—Number of Packages

Number	Percent
1	24.3
2	25.4
3	21.7
4	9.5
5	9.0
6	4.6
7+	5.5
	100.0

* Documentation for OSIRIS is maintained in machine-readable form for frequent updating and is available upon request from the Institute for Social Research, The University of Michigan.

from some sense of pride in "our thing," most social scientists avoid using the more widely distributed packages. This preference for the local package becomes a more serious problem when it is limited in the number of data analysis routines offered to the user. For example, many of the local packages only have routines for cross-tabulations. This means that both students and faculty are indirectly encouraged to conceive all their substantive problems in a cross-tabulation research design.

Despite the excessive duplication of insufficient efforts in producing packages, there are still many universities that are attempting to design new packages for data processing and statistical analysis. Clearly there is a need for some duplication and competition; but what seems more critical now is leadership in establishing some cooperation, uniformity, and standards in the development of these packages.

Of course, the availability of adequate hardware and software is not sufficient for solving the problems of effectively using computers in social science research and instruction. Most social scientists have become painfully aware of the fact that it is necessary to develop some competence in computing to use these machines in pursuing substantive research problems. In order to assess the extent to which social scientists are gaining some competence in computing, the respondents were asked to indicate separately for undergraduates, graduates, and faculty members the proportion who: (1) can write programs in higher-level languages; (2) can use statistical package programs; and (3) use computers in research problems. Table X lists the average proportions reported.

Among the undergraduates, only 15.2 percent could write programs in higher-level languages; 18.8 percent could use statistical packages; and 16.4 percent used computers in research. For graduate students the figures are slightly higher. Roughly one-quarter, 23.6 percent, knew a higher-level language; almost one-half, 41.3 percent, could use statistical packages; and slightly over one-half, 50.6 percent, used computers in their research. On the other hand, faculty members really possessed no more competence in writing programs than undergraduates, 16.9 percent. Fewer faculty, 32.7 percent, than graduate students were able to use statistical packages. Finally, just under half, 48.7 percent, of the faculty members were reported as using computers in their research.

TABLE X—Levels of Competence

Proportion of Individuals Who	Percent		
	Undergraduate	Graduate	Faculty
Can Write in High Level Languages	15.2	23.6	16.9
Can Use Statistical Packages	18.8	41.3	32.7
Use Computers in Research	16.4	50.6	48.7

Without getting into the old argument as to whether or not the social science disciplines should be using quantitative analyses in their research, it is still quite interesting that in these disciplines, where at the most basic level research involves symbol manipulation, only one-half of the faculty members are currently using computers in their research activities. In addition, the graduate students are more competent than the faculty. At the minimum, one can conclude from these data that social scientists have been slow in building computer competence in their disciplines.

It is often the case that effective use of computers in social science research depends upon the availability of at least one individual who can serve as a liaison between his colleagues' substantive problems and the computer. This individual can frequently be of great assistance in preparing data and programs for computer processing. In an effort to assess the extent to which such individuals were available, the chairmen were asked a series of short questions concerning the computing skills of the most competent member of the department.

Only 26.1 percent of the departments report that they have someone who is able to instruct himself on the use of statistical packages; only 21.4 percent of the departments report the availability of anyone who is able to write computer programs; and only 18.1 percent of the departments report one member who can interpret error messages and memory dumps to determine the reasons for unsuccessful runs. This very low report of computer competent colleagues accounts for some of the difficulty which many social scientists experience in trying to use the computer in their research.

Given this low level of computer competence, one could expect some evidence of concerted attempts to introduce new instructional programs to produce scholars with some training in computing skills. The chairmen of the departments were asked to indicate separately for their undergraduates, graduate students, and faculty members, the options available for obtaining instruction in computing. The proportion of departments which reported the different ways in which members can learn about computing is listed in Table XI.

The data show clearly that most of the computer instruction given to social scientists at all levels comes

TABLE XI—Computer Instruction

Instruction Available	Percent		
	Undergraduate	Graduate	Faculty
Department Computer Course	7.9	12.6	7.6
Department Research Course	4.6	19.8	4.9
Other Department Computer Course	47.0	27.5	16.6
Non-credit Computer Center Course	31.8	31.4	50.3
Self-instruction	2.6	2.9	9.7

either from other departments or the university computer centers. This is reminiscent of the debate popular some years ago on the question of who should teach social scientists in statistics courses. The consensus on that issue now seems to be that the instructors should be individuals who know social science research. It seems unlikely that the staff of other departments or computer centers will have this knowledge. Yet, very few departments taught undergraduates any computing in courses taught within the department. A slightly higher but still disappointingly low proportion of the departments reported that their graduate students learned in either a departmental computing course or a departmental research course, 12.6 percent and 19.8 percent respectively. Both the non-credit computer center courses and courses taught in other departments were the most common options available to all social science students. The most common option for faculty members, on the other hand, was only the short non-credit course at the computer center. These courses are typically crash courses which either teach one higher-level language, most commonly FORTRAN, or the details of job submission and operating system control languages for that particular computing facility.

Given the problems noted above concerning the availability of computer hardware and software for the social sciences, it also appears that there is a critical shortage of individuals who understand both substantive social science problems and computing. A very low proportion of departments reported that undergraduates, graduates, or faculty members are learning about computing either within their own departments or elsewhere, and apparently very little is being done to solve the manpower problem. Graduate students are the most competent group of social scientists in computing, and even they are severely limited to the use of packages in pursuing substantive problems.

Although much progress has been made in social science computing in the past five years, the data from this study indicate that there are a number of major problems which severely restrict more effective computer-assisted research. These include providing more equal access to adequate hardware, decreasing the number of packages under development, and providing better support for the documentation and debugging of the more widely used packages. In conclusion I should like to point to two additional problems, whose successful solution I consider as critical.

Perhaps the most immediately pressing problem is the low level of competence. Social scientists must insure that adequate instructional programs are offered in all graduate departments, and students should learn more than simply how to use the locally developed software. I would argue that it is irresponsible to produce professional social scientists today who will have an active career in social science research for the next forty years without at least some introduction to the basic design and logic of computers.

A second very pressing problem which is still not satisfactorily resolved is that of compatibility. It is still true that most computer programs and data files cannot easily be exchanged among social scientists using different computers. Very few of the early pioneers in social science computing appreciated the need for preparing programs and data files for export to colleagues using different computers. Today, the problem of exportability has reached staggering proportions. Individuals find that many programs and data prepared for initial processing on one computer simply cannot be run at another computer center which uses exactly the same model and manufacturer. Local variations in peripheral devices and programming procedures make it extremely difficult and sometimes impossible to move from one computer to another.

Although one may place the blame upon the designers of the early computing systems for not having the foresight to think in terms of standardized data files and programming conventions, or one may cite the commercial manufacturers for not establishing industry-wide standards, the problem still remains; and social scientists cannot now realistically look to others for solutions. They must among themselves agree upon common standards for program design and data file preparation which will minimize the problem of exportability. Granting agencies, both public and private, which support the development of social science computing can be of great assistance in insisting upon adherence to standards; but the original impetus for this movement must come from the social science community.

Future developments in social science computing

by GEORGE SADOWSKY

The Urban Institute
Washington, D.C.

INTRODUCTION

The set of computer related activities characterized by the term "social science computing" is both diverse and extensive. During the past 15 years, such activities have grown substantially both in scope and in volume and have become increasingly important both for basic research in the social and behavioral sciences and for public policy formation and evaluation.

In this paper I will present an overview of the evolution and present status of social science computing and examine several factors that are likely to have a significant effect upon its development during the next 10 years. Predicting the future is generally hazardous and is complicated in this instance by being dependent upon the development of future computing technology. During the relatively short history of automatic digital computing there have been many predictions—both optimistic and pessimistic—that have returned in short order to plague those who made them. Despite the high risk of error, attempts to predict the future have some value in planning for that future state. Attempts to forecast the future also can often provide a more accurate assessment of the present, a process from which social science computing might benefit considerably.

The term "social science computing" is somewhat misleading in that it implies a homogeneity of computing activities that does not now exist. Activities as diverse as process control in computer controlled experimentation laboratories, dynamic macroeconomic simulation, large survey data collection and analysis, simulation of alternative social policies, dissemination of census results, multivariate statistical techniques, and natural language text processing for content analysis and concordance production are all included. Social science computing activities may be observed as a part of research activity in universities and research institutions, in commercial organizations that produce social science computing products and in those that use them, and in government administrative processes and policy evaluation functions. Statements regarding social science computing generally are true of a subset of these activities only. To the extent that there is a commonality among activities in the field, it is that they are a collection of processes centered upon observed data relating to behavioral phenomena.

Many aspects of social science computing enjoy an independent tradition. The methodologies of commercial data processing, information retrieval, source data capture, statistical inference and digital system simulation all apply to social science computing activity, yet professional and methodological development in these fields generally occurs independently of it. The dependence of social science computing upon a variety of existing methodological traditions reduces its cohesiveness as a discipline and complicates the process of training social scientists for research careers in which a knowledge of quantitative methodologies is becoming increasingly important.

HISTORICAL OVERVIEW

Social science automatic computing activity dates from the introduction of automatic data processing equipment in the 1880s by Herman Hollerith. Hollerith's machinery was initially used in 1887 by the City of Baltimore to tabulate mortality statistics,[17] and was later used by other local governments for similar functions. However, its use in sorting and tabulating the results of the 1890 U. S. Decennial Census of Population marks the beginning of large scale social science computing. Hollerith's initial innovations led to the development of a family of "unit record" electromechanical accounting machinery for general data processing applications. A primary use of these machines was to collect, process, and disseminate statistics for public purposes. The introduction of Hollerith's automatic machinery in the census process was followed by a period of increasing use of automatic accounting machinery by government for processing social and economic statistics. Shortly after the production of electronic digital computers, the first computer produced commercially—a Remington Rand Univac I—was installed at the U. S. Bureau of the Census in 1951 for processing data collected during the 1950 U. S. Decennial Census of Population.[19]

The automation of statistical computing activities began well before the invention of the automatic digital computer. Many statisticians made intensive use of the commercial unit record equipment available prior to the digital computer. Despite the fact that calculations performed using this equipment were slow, required extensive wiring of plug boards, and required repetitive use of different specialized machines, the resulting procedures were generally more accurate and faster than the corresponding calculations performed by hand. Thus statisticians quickly took advantage of the opportunities offered by automatic digital computation.

During the initial years of automatic digital computer use, social science computing tasks were similar to many other computing tasks. Computers were programmed almost exclusively in primitive assembly languages, the programmer often operated the computing equipment himself, and computing activity was localized around the few computer installations then available. Survey research centers and individual social scientists analyzing empirical data continued to rely heavily upon unit record processing equipment, especially specialized equipment such as the IBM 101 Counter-Sorter. The development of higher level programming languages such as Fortran and Comtran allowed programmers to write programs that were more easily understandable by non-programmers and more easily exportable to colleagues using different computing equipment. During this period the initial "general purpose" statistical and data processing programs were produced; such programs were often referred to as "canned" programs or "program packages." They were characterized by being machine dependent, having numeric field control cards and fixed field punched cards as input, and producing a limited range of outputs, usually sparsely labelled. Substantial emphasis was placed upon internal execution efficiency.

An initial milestone in the development of statistical computing was achieved when W. J. Dixon and his colleagues at UCLA created the original set of biomedical statistical programs[6] in 1962. This set, initially known as the BIMD series, provided the user with an integrated set of programs containing a large number of statistical procedures; the series included such features as a common vocabulary across programs, a comprehensive method of specifying data transformations, adequate user documentation, and readable and intelligible printed and graphic output. The BIMD series surpassed previous products by its completeness, increased user orientation, and emphasis upon exportability to other computer centers. While some aspects of the original BIMD programs now appear primitive, the initial impact of this set of programs upon statistical computing was substantial. The BIMD programs were developed during a time of intense batch program construction activity; some of the batch systems that followed BIMD such as P-STAT[2] and DATA-BANK-MASSAGER[13] were oriented specifically to social science users.

Another milestone in the development of social science computing was the creation and implementation of higher level languages oriented specifically to tasks in the field. Shortly after the concept of higher level languages became generally accepted, a number of social scientists began to develop languages oriented specifically to social science computation. I believe primary credit should go to Arthur Couch and David Armor at Harvard University for their development of the Data-Text language.[8] Although implemented originally in assembly language, Data-Text provided social scientists with free form statement types linked directly to behavioral science computing procedures. Considerable effort was spent upon organizing printed output to the user's specifications. The development of Data-Text led to other efforts such as BEAST[1] and SPSS[16] which have been useful as system design experiments and as applications programs for obtaining statistical outputs and tabulations from rectangular data files.

A third milestone in social science computing was the successful exploitation of interactive computing systems for research and instruction in the social sciences. Using computer systems that support economical interactive computing, a number of such programs have been developed. These include IMPRESS[15] for on-line instruction in social science computer based research methods, BASIS[20] for on-line statistical analysis, TROLL[12] for on-line time series analysis, equation system estimation, and econometric simulation, and others such as TRACE-III,[3] OPS-3,[7] and ADMINS.[14] These systems are examples of the manner in which interactive environments have been used to support powerful tools for social science computing tasks.

Most social science computing activity has depended critically upon access to behavioral data in machine readable form. Government agencies and survey research organizations pioneered in developing techniques for recording survey data on punch cards and analyzing these data mechanically. Universities and private survey research centers today have substantial holdings of sample survey data, and much of this material is available for secondary analysis. Several specialized data distribution networks have evolved; for example, the Inter-University Consortium for Political Research at the University of Michigan distributes political data by mail from its archive to over 100 member academic organizations, and the National Bureau of Economic Research makes available its on-line data bank of aggregate economic time series to its subscribers.

Government statistical agencies have historically been important sources of data for quantitative social science research. The publications of these agencies were an important source well before the widespread availability of automatic computing machinery. The U.S. Bureau of the Census provided a wide variety of population, housing, labor force and manufacturing data on an aggregated basis for many years; and after the 1960 census the Bureau initiated a policy of disseminating population microdata on magnetic tape for 1/10000 and 1/1000 random samples of U.S. families. Since 1969, microdata collected by the monthly Current Population Survey have been available in machine readable form to qualified researchers. Availability of public data in machine readable form has increased in recent years as government statistical operations have become more mechanized and as social scientists have learned to obtain and use the data effectively.

CURRENT STATUS

Social scientists have available to them today a wide variety of computer programs for their use. Batch-oriented programs for statistical analysis of rectangular file structures are most common; in addition to the better known and more reliable of these programs, there exist many locally developed programs that perform frequently used statistical procedures. The quality, accuracy and documentation of these programs vary substantially, and recent evidence presented by Longley[11] and Wampler[21] indicates that increased quality control is needed in their production. Computing languages for the social sciences are relatively new; however, there has been sufficient development to indicate the power that such languages provide, and their continued development seems warranted. More recently, interactive programs have been developed that give social scientists flexible control over their procedures and their data. Some very useful interactive tools have already been produced, but much work will be required to exploit current interactive computer systems in a truly productive manner.

An increasingly copious flow of behavioral data is now generated by individual researchers, private firms, public organizations and governmental organizations, and much of it is in machine readable form. The increase in complexity of the processing operations now being used require the input data to be more error free than was required in the past; present consumers of microdata especially must be much more sensitive to noise in their data. There is now increased demand for government data by private researchers, and the conflict between the use of individual data for legitimate public purposes and the confidentiality of such data has yet to be resolved in a satisfactory manner.

Major problems currently exist within the field of social science computing. Among the most serious appear to be: (1) inadequate standards for data documentation and problems of data transfer; (2) the low level of computational knowledge among social scientists and the lack of adequate training available; (3) the slow rate of diffusion of computing innovations into social science computing, especially in government; (4) problems of program inaccuracy, documentation and transfer; (5) lack of adequate software tools for many types of complex processing operations; and (6) the low level of professionalism in social science computing activities generally.

Some of the problems that exist in social science computing are common to most areas of computing and will be ameliorated by advances in computing generally. Other problems have been aggravated by the lack of resources allocated to the social sciences relative to other disciplines. Still others can be traced to misallocation of those resources made available. Finally, it appears that the current organization of the social science computing industry has itself produced or aggravated a number of present problems.

INDUSTRIAL ORGANIZATION

It seems both appropriate and relevant to employ one of the social sciences, economics, to study the industrial organization of the social science computing industry. For the totality of social science computing activity is an industry; it encompasses a variety of products, their producers and consumers, the markets in which they interact, the mechanisms for distributing goods, the reward structure for producers, the rate of investment in capital, incentives for investment, the rate of technical progress, and other industry characteristics. The institutional structure of social science computing directly affects the manner in which individuals and organizations allocate resources to produce a wide variety of products. Solutions to current problems in social science computing are as likely to result from organizational change as from technical advances or increased resource supplies.

Most products within the social science computing industry fall into four general groups: (1) computer programs; (2) numeric data files; (3) knowledge regarding numerical methods, statistical procedures and computing techniques; and (4) personal services. Within each of these groups, the products produced are heterogeneous, although there is some evidence of product differentiation that is largely artificial.

Computer programs range in generality from specialized applications programs to general purpose applications systems and translators for high level programming languages. The former are final goods; they represent unique products designed to satisfy specific requirements. General purpose programs are intermediate goods, or producer goods; once created, they are then used repeatedly to produce a variety of final goods specified by non-programming computer users. Data files vary in size and complexity from those having a rectangular structure with few observations and variables to those resulting from the 1970 Decennial Census of Population and Housing.

The market for social science computing products appears to have four important dimensions: (1) locality; (2) computer type; (3) substantive focus; and (4) profit/non-profit. Markets have a strong local component because computing installations serve as centers of knowledge and expertise for their users, and rapid and inexpensive access to assistance is often essential for the success of computer related work. In addition, an organization having a computer center within its administrative jurisdiction frequently raises barriers to use of other centers by their staff. Also, the market is divided according to the manufacturer, model, and configuration of computing equipment available because programs, data and technical information can often be transferred at low cost between quite similar computers but not between dissimilar computers. The market is also stratified by substantive social science discipline or research or policy focus, especially with regard to machine readable data files and computer programs and hardware configurations that perform specialized processes within that discipline. Finally, there is infrequent interchange of programs between commercial firms and academic and research institutions.

There are a large number of producers of social science computing products, many of whom are individual social scientists and programmers. In addition, producers include social science computing groups within research organizations and universities, survey research centers, private firms, and various agencies of federal, state, and local governments. Many of these producers are also consumers; often production is initiated primarily or wholly for internal consumption. Most producers are active primarily within one of the above markets, although private firms can generally respond quickly to changes in demand by acquiring and reallocating resources.

With one outstanding exception, the subsets of the industry corresponding to the above broad product groups exhibit a low degree of industrial concentration, i.e., no small number of producers command a major share of these sub-markets. There currently exist a large number of producers of social science software, and except for large applications systems barriers to entry into the industry are almost non-existent. The number of producers (suppliers) of data is smaller, and entry into this industry generally requires a higher level of investment than entry into program production. Several organizations have made an investment in data banks containing economic time series, and competition to provide these data and associated computer software is now vigorous. Government agencies enjoy a natural monopoly position in collecting and disseminating data when the data must be made available to the government by law and is unlikely to be disclosed otherwise; examples include population census information and individual and corporate tax return data. In addition, government agencies enjoy substantial competitive advantages in collecting such data when it results as a byproduct of on-going administrative procedures or when the resources required to produce the data are larger than most potential producers can mobilize.

The performance of government in producing data in such a quasi-monopoly position has not been without fault. Under monopoly conditions, economic theory would predict that prices would be higher than if competition existed and the single producer would earn monopoly profits because of it. Government agencies are generally prohibited from pricing their products above average cost at most; but instead the monopoly position appears to encourage inefficient use of resources and technology and a lack of responsiveness to consumer demands. This results in higher prices for the consumer than would have prevailed in a competitive environment, a sluggish rate of innovation and less consumer choice.

The distribution mechanism for social science computing products is in the process of substantial change. Products have been generally recorded on physical storage media such as punch cards, printed paper, and magnetic tape and these media were physically distributed to consumers. In the past, high costs associated with this distribution technology were partially responsible for product markets being segmented by computer installations and by hardware type. More recently, an increasing number of products are being distributed by transmitting digital data over common carrier telephone networks and specialized communications networks, and it appears that this growth will continue both in relative and absolute terms for some time.

Knowledge about social science computing products, statistical procedures, and related computing techniques reaches potential consumers in a number of ways. Inter-personal communication now forms one of the most important means of transmitting such knowledge. Some dissemenation of this information is made in publications of computer societies, social science professional societies, research institutions, and various related academic disciplines. Informal publications, workshops and conferences also play an important part in collecting and distributing knowledge. However, at the present time there are no information centers or professional societies focused primarily upon social science computing. SIGSOC, the Special Interest Group for Social and Behavioral Science Computing of the Association for Computing Machinery, is a likely candidate for this position, but its development into a professional society will take at least 5 to 10 years.

Social science computing products are created in accordance with the production processes available to the industry at the time of production. A production process or function is a set of technical rules that specify how goods and services called inputs may be transformed into other goods and services called outputs.[19] The levels of knowledge and technology available dictate what production functions are available for obtaining specified outputs. If a production process requires more than one input, there are usually a variety of combinations of inputs that are capable of producing the same set of outputs, i.e., the production function may allow input substitution. In computing, a typical example of input substitution is provided by the frequent tradeoff in program design between the use of main memory and processor time; using more of one generally provides savings in use of the other. Resource constraints and the relative prices of the inputs enter into the choice made by producers of which production process to use for obtaining output.

For many social science computing products, the cost of producing the first unit of a specific output is high relative to the marginal cost of producing subsequent duplicate units. The cost of duplicating a computer program or a machine readable data file, once the product has been created, is low and requires only the use of well-known duplication procedures. However, the costs paid by social scientists to import programs and data are generally much higher; the principal reason is that the distribution technology for these products is still rather primitive since the products often do not adapt easily to computing environments other than those very similar to the environment in which they were created. The total costs of distribution are therefore often much higher than the costs of duplication.

If the marginal cost of a unit of production is low relative to the initial investment required to produce the first unit, then resources are allocated more efficiently if there exist a few large producers rather than many small producers. Yet with the exception of the production and distribution of large data files and a few other products, it appears that the market is dominated by small producers. There are a number of factors that help to explain this phenomenon. First, many of these products are differentiated slightly but meaningfully for their consumers. Second, computing products may be one of a number of outputs of a joint production process; often another output is increased education for the producer. Also, the very low barriers to entry encourage new producers into these markets at low cost to the new entrants.

The above factors help to explain the existence of small producers of social science computing products, but they do not explain the relative absence of larger producers who are able to make substantial investments in more general and more powerful products. Even for the first unit of production, there appear to be substantial economies of scale. That is, there are some fixed costs in program preparation that must be incurred regardless of program size. Examples of such fixed costs in social science computing systems are code to read the data file and interpret its values, code to provide elementary output displays and code to perform standard data transformations; they are almost always included regardless of how the data are processed. To the extent that fixed costs influence the production process, a more comprehensive and more general program appears to be cheaper to construct than the many smaller programs that duplicate its functions.

A very important factor limiting substantial investment in computing products is that although the return to such investment may be high for the industry as a whole, most of the return cannot be captured by the investor. Another factor is the segmentation of the market discussed previously; if individual markets are limited in size, then the cost of sales increases and potential returns are more limited.

Much social science computing activity occurs in universities, research organizations, government agencies and other environments that often do not enter the commercial marketplace to buy and sell these products. Within these organizations, producers are generally individuals, and the rewards sought are primarily nonfinancial; rather they are prestige and recognition for the producer's accomplishment. At the present time, however, the technical activity associated with producing computer products for social scientists does not enjoy high prestige or substantial recognition for the individual involved. "Tool using," or substantive activity, has higher status within social science professions than "tool building," or technical activity. Thus, although changes in the level and allocation of investment in computing tools for social scientists would lead to a more efficient allocation of individual skills and technical resources and would be expected to provide substantial externalities to social science as a whole, the reward structure of academic social science disciplines prevents the individual innovator from collecting his rewards. The lack of a satisfactory reward structure for non-commercial producers of social science computing tools is very unfortunate, since it discourages innovative investment in production for those who are often able to make substantial contributions to the field. The inadequate reward structure contains another unfortunate aspect; it perpetuates a lack of interest and involvement in computer oriented training by persons in the social science professions.

THE FUTURE

During the next ten years, continued substantial growth in social science computing activity is likely to occur. Social scientists currently being trained are taught quantitative methods to a greater degree than any of their predecessors. The amount of data in machine readable form is increasing rapidly. The decreasing cost of computation is shifting the balance in favor of using computers rather than using manual labor or not performing a task at all. Furthermore, as inventories of data and quantitative methods grow and as the number of practitioners in social science computing increases, important issues in social and economic policy become more tractable using the computer. Although growth in social science computing will not be uniform and will be unevenly divided among disciplines and applications, there is little doubt that it will occur.

Advances in computing hardware and software during the past 15 years have been responsible for a dramatic decline in the cost of computing. Current evidence suggests that logic and memory costs will continue to decline substantially during the next decade. These declines in cost will benefit social science computing activity by reducing the cost of those computing inputs.

In addition to declines in computing cost, three specific areas of development within the computer industry are likely to benefit social science computing substantially and should be assisted and encouraged. These areas are: (1) communications terminal technology and interactive system development; (2) digital data networks linking computers; and (3) data storage technology. Developments in these three areas will impact different aspects of the social science computing industry.

The development of reliable and responsive interactive computing systems has already had an impact upon the manner in which social science computing is performed. Previous reliance upon batch computing systems forced social science programs into a mold in which output decisions had to be made simultaneously rather than sequentially, computations producing large amounts of (often unread) output were the rule, and errors in input preparation resulted in increased computer costs and turnaround time delays that were generally large relative to the magnitude of the error. In general, batch systems have had the effect of separating a non-programming investigator from his procedures and his data.

Recent uses of interactive systems provide convincing evidence that it is possible to exploit such hardware in a manner that allows a user considerably more freedom and flexibility with his data and the procedures he employs. The TROLL system[12] provides an example of such a use. Furthermore, in some general interactive systems including the first, CTSS,[4] batch and interactive modes of computation are not antithetical but combine naturally to use common system resources. The appropriate mode of computation may be chosen according to the characteristics of the task and the preferences of the user. Recent systems such as Digital Equipment Corporation's PDP-10 include interactive-batch compatibility as a basic design feature; such a feature is not costly relative to the benefits it provides and should be more common in the future.

The widespread availability of interactive systems plus the development of faster and less expensive user terminals should cause a shift of much social science computing to these systems. Among the reasons are: (1) the ability to specify tasks of analysis incrementally rather than collectively; (2) the potential of on-line interaction with data bases and the ability to browse through them with flexible computer support functions; (3) the generally lower cost of making a mistake in procedure and the ability to detect it more rapidly; and (4) the resynchronization of the user's processes of hypothesis formulation, testing, and analysis and the computer's use in supporting these functions. Batch processing will not and should not disappear; it will continue to be used for routine tasks in which interaction is not required or is inappropriate.

The computer terminal market has just begun a period of rapid development. In the past the terminal industry was dominated by two large firms, AT&T and IBM, and the market for terminals grew slowly; the rate of innovation in the industry was sluggish. As interactive computing began to increase, the market for terminals grew rapidly and many new firms entered the industry. The results have been increased competition, more product variety for consumers, lower costs, and an increase in the rate of innovation. If the growth in interactive computing continues, the terminal market should continue growing rapidly. Bigger markets should lead to increased specialization, some of which will benefit social science computing directly. For example, a low cost interactive graphics terminal having moderate power is well within the scope of present technology. Only a larger market is required for it to be introduced commercially. Cheaper, faster and more powerful terminals will make widespread use of terminals economically feasible and will allow enchancement of the quality and power of interaction.

The development and availability of general purpose computer networks is important because they will remove significant limitations on market size for social science computing products. By a general purpose network I refer to a network that can transmit digital data between any two of its members without knowing the content of the transmission. Such a network might exist on a permanent basis, such as the ARPA network[18] with its dedicated interface message processors and reserved communications circuits, or it might consist only of interface protocols between its members with common carrier transmission initiated whenever any member wants to activate a part of the network.

Social science computing product markets are now segmented by locality and by machine type. One of the major reasons for this segmentation is the high cost of importing both programs and large files containing behavioral data. One of the major effects of such segmentation is that investment in each market is limited by its size. Thus, investments in special products are made and replicated in many small markets.

The existence of general purpose networks should alter this resource allocation pattern. Suppliers of programs and data bases will have access to a much larger market for their products; the prospect of larger returns should serve to increase both the degree of specialization of those producers and the amount of investment they are willing to make in their products.

For consumers of social science computing products, such networks will increase substantially the number and variety of products available to them. As an example, consider the problem of accessing data files residing at a remote computer center. In the past, data have generally been exported by moving the data file from its initial computing environment to the data requestor's computing environment; usually the environments are technically and administratively dissimilar. The technical problems involved in such transfers are solvable, but they are generally time consuming and tedious. Computer networks offer viable technical alternatives to this procedure. Using a network, it would be possible to transmit a request for processing and output to the computer environment in which the data are stored and transmit the results back to the requestor. If the cost of transmission is low and there are few administrative barriers to access, every user can regard any program or data file on the network as being within his own facility and available to him at only moderately higher cost. Alternatively, the data could be transferred directly to the user's computer, since the existence of the network implies functional interfaces between each computer in the network and the network circuit itself.

The availability of computer networks should substantially reduce the inconvenience and costs of accessing remote computers, provided that the institutional and administrative problems of interorganizational computer access can be solved. This will create larger markets for social science computing tools and will lead producers to raise their level of investment in the products they offer. In addition, there should take place a trend toward specialization in the construction of tools for use, and collection and maintenance of specialized data bases at various research-oriented computer centers. An example of this process is provided by TROLL,[12] an on-line system for macroeconomic estimation and simulation. TROLL is available to its customers on-line using the AT&T telephone network. Partially as an outgrowth of the development of TROLL, a Computer Center for Economics and Management Sciences has been established by the National Bureau of Economic Research to continue and extend the production of quantitative methodology and computing tools. It is anticipated that access to programs and data will be made on-line, using the telephone system to support network communication.

Initially, the existence of network communication links will be far more important than how the network is implemented. The existence of some form of interprocessor communication will allow substantial changes in how and where social science computing is accomplished. The configuration and the nature of implementation of the network is a matter of economics; it depends upon such factors as anticipated pattern and volume of traffic, number and location of subscribers, and required response characteristics. Until a general purpose network becomes available, more primitive network communication can be supported using the existing telephone network. It seems unwise to build a computing network dedicated to social science computing traffic either now or in the near future. Such an act would be comparable to allocating some of the industry's limited resources to design special computer architecture that would be dedicated to social science computing.

Of all components of computer hardware, the current status and use of data storage technology represents a major constraint on the fashioning of better social science computing programs. As social science programs grow in scope, they grow in memory required also. It is now common for large social science applications systems to use elaborate manual segmentation systems to accommodate themselves to a small amount of address space. Either the memory resources for ameliorating these restrictions do not exist, or the techniques for accessing them are not known or available.

In the absence of a fundamental breakthrough in providing substantially lower cost immediate access memory, computers with virtual memory organization[5] appear to offer a solution to this problem. Virtual memory machines provide both increased program address space and data address space; the latter would provide the ability to process more complex data structures without making a substantial investment in file manipulation software. Virtual memory environments for building and using social science computing tools should obviate some of the ungraceful degradation characteristics which many social science computing programs exhibit upon reaching a capacity constraint. Perhaps most important, the availability of virtual memory would remove most memory management concerns from programmers and allow them to concentrate upon producing more useful computing tools. The opportunity cost of *not* using automatic memory management techniques is measured in terms of programmer time used in its place and investigator time waiting longer for results. This cost is already substantial in some cases, and it will increase as the cost of hardware declines relative to the cost of labor.

If the technical developments described above materialize, then their impact upon the social science computing industry should have very beneficial effects upon its performance. However, several problems exist within the industry that detract from its performance and that are not likely to be altered by changes in technology.

The first problem concerns access to data. While there has been much progress in recent years by private firms making data available in machine readable form, most behavioral and economic data generated by government agencies and private researchers is unknown to other potential users or underutilized by them. The principal reasons appear to be that: (1) within government agencies, quasi-monopoly positions have discouraged efficiency in both production and distribution; and (2) in academic and research institutions, the prevailing reward structure offers few professional rewards for data production alone. As a result, it is common to observe much duplication of data collection activity, underutilization of existing data sources, and lack of availability of existing timely and detailed data for research and policy analysis.

Another problem is closely related. Social science disciplines currently assign lower status to most "technical" work and higher status to "substantive" work. To the extent that this status difference is perceived, new entrants into social science professions are more likely to elect to do substantive work. Those entrants with strong preferences for the computational aspects of the social sciences are more likely to gravitate toward academic computer science rather than toward involvement in a service role in which room for professional growth appears limited.

Within the present industry structure, academically oriented producers of both programs and data find it difficult to obtain academic rewards for their output. The production of a useful, accurate and well-documented social science computer program or machine readable data file may generate substantial externalities for social science as a whole, yet there is no adequate mechanism that allows its producer to capture these externalities. The long run effect of this situation must be to discourage production by those able to produce successfully in other fields.

The problem of developing a reward structure for the social science computing industry is not a new one. Its solution could result in substantial benefits to social scientists in terms of substantially more efficient use of the computing and data resources available to them.

CONCLUSION

During the next ten years there will be a substantial increase in demand for social science computing products from government, universities, research institutions and private businesses. A continued decline in the cost of computing will benefit all these consumers. In addition, the development of reliable general purpose interactive systems and inexpensive terminals will enhance the quality and power of social science computing activities; general purpose networks will enlarge traditional markets and lead to increased competition and better consumer choice; and the development of quite large addressable memories should remove an important existing constraint on the development of large applications systems and complex file processing tools. These developments should be supported by the social science computing industry. Problems concerning access to data and achieving a reward structure for social science computing exist and are important, but remain to be solved in a satisfactory manner.

ACKNOWLEDGMENTS

I would like to acknowledge helpful discussions with and criticisms from Mr. Ben A. Okner and Mr. Gregory A. Marks.

A computer model of simple forms of learning in infants

by THOMAS L. JONES

National Institutes of Health
Bethesda, Maryland

INTRODUCTION AND SUMMARY

Many workers have studied the problem of getting machines to exhibit aspects of intelligent behavior. It has become clear that a major limitation of the artificial intelligence field is the cost and difficulty of programming, which remains essentially a handicraft technique. What we need in artificial intelligence research are methods for the machine to be self-programming in a much deeper sense than the compilation process in use today. Briefly, we would like for the machine to "learn" to solve a problem, rather than being programmed in the usual laborious way. This report presents a computer program, using what I will call an "experience-driven compiler," which is able to program itself to solve a restricted class of problems involving cause-and-effect relationships. Although the program is not yet able to learn to solve problems of practical significance, it is hoped that the technique will be developed to the point where this can be done. I am in agreement with Turing's suggestion (1950) that the best way to achieve artificial intelligence is to find out what an infant has in his brain that allows him to become intelligent, put this capability into a computer, then allow the machine to "grow up" in much the same way as the baby does. (Of course, this is a statement of the problem rather than an explanation of how to solve it.) An additional purpose of the work is in psychology: we would like to have computer methods for testing theories of how learning might occur in living creatures.

There have been many reports of techniques for getting machines to exhibit various forms of learning (Friedberg, 1958; Samuel, 1959; Waterman, 1970). Usually they are concerned either with coefficient learning, where some parameter given by the human programmer is optimized, or with rote learning, involving the formation of some table or file of data. This report describes a different form of learning, *program learning*, where the output of the learning process is a computer program. Greene and Ruggles (1963) described a computer model of behavior in human infants. In psychology, Piaget (1952) and Hull (1952), among others, have studied the process of behavior acquisition. The methodology used in the present report can be considered an extension of Hull's method of formulating assumptions in a precise, formal way, deducing the consequences of the assumptions, and comparing the results with observed behavior. The computer permits us to evaluate a learning model by turning it on and running it; the model's capabilities are there for all to see, and its weaknesses are glaringly obvious. The model may be made more like the real organism by improving it in an engineering sense, since a dissimilarity is almost always something which the living organism can do and the model cannot.

This report describes a computer program called INSIM (for "INfant SIMulator"), written in LISP (McCarthy, 1960) for the PDP-10 computer. The program operates by learning cause and effect relationships, such as "turn head" causes "mouth touch." A cause-effect chain is formed; if A causes B, and B causes C, and if C is pleasurable, the program will work backward along the chain until it reaches something it can control directly (a muscle pull). The simulated infant's behavior is under the control of a so-called performance program. The performance program is, in turn, written, as learning proceeds, by a section of the learning program called the "experience-driven compiler."

A typical problem solved by INSIM involves a behavior pattern which is all too familiar to parents of small children: That of sucking the thumb. (We will soon see that this involves quite a virtuoso feat of information processing.) The problem can be described in logical notation as follows:

(1) object touching mouth→pleasure
(2) (left cheek touch AND turn head left)→
mouth touch

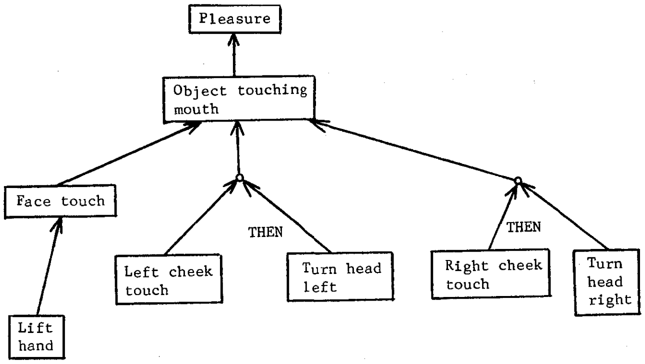

Figure 1

(3) (right cheek touch AND turn head right)→ mouth touch
(4) (left cheek touch OR right cheek touch) = face touch
(5) face touch→mouth touch (sometimes)
(6) lift hand→face touch

(See Figure 1.)

After the program has learned these connections, it will emit the behavior sequence, "lift hand, turn head (left or right)," resulting in pleasure.

Figure 2 is a block diagram of INSIM:

The *performance program* has the direct responsibility for synthesizing behavior. It is written in an interpretive language called PSIM (parallel simulator). The performance program receives stimuli from and sends responses to a *body and environment simulator*. The *display section* provides monitoring on the cathode-ray tube. The *motivation section* activates the main goal (oral gratification or curiosity).

Relatively little of the performance program is innate. Most of it is generated by an *experience-driven compiler* which is the core of the learning part of the program.

Causality is detected by statistical correlation; if a signal occurs on line A followed by one on line B, and if this sequence is repeated sufficiently many times, the program assumes that A causes B. The program is equipped for the simplest type of pattern recognition and concept formation: the formation of logical AND's and OR's of previously known variables. The program has an intellectual motivation system which causes it to exhibit simple forms of curiosity, play, and exploratory behavior.

THE PERFORMANCE PROGRAM

As described above, the performance program has the direct responsibility for receiving cues from the environment and emitting properly timed and sequenced behavior. The performance program consists of a set of PSIM statements arranged in a *goal tree*, each node of which is a *variable cluster*. A variable cluster consists of a *basis variable* such as "mouth touch," together with variables which indicate the status of the goal defined by the basis variable (e.g., achieving mouth touch). These include:

(1) The PR of the goal. This is defined as the probability that the goal can be achieved "soon" (in a sense to be defined precisely below), provided that an attempt is made by the infant to achieve it.
(2) The C (cost) of the goal. This is the program's estimate of the time delay required to achieve the goal.
(3) The WANT of the goal. This is TRUE or FALSE depending on whether or not the program is trying to achieve the goal. A goal is defined to be *active* if its WANT variable is TRUE: i.e., if the program is trying to achieve it.

In addition, the variable cluster associated with a goal contains other variables as described below.

The performance program, then, consists of a set of variable clusters for various goals, with *connections* between variable clusters for goals which are causally related. Thus, there will be a connection between the variable clusters for "turn head left" and "mouth touch." Figure 3 shows the goal tree for the thumb-sucking problem, with the variable clusters shown explicitly.

Psychologists will wish to compare this setup with Guthrie's "connectionism" concept (1952). Note again the resemblance to a nerve net. INSIM may be interpreted as a neurological model of how learning might take place in the brain, although, of course, it is a very

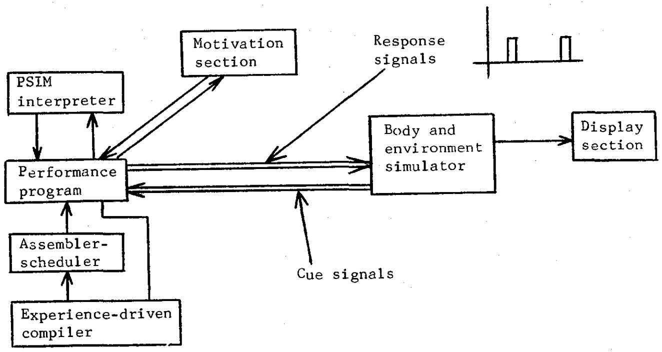

Figure 2

imperfect model and one for which no direct neurological evidence exists.

The performance program operates by *activating* various branches of the goal tree at the appropriate times. Recall that the active nodes of the tree are the nodes which define goals which the machine is trying to achieve at the current time. In the thumb-sucking problem, assume that the motivation section has activated the main goal "oral gratification." The performance program will activate the extreme left branch of the goal tree (see Figure 1), ending in "lift hand." The "lift hand" response will be emitted to the body and environment simulator. After a delay of roughly two simulated-time seconds, a cue, e.g., "left cheek touch," comes back, indicating that the simulated hand has been lifted to touch the (simulated) left cheek. Next, the branch ending in "turn head left" is activated. A "mouth touch" signal comes back from the body and environment simulator, indicating that this goal has been reached, and the motivation section turns on the oral gratificaticn flag, "rewarding" the program for its successful effort.

The basic problem is to decide which branch of the goal tree to activate. (INSIM performance programs allow only one branch to be active at a time; hence there is no way to work on two goals simultaneously.) In a given situation, the decision is made in two phases, a *feasibility study phase* and a *choice phase.* In the feasibility study phase, each branch of the tree is assessed, and an estimate is made of which branch is the quickest and surest way to the main goal. In the choice phase, this branch is activated. During the feasibility study phase, the PR (probability) and C (cost) are computed for each goal.

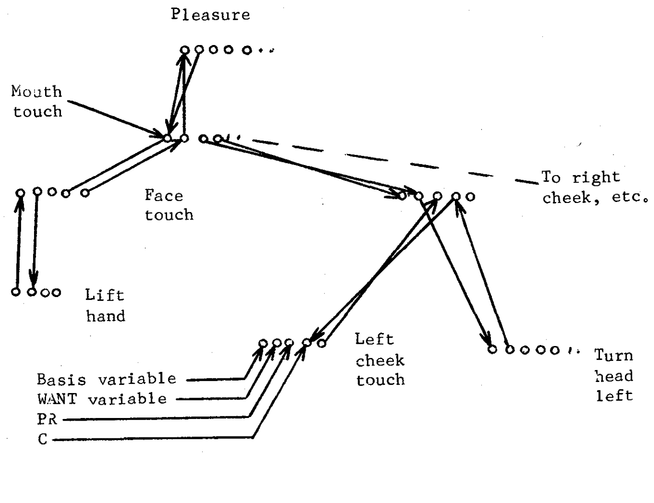

Figure 3

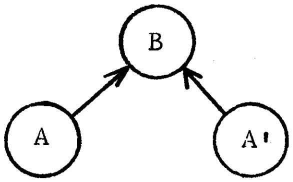

Figure 4

Computation of PR and C

This section is devoted to a detailed discussion of how PR and C are computed. On a first reading, readers may skip to the section on the choice phase.

PR is defined recursively as follows:

(1) For a "response" (directly controllable) variable, such as "lift hand" or "turn head left," PR = 1.

(2) Suppose that A is one of several OR'ed subgoals of B (see Figure 4).

If A is the "best" subgoal according to a criterion to be presented momentarily, then PR(B) = PR(A) Pr(B | A), where Pr(B | A) is the conditional probability of B given A (i.e., the probability of getting from A to B) as estimated by the coefficient learning program PRDLRN, discussed below.

The "best" subgoal is selected so as to maximize the Slagle coefficient (1964)

$$\frac{\mathrm{PR(B)}}{\mathrm{C(B)}}$$

This subgoal may not really prove to be the best one, if, say, the probability or cost estimates turn out to be incorrect. The performance program is a heuristic program and is forced to make decisions based on imperfect evidence.

A more sophisticated program would take into account the possibility of trying to achieve A, failing, then trying to achieve A′ and succeeding. Thus a goal with several good subgoals would have a larger PR for this reason. However, INSIM considers only the one best subgoal.

(3) Suppose that A1 and A2 are components of the ordered-AND goal A1THA2 (A1 then A2). Then PR (A1THA2) = PR (A1) PR (A2).

(4) Notwithstanding any of the above, if a goal has already been achieved, its PR = 1. A goal is defined as "already achieved" if the corresponding signal has occurred within the last five seconds.

Similarly, the C (cost) of a subgoal is defined recursively as follows:

(1) For a response variable, C = 0.
(2) If A is the best of several OR'ed subgoals of B, then C (B) = C (A) + PR (A) Delay (A→B).
(3) The C of an ordered-AND goal A1THA2 (A1 then A2) is C (A1THA2) = C (A1) + PR (A1) C (A2)
(4) Notwithstanding any of the above, the C of a goal is 0 if the goal is already achieved (in the past five seconds).

To summarize, in the feasibility study phase, estimates are made of the success probability and time delay of each path to the main goal.

The choice phase

The next step is to activate the goal tree branch which is estimated, according to simple heuristics, to be the quickest and surest path to the main goal. A goal is *active* if, and only if, its WANT variable has the value TRUE.

(On a first reading, readers may skip to the section on the inner loop.) The WANT variable of a goal A is defined recursively as follows:

(1) If A is a main goal, WANT (A) is TRUE or FALSE as set by the motivation system.
(2) If A is one of several OR'ed subgoals of B, WANT (A) = (WANT (B)) AND (A is not already achieved) AND (A is the best subgoal of B)) OR
  (A is a curiosity goal (see below)).
(3) If A1THA2 is the ordered-AND subgoal "A1 then A2,"
WANT (A1) = WANT (A1THA2) AND (A1 is not already achieved)
WANT (A2) = WANT (A1THA2) AND (A1 is achieved) AND (A2 is not achieved).
(4) If G is a response (directly controllable) variable, WANT (G) causes the response to be emitted.

The inner loop

Since the computation of the PR, C, and WANT variables is under control of PSIM, they will be recomputed in a wavefront-like manner, with the stimulus variable as the starting point of the wave. Thus the PR and C and the program's decisions are constantly being updated on the basis of changing conditions. PSIM will update only those tree branches which depend on some variable which has changed since the last TCLOCK time.

Discussion

INSIM performance programs incorporate simple heuristics which work well in cases where the assumptions on which they are based hold true.

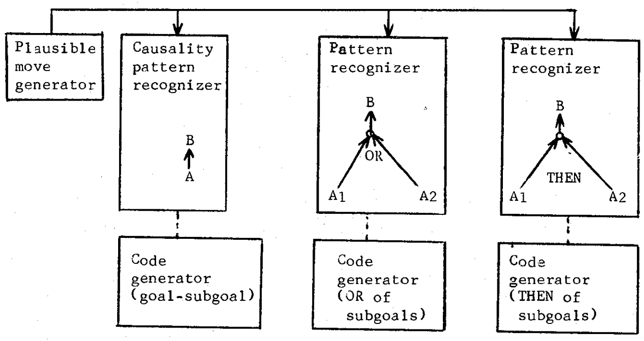
Among the assumptions are:

(1) Success probabilities and time delays are assumed to be statistically independent. If this is not true, the chaining formulas used in computing success probabilities and time delays will not be accurate.
(2) It is assumed that goals do not conflict; i.e., that the achievement of one goal does not decrease the probability of achieving another goal.

Removing these performance limitations would require additional machinery beyond the scope of the INSIM project, such as a look-ahead method of the type used in chess programs.

THE EXPERIENCE-DRIVEN COMPILER

As mentioned previously, most of the performance program is coded by an internal compiler which, instead of using as its input a source code prepared by a human, is controlled by the experience acquired by the program as it interacts with its (simulated) environment. In keeping with the dictum that in order to learn something, one must know something already, the compiler incorporates the probability and delay formulas described above, plus knowledge of basic aspects of the physical world, including time and causality (see Figure 5).



Plausible move generator

Code generator (THEN of subgoals)

Figure 5

The plausible move generator is used instead of testing for causality between all possible variables A, B. The latter approach would involve on the order of n^2 tests, where n is the number of variables.

It is the compiler which sets the upper limit on the program's ability to learn. For example, INSIM could never learn to play chess even with very long training, because the necessary pattern recognizers and code generators are not present.

The experience-driven compiler operates as follows: The program starts out with an innate main goal which is "oral gratification" in the thumb-sucking problem. First, the plausible move generator is called to generate a list of variables which are likely to be "relevant" to the oral gratification goal, and *causality test links* are formed. (The plausible move generator is discussed below.)

Next, the *causality pattern recognizer* learns which test links represent actual causal relationships. The pattern it is looking for is shown in Figure 6.

If a pulse on variable A is followed by a pulse on variable B sufficiently often, A is assumed to cause B. More precisely, if $\Pr(B \mid A) > 0.20$ after at least 15 pulses on A and 15 pulses on B have occurred, A is assumed to cause B. The pulses on A and B must be less than five simulated-time seconds apart. (If there are any pulses at all on B, then a pulse on A will always be "followed" by a pulse on B if we wait sufficiently long.) $\Pr(B \mid A)$ is estimated by the *probability-delay learner,* discussed below.

The simple heuristics will miss some actual causal relationships when the delay is more than five seconds. It would not be hard to make the program "adaptive" to this arbitrary parameter, say by matching the time delay to the recent density of pulses on the two lines.

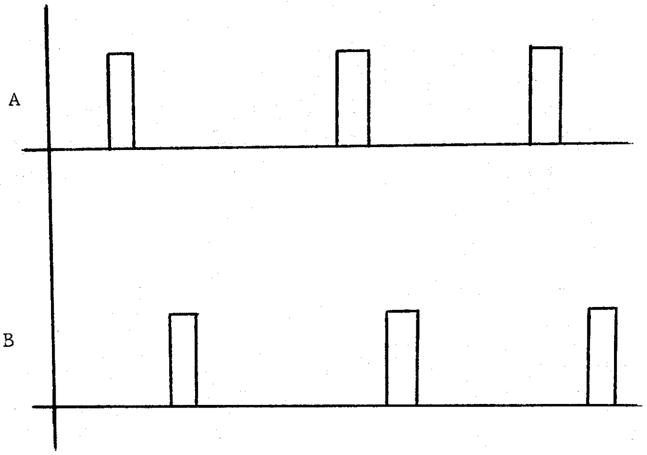

Figure 6

Thus, if there were only one pulse on B about every 15 minutes, the allowable delay might be five minutes rather than five seconds. Also, the heuristics will sometimes "identify" a causal relationship where none actually exists. E.g., if the allowable time delay were long enough, the program would think that day causes night. (Piaget has found that small children also think that day causes night.)

In some cases, it is sufficient to wait passively for a pulse on A. In other cases, the *curiosity section* of the performance program sets WANT (A) to TRUE, activating some goal tree branch ending in A and initiating behavior which hopefully will lead to a pulse on A, in order to see if B follows (e.g., it activates "turn head left" to see if "mouth touch" follows): this is the "play" or "exploratory behavior" mentioned above. The curiosity section attempts to test links which are new and have not been tested many times; links where the initial variable, A, is reasonably easy to obtain; and where the final variable, B, is "biologically useful" in that ability to obtain B would contribute to the program's ability to obtain pleasure (primary reward). Specifically, the curiosity section tests the link A→B which maximizes

$$(PR(A)/C(A)) * Satfunc(A, B) * Need (B)$$

where Satfunc (A, B) (saturation function) decreases linearly from 1 to 0 as the number of times when A→B has been tested increases from 0 to 15. Need (B) is an index of how much the ability of the program to obtain primary reward would be improved by improvements in its ability to obtain B. See Jones (1970) for a description of the heuristics used to compute Need (B). Only links which have been designated as "plausible" by the plausible move generator are tested.

When the causality pattern recognizer detects that two variables, A and B, are causally related, the corresponding code generator is called to compile the link A→B in the goal tree, provided that the connection has not already been made. This code generator is a LISP function called MAKEORGOAL (A, B), so named because it also handles the case where A is one of several logically OR'ed goals. In LISP, the code generator turns out to be a straightforward and rather prosaic, if slightly long, program. Separate sections are provided for compiling the entries for WANT, PR, C, and each variable associated with the curiosity system. Each section looks up the names of the variables involved in the formula in question and substitutes them in the formula, using LISP's symbol-substituting capability.

In the thumb-sucking problem, the program first learns the links shown in Figure 7.

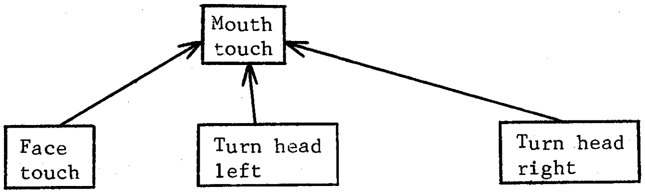

Figure 7

Although this version of the performance program will sometimes succeed in obtaining "mouth touch," it does not yet know which way to turn the (simulated) head. Next, the plausible move generator is called to provide a list of variables to be THEN'ed with the partially successful subgoals. Causality test links are compiled for the ordered-AND variables. Among them are the ones shown in Figure 8.

V1 correlates very poorly with mouth touch; V2 correlates very well. Since Pr (mouth touch V2) is very high, the performance program will activate this branch, rather than the others, and the simulated infant will emit "turn head left" in response to "left cheek touch." Similarly, it learns to emit "turn head right" in response to "right cheek touch." Finally, "face touch" is identified as a "biologically useful" variable, and the program learns to activate "lift hand"; when the (simulated) hand touches the face, the previously learned program takes over and completes the thumb-sucking operation.

One way of looking at the learning process is that the program builds a subroutine hierarchy. Each node on the goal tree defines a subroutine, the process of achieving a stimulus on the variable defined by the node; e.g., the "obtain mouth touch" subroutine. Each link on the tree defines a subroutine call. Thus, the "obtain face touch" subroutine calls the "lift hand" subroutine.

See Jones (1970) for a fuller discussion of how the experience-driven compiler is organized and programmed.

It is interesting to note the similarity between the learning sequence and Piaget's observations on the learning of human infants. Although the real infant's learning is much more complicated, it follows the same gross sequence of stages; the real infant first learns to search from left to right with its head; then it learns which way to turn; then it learns to lift its hand and suck its thumb. (Real infants also show considerable variability in their learning; for example, some have been observed to suck the thumb in the womb.)

PSIM

In order to simplify the experience-driven compiler, an interpreter called PSIM (parallel simulator) was written. The experience-driven compiler "sees" a pseudo-machine which is quite different from the actual PDP-10 for which the program is written. The pseudo-machine is much like an analog computer in which each component has the versatility of a digital computer, but where one does not need to worry about the sequence of computations; instead, each component "continuously" monitors its input lines and responds to whatever signals it finds there. Thus PSIM is a "stimulus-response" oriented interpreter which is convenient for writing programs which simulate actions in the real world.

More precisely, a PSIM program consists of a network of *variables* whose values change with simulated time and *functional relationships* which describe the way the variables depend upon each other. There is a *simulated-time clock*, TCLOCK, calibrated in seconds, which is set to zero at the start of a simulation and advances as the simulation proceeds. There is an *event file* which contains computations which are scheduled to occur at a future TCLOCK time. Each PSIM entry is of the form VAR = EXPR, where the EXPR is a LISP expression which is evaluated to get the value of the variable VAR.

If a variable V2 depends on another variable V1, and V1 changes, V2 is automatically updated. This process occurs in an interesting way: In addition to the variable TCLOCK, which records simulated time, there is another "clock," called BTIME (base time) which cycles from one up to some maximum value during each TCLOCK time. Each variable has a base time at which it is updated. The base time of a variable is set as follows:

(1) If a variable depends on the other variables only through a TCLOCK delay, its base time is 1.

(2) Otherwise, its base time equals one plus the maximum of the base times of the variables on which it directly depends; i.e., the variables in its EXPR.

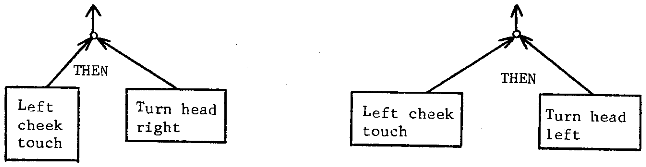

Figure 8

Variables with base time 1 are updated first, then variables with base time 2, etc. This arrangement ensures that a variable is not updated until after the correct values of all variables in its EXPR are available.

During most TCLOCK events, only a few variables change their values. PSIM ensures reasonable efficiency by recomputing only those variables which depend on a variable which has changed at the current TCLOCK time. The updating proceeds in a "wave-front like" manner, starting with a variable X which has been changed through a TCLOCK delay, then updating the variables V_i which depend on X, then the variables which depend on some V_i, etc. (See Figure 9).

Note the resemblance to a hard-wired device or a nerve net.

THE PROBABILITY-DELAY LEARNER

Conditional probabilities and time delays are estimated by a rather orthodox coefficient learning procedure (Samuel, 1959). Suppose there is a link between A and B. Whenever A occurs, followed within five seconds by B, Pr (B | A) is incremented by an amount θ (1-old value of Pr (B | A)), and Delay (A→B) is incremented by θ (actual delay—old estimate of delay). If A occurs, but not B, Pr (B | A) is decremented by an amount θ (old value of Pr (B | A)) and Delay (A→B) is incremented by θ (five seconds—old estimate of delay). It can be shown that this procedure gives unbiased estimates of Pr (B | A) and Delay (A→B), with an exponential weighting such that old occurrences of A affect the estimates less than new ones. θ, the decay coefficient, is currently 0.1. The initial estimate of Pr (B | A) is obtained by observing the first 10 occurrences of A. Pr (B | A) is set to

(Number of A's followed by B's)/(Number of A's)

The initial estimate of Delay (A→B) is the observed average over the first 10 occurrences of A.

\vdots & \vdots & \vdots & \vdots &
\end{array}$$

Figure 10

THE PLAUSIBLE MOVE GENERATOR

Recall that, mention was made of a not yet implemented plausible move generator which was to be called to make hypotheses about which variables might be causally related to some goal B. These variables are defined as "relevant" to B; the causality pattern recognizer will determine if an actual causal relationship exists. (At present, the program is running with a patch which merely looks up plausible variables in a manually prepared table.) If we tested all possible variable pairs, the machine time needed would increase on the order of n^2 where n is the number of variables, constituting an intolerably large CPU and core storage load for large n. The plausible move generator will use three relevance heuristics:

(1) (implemented) Innately known relevance—A variable A is innately known to be relevant to a variable B if A appears under B in an innately known file (i.e., a manually prepared file).

(2) The diagonal search—This will be used to associate variables which are very "important," such as a "large moving visual stimulus" and "arm motion," and will be used to make the initial connections between sensory modalities (e.g., vision and hearing) and motor units such as the arms or the head. The "important" variables will be placed on an innate list in decreasing order of importance. Let V_k be the kth most important variable. Make a square matrix as shown

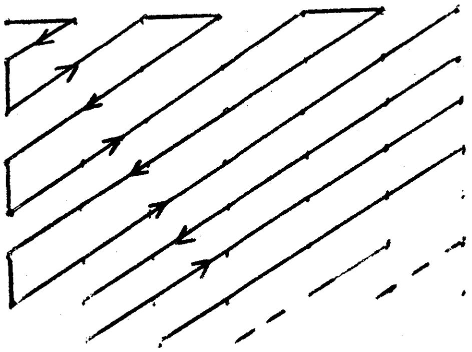

Figure 11

in Figure 10. Now let a dot represent a matrix entry and search the matrix in the order specified by the arrows in Figure 11. Roughly, the concept is that the most important variables are associated with each other first.

(3) The relevance chainer and the innate net—The innately known relevance subroutine and diagonal search subroutine will be used to get the learning process started. To continue it, the *relevance chainer* section of the plausible move generator will be used. The relevance chainer will incorporate two heuristics: (1) If x is relevant to y, then y is relevant to x (symmetry). (2) If x is relevant to y, and y is relevant to z, then x is relevant to z (transitivity). A depth cutoff will be used, so that all variables are not relevant to each other.

The relevance chainer will be used with an *innate net* which will incorporate innate knowledge about which sensory modality a given signal belongs to and innate information about space (which signals "belong together"). For a simple example, assume a one-dimensional space of touch receptors. The receptors will be arranged in an OR tree with a hierarchy of larger and larger sectors (see Figure 12). (Do not confuse this with a goal tree; the upper level variables are defined as OR's of the lower level variables.)

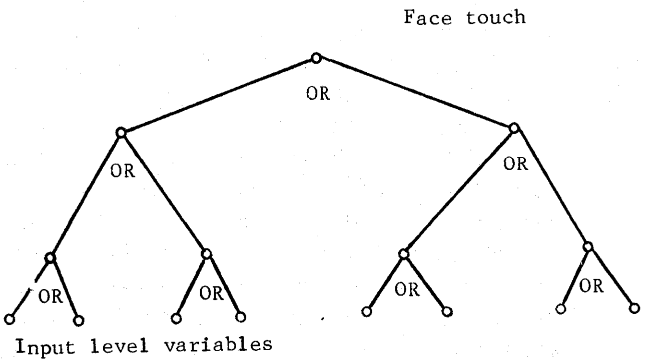

Figure 12

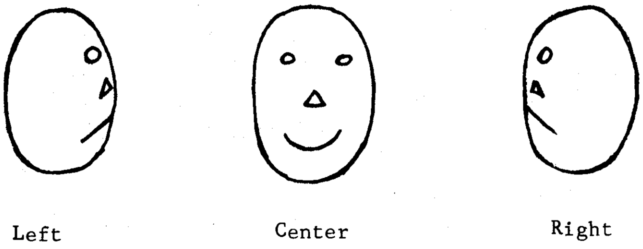

Figure 13

EXPERIMENTAL RESULTS

INSIM was tested with a simple body-and-environment simulator, with a problem environment which is a simplified version of that seen by a newborn human infant. Let us follow the growth of the simulated infant as it develops, starting from a state of passivity, then learning gradually to distinguish right from left and turn its head in the proper direction. Its ultimate achievement is to suck its thumb.

The simulated infant has a head with three positions, left, center, and right (see Figure 13). It has a blanket (Figure 14) and a bottle (Figure 15). The blanket and bottle are under the control of special manually prepared subroutines in the test package.

The simulated infant begins its life with an essentially blank performance program. At first it is completely helpless and does not move at all, since there are no motor operators in the goal tree. When it gets hungry, or, more precisely, wants pleasure, it must wait passively until its bottle appears. Although it is immobile, the infant is learning the connection "mouth touch" yields "pleasure."

Figure 14

At age 605 seconds, the experience-driven compiler is activated. The new performance program contains additional lines of PSIM code which express the goal tree link "mouth touch" yields "pleasure." The new PSIM code is then fed to the assembler-scheduler, which makes up, for each variable V, a list of variables which depend on V and a list of variables which V depends upon. Next, the scheduler assigns a "btime" (base time) to each variable, starting with btime = 1 for input variables such as mouth touch. The new performance program contains the connection "mouth touch" yields "pleasure." Mouth touch has become "important" to the infant; hence the new performance program is "curious" about things which are plausibly related to mouth touch. Among these are the head-turning responses. There are two head-turning operators, "turn head left" and "turn head right." After 10 seconds, the head automatically returns to the center position. This version of the performance program turns the head only out of curiosity; when it actually activates the mouth touch goal, it is unable to turn the head. Meanwhile, the connection "face touch" yields "mouth touch" has been made, and the "lift hand" response is enabled. Whenever the hand control subroutine receives a "lift hand" response, it computes a pseudo-random number and uses it to determine the outcome of the lift-hand operation; the hand winds up at either the left, center, or right positions relative to the infant's face.

At age 1405 seconds, the head-turning operators become subgoals of mouth touch. In this stage, the program exhibits for the first time a simple form of what psychologists call "operant conditioning" (Skinner, 1953). In the past, the program has been rewarded by a mouth touch for turning its head. Now, when it wants mouth touch, it turns its head. The program is still not very successful. It exhibits a stereotyped behavior pattern, first turning right, then left, without regard to where the object is, or, indeed, whether there is an object present or not. During this phase, the program is keeping records of the conditions under which "turn head left" and "turn head right" succeed in achieving mouth touch, laying the groundwork for the next phase of development.

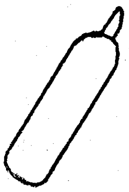

Figure 15

At age 2405 seconds, the sixth and final version of the performance program is compiled. When an object is present, the program can reliably turn the head in the proper direction. Thus the program exhibits a simple form of what psychologists call "discrimination learning"; it responds appropriately to the stimuli "left cheek touch" and "right cheek touch." The program's most advanced behavior involves providing its own stimulus object: its hand. This exhibits what psychologists call "chaining." Let us review the operating principles of the program by tracing in some detail what happens when, say, a "left cheek touch" pulse is received from the body-and-environment simulator. Variables which depend on "left cheek touch" are recomputed in a "wave-like" fashion, starting with variables which depend directly on "left cheek touch," then variables which depend on the latter class of variables, etc. Before the "left cheek touch" signal is received, the program assigns a low PR to achieving "left cheek touch." After the signal is received, the PR is set to one. Now the program assigns a high success probability to the composite goal "left cheek touch then turn head left"; previously, the composite goal also had a low success probability. This composite goal now has a higher success probability and figure of merit than the other subgoals of mouth touch; hence it is activated. Since the first half of the composite goal (left cheek touch) has already been achieved, the goal (and response) "turn head left" is activated.

ANALYSIS

The fundamental scientific issues to which the INSIM work addresses itself are:

(1) Can one make use of a relatively small amount of very general innate knowledge in order to obtain a much larger amount of specialized knowledge, and, if so, how?
(2) What should the innate knowledge be?
(3) How should the innate knowledge be incorporated into an information-processing system?

These issues are as old as epistemology itself, but the first really careful analyses were by Hume (1777) and Kant (1781). Hume took the position that the human mind was a "tabula rasa" (blank tablet) at birth and that all knowledge was acquired through the forming of associations (compare Hebb's [1949] synaptic connections). Kant, on the other hand, believed that the infant had a store of innate (categorical, or "a priori") knowledge at birth and that this was necessary to make the learning process work properly. The INSIM research supports Kant's viewpoint, based on practical engineering experience with information processing systems of this type. INSIM is associationist ("turn head left" is associated with "mouth touch"); however, in order to make the association proceed properly, innate knowledge had to be incorporated into the learning program, knowledge that there are such things as causality and time, and that causally related events are likely to occur in close temporal sequence.

A question immediately arises as to just what is meant by statements such as "INSIM knows that there is such a thing as causality." The word "know" can be used in several senses. Obviously INSIM does not know about causality in the same sense that an adult knows about causality; the program cannot explain causality, cite examples, or answer questions about causes and effects; it has no verbal behavior at all. Instead, to say that INSIM knows about a certain type of causality is to say that the INSIM program is optimized to a universe in which certain types of causal relationships exist. Thus, in a universe where there were no such things as causality or time, or where cause and effect were always separated by hours or days, INSIM would not work properly. In other words, the innate knowledge of INSIM is incorporated in the form of algorithms rather than as facts.

The learned knowledge is also incorporated into the system in the form of algorithms rather than facts. Thus the final version of the performance program knows right from left in the sense that it can turn its head in the proper direction if stimulated; yet it has no verbal knowledge of space at all. Expressing knowledge as algorithms, as in program learning, is meritorious in that it is algorithms which we know best how to combine into complex integrated systems. Thus INSIM learns a nursing subroutine, then adds additional code to form a thumb-sucking subroutine. By contrast, for a machine to learn facts is at present often like adding more books to a library; the machine cannot do much with them. Many of the theorem-proving efforts suffer from this problem. Expressing knowledge as facts has its complementary merits, as discussed by Hewitt (1969) and the present author (1966).

Given the concept of using a base of very general innate knowledge to obtain a much larger repertoire of learned knowledge, what can we say about what the innate knowledge (innate algorithm) should be; in particular, how much innate knowledge is needed and how problem-specific should it be. Why was the innate knowledge basis of INSIM chosen the way it was? For several reasons:

(1) The INSIM program has a high "bootstrapping leverage" ratio:

$$\frac{\text{(learned problem solving ability)}}{\text{(innate knowledge)}}$$

where the "amount" is to be indexed by some criterion or other. Although this is not a fact which can be easily demonstrated now, since the learning is severely limited by the body-and-environment simulator, INSIM is capable in principle of synthesizing very large trees of OR'ed and THEN'ed goals (limited by core storage), implementing long chains of behavior.

(2) INSIM is based upon a strong general theory of problem-solving, means-end analysis (Newell, Shaw, and Simon, 1959), and one can be confident of the program's ability to be extended to other goal types and to solve harder problems.

(3) INSIM performance programs are free to some extent from the "exponential explosion" problem which plagues many problem-solving systems. The simulated time to learn a tree grows only linearly with the length of the tree; the CPU time per simulated time second grows a little worse than linearly with the number of branches on the tree, and the number of branches is limited by the causality pattern recognizer.

(4) Lastly, the INSIM setup was chosen because it works; i.e., it constitutes an integrated learning-behaving system. This requirement is harder to meet than appears on the surface; I have 1100 pages of notes on setups which did not work, developed before arriving at INSIM. The incompletely successful efforts of Pavlov and Hull are also testimony to the difficulty of getting anything which will work at all.

Among the additional capabilities which are being considered for inclusion in INSIM are the ability to handle binary (non-pulse) goals, goals involving continuous valued variables, goal conflict situations, goals stated in terms of objects with property lists one-trial learning, and a look-ahead system of the type used in chess programs. An important lesson to be learned from a program of this type is that learning, rather than being a single process, actually involves a variety of ways for improving behavior based on experience.

A future objective of this work is to make it easier, in certain cases, for the machine to learn for itself how to do something than to write a program in the usual way. The learning program would need to be equipped for more advanced types of learning, including one-trial learning, and it would be restricted to problems involving long chains of cause and effect, such as robot control problems. In psychology, the objective is to use computer modeling, in conjunction with research on living creatures, to gain insight into that fascinating enigma—the human mind.

ACKNOWLEDGMENTS

This report is based in part on a Ph.D. thesis submitted to M.I.T. in September, 1970. I would like to thank Marvin Minsky and Seymour Papert for their support and encouragement, and for several ideas expressed in this paper.

An information management system for scientific gaming in the social sciences

by ROBERT C. NOEL and THOMAS JACKSON

University of California
Santa Barbara, California

INTRODUCTION

During the past decade, the use of gaming techniques has spread among social scientists. Beginning primarily in the fields of international strategic studies and business management, gaming is now used in such areas as urban studies, general economics, political science, environmental studies, educational administration, and sociology. The purposes to which gaming techniques have been put are varied. Education and training applications have been by far the most numerous, and these continue to be the areas of broadest consensus about the value of gaming. Second most common are policy-analytic applications wherein present and future problems of policy choice are examined through gaming by expert analysts and policymakers. Finally, there have been basic research applications in which gaming exercises are used as settings for more or less controlled experimentation dealing with social psychological, sociological, and political variables.

The computer has played a role throughout most of the history of gaming. Computer support has usually taken the form of discrete, man-model simulation. That is, a computer-based model of some object system is solved reiteratively, taking the decisions of human participants as inputs and reporting changes in system states as stimuli for subsequent human decisions. Another kind of computer supported gaming differs from simple man-model simulation in that it involves two or more participating entities (teams) who, while interacting with each other directly in writing and/or face-to-face, also interact with each other indirectly through their interactions with a common computer-based model (for example, a multi-firm business game or an n-player international political game). Various names have been applied to such games, including "game-simulations."

Beyond performing these simulation functions, computer support for gaming has been far less common. Bloomfield has experimented with computer-based information retrieval as an aid to decision-makers in an all-man international strategic exercise, a so-called "free-form game," in which expert judgment performs functions analogous to the computer model in a man-model simulation (Beattie and Bloomfield, 1969).[1] Gerald Shure developed a system for team-to-team written communications on a time shared computer.[2] But, to our knowledge, no comprehensive computer-based system has yet been developed for the overall administration of gaming exercises.

The purpose of this paper is to describe such a system. It is under development at the POLIS Laboratory at the University of California, Santa Barbara.* Its first version is operational on a dedicated PDP-11. It is currently undergoing major revision; an expanded version should be completed within a year. Part 1 will give a non-technical description of the system, and Part 2 will provide technical information about the architecture of the system.

GENERAL DESCRIPTION OF THE POLIS SYSTEM FOR THE ADMINISTRATION OF GAMING EXERCISES

The system performs a variety of information management functions for gaming. First, it provides chan-

* The acronym "POLIS" stands for "Political Institutions Simulation." The POLIS Lab is a state-of-the-art facility for social gaming and simulation (see Robert C. Noel, "The POLIS Laboratory," AMERICAN BEHAVIORAL SCIENTIST, vol. XII, no. 6, (1969), pp. 30-35). The Lab was established under funding from the Regents of the University of California, the National Science Foundation (GY-6345), and the Chancellor's special funds at UC Santa Barbara. This support is gratefully acknowledged.

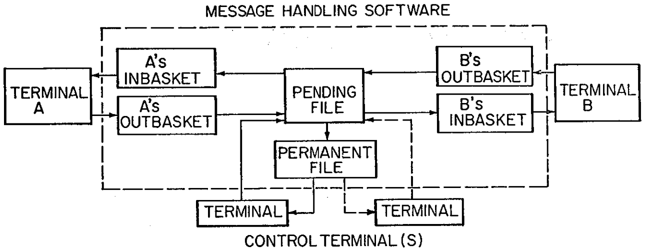

Diagram 1—*Message-handling: Manual intercept mode*

nels for written communications among player teams. Physically, the teams may all be at one site, or they may be dispersed at remote locations. In this sense, the system is essentially the same as a computer controlled teletype network. Second, the system provides control capabilities for the game director(s), including the capability to define specific communications networks, the capability to monitor communications content, and the capability to maintain complete game data files. Third, the system interfaces both game players and control staff interactively to man-model simulation programs.

In the following sections, the component programs of the system are briefly described. These descriptions are organized around two perspectives, that of the player and that of the game control staff.

Player oriented programs

The program modules described in this section perform a variety of functions for the players in a gaming exercise. They include a message handler, a text editor, and a simulation program interface module.

Message-handling

The message-handling programs in the system are designed according to an "inbasket/outbasket" principle. The system accepts a message from a user terminal when a user request is made for "OUTBASKET." The message is routed to an intervening file structure where it stays until its recipient makes an "INBASKET" request; at that time the message is printed on his terminal. These input and output events may occur at any time; they may be nearly simultaneous or hours or even days apart. How often a player interrogates his INBASKET may be left to his discretion or scheduled as part of a game's operating procedures. Straight-through, real-time communications will also be possible as a result of scheduled system revisions.

The message handler has capabilities for three modes of operation: the manual-intercept mode, the automatic mode, and a mixed mode. In addition, it embodies flexible addressing capabilities.

Message-handling: Manual-intercept mode

Diagram 1 depicts two player terminals interacting within the framework of the message handler. The routing of a message, say, from terminal A to terminal B is as follows. The message is input via A's OUTBASKET, which, in effect, stores it in a "pending file." It will remain in the "pending file" until it is acted upon by a control terminal. The system permits two or more control terminals to have this function; one or more might serve as an umpire terminal and another as an observer terminal. As will be discussed below, an operator at a control terminal can do three things to a message. First, he can reject it as is; that is, the message will be returned to A by way of A's INBASKET. Second, he can forward the message as is. Third, he can forward or reject the message after making editorial comments and changes on it.

Diagram 1 also depicts the fact that each message is entered into a permanent game file automatically as it is handled.

The idea of having control terminals as part of the communications channels stems primarily from the requirements of free-form games in which judgments by the game control staff (umpire) play an important role in the game. It also pertains to messages and documents sent from player teams to the game control staff, for example, position papers and moves.

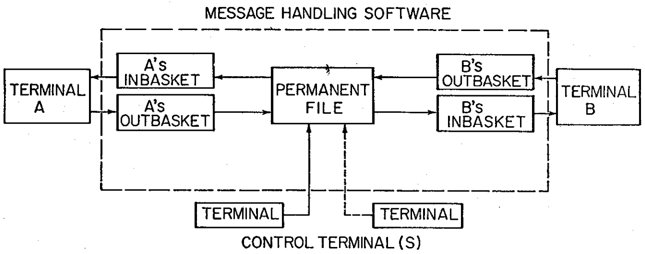

Diagram 2—*Message-handling: Automatic mode*

Message-handling: Automatic mode

When the message handler is set for automatic mode, all messages are routed to their destinations without being intercepted by control terminals (Diagram 2). As with the manual-intercept mode, each message is entered into a permanent game file automatically as it is routed through the system.

Message-handling: Mixed mode

The system provides the capability of having some sets of teams linked together in the automatic mode and other sets of teams linked in the manual-intercept mode, all within the same gaming exercise.

Message-handling: Addressing options

The message-handling software also provides the user with several addressing options. Of course, he may address a message to any other team in an exercise and to the control terminal(s). Additionally, he may input messages with multiple addresses; the system will route them accordingly. At the discretion of the primary control terminal, a particular exercise may include collective actors with group names. For example, the address "Security-Council" may include all members of the Council who are represented by teams in the game; each member of this group will receive the message accordingly. A special case of a group name is "ALL," in which case all active terminals will receive the message.

The system is able to accept player team names in natural language; it does not require numerical designations for the teams.

Message-handling: formatting

The system also embodies a few features which are designed to assist the participants in exercises in maintaining their own records. One such feature is the "paginator." At the present time it has been implemented only for messages being retrieved from one's inbasket. It prints each message on a separate page, which it measures to eleven inches in length and numbers in serial order. Anyone who has attempted to maintain order among the myriad scraps of paper which accumulate in a busy game will appreciate this feature.

Another aid to the participants and to one who is trying to reconstruct game events after the game is over is the "date/time clock." It prints a calendar date and zulu time on all incoming and outgoing messages. The clock may be set to print actual times or any past or future times desired by the game control staff.

User text editing

A second set of player oriented capabilities complements the message-handling programs. A text editor will be made available to player terminals in the future revision of the system. It will serve as an aid in the on-line composition of messages. It allows the user to delete and rewrite all or part of the line of text on which he is currently working and to delete and rewrite the entire message so long as it has not become input to the system through an "END" command.

With the scheduled revisions, the system will also accept paper tape input of messages composed off-line.

Player interaction with simulation models

A third set of player oriented capabilities allows the user to call a particular simulation program from a simulation program library. The user's request is "LIBR." The system responds with an interactive version of the particular man-model simulation called from the library. The player is given data upon which to base his decisions and the simulation program leads him conversationally through the decision sequence ending with a printed report of the results of his decisions. From each team's point of view, this capability is very much like having access to a time-shared system which computes only its portion of the simulation model. Game procedures determine the timing of these interactions. The model itself is initialized and updated by the game control staff.

Control-oriented programs

A more extensive set of control capabilities have been programmed into the POLIS game-administration system. They include programs for defining and modifying particular gaming communication structures, programs for monitoring and editing player interactions, and programs which assist in the reconstruction and analysis of games after they have been completed. These capabilities are described briefly in the following sub-sections.

Creating a game

Both logically and temporally, the primary control oriented capabilities of the system have to do with the creation of a game. These capabilities are embodied in the system's "CREATE" functions. These CREATE functions are the only control functions that cannot be delegated to any participating entity other than "POLCON," (POLIS Control), the primary control terminal.

The CREATE function enables POLCON to do the following.

(a) Set the date/time clock for the game.

(b) Specify up to forty-eight participating entities (player-teams, control teams, etc.) in a game by proper name and user code. These names may include group names, including specification of which teams belong in which groups.

(c) Restart from a previous game (the same game, in case of system failure), which eliminates the need to recreate the game.

(d) Assign functions to participating terminals, including delegating control functions. For each entity in the game, including both player terminals and control terminals, POLCON may designate:

    (1) whether it is to be able to send messages (outbasket function) and/or to receive messages (inbasket function);

    (2) whether its messages will be handled in the automatic or the manual-intercept mode;

    (3) whether it is to be able to "CALL" Control in real-time, bypassing the outbasket/inbasket message-handler;

    (4) whether it is to be able to call "LIBR" in order to interact with a particular man-model simulation program; and

    (5) whether it is to have such control functions as: "STATUS," "RETRIEVE," and "UMPIRE" (described below).

Updating a game

Another control oriented program complements the CREATE functions. It is an UPDATE program. It permits the dynamic modification of most CREATE functions, including the addition of new participating entities (by proper name), resetting the date/time clock (forward or backward), and the reassignment of message-handling functions.

"Control's" message management functions

When the system is in manual intercept mode, several message management capabilities are at the disposal of the game control staff.

(a) A "STATUS" request enables the game control staff to determine the contents of the game file for any time period and any set of participating teams. All messages are listed by time, parties, and subject matter. Their status is noted, that is, whether they are pending or whether and at what time they were forwarded or rejected.

(b) A "RETRIEVE" function is also available to the control staff. It extends monitoring capabilities to enable complete messages to be examined after they have been identified via a STATUS check.

(c) Control terminal(s) can also perform "UMPIRE" functions. These pertain to any message in the pending file. They include "EDIT" and "FORWARD/REJECT" options. That is, messages may be forwarded without alteration; they may be commented upon and edited (deletions, insertions); and messages and papers may be returned to their points of origin.

"Control" interface to simulation library programs

From a control point of view, simulation interface primarily involves calling up the appropriate simulation model from the program library, initializing the model's variables and parameters (analogous to, but different from the CREATE function), and establishing files for recording time-series data on the model in operation.

"Control's" data-making functions

The system also provides some textual analysis capabilities for the game control staff. Supplementary control terminal(s) may be established from which observer(s) may engage in real-time content analysis and commentary. This is done through a part of the umpire function. The request, "CODE," elicits a system response providing the observer with up to six empty coding categories which he may use to define content dimensions (for example, a threat) and to assign numerical rating for a particular message on that dimension. The request "COMMENT" enables the observer to append open-ended commentary to a message—perhaps an explanation of his coding judgments, or perhaps some information about the context surrounding the particular message. Neither observer coding nor observer commentary information is seen by the players; both kinds of information become part of the game file.

SYSTEM ARCHITECTURE

Hardware configuration

The POLIS system for the administration of gaming exercises was designed and programmed to execute in a hardware environment consisting of the following:

(a) PDP 11/20 CPU (with 60 Hz Clock Interrupt)

(b) 8K (16 Bit) Words Core Memory

(c) 2 Magnetic Tape Drives (Dual "Dectape")*

(d) Primary Teletype Console

(e) Alphanumeric Television Display

(f) 2 Acoustic Couplers with telephone answerers and associated control and interface logic.

Although the current system executes in the above configuration, extensive modifications are under way to take advantage of a recently acquired 64K word fixed head disc. This will result in a revised version of the system which will have features identical to the present version, but will eliminate some long interaction delays (up to 30 seconds) currently caused by frequent accesses to magnetic tape.

There is no limit to the number of acoustic couplers which can be simultaneously accommodated by the software. The number specified above reflects a core memory limitation only, that is, each additional 4K words of core above the basic 8K would allow eight more couplers to be accommodated. This is a result of the fact that 512 contiguous words of core memory are required for each coupler.

System-management software

Hardware drivers

Two peripheral-device drivers are employed by the system to manage asynchronous, interrupt-controlled I/O, a teletype driver and a magnetic tape driver. Both drivers operate in conjunction with a TASK SWITCHING PROGRAM (discussed below) to initiate an I/O transfer, to set the appropriate interrupt status bits, and to relinquish control to some other user. When the I/O transfer is complete, a hardware interrupt returns control to the particular driver which then processes errors if necessary, sets the "I/O Done" bit associated with this user and returns control to the TASK SWITCHING PROGRAM. Both drivers can manage I/O transfers simultaneously for any number of users.

Initialization and system restart

These programs operate together to initialize the following information for the system after either an initial start-up or a start-over from a system or power failure.

(a) An entity called "POLCON" (POLIS Control) is specified and allocated all of the available system functions.

(b) A Task Control Block (TCB) is created for the primary teletype console and each acoustic coupler.

(c) A Master Reset is executed to remove all interrupts pending, and control is passed to the USER REQUEST DISPATCHER.

This minimum system state is sufficient to allow POLIS Control (POLCON) to log-in and create a new game environment or reestablish the environment that existed before a system failure.

Task switching program

This program "time-shares" the use of the system among all of the I/O drivers. Control is relinquished to the TASK SWITCHING PROGRAM, which then checks sequentially the "Done" bit in each Task Control Block (TCB) and transfers control (back) to the first user it encounters whose "Done" bit is set. Thus, the following sequence of activity occurs (assuming, for example, that only two consoles are active).

(a) The program being executed by User "A" requests an I/O transfer.

(b) Control is transferred to the appropriate driver which clears the "Done" bit in the TCB associated with User "A's" console and the I/O transfer is initiated.

* Copyright Digital Equipment Corporation.

(c) Control is transferred to the TASK SWITCHING PROGRAM which then checks the "Done" bit in each TCB until it finds one that is set. If the "Done" bit in the TCB associated with User "B's" console is set, control is then returned to the program being executed by User "B."

(d) While User "B" is executing, the I/O transfer requested by User "A" is terminated under interrupt control and the "Done" bit in his associated TCB is set. When the program being executed by User "B" requests an I/O transfer, steps 1-3 again take place and User "A's" program will again gain control.

Since the system is inherently I/O-bound, this method permits each user to consider the system to be dedicated to him alone.

Clock interrupt handler

This program maintains an internal calendar/clock which is initialized and updated via "CREATE" and "UPDATE" functions.

User-interactive software

User request dispatcher

This program permits a user to log-in and execute those system functions which he requires.

The user initially gains access to the system by typing in "CTRL/P". This program then requests that the user enter his game name and two-character protection code. After validity-checking this information, the program then asks the user for the system function he wishes to execute and, if this user has been allocated this function by POLIS CONTROL, control is passed to the requested program.

All of the user-interactive programs discussed immediately below are executed as subroutines of the USER REQUEST DISPATCHER.

Message switching programs

The primary function of the POLIS system is to route messages from one user to another. Each message entered into the system is recorded on magnetic tape before being routed to its destination.

(a) *Send Message Program.* This program allows a user to enter a message into the system to be delivered at a later time to another user. The program first asks for the address of the message. This may be a single name, a group of names, a special name which represents a group of names, or all players in the game. Next, the user is asked to enter the text of the message.

The program then records on magnetic tape the addressing information, the text, and the time that the message was input.

A particular user may operate in one of two modes: manual or automatic. In the former, any message input by the user will be given a pending status and will not be made available to its recipients until POLIS CONTROL has taken a specific forwarding action. In the later mode, any message input by the user will be made immediately available to its recipients.

(b) *Receive Message Program.* This program allows a user to receive all non-pending messages addressed to him since the last time he executed this program. The program prints out the body of the text as well as the time it was received.

(c) *Console-to-Console Communication.* This function is not implemented in the present version, but it will be made available in a revised version. The purpose of the program is to link POLIS Control's (POLCON) console with that of some other user in order either to carry on a telephone-like conversation or to monitor the user's inputs to the system.

Control programs

(a) *Create Game.* This program allows POLIS Control initially to specify the entire environment for a game. The environment includes the following information.

(1) the date and time

(2) the simulation names of all users in the game

(3) the two-character protection code associated with each name

(4) any special group names (i.e., names which represent groups of users)

(5) the system functions which each of the users will be allowed to execute during the course of the game

This information is stored in the system tables discussed below. The program also makes a copy of this information on magnetic tape to permit a recovery in case of a system failure or to run an identical game at some later time. This function cannot be allocated to any user except POLIS CONTROL.

(b) *Update Game.* This program allows a (control) user to make dynamic changes in the game environment (such as the date-time). The game environment may be changed in any way, with the exception that names may not be deleted.

(c) *Message Tape Status.* This program allows a user to get a report of the messages stored on the magnetic tape. The report may be requested for any time period from the beginning of the game to the present, for any subset of senders, and/or for any subset of recipients. The report consists of the following information about each message.

(1) the sender
(2) the recipients
(3) the time sent
(4) the status of the message (i.e., pending, forwarded, or rejected)
(5) the sequential number assigned to the message by the SEND program
(6) the capsule summary of message content

(d) *Retrieve Messages Program.* The execution of this program is identical to that of the message Tape Status program except that, in addition to the information reported, the entire text of the messages is printed. This function is used in conjunction with the program discussed next to allow a controller to effectively monitor the course of a game.

(e) *Umpiring Program.* This program provides the means for a controller (such as POLIS CONTROL) to monitor the course of a game and to make significant modifications to the messages that are routed between the participants in the game. Specifically, the controller is allowed:

(1) to forward a message to its recipients or, if the message is deemed to be inappropriate, reject it back to its originator;

(2) to delete and/or insert text in the body of a message;

(3) to encode a group of categories pertaining to the content of a message; and

(4) to append an opaque comment about the message to be used in a post-game analysis of the game.

Whenever a message is modified in any way, a copy of the original is retained in order to maintain the continuity of the game for subsequent analysis.

POLIS network explanation

This program allows a user to interrogate the system to get a brief description of any or all aspects of the system.

Non-system software

The POLIS system is designed to allow execution of non-communication system programs in either of two modes; stand-alone or interactive.

Stand-alone (Library) programs

In this mode, man-model simulation programs which require the facilities of the entire computer are stored on a library tape and, when requested, preempt the execution of the system. A core image of the system is saved and the requested program is swapped into core. After completion of the program the system is restored and any game which was in progress can continue as though no break had occurred.

Interactive programs

In this mode, simulation models may interact with an on-going game in much the same way as a live participant. That is, inputs to and outputs from the model will be stored on the message tape as though they were actual messages. This function will be implemented in the 1972 revisions of the system.

Data-base structures

Task control block (TCB)

The TCB is a table of 512 core words which contains all of the information associated with a particular user console. In the current configuration there are three TCB's, one for the primary teletype console and one for each of the acoustic couplers.

The TCB contains the following information.

(a) a pointer to the next TCB
(b) the contents of the stack pointer (relative to this user's stack) at the time this TCB last lost control due to an I/O request
(c) this user's stack (64 words)
(d) the program restart address for this user
(e) the device number associated with this TCB
(f) the status of the I/O device associated with this TCB
(g) an input buffer (72 bytes)
(h) items for the address of a message to be output and the length of the message
(i) Dectape status
(j) Dectape block number to be input/output
(k) Dectape buffer (512 bytes)
(l) the entry number in the name table of the user currently using this TCB
(m) work space for the various programs which this user may execute (139 words)

System tables

The system tables contain all of the information about the current game which was initialized by the Create Game program.

(a) *Permanent Bit-Map,* which maintains an account of the currently available blocks on the message tape. There are 576 blocks of 512 bytes on a Dectape. A zero bit indicates that the associated block is available. A one bit indicates that the associated block has been used.
(b) *Date and Time calendar/clock,* consisting of twelve numerical ASCII characters which represent the date/time (formatted as: 11/1/71-09:30:30).
(c) *Name Table,* consisting of a packed table of ASCII characters which comprise the names of all of the users in the game. The names may be composed of any ASCII characters and may be of any length.
(d) *Protection Codes* (two characters), associated with each name in the Name Table.
(e) *Privilege Table,* consisting of a table of 16-bit bitmaps indicating the system functions which have been allocated to the associated name in the Name Table.
(f) *Subordinate Name Table,* which links the entry numbers of group names with the entry numbers of the participant names which they represent.

Magnetic tape files

Files on the magnetic message tape are composed of linked blocks. The first word in each block is a pointer to the next block in sequence. Files may be of any length, and a block-pointer of Zero indicates the last block in the file. Consecutive blocks in a file are physically at least four blocks apart. Each file contains the image of one message.

The Tape File Directory consists of ten blocks on the tape and is composed of 226 entries of eleven words each. Each entry contains the following information about the message contained in the file.

(a) the number of the first tape block in the associated file
(b) the status of the message (e.g., PENDING)
(c) the Name Table entry number of the sender
(d) the date/time that the message was sent (coded as twelve 4-bit segments)
(e) a bit-map indicating which of the original recipients have not yet received the message

SUMMARY

In this paper we have tried to identify the main characteristics that should be incorporated into a comprehensive, computer-based system for the administration of social gaming exercises. We have described, first functionally and then technically, the game administration system developed at the POLIS Laboratory. Our system design combines information management, simulation, and data structuring and analysis capabilities into an integrated, user-oriented package. A limited, first version of the system is currently operational on the Lab's PDP-11 system. Realization of the full design is our development goal for 1972.

ACKNOWLEDGMENTS

The authors would like to thank Messrs. Robert Dolan and Carl Magagnosc for their invaluable contributions to the programming effort described in this paper. In addition, we gratefully acknowledge the assistance of

Mr. Michael Spafford, the POLIS Lab's engineer, who kept the computer hardware operational when needed.

The senior author wishes to acknowledge his indebtedness to Gerald H. Shure and his associates at the Center for Computer-Based Behavioral Studies at UCLA. His association with that group, which included Drs. Robert Meeker, Harvey DeWeerd and Richard A. Brody, led to the development of the work described in this paper.

The development of process control software

by JAMES D. SCHOEFFLER

Case Western Reserve University
Cleveland, Ohio

INTRODUCTION

The use of on-line, real-time computers for control of industrial processes has been increasing rapidly during the past ten years. That the cost of the software necessary to implement such systems exceeds even the hardware costs became clear in the initial installations. As a consequence, much effort was devoted to the development of efficient, economical software and software approaches for use in industrial process control applications. During the past five years, there has emerged from these efforts the realization that process control software is different from software for large scale batch processing, time-sharing, message switching, or any other computer applications. It contains its own requirements and problems and leads to a distinct set of solutions. Moreover, this difference is due to more than the size of the computers involved in industrial process control. The objective of this paper is not to catalog the significant features of various software systems in existence today for this has been done very well in a number of recent survey papers. Rather, the objective is to describe the basic structure of current industrial process control software, emphasizing the unique structure of that software, how it evolved, and its current points of controversy and problems.

THE PROCESS CONTROL APPLICATION

The source of the uniqueness of process control software is due to the nature of the application, environment, vendors, and users. There is a large variety of processes in the paper, rubber, chemical, petroleum primary metals industries. Control of such processes generally involves a set of plant instrumentation including sensors, transmitters, and special instruments which provide measurements of physical and quality variables important in the process application. Such measurements may be continuous in time (temperatures, pressures, flows, thickness, speed) or discrete in time (concentrations of a stream as measured by an on-line chromatograph from periodic samples from the stream, average cross machine basis weight as measured by a scanning beta gauge, quality variables which are measured off-line in a laboratory). Process control involves the use of these measurements in order to help the human operator more economically run the process.

This objective may take one of several specific forms. For example, regulation or direct control has as its objectives the maintenance of critical process variables at prescribed values called operating or setpoints. The need for regulation of pressures, temperatures, speeds and the like, are obvious. Quality variables too may be regulated as for example maximum moisture in a sheet of paper or thickness of sheet steel. Regulation involves the basic feedback process: the comparison of measured and desired values (set points) to produce an error and the use of that error signal via a control algorithm to change some manipulated variable by a physical actuator. For example, the regulation of tank liquid level might be carried out by manipulating the position of a valve in an input stream. Such control is relatively fast, involving sampling of hundreds of variables several times per second, and outputting to actuators at the same rate. The periodic nature of this task is one of the dominant features of industrial process control in that the time sharing of the computer among many such tasks results in critical response requirements on the hardware and software.

Control is a tool rather than the end in itself and necessarily is modified from time to time as the process needs or physical structure change. The application, however, does not permit the taking of the computer off-line for program preparation but rather demands that the software be capable of modification while the process is running on-line with attendant guarantees and assurances of safe reliable bug-free operation. Hence, an essential ingredient in process control applications is operator integration which takes place through special purpose consoles oriented toward the particular application. From these consoles, an operator may examine any variable in the system, produce summary logs of the operation of the process, demand changes in parameters being used for control of the process (setpoints for example), and may even call for changes in the structure of the control system: adding variables to be scanned, adding control calculations for regulatory purposes, or deleting control loops. This implies that all of the parameters and data associated with the process control regulat:on program must be in a form which can be mnemonically referenced and modified by an operator. Thus, the data base associated with regulatory control cannot be imbedded in the programs. This leads to the special structure of this software.

Supervisory control differs from regulatory control in that the objectives are not the maintenance of process variables at particular values but rather the determination of those operating or set points. For example, operating guides are operating conditions which have been deduced during previous successful operations of the process. When similar conditions hold, the computer directs the operator to use these operating points or else justify any deviations. This takes away the option of operating the process in a safe but uneconomical manner.

Optimization of operating conditions may be the goal of the supervisory control system. Optimizing control is the determination of set points from an analytical performance criterion plus a mathematical model of the process. Successful optimal control has been carried out in the petroleum, steel, and electrical power industries among others. Supervisory control is characterized by much more complex programs than regulatory control but carries with it the same demands on reliability, centralized data base, and operator communication. That is, mathematical models of the process imply knowledge of the process state which in turn implies knowledge of all the variables, scale factors, offsets, calibration factors and other parameters which make up the process data base. The operation or status of every instrument, actuator, and control in the process is needed to determine the current state of the process. All of this information must be made available to the operator on demand and so it too must be organized in a central, accessible data base.

Many special purpose programs are necessary to support the basic application including calibration, hardware checkout, special logging and data reduction programs, startup and restart routines, and general programs to maintain and update the data base, including tables of mnemonics. In addition, the functions which are not automatically scheduled according to time or event information must be available on demand of the operator, implying an on-line, interactive command interpretive program. All of these many programs must co-exist, interact through the data base and executive control programs and hence lead to a far from trivial implementation problem. The result is the current process control software organization described in the following sections.

PROCESS CONTROL SOFTWARE

For a very brief interval, it was thought that process control software would, after initial debugging, run without change for a long period of time. If this were true, many of the problems of the initial systems would not have existed and the current structure of process control software might be radically different. The process changes often, necessitating similar changes to the software. The chief characteristic of modern process control software is its ease of change, permitting on-line modification of control algorithms and even addition and checkout of programs while the system is running. The typical computer used for industrial process control during the last five years is what today would be considered a medium-sized machine, significantly larger than today's minicomputer in the sense of attached peripherals. As a consequence, it was necessary to provide an executive control program to oversee the multiple interacting programs operating in a real-time, concurrent manner. This need, plus a desire for ease of modification and the demand for a flexible, general process data base leads to the structure shown in Figure 1.

That figure shows a conventional real-time executive control program (a monitor) along with a process data base and application programs. The distinctive part which makes it uniquely process control software is the set of application packages which are designed to carry out specific tasks in a very efficient manner while at the same time permitting easy communication among themselves, the executive, and the application programs.

Process control executive

Successful process control involves the implementation of many concurrent tasks. Process control programs doing data acquisition, control calculations, analog and digital output, operator communication and the like call for some multiprogramming capability. Executive control programs recognized this and incorporated the multiprogramming in one form or another. Early executives organized core into two partitions, one containing

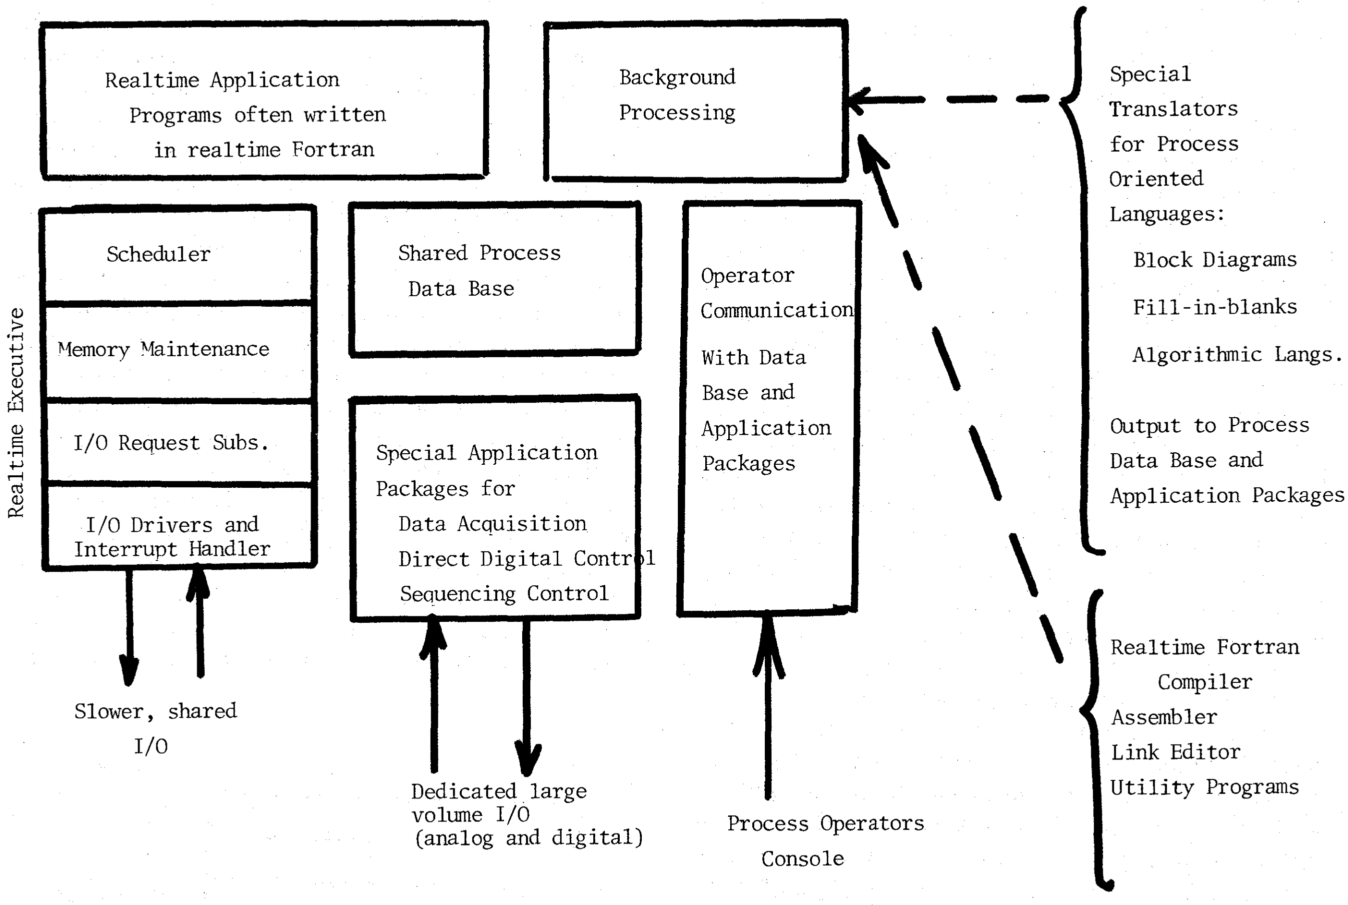

Figure 1—Structure of process control software

permanent resident programs (those requring fast response or maintaining control system integrity in case of failure of the bulk storage system) and the second being used to swap program modules called coreloads in and out of core. A coreload consists of one or more mainline application programs plus subroutines used by these programs and not contained in the permanent resident software. Coreloads may have different priorities in which case the executive often interrupts execution, swaps the coreload out (saving it on bulk storage), swaps in and executes the higher priority coreload and later restores execution of the interrupted core load.

Multiprogramming based on coreload swaps proved too slow for many applications. This led, of course, to a need for large and larger core storage so that critical programs could be permanently core resident. This motivated a change toward a more dynamic allocation of memory. The most common system is a multipartition system in which all programs assigned to a partition run with the same priority. This implies that a program, once loaded into a given partition and execution begun remains in that partition until its task is completed. Then the next scheduled task for that partition is swapped in to replace the completed program.

The partition system recognized a perhaps nonobvious fact of life of process control systems: the critical resource is not main memory but rather the bulk storage channel (usually the disk). This is especially true of systems based on moving head disks of course. Running tasks to completion minimizes the number of bulk storage swaps while maintaining the priority levels of tasks.

The multipartition system requires the allocation of a program or task to a partition and the assurance that all such programs fit in a given partition and have the same priority. This requires a careful analysis of the application but results in a smooth, controllable realtime implementation.

Most machines today are of the 16 or 24 bit word length variety. The 16 bit machines in particular take advantage of the partition system because there is no need for dynamic relocation of programs. The 24 bit machines can relatively address ±8K of core, a value sufficient to permit dynamic relocation of most process control programs (but not of the data base). In some executives, core is divided into partitions with some of the partitions being used as indicated above but with one dynamically allocated by the executive. The latter facilitates background Fortran-level processing.

Process control executives contain extensive error recovery capability because of the difficulty of restarting the system in case of a crash with critical data in core. Error recovery includes backup of I/O devices where feasible, specification of alternative devices, multiple tries at attempting reading of bulk storage, automatic power fail program backup, and automatic maintenance of copies of critical files like the process data base.

Such executives permit multitasking in one form or another but not usually in the completely general case. That is, tasks in a partition are permitted to schedule (turn on, turn off, delay, or queue) other tasks in that and other partitions. However, the allocation of the task to core is predetermined and its priority is not dynamic, but rather pre-assigned. This has proved necessary not only because of the difficulty of dynamic relocation but also because of the need to guarantee a maximum response time for critical real-time programs.

I/O in these executives is handled in the straightforward manner, using I/O drivers and I/O request subroutines. Drivers are responsible for the maintenance of the interrupt driven I/O with the actual device, outputting or inputting one character or word at a time usually with one interrupt per data item transferred. Little I/O is done through direct memory channels except in the case of bulk storage devices. The I/O request subroutine is used to control the competition among many tasks at different priority levels from interfering with one another. Such routines queue requests, notify routines (reschedule them) when a requested I/O operation is complete, test device status, etc.

As long as the volume of I/O is low or the response time of tasks not critical, such an organization is quite sufficient and essentially like any other application. That is, none of this software is unique to process control.

Two situations arise, however, which call for unique process control software. They are: the need for high volume, very flexibly organized process I/O; and the need for mnemonically oriented operator communication. These require special packages for their implementation and are discussed below.

Special packages for data acquisition and control

The need for generality and flexibility in the typical industrial data acquisition system is paramount. Not only is it desirable to be able to change the parameters of the data acquisition loop or the status of a sensor from active to inactive, but also to be able to add and delete from the list of points in a flexible fashion. Thus, if a sensor is added to the system, it is desirable that the operator be able to add the point to the list of converted values, including all the appropriate parameters necessary for the conversion and all the linkages to control programs associated with the variable out of limits, bad data, and so on. This, of course, can be done by reprogramming the routine, but is undesirable and not necessary. The basic operations involved in converting a point are similar from point to point. The scan routine uses the address of the point, values for the amplifier gain, limits, etc., and in effect, applies similar sequences of algorithms to each of the points to be converted. A data acquisition package takes advantage of this as shown in Figure 2 which shows an interpretive scan program and a set of data structures called loop records, with one loop record associated with each point to be converted. All the data and parameters associated with a particular point is stored in the record, including the

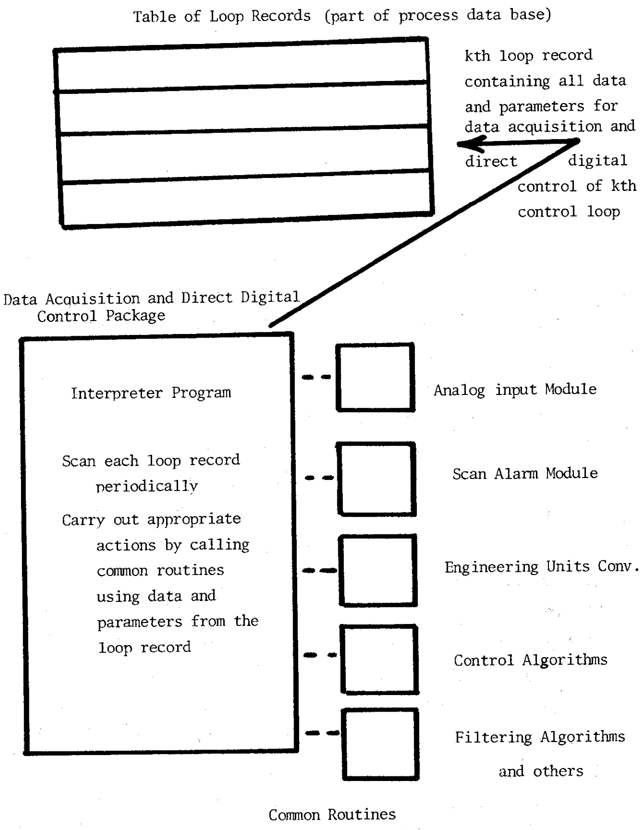

Table of Loop Records (part of process data base)
kth loop record containing all data and parameters for data acquisition and direct digital control of kth control loop

Filtering Algorithms and others
Common Routines

Figure 2—Example of data acquisition and direct digital control package

period or time between conversions, status of the point, external names, etc. The interpretive program scans the records in some sequence until it finds one which is scheduled for conversion. It then examines the loop record to determine the appropriate data and algorithms to be carried out on that data point. Pointers to the individual algorithms to be carried out on the point, followed by the parameters to be used by that algorithm, are stored in the loop record. If any error is detected in the conversion, an error recovery routine is entered and executed. This might include an attempt to reconvert the point or to estimate the current value in terms of the previous value (which is stored in the loop record), or preparation or notification of either a program or the operator. The interpretive program then continues through the loop records, is offset and scaled. After conversion to engineering units, the data is limit checked for validity, alarm checked, and perhaps digitally filtered by a moving average filter involving the current value and the previous several values. The set of loop records is a very well organized process data base. The loop record concept is a very flexible one in that the actual algorithms carried out on any particular data point may vary considerably by simply changing the parameters and pointers in the loop record.

The only portion of the program particular to a specific set of data points to be read is the information stored in the loop records. It follows that the interpretive scan program can be written and debugged without actual knowledge of a particular application except that all algorithms which might be needed in the application must, of course, be provided. Individual points can be added or deleted by creating or deleting one of the loop records. Because of the fixed format of the system, it is possible to organize the various loops so that not all points with the same conversion period need be carried out at exactly the same instant of time. That is, points with the same conversion frequency can be subdivided into smaller groups which are converted at the correct frequency but offset or phased with respect to one another in time.

The efficiency of such a system must be considered. The interpreter scans through items in a loop record and in effect calls small modules or sub-routines to carry out the desired operations. There is a certain amount of overhead associated with scanning through the loop record, determining which routine is to be carried out, transferring to this module or routine, as well as extracting from the loop record the parameters and data needed by that algorithm. If the module or algorithm is too small, it follows that this overhead involved in scanning, transferring and extracting parameters, may be comparable to or even large compared to the time to carry out the algorithm. The result would be excessive overhead, for inline code to carry out the same task would be more efficient. The objective is, of course, to use modules whose execution time is large compared to the overhead or scan time so that no real overhead penalty is incurred. The overhead associated with interpreting the loop records is offset by the flexibility of the system. Most important is the ease of operator communication with the data base.

If this can be done, of course, the generality and flexibility of the interpretive loop record organization can be achieved without discernible overhead penalties. Whether or not this can be done is dependent upon the organization of the loop record, the instruction set of the computer, and the addressing modes available in the computer.

Control loops lend themselves to a similar loop record organization. Additional functions (filtering, control algorithms, error checking, outputting, etc.) are listed in loop records often along with the data acquisition information and interpreted by the same or a similar routine. The result is a separate data base and data acquisition and control package which may be interrupt driven independent of the executive or possibly assigned a high priority level and controlled by the executive.

The special purpose packag? relieves the application programs from considering the data acquisition and direct control task in great detail including error checking, organization of operator communication, and startup. Other applications are similarly best handled by special purpose packages. These include sequencing control—monitoring the state of the process and causing events to occur (turn on burners, valves, etc.), in the correct sequence and when prescribed conditions are met. Examples include batch processing of chemical processes, control of annealing lines, and the like.

Operator communication becomes a straightforward task with a data base arranged as described above. Interface routines to the data base provide application programs the ability to read or write any particular item in any record (including a full complement of error checking). Copies for backup and restart are available because of the centralized location of data as opposed to its distribution throughout application software.

Operator interaction through a console limits the amount of error checking necessary and makes a very acceptable system for use in an on-line situation with operators who are not trained computer operators. Function keys are the most common communication scheme with labeling in industry-sensible terms. Functions limit the complexity of the operator console support routines but nonetheless are nontrivial in size.

In larger systems, it is convenient to separate the data base into two parts, that which is essential to incore reliable operation in case of disk failure and the remainder which is then swapped in and out of core (perhaps on a single record basis) as needed.

In addition to special packages which are unique to process control, other application programs are provided which may interface to the executive and the special purpose packages. Optimization is an example, permitting optimal control of a process unit provided a mathematical model and sufficient measurements are available. These differ from other application programs only in that they are "canned" rather than written by the user in a higher level language. Typically, they interact considerably with the data base and its support routines.

SOFTWARE PREPARATION FOR PROCESS CONTROL

Current medium-sized and larger systems universally provide the ability to write application programs in higher level languages, most notably, extended Fortran. This is both to limit the level of expertise of programmers but also to permit control engineers to produce application software. With intelligent use of data acquisition and control data base packages provided by the vendor and the general process control real-time executive control program (including all its entries for scheduling, error checking, I/O control, etc.), higher level language programming becomes quite feasible, especially in applications which involve significant computation. Other applications are developed more efficiently via packages like the data acquisition or direct digital control packages described above. These are usually programmed in assembly languages and linked tightly with the executive. In some cases, they are assembled as part of the executive.

The net result in Figure 1 is an executive which does not control all I/O but only that which is shared among application programs. Special purpose packages maintain a centralized data base and perform specialized control functions. Application programs perform tasks on a somewhat slower basis, but interface extensively to these packages through normal system subroutines.

Because of the need for flexibility and change, on-line program preparation is needed in most process control systems. This takes the form of a background command processor, compilers and assemblers and library maintenance routines as well as link edit routines. Program preparation including debugging can be done in a controlled manner in one of the partitions, without upsetting the remainder of the software system.

In recent systems, macro assemblers have become available, even including libraries of system macros which permit a user to custom tailor the operating system software to his particular application (at least in the minicomputer process control systems). At present, few cross assemblers are available and even fewer cross compilers for software preparation on time-sharing or batch data processing systems.

Much more significant is the preparation of data inputs for the dedicated application packages. The data base contains all the information needed for the carrying out of these dedicated tasks. The operator console, with its function keys, provides on-line data entry, program change, control application modification, and the carrying out of operator commands. Off-line program preparation is through translators of one form or another. The natural language for the application might be a block diagram indicating the interconnection of the measurements, setpoints, filtering, control and feedforward algorithms. Specified this way, they must be translated to data to be stored in the internal data base for interpretation.

Many such communication languages have been developed in order to provide a means for process engineers who are not trained programmers to set up and maintain an application involving hundreds and even thousands of variables. Such systems specify the application in an English language fashion which is then translated to internal data storage. Others are of the "fill in the blanks" form which is a questionnaire which is completely self documenting (and 100% of the documentation) and which, when punched line for line on cards, provides input to a translator which generates interval entries in the tables of the various packages.

With these programs, an application can be put onstream very rapidly since the essential programming is done and debugged independently of the particular application. Moreover, the change from one control structure to another (one startup procedure to another, etc.) is very straightforward, amounting only to change of data but no essential reprogramming. There is little penalty incurred in changing the control software, even less than in the case of Fortran programming of application programs. As mentioned in the next section, this package concept is less economical today because of the introduction of minicomputers.

The other trend today is toward the use of "realtime languages" for process control, even involving an attempt at a worldwide standard. There is a difference of opinion as to the economics of standard process control languages. As noted in Figure 1, the bulk of process control software lies in the executive and the application packages. Application programs tend to be written to use these programs and hence are less expensive (the complexity of the real-time application is imbedded in the application packages and the executive). One school of thought advocates the need for a higher level system programming language for the economic and efficient production of the executive and the application package or at least the tailoring of these standard packages to a given configuration and application. The other school of thought argues that these should not be specialized or customized but be standard so that they can be supplied by any vendor (and at reasonable cost since they can be written off over a large number of installations). This school of thought then argues that the remaining cost is in the application programs and that a language ought to be adopted for this purpose (extended Fortran, or some modification of PL/1 or Algol are among the suggestions).

It appears that no economic study has actually been carried out to determine the savings which might result from either of these approaches. The latter case already provides extended Fortran so that only incremental gains can be expected. The former case is difficult to assess because it depends upon the need for changing of standardized software packages or adaptation of these to various configurations of computers. If it were not for the minicomputer, data could eventually be gathered. However, as indicated in the next section, the minicomputer is changing the economics of process control software significantly.

CURRENT PROBLEMS IN PROCESS CONTROL SOFTWARE

The development of process control software over the past five years or so was directed toward the organization of Figure 1. Recently, packages for data acquisition and direct digital control, sequencing control, batch processing, process optimization, model identification, graphic operator communication, and others were developed. If the use of medium-sized machines continued, this software would have resulted in significant decreases in costs of process control software implementation. Several problems, however, indicate that further development is necessary.

First, the use of a medium-sized machine is difficult to justify economically in many applications. The capability of such machines is such that many tasks can be carried out by a single machine. This, in turn, places severe demands on the executive and application software in order that the installation can be carried out smoothly. Moreover, the process itself must be large enough to justify such a machine and such extensive software costs.

The advent of the minicomputer with its low cost has changed the picture considerably. The lower cost of small configurations implies that several tasks need not be implemented in a single machine in order to justify the use of a computer for control. This, in turn, implies that perhaps the extensive software developments of Figure 1 are not necessary for any smaller applications. The result has been the use of minicomputers for many small applications which in previous years had used larger machines. This, in turn, implies that the number of systems to write off software package development has decreased considerably. Hence, larger systems with very sophisticated software packages have recently been more difficult to economically justify.

The minicomputer poses a set of problems which are considerably different. First, the varied configurations and applications do not always require complex executive or monitor systems. Consequently, there is less justification for the development of extensive executives on the part of vendors. The result is sometimes more software development for the minicomputer system than for a larger installation, robbing the system of its apparent economic advantage over the larger system.

A second source of difficulty is the multicomputer configuration. The use of minicomputers for dedicated applications still requires the coordination of the systems to achieve overall process control including scheduling and higher levels of control. Hooking together a number of small machines each implementing a portion of the application is far from trivial for there is still a need for a coordinated data base and operator communication even if the application is distributed over a number of machines.

A related problem affecting the development of software for smaller machines is the rather commonplace prediction that the bulk of sales for systems will lie in discrete parts manufacturing rather than process control. The software necessary for this application has not been widely developed and agreed upon but will certainly affect the organization and structure of future minicomputer process control software.

The current question in process control software is how to economically produce the special purpose real-time programs necessary for a low cost but efficient implementation in a stand-alone minicomputer. In addition, how can the advantages of packages for specific applications be gained since it is difficult to develop them such that they are compatible with the varied configurations and computer systems arising today? Perhaps the answer is a higher level systems programming language with program preparation on a host machine. Perhaps the answer lies in generalized software preparation schemes such as are used to generate execution programs for large data processing machines. Perhaps the answer lies in the use of sophisticated template macro assembly languages. Whatever the answer, the well developed process control software concept is today facing a period of rapid change similar to that of five years ago.

Future trends in software development for real-time industrial automation

by H. E. PIKE

General Electric Manufacturing & Process Automation Advanced Development Operation
Lynn, Massachusetts

INTRODUCTION

"The __________ is a desk-size, stored program computer. It has a medium-scale capacity and uses a single address system. The __________ has all the advantages of high component reliability, automatic operation, and ease of programming." [1]

These words are from the introduction of the operations manual for one of the first minicomputers—the "LGP 30 Royal Precision Electronic Digital Computer." The manual was written in 1959. In twelve years we have just barely begun to understand the impact of this size computer upon the industrial automation.

In this paper we will examine future trends for programming for process control and real-time applications of industrial automation. Although blind forecasting is exciting, we will take the more conservative approach of examining past history and our current environment for factors which will lead to future developments. A short definition of the scope of applications considered will be followed by examination of current technological and economic trends. A brief recap of the companion survey paper by Schoeffler[2] will serve to establish the current state-of-the-art and a survey of current active development and/or standardization activities will be followed by predictions for the future. These predictions will be made from the fundamental viewpoint that future developments are determined by three factors: the current state-of-the-art, current problem areas, and new technological tools available for reduction to practical use. An underlying assumption is that there is or will be sufficient economic motivation to undertake the developments required, with timing being the only uncertainty.

RANGE OF APPLICATIONS

It is necessary to be more specific about the range of applications to be discussed. Future trends in real-time industrial automation will be discussed, rather than the more encompassing possibility of all real-time applications. Not included in our considerations are the applications typically called command and control, teleprocessing and interactive management information systems (certain portions of our discussions will, of course, apply to these areas).

Typical real-time industrial automation applications span a range from direct numerical control to load flow control and economic dispatch in the electric utility industry. Also included are direct digital control of chemical processes, supervisory control of chemical processes, sequencing control on assembly lines, control of batch chemical processes and computerized numerical control (see References 3-13).

In direct numerical control a small, fast, dedicated computer is used to control a machine tool directly. Typical required response times are on the order of milliseconds. Load flow control calculations on the other hand involve large data-handling requirements because of large matrix inversions, and involve response times of minutes.[14]

In direct digital control the computer directly manipulates the positions of control elements such as valves without an intermediate mechanical control device. Direct digital control requires response times on the order of seconds to disturbances in the controlled variable.[15,16,17]

In supervisory control the computer is used to provide setpoints which are then actually controlled by hard-wired analog equipment. In this case, the real-time response capability of the control system is on the order of minutes.

We could go on, but the point is clear: there exists a tremendous range of application requirements in this area which we have labeled industrial automation.

PRESENT STATE-OF-THE-ART

Schoeffler[2] has assessed the current available tools for software development. To summarize, in practical

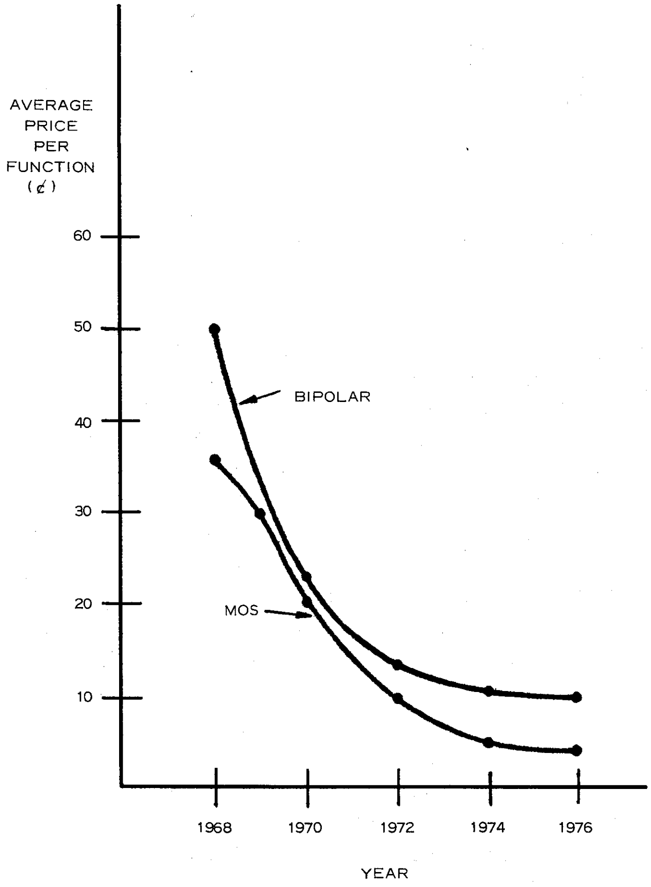

Figure 1—Digital integrated circuit cost trends

use today we have as wide a range of software approaches as there are applications,[18,19] about which the following statements seem to hold.

- Most of the real-time programming is still done in assembly language.
- Various dialects of Fortran have been tried, with mixed results. They have been most successful where a high content of engineering calculations is included (References 20 through 27).
- Initial experiences with problem-oriented programming systems appear very promising, particularly when two conditions are met:
  —functional similarity between installations, allowing a reasonable match between programming system and control problem (References 28 through 38).
  —sufficient economic base to merit development of general purpose packages.
- Various attempts at general purpose real-time languages have shown the concept to be feasible, but have remained as academic exercises, in part because of the inherent restrictions due to programming architectures of current computers (References 39-47).

CURRENT TRENDS

Two current trends will combine to motivate future development of improved programming techniques: microelectronics, and recognition of the cost and complexity of the software production process.

Microelectronics

The dramatic downward trend in price/function in microelectronics is widely recognized. Figure 1 is typical of the current extrapolations of this trend. An easily customized MOS/LSI desk calculator chip has been recently announced at a reported volume price of less than $20.48. Our colleagues in the hardware design area confirm that this device is comparable in logic power (in terms of gate equivalents) to the LGP/30 of ten years ago discussed above.

If this isn't enough, a major manufacturer has announced a CPU on a chip, of perhaps five times the complexity of the LGP/30, and our R&D associates advise us that such devices with electrically alterable ROM's are feasible, for the ultimate in flexibility.

The message is clear—Software functions will disappear into hardware (or firmware) and modest investments in increased hardware capability (if made correctly) will reap outstanding software cost savings.

The software development process

Another important trend is increasing recognition of the difference between "programming" and "software development." Examining the following breakdown of the software production process makes this distinction clear:

1. Problem analysis
2. System structure design
3. Logic design
4. Program coding
5. Language processing
6. Unit test and debug
7. System test and debug
8. Installation
9. Maintenance

Although we all agree that the cost of software development exceeds the cost of hardware, we cannot find any common agreement as to particular areas of concentration of cost within this breakdown of the software development process.

CURRENT ACTIVE DEVELOPMENT AND STANDARDIZATION ACTIVITIES

A number of industry-wide and university related standardization and development activities are taking place which will influence trends for process control programming. Among these are the Purdue Workshop on Standardization of Industrial Computer Languages,[49] the American National Standards Institute's PL/I Standardization and Development effort, and several university programs in industrial automation.

Purdue workshop

The Purdue Workshop on Standardization of industrial computer languages has stated as its objectives:

1. To make procurement, programming, installation and maintenance of industrial computer systems more efficient and economical through the development and standardization of industrial computer languages.
2. To minimize educational and training requirements for the use of industrial computer languages.
3. To promote program interchangeability of application programs between different computer systems.

The standing committees of the workshop include:

1. Long Term Procedural Language Committee
2. Problem Oriented Language Committee
3. Glossary Committee
4. Fortran Committee
5. Steering Committee

The workshop met first in the spring of 1969 and approximately every six months thereafter.

AMERICAN NATIONAL STANDARDS INSTITUTE SUB-COMMITTEE X3J1

X3J1 is a sub-committee of Committee X3 of the American National Standards Institute whose scope is the proposal of a draft American National/ISO Standard Composite Programming Language based on PL/I. X3J1 is organized into four working subcommittees which are responsible for:

1. Standardization
2. Development
3. Subsets
4. Development for Industrial Computers

The scope of Committee X3J1.4, PL/I Development for Industrial Computers, is the development of a version of PL/I suitable for application to process control and manufacturing automation by defining and fulfilling the functional requirements of this application area. A basic rule governing this activity is that any string of characters which has validity in the language being developed and the PL/I that X3J1 proposes as a standard must have the same semantics.

X3J1.4 and the Long Term Procedural Language Committee of the Purdue Workshop are currently cooperating to determine if the production of a single result is feasible.

UNIVERSITY AND OTHER ACTIVITIES

Various university laboratories both within the United States and abroad are active in the development of real-time languages and/or programming techniques for industrial computers.

Some of the germinal early real-time language work in the United States was done at Case-Western Reserve University in their Systems Research Center. The Purdue Laboratory for Applied Industrial control continues as sponsor of the Purdue Workshop. Results of significant interest have appeared from the University of Toronto, and German, French and British working groups.

FUTURE TRENDS IN SOFTWARE DEVELOPMENT FOR REAL-TIME INDUSTRIAL AUTOMATION

We have noted above a number of forces which are currently at work to influence future trends:

1. Microelectronics—a capability to produce very powerful central processors at reduced cost.
2. A complex software development problem for real-time application.
3. A current proliferation of programming techniques which are more or less satisfactory, depending upon their match to the application for which they are used.
4. A number of currently active development and standardization activities working in areas which range from customized problem-oriented languages to development of real-time version of PL/I.

Consideration of these forces leads us to believe that the following trends will become evident in the future.

1. Computers with architectures more oriented to the use of special purpose real-time programming languages.
2. Hidden computers.
3. High-level real-time languages.
4. Problem-oriented languages.
5. Software factories combining sophisticated languages and debugging tools for the more effective and efficient production of software on host computers.

New real-time computer architectures

Because real-time computers are special purpose rather than "general purpose" machines, a trend will occur toward more customized architectures, particularly from a programming point of view. Characteristics of these new architectures are likely to include:

1. Bit addressability
   Arrangement of data in a real-time computer in quanta of 8 bits is not very meaningful in the real-time environment. Character oriented data is manipulated relatively seldom in a real-time environment. Convenient methods of accessing data fields of varying widths will be required for convenient implementation of data structures, for example.
2. Direct implementation of real-time features
   Real-time features such as semaphores, more powerful interrupt structures with less inertia, and direct hardware support of event data will ultimately be implemented directly in the hardware.
3. Control structures
   Because sequencing problems represent a high percentage of real time calculations, the instruction repertoire of real-time computers will become more oriented to the easy implementation of more sophisticated control structures.
4. More sophisticated addressing techniques
   Although recursion is not high on the list of requirements for real-time applications, the ability to handle reentrancy in a concise manner is important. This and other requirements such as the manipulation of inhomogeneous data aggregates will dictate more sophisticated addressing modes.

When these more powerful architectures will occur is not entirely evident at this time. It seems that an orderly approach would be to pursue a more consistent definition and understanding of the true real-time language requirements and then let these architectures be designed to support such languages (Refs. 50 through 60).

Hidden computers

The capability to build special purpose hardware will, in the future, increase the trend toward distributed digital systems. The computational capability of real-time process control systems will not be concentrated in one central processor as is typical now but will appear both in the central processor and a number of remote dedicated processors which function to gather intelligence about the process under control, execute direct control functions and communicate to the central processor for supervisory control functions. The major force which will cause this to occur is what is sometimes called "the cost of copper." This expression refers to the fact that in many installations it is possible to spend as much installing the wiring to carry signals from sensors and control devices back to the computer as on the computer itself. The impact of this trend upon programming techniques is that these devices will, to all intents and purposes, be hidden from the user. They will perform their functions in a manner analogous to hardwired hardware devices in current use, and the programming problems associated with direct control will frequently be segregated from the rest of the system. As an example of the importance of this, it has been found that in the development of large systems for both supervisory and direct digital control that such major differences in operating systems are required to support these two control techniques as to make organization of a system with a combination of them rather difficult and costly. The use of hidden computers will reduce this problem significantly.

Problem oriented languages

For those users who have applications of some generality, problem oriented languages and systems seem to be unquestionably the best long term solution to their software development problems. There is no question but that a truly general package incurs a penalty in overhead and excess hardware requirements, but with the cost trends in hardware which we have discussed, it will become more and more apparent that this is the most economical solution. As an example, our experiences with certain problem oriented packages have been that they can reduce the programming requirements by a factor of 10 and allow personnel whose major area of specialty is the application rather than software to do the programming. This usually results in a much better control system. Thus, on the belief that what is best for the user will eventually ensue, we predict that for many of them, their problems will be solved by problem oriented systems which will very much minimize their requirements for a professional programming staff.

Real-time procedural languages

As we have seen, the major real-time languages in current use are variants of Fortran. Table I shows some of the typical extensions which have been made in Fortran for this application area. It is clear from examining the length and breadth of these extensions that if an all-encompassing procedural language based on Fortran were to be implemented, the base language would disappear. For this reason, current development activities are now turning in a different direction.

The general goals of real-time procedural language development activities under way today are to develop a language which leads to:

1. Lucidity—the clear expression of what is to occur when a program is executed, providing a higher level of self documentation.
2. Freedom from side effects—in a real-time environment a predictable system behavior is extremely important and real-time programming languages must be free from side effects.
3. Enforcement of programming discipline—in the business of producing software, it is clear that programming discipline is increasingly important. A well designed language will help maintain this discipline.
4. Natural modularity—the language must be constructed so as to make easy increased modularization of real-time systems.
5. Ease of learning and use—it must not require a major investment in training to put a new language into use, if possible.

Also of particular interest to the designer of a real-time procedural language is the maintenance of a proper balance between run time efficiency, integrity

TABLE I—Typical FORTRAN Extensions

- 1 Program & Data Structure
  - (a) Data types
    - Fixed point
    - Bit

TABLE II—Some Functional Requirements for a Real-Time Language

I. *INTERRUPT HANDLING & SYNCHRONIZATION*

- A. Interrupts
  1. Ability to indicate that some program segment is to be executed upon the occurrence of some particular interrupt.
- B. Events
  1. Ability to retain the flow of control at a point in a computational process until some event has occurred.
  2. Ability to cause the occurrence of an event at some point in a computational process.
- C. Synchronization
  1. Ability to synchronize parallel computational processes with security.

II. *TASKING*

- A. By a task on itself.
  1. Schedule Execution
  2. Find Status
  3. Exit
  4. Kill
  5. Delay
  6. Wait
- B. On another task
  1. Execute
  2. Schedule
  3. Suspend
  4. Delay
  5. Terminate
  6. Set Priority
  7. Find Status

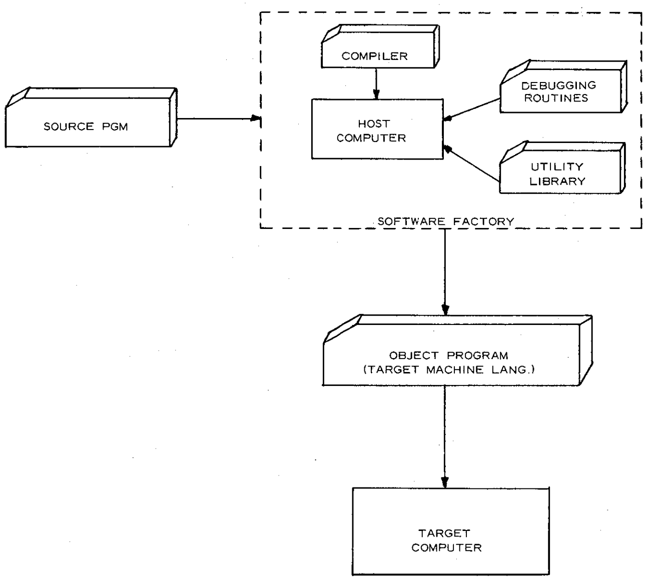

Figure 2—Software factory

of the system and ease of programming. A general set of functional requirements for a real-time language is shown in Table II. Whether these languages will be general purpose[61] or dedicated to particular architectures[62] remains to be seen.

Software factories

Just as the ultimate elimination of the requirements do a great deal of custom programming by the use of special purpose application packages is the ultimate answer in reducing software costs for the users of real-time automation systems, the development of a unified, well-designed software will provide the mechanisms for more economical development of such systems. Figure 2 shows the general nature of such a software factory. It consists of four major elements; a compiler for a high-level language for systems software development, a utility library of building block software modules, a well organized approach to debugging software produced in the software factory, and a powerful host computer upon which the system is run.

The general-purpose real-time language described above will be used with the debugging system to develop the utility library and various application packages.

Debugging system

One of the major motivations for using a large host computer for software production is the more powerful facilities which it makes available for software debugging. The well designed debugging system for the software factory will attack three problem areas:

1. Observability—to make more visible the actions of the program being tested.
2. Controllability—to allow the programmer to control the flow of control within his program to suspect control paths.
3. Repeatability—to insure that the same response occurs from given stimuli, aiding problem diagnosis.

Table III lists the features generally used in such a system to achieve these goals.

There is still some disagreement between the use of source language debugging through compilation to host machine executable programs, and direct instruction simulation of the target computer. Each point of view has merit. The source language execution approach allows speedier execution and provides for quick elimination of gross structural errors in the program. Simulation of the target computer at the instruction level is generally more expensive because of increased execution requirements on the host computer, but allows one to locate more subtle errors, particularly those with respect to behavior of the target machine hardware in unusual timing circumstances. (The latter requires, of course, an extremely sophisticated simulation of the target computer system.) In the future both techniques will play an important role (References 63-68). (It is interesting to note, however, that the ultimate distinction may be moot as target machines come closer and closer to executing high level languages directly.)

Utility library development

Perhaps the most significant aspect of this overall software factory will be the availability of software modules for use in building real-time systems. The

TABLE III—Features Required in Debugging Systems

1. Breakpoint removal and insertion
2. Online variable revision
3. Insertion and removal of snapshot dumps
4. Execution initiation or transfer of control to any point
5. Fault trapping
6. Incremental addition of new instruction
7. Variable searches by value
8. Subroutine call and operating system linkage tracing
9. Input/output and interrupt simulation
10. Control of internal timing

modules required may be grouped in four categories:

1. System building modules
   These modules will form the components of various language processing systems desired by the user. With the use of these modules, the development of special purpose language processors for various applications areas will be made much more economical.
2. Application modules
   Modules of on-line application software will be available for combination into application-oriented control software packages. Examples of these modules will be software for direct digital control, supervisory control, and real-time data base management.
3. Systems operating modules
   Operating systems as we know them today may very well disappear in the future. Instead, the various operating system components like interrupt handlers, generalized input/output systems, priority schedulers and executives will be available for combination as required.
4. User interface modules
   Customized user interface modules will be available for each application area. These modules will actually include the linkages necessary to combine the library modules and any specially developed software into a functioning control system.

SUMMARY AND DISCUSSION

We have examined a number of interesting trends in real-time software development. Of particular interest is the three-way interaction foreseen between the development of new, more powerful architectures for real-time computers, more powerful high-level programming languages, and the integration of these programming languages into a more efficient software production system.

The most interesting technical challenge in this situation is the opportunity to develop languages and architectures in a unified manner. In the past the designer of computer architectures has been far removed from consideration of the application requirements, and his products have been extremely difficult to apply. The designer of real-time programming languages now has the opportunity to act as a coordinator in this overall process while insuring that the language fulfills the functional requirements of the application area hand, he will coordinate with the compiler developer and computer architecture designer to insure that the resultant combination of languages, software factory, and computer form an integrated system for the efficient solution of real-time automation problems.

Exact timing of these trends is very hard to forecast. Working prototypes of most of the items discussed exist today. When the economics of the marketplace are satisfactory, these prototypes will be turned into smoothly functioning systems for general use. Development of languages and architectures are already under way. As this work matures the software factory concept will provide the unifying factor which knits this all together.

Scheduling of time critical processes

by OMRI SERLIN

SYSTEMS Engineering Laboratories
Fort Lauderdale, Florida

INTRODUCTION

In real-time applications, the computer is often required to service programs in response to external signals, and to guarantee that each such program is completely processed within a specified interval following the occurrence of the initiating signal. Such programs are referred to in this paper as time-critical processes, or TCPs.

A problem of considerable practical significance in connection with such applications is that of devising scheduling algorithms for servicing multiple time-critical processes. The primary objective of any such algorithm is to guarantee that each TCP can be processed within its allowed interval, taking into account the possible activities of other TCPs. It is clear that, assuming an upper limit can be placed on the repetition rate of the prompting signals, this objective can always be met if, for example, each TCP executes in a separate, sufficiently fast CPU; or, if a single CPU of some high, but finite, execution speed is furnished. Either approach is wasteful in the sense that the CPU (or CPU's) must sometimes remain idle in order to allow for some "worst-case" condition that occasionally may obtain; for example, when all interrupts occur simultaneously. Thus the scheduling problem becomes non-trivial only if additional constraints are imposed. Two such practical constraints are that only one CPU is available, and that the processor idle time is to be minimized.

This paper examines four specific scheduling policies, subject to these constraints, and outlines some of the more interesting properties of each.

DEFINITIONS

Time critical processes

In the context of computing systems, time critical scheduling is the problem of devising *efficient* CPU allocation policies that satisfy the requirements of multiple *time-critical processes* (TCPs). These processes, arising naturally in real-time environments, are computational procedures bound by *hard deadlines.* A process bound by a deadline must, once initiated, complete its computation on or before the specified deadline. A *hard* deadline implies that a failure to meet it results in an irreparable damage to the computation. Such deadlines are typically due to stability and accuracy considerations in the process being controlled (e.g., the analog computation portion of a hybrid system).

An efficient CPU allocation algorithm is one that guarantees to each TCP sufficient processor time to complete its task before its deadline, while minimizing *forced* idle CPU time. By "forced idle time" is meant the time during which the CPU must remain idle in order to accommodate the occasional worst-case condition. This constraint is essential if the problem is to be non-trivial.

A basic assumption underlying this study is that all TCPs are preemptible.

Time-critical processes are most commonly initiated by the occurrence of external events (*interrupt signals*). Time-of-day or elapsed-time prompting of these processes may be regarded as special cases of the general class of external events. These events, and the associated TCPs, may be further classified as *periodic* or *asynchronous.*

The TCPs to be serviced are assumed to form an unordered set, that is, they are not interrelated by precedence rules. This assumption is consistent with the premise that the TCPs are initiated by unrelated external signals. If a TCP calls on other tasks, then such secondary tasks can be regarded simply as chronological extensions of the calling TCP, either because the called task is private to the calling TCP, or because all shared tasks are reentrant. In fact, the concept of precedence rules is relevant only in the case of scheduling for multiprocessor systems (Ref. 3). Multiprocessor configurations, however, seem to offer no advantages in

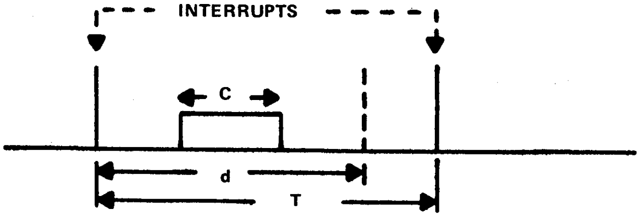

Figure 1—A model of a time critical process (TCP). The parameters associated with the TCP are the deadline (d), repetition period (T), and required CPU time (C)

the implementation of time critical schedules of the type discussed here. This subject is discussed later.

Note, incidentally, that the grouping of interrupt-driven processes into entities called *jobs* is primarily a bookkeeping measure. Such groupings carry certain implications as to the sequence of events before and after the time critical phase of the operation; they are of interest to the loader and accounting mechanisms. From the scheduling viewpoint, however, TCPs are independent entities; it does not matter whether all belong to a single user ("job") or whether sets of one or more TCPs each belong to one of several users.

TCP models

Figure 1 is a model of a simple TCP, depicting its repetition period (T), deadline (d), and required compute time (C). The required compute time is the maximum time required to completely process the given TCP on a given CPU, assuming no interruptions. That is, C is the amount of CPU service, in terms of CPU-seconds, required by the TCP. Evidently, C depends on the number and type of executable instructions in the TCP and the speed of the processor. The required compute time may be obtained empirically by timing the process running alone, or it could be predicted by deriving, through such procedure as the Gibson mix, an average instruction execution time for the processor and multiplying this figure by the instruction count of the given process.

A basic assumption underlying the study of TCP scheduling is that the external world is insensitive to the actual time at which the process is executed, so long as the process receives C CPU-seconds somewhere between the occurrence of the associated interrupt and the deadline. This is typically achieved by incorporating in the process predictive algorithms that extrapolate the results computed from data obtained at time t_i to t_i+d, when these results are actually transferred out of the computer.

T is the repetition period, i.e., the period between successive occurrences of the interrupt signal associated with the process. In practice, TCPs often are periodic and have $d=T=$constant; i.e., the constant repetition period and the deadline are identical. The repetition period is often called the frame time. Typical asynchronous TCPs have $d<T$, and T is variable. Nevertheless, these processes may still be represented by the model of Figure 1, as the following considerations show. It must be possible to define for an asynchronous TCP a *minimum* T; for if this cannot be done, then either the process cannot be time-critical—namely, it cannot be bound by a hard deadline—or else a processor of infinite execution speed is required. Hence, in the discussions to follow, T is taken to mean either the constant repetition period of a periodic TCP, or the minimum time between interrupts for an asynchronous process.

It is generally necessary to assume that TCPs can become active, either periodically or asynchronously, at unpredictable times. Furthermore, it is necessary to assume that no special relationships exist between or may be imposed on the frame times and compute times of the various processes. In practical situations, however, the resolution of the system's timing mechanisms may dictate that all Ts and Cs be integer multiples of some basic time unit, so that all Cs and Ts are *mutually commensurable*. This property can be quite significant in devising realistic schedulers.

As a rule, time-critical processes require the input of external data before they may proceed, and must allow some time after their completion and before the occurrence of their next interrupt for computed date to be output to external devices. Figure 2 is a model of a TCP of this type. A simple re-definition of the repetition period and deadline (T' and d' in Figure 2) transforms this type to the basic model of Figure 1. This transformation notwithstanding, consideration of I/O requirements complicate the scheduling problem, as will be pointed out later. It is assumed that, apart from an initial input and a final output operations, TCPs do not perform I/O.

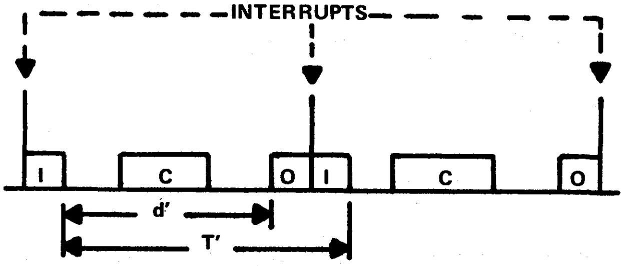

Figure 2—A TCP with I/O. By transforming the deadline into d' and the repetition period into T' this TCP is made to conform to the basic TCP shown in Figure 1

Load factor

The *load factor* (L) of a given process is equal to C/T, the ratio of the required CPU time to the repetition period. The load factor is a measure of the CPU load represented by the given TCP. Because the load factor can be readily defined in terms of quantities that are private to a given TCP and are easily obtained, it is natural to seek to establish a clear relationship between the individual load factors and the total CPU load. For instance, it is clear that in the global sense—i.e., over a very long period compared to all the frame times—the sum of the load factors approximates the total CPU load; hence, the condition $\sum L > 1$ is sufficient to guarantee the failure of all scheduling policies. On the other hand, the condition $\sum L \leq 1$ is *not* sufficient to guarantee success, as will be demonstrated shortly. An efficient scheduler will maximize the sum of the load factors without violating any deadlines.

Overhead

Overhead is the time required to switch the processor state from one TCP to another. In the following discussions, overhead is assumed to be zero. For that reason a more detailed definition of overhead, which takes into account the variety of possible hardware and software configurations affecting it, is unnecessary. In many practical cases the assumption of zero overhead is a good first approximation, since the state switching time is indeed small compared to the frame times.

THE INTELLIGENT FIXED PRIORITY (IFP) ALGORITHM

In the most commonly used scheduling technique, each TCP is assigned a fixed priority at the time it enters its time-critical phase—that is, when its associated interrupt is armed and enabled. If the priority levels are such that *processes having shorter deadline intervals receive higher priorities*, the algorithm is termed "intelligent" fixed priority, to distinguish it from other fixed-priority systems in which the allocation of priority levels is based on other criteria. This should not be taken to mean that the choice of such other criteria is unintelligent; for example, a scheduling policy based on *no* priorities ("round robin"), or one in which "CPU hogs" receive low priorities, can be quite effective in time sharing environments or in multiprogrammed batch systems. For the time-critical environment relevant to this discussion, the allocation of priorities based on the relative lengths of deadlines is most appropriate.

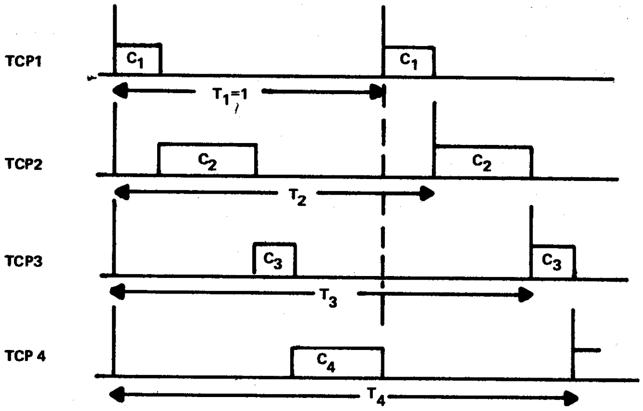

Figure 3—Assumed worst case under IFP. Four TCPs are shown, satisfying the conditions that are considered "worst-case": (a) all interrupts occur simultaneously; (b) the frame times are so related that the CPU must process all TCPs completely within the shortest frame time

Priorities under IFP need not be truly fixed. In a multiprogrammed real-time system, groups of TCPs ("jobs") may enter and leave the system at arbitrary times; the priority structure must be adjusted occasionally in response to such changes in the relative deadlines. Also, real-time processes often go through pre- and post-time-critical phases, during which their priorities may be much lower than the ones they assume in their time-critical phase, again suggesting a dynamic readjustment.

An important property of IFP, which has been alluded to in References 1 and 2 but heretofore not substantiated, is that the permissible sum of the load factors must be considerably less than 1 in order to guarantee that each TCP meets its deadline. The higher the number of TCPs to be scheduled, the closer this permissible sum gets to $\log_e 2 = 0.693$. In other words, under IFP, more than 30 percent of the CPU power must remain idle. The following is a sketch of the proof.

Assume there are n TCPs, all with constant frame times, and that, at one instant, all of their interrupts occur simultaneously. The CPU at that time is required to provide maximum service in minimum time, so that this condition represents the worst possible case. Furthermore, assume that the frame time of each TCP is related to the next shorter one by $T_i = T_{i-1} + C_{i-1}$ where $T_{i-1} < T_i < 2T_{i-1}$ and $d_i = T_i$ or $d_i = \sum_{j=1}^{i} C_j$ (See Figure 3).

These conditions assure that the CPU will be 100 percent busy during the longest frame time Tn following the simultaneous occurrence of the interrupt signals. We wish to establish the set of T_i, C_i that lead to the smallest possible sum of the load factors, i.e., the largest possible forced CPU idle time.

Normalize the frame times by letting $T_1=1$. Designate the sum of the load factors by z. Then

$$z=C_1+C_2/(1+C_1)+C_3/(1+C_1+C_2)+\cdots+C_n/(1+C_1+C_2+\cdots+C_{n-1})$$

Because of the assumptions (see Figure 3),

$$\sum_{j=1}^{n} C_j=1$$

Let

$$f=z+L\left(\sum_{j=1}^{n} C_j-1\right)$$

where L is a Lagrange multiplier used for convenience to obtain symmetry in the following equations. Also let

$$1+\sum_{j=1}^{n} C_j=S_i.$$

We wish to find the conditions leading to the minimum z. Hence:

$$\begin{aligned}
\partial f/\partial C_1 &= 1-C_2/S_1^2-C_3/S_2^2-\cdots-Cn/S_{n-1}^2+L=0\\
\partial f/\partial C_2 &= 1/S_1-C_3/S_2^2-\cdots-Cn/S_{n-1}^2+L=0\\
\partial f/\partial C_3 &= 1/S_2-\cdots-Cn/S_{n-1}^2+L=0\\
&\vdots\\
\partial f/\partial C_{n-1} &= 1/S_{n-1}-Cn/S_{n-1}+L=0\\
\partial f/\partial C_n &= 1/S_{n-1}+L=0
\end{aligned}$$

By subtracting each of these equations from the one above it we obtain

$$\begin{aligned}
S_n &= S_{n-1}^2/S_{n-2}\\
S_{n-1} &= S_{n-2}^2/S_{n-3}\\
&\vdots\\
1+C_1+C_2 &= (1+C_1)^2
\end{aligned}$$

where the last equation is obtained from

$$\partial f/\partial C_1-\partial f/\partial C_2=1-C_2/(1+C_1)^2-1/(1+C_1)=0$$

Continual upward substitution in the above set leads to

$$1+C_1+C_2+\cdots+C_n=(1+C)^{2(n-1)}/(1+C)^{n-2}$$

The left hand side of the equation above equals 2 since $S_n=1$; hence

$$2=(1+C_1)^n$$

so that

$$C_1=2^{1/n}-1$$

This represents both the required compute time and load factor for TCP 1 under the "worst case" condition of Figure 3 with the side constraint of worst (minimum) load-factor sum. The other TCPs have

$$C_i=S_{i-1}/S_{i-2}^2-S_{i-1}$$

By continual substitution, we have

$$S_i=(1+C_1)^i$$

The load factor L_i of each TCP$_i$ is C_i/T_i where $T=S_{i-1}$; so

$$L_i=[(S_{i-1}^2/S_{i-2})-S_{i-1}]/S_{i-1}=C_1$$

so all the load factors equal C_1. Thus the sum of the load factors is

$$z=n(2^{1/n}-1)$$

Note, incidentally, that the frame times for this worst-case core given by

$$T_i=S_{i-1}=(1+C_1)^{i-1}=2^{(i-1)/n}$$

The table below summarizes the worst-case situation for two, three and four TCPs.

n	z (max. L)	T relationships
2	$2(\sqrt{2}-1)\cong$82.8 percent	$1:\sqrt{2}$
3	$3(\sqrt[3]{2}-1)\cong$78.0 percent	$1:\sqrt[3]{2}:\sqrt[3]{4}$
4	$4(\sqrt[4]{2}-1)\cong$75.7 percent	$1:\sqrt[4]{2}:\sqrt[4]{4}:\sqrt[4]{8}$

To establish the trend as the number of TCPs increases, we take the limit of z as n approaches infinity:

$$\begin{aligned}
\lim_{n\to\infty} n(2^{1/n}-1) &= \lim_{n\to\infty} n[1+\ln 2/n+(\ln 2/n)^2/2!\\
&\quad+(\ln 2/n)^3/3!+\cdots-1]\\
&= \log_e 2=.69315
\end{aligned}$$

thereby substantiating the original assertion. Figure 4

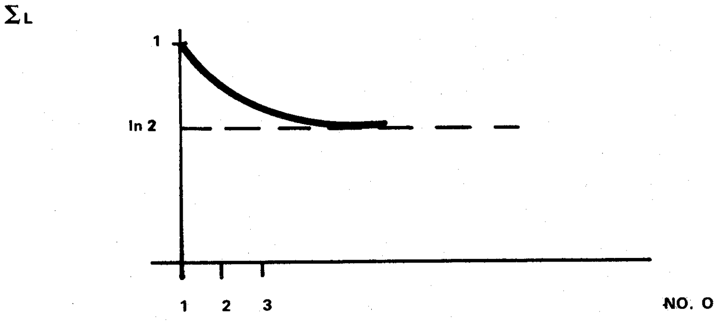

Figure 4—Load factor sum as a function of the number of TCPs under IFP. As the number of TCPs increases, the CPU must remain idle a larger percent of the time (i.e., the permissible sum of the load factors must be reduced). In the case of many TCPs, about 30 percent of the total CPU power must be held in reserve to accommodate the worst-case condition

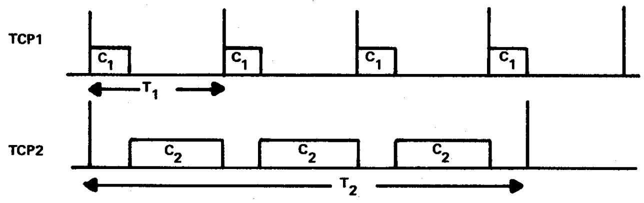

Figure 5—Worst case situation for two TCPs under IFP when the condition $T_1 < T_2 < 2T_1$ does not apply

shows the maximum permissible load factor sum as a function of the number of TCPs.

It is of interest to investigate the case where the frame times are not restricted to the range $T_{i-1} < T_i < 2T_{i-1}$. Figure 5 shows the effect of removing this restriction for the case $n=2$. For the situation shown in Figure 5 we have:

$$T_2 = kT_1 = mT_1 + C_1$$

where $m > 1$ and is an integer. Also,

$$C_2 = m(T_1 - C_1)$$

hence the sum of the load factors is

$$z = C_1/T_1 + m(T_1 - C_1)/kT_1$$
$$= k - m + m(1 - k + m)/k$$

For a minimum z we require

$$\partial z/\partial k = 1 - (m^2 + m)/k^2 = 0$$

Hence,

$$k = \sqrt{m(m+1)}$$

describes the points at which the ratio T_2/T_1 minimizes the available CPU time. At these points, the load factors are

$$C_1/T_1 = \sqrt{m(m+1)} - m = C_2/kT_2$$

and the sum of the load factors is

$$z = 2(\sqrt{m(m+1)} - m)$$

By assuming a given ratio of T_1 to T_2 with the "worst case" constraints $T_2 = mT_1 + C_1$ and $C_2 = m(T_1 - C_1)$ it can be shown that the sum of the load factors as a function of T_2 (or C_1) is given by

$$z = C_1 + m(1 - C_1)/(m + C_1)$$

Using these last two results for z it is possible to develop Figure 6 which shows how the maximum permissible sum of the load factors varies as a function of the ratio T_2/T_1. When this ratio is an integer, there is no problem in allocating 100 percent of the CPU using IFP. When T_2/T_1 is not an integer, some CPU time must remain idle in order to accommodate the "worst case." It is interesting to note that the CPU utilization drops to its minima always when T_1 and T_2 are *mutually incommensurate.*

EFFECT OF I/O

It was pointed out earlier that TCPs with nonzero I/O times can be transformed to the model of Figure 1. Such a transformation does not, however, remove a basic difficulty associated with I/O: during the input or output phases of a given TCP, the CPU may not be allocated to it. During the time that the I/O operations of all TCPs overlap, the CPU may not be allocated to any. For example, with two TCPs of identical repetition periods T and equal input-output phases I, the maximum permissible sum of the load factors is $(T-2I)/T$. This difficulty may be further complicated by the need to schedule the I/O operations that use the same I/O facilities.

Assuming, however, that all I/O operations can be performed simultaneously, one possible approach to incorporating the effect of I/O in CPU scheduling policies may be as follows. Regard I/O as a TCP with $d_i = T_i = C_i$, which is always executed on a second, "dummy" CPU. Furthermore, introduce precedence rules enforcing the sequence $I_i < \mathrm{TCP}_i < O_i$ (read: task I_i precedes task TCP_i etc.). Unfortunately, these artifices do not simplify significantly the analysis of scheduling problems with non-zero I/O times. In the remainder of this paper, zero I/O times are assumed.

THE INFINITE TIME SLICING (ITS) ALGORITHM

Although this algorithm cannot be implemented, it is nevertheless a valuable tool in the study of time critical

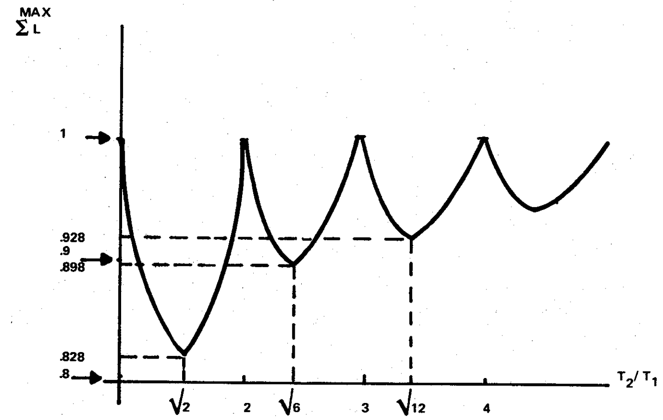

Figure 6—Maximum permissible load factor sum as a function of the frame times ratio T_2/T_1, Two TCPs. The minima occur when T_2 and T_1 are mutually incommensurate

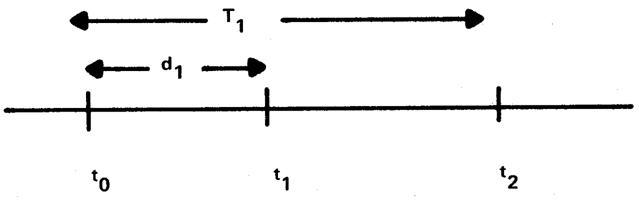

Figure 7—Nomenclature for the proof that 100 percent scheduling is impossible unless $d_i = T_i$ or $T_i = mT_1$

scheduling. ITS provides a conceptual link between the sum of the individual load factors and the instantaneous CPU load. Namely, given a set of TCPs for which the sum of the load factors is L, then, using ITS it is possible to guarantee that (as long as $d_i = T_i$) all deadlines are met while the CPU is busy exactly $100L$ percent of the time in any given time span.

ITS may be approached in the following way. Suppose it were possible to regard the power of the CPU as a continuous quantity; it may then be distributed to the TCPs according to the load factors. In other words, assuming $d_i = T_i$ for all TCPs, then a TCP whose load factor is $L_i < 1$ is allocated a fraction of the CPU equal to L_i. This may be taken to mean that if the CPU is capable of executing G instructions per second, then an L_i fraction of the CPU has the ability to execute L_iG instructions/sec; or, the CPU may be regarded as a composite of a number of slower CPUs, each performing L_iG instructions/sec. If this is done, then each process executes exactly L_iGT_i instructions in its period T_i. Since $L_i = C_i/T_i$, the instruction sum is C_iG, which is exactly the TCP's requirement when assuming C_i cpu seconds at G instructions/sec.

To achieve such a distribution of the CPU power one can start by dividing the time axis into small increments ΔT. In each increment, the CPU is allocated, in some arbitrary order, to each TCP for a period $L_i\Delta T$. If ΔT is made small compared to all the repetition periods T_i involved, we have a good approximation to the infinite-time-slicing algorithm. An "exact" ITS policy is obtained if we let ΔT approach 0. Approximate ITS algorithms can be—and, in fact, have been—implemented on computers that provide rapid context switching. With context-switch time of, say, 5 microseconds, and ΔT set at 250 microseconds, it is possible to service five TCPs with 10 percent switching overhead.

Note however that ITS is weak when required to schedule TCPs for which $d_i < T_i$. For such processes, ITS must allocate C_i/d_i fraction of the CPU. This leads to situations where a specific TCP set that can be successfully scheduled by IFP (and other policies) fails under ITS. For instance, given a periodic process with $d_1 = T_1 = 100$ milliseconds and $C_1 = 85$ milliseconds, and an asynchronous process with minimum $T_2 = 2$ *ms*, $d_2 = 1$ *ms*, and $C_2 = 200$ microseconds. To schedule these, ITS must allocate $85/100 = 85$ percent of the CPU to TCP 1 and $0.2/1 = 20$ percent to TCP 2; hence these TCPs cannot be scheduled together. Under IFP, both TCPs can easily be accommodated if TCP2 is given the higher priority, since TCP2 requires a maximum of 10 *ms* CPU time during the frame time of TCP 1.

A BASIC SCHEDULING RESTRICTION?

At least in the case of two TCPs it appears that the following statement is true. It is never possible to allocate the CPU at full efficiency (i.e., keep it busy doing useful work 100 percent of the time) unless either $d_i = T_i$ or $T_2 = mT_1$, where m is an integer.

For the case $d_i < T_i$, consider Figure 7. Assume the CPU is allocated 100 percent, i.e., no idle time. Further assume this figure shows the TCP with shortest frame time T_1. Since $T_2 \geq T_1$, the deadline of TCP 2, d_2, can occur in the frame T_1 at most once. Now d_2 cannot occur in the interval t_1t_2 since this means that the CPU is idle for some time in that interval; the only exception occurs if $d_2 = T_2$, (since then the CPU can work for TCP_2 in the remainder of t_1t_2); or if d_2 always coincides with either t_1 or t_2, or if d_2 always falls in the interval t_0t_1. To maintain these restrictions it is necessary that any two occurrences of d_2 must be separated by mT_1; therefore $T_2 = mT_1$.

It is tempting to conclude that this condition can be extended to the case of more than two TCPs by requiring $d_i = T_i$ for all i or $T_i = m_iT_1$. A proof is not yet available, however.

Note that the scheduling property just derived is *not* responsible for the failure of IFP to schedule more than about 69 percent of the CPU (Figure 3); the development of that case remains unchanged if in Figure 3 we let all $d_i = T_i$. Thus this failure is peculiar to IFP and, in fact, we will show later that for $d_i = T_i$, the relative urgency (RU) and other algorithms do not suffer from this restriction.

THE MINIMAL TIME SLICING (MTS) ALGORITHM

In implementing ITS, ΔT is assumed to be infinitely small. For any given set of TCPs, a time slicing algorithm which retains most features of ITS with a *finite* ΔT can be developed. This is the minimal time slicing (MTS) policy. It is based on the realization that, for a given set of TCPs, the smallest time unit of interest

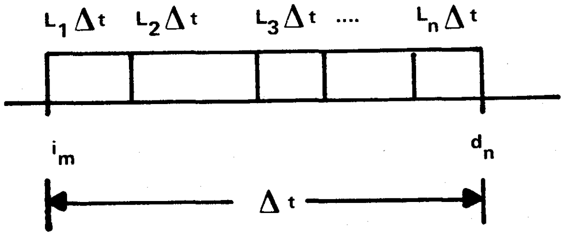

Figure 8—The MTS policy in a scheduling interval. In every scheduling interval Δt, the CPU is allocated in some arbitrary order to all TCPs, such that each receives $L_i \Delta t$ CPU-seconds

from the scheduling viewpoint, called a *scheduling interval*, is the time between the occurrence of two successive "scheduling events." By "scheduling events" we mean events that affect the CPU loading; namely, interrupt instances and deadlines. The scheduler can guarantee that each TCP meets its dealine by allocating the CPU, in *each* scheduling interval, in some arbitrary order, according to the load factors. Figure 8 is a graphic illustration of this policy. The practical implementation of MTS requires all TCPs to be periodic so their interrupt instances are predictable.

MTS suffers from the same weakness as ITS in scheduling processes for which $d_i < T_i$; MTS, however, is a practical algorithm as long as all T_i are known to the scheduler and the context-switching time is small.

Note that both ITS and MTS are *self regulating* in that the CPU time used by each TCP is always under the control of the system so that CPU *protection* is guaranteed to all TCPs. IFP, in contrast, does not have this feature; it requires additional hardware and software safeguards and monitoring. However, the required watch-dog programmable timer and the associated added overhead in context switching are not more complex than those required in implementing the MTS or approximate ITS policies.

THE RELATIVE URGENCY (RU) ALGORITHM

The Relative Urgency (RU) policy, developed by M. S. Fineberg and first reported in Reference 1, is similar to MTS in that it requires the scheduler to reevaluate the scheduling environment on every interrupt. RU differs from MTS in that during the period between two successive interrupts, RU is priority-oriented: the highest priority TCP is given control at the start of that period, and allowed to continue until it completes its computation or until the next interrupt. Priorities are re-allocated on every interrupt and are proportional to deadlines *as they exist at the interrupt instance* (i.e., not simply to their relative lengths); the TCP whose deadline is most imminent (and that has not yet completed its computation for its current frame) receives the highest priority. If a TCP completes its computation during an interval, then the next-highest priority TCP receives the CPU; priority re-evaluation is not required at completion instants.

RU has an obvious advantage over MTS: in general, RU performs less context switching; overhead is therefore smaller under RU.

At least for the case of two TCPs, it can be shown that RU can schedule the CPU at 100 percent efficiency. This is done by showing that, for this case, an RU can always be constructed from an MTS. The proof is carried out by induction.

Assume two TCPs $(T_2 > T_1)$ with $d_i = T_i$, whose interrupts coincide at $t = 0$. Construct an MTS for this case, taking care to, in each scheduling interval, assign the CPU to the TCP whose deadline is nearest. No generality is lost since the order is immaterial under MTS. Let an RU be constructed, and assume that up to scheduling event L, RU and MTS are indeed identical. Consider the event at L and the one following it. There are only three possibilities (see Figure 9): a) at L we have t_1 (interrupt due to TCP 1) and the next event is also t_1, b) $L = t_1$, then t_2; c) $L = t_2$, then t_1. Note that, since $T_2 > T_1$, it is impossible to have two consecutive t_2 without an intervening t_1. Now, for the case (a), under RU we would allocate the CPU at L to TCP 1 (its deadline is nearest); it would execute for $L_1 T_1$ seconds, since the interval $t_1 t_1$ is T_1. Since the CPU is assumed 100 percent scheduled, the remainder of $t_1 t_1$, namely $T(1 - L_1)$ would be allocated to TCP 2. Since $L_1 + L_2 = 1$, $L_2 = 1 - L_1$, so this remainder equals $L_2 T_1$.

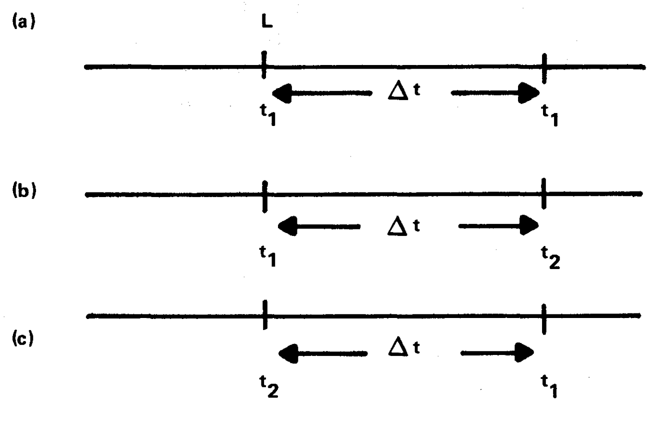

Figure 9—Nomenclature for the proof that MTS and RU are equivalent for two TCPs. The proof is by induction, assuming that up to scheduling event L, RU and MTS are identical, and showing that based on this assumption, RU and MTS must also be identical in the interval Δt

This is precisely the division of t_1t_1, under MTS. For case (b), TCP 2 will receive the CPU, and is short exactly $L_2\Delta t$ CPU-seconds, since by the assumption it received $L_2(T_2-\Delta T)$ CPU-seconds up to event L. This leaves $\Delta t(1-L_2)$ for TCP 1 in Δt, which is equal to $L_1\Delta t$, again showing the equivalence of RU and MTS in Δt. Similar conditions apply in case (c). Finally, at $t=0$ we have case (a) (with $L=t_1=t_2$) but for this case we already showed that RU = MTS. Hence the assertion is proved by induction.

There is considerable empirical evidence that RU is capable of scheduling the CPU at 100 percent efficiency for all T_i/T_{i-1} ratios when all $d_i=T_i$; in this case, RU is at least as efficient as MTS or ITS (more efficient in fact, due to lower switching overhead); when the T_i are not integer multiples of T_1 (the shortest frame time), IFP is known to be less efficient than either MTS, ITS or RU. When $d_i<T_i$, RU is capable of scheduling more of the CPU than MTS or ITS, i.e., more TCPs can be accommodated under RU.

REGARDING MULTIPROCESSING

Considerable effort has been expended on time-critical scheduling techniques for multiprocessor systems (e.g., References 3 and 4). For TCPs of the type considered in this paper, multiprocessor systems do not offer any advantages (if one excludes redundancy or backup requirements). In fact, it appears that in some cases, multiprocessor systems are definitely less desirable than an "equivalent" single processor. By "equivalent" is meant that each of m CPUs execute at a rate $1/m$ as fast as the single CPU.

Given m processors and n TCPs $(m<n)$ with equal C_i and such that all n TCPs can be executed serially on the single, fast processor in time Δt. Then each of the m processor can completely process at most p TCPs, where p is an integer that satisfies $p(\Delta t/n)\ m \overline{<} \Delta t$. In other words, $mp \overline{<} n$, which means that whenever the number of TCPs n is not a multiple of the number of CPUs m, there will remain one TCP that cannot be accommodated within Δt using m processors, whereas the fast processor accommodates all TCPs within Δt. Furthermore, if Grosch's Law holds, the faster CPU should cost less than the m slower units, so that even from the economic standpoint, multiprocessor systems do not appear desirable.

CONCLUSION

This paper presented primarily heuristic extensions and generalizations of concepts that were for the most part first sketched in Reference 1. Much work remains to be done in strengthening and extending the proofs and in discovering the properties of scheduling with I/O constraints. The relation between RU and MTS is particularly intriguing. A consistent theory of scheduling of time-critical processes is within reach.

ACKNOWLEDGMENT

I am indebted to the referees for their excellent, constructive critiques of the original version of this paper.

A class of allocation strategies inducing bounded delays only

by EDSGER W. DIJKSTRA

Technological University
Eindhoven, The Netherlands

We consider a finite set of persons, say numbered from 1 through M, whose never ending life consists of an alternation of eating and thinking, i.e., (in the first instance) they all behave according to the program

```
cycle begin eat;
            think
      end.
```

The persons are living in parallel and their common accommodations are such that not all combinations of simultaneous eaters are permitted. As a result: when a person has finished thinking, some inspection has to take place in order to decide whether he can (and shall) be granted access to the table or not. Similarly, when a person leaves the table, some inspection has to take place in order to discover whether on account of the changed occupancy of the table one or more hungry persons could (and should) be admitted to the table. This situation is reflected by writing their program

```
cycle begin ENTRY;
            eat;
            EXIT;
            think
      end
```

with the understanding that

(1) all inspection processes "ENTRY" and "EXIT" take only a finite period of time and exclude each other in time. (As a result of the postulated mutual exclusion of the inspections "ENTRY" and "EXIT," a "local delay" of person i, wanting to invoke such an inspection, may be needed. We postulate that such a "local delay" will only last a finite period of time—the requests for these inspections could be dealt with on the basis of "first come, first served"—and we shall not mention these local delays any further, because they are now irrelevant for the remainder of our considerations.)

(2) as a result of such an inspection the person invoking it may be put to sleep (i.e., prevented, for the time being, from proceeding with his life as prescribed by the program).

(3) as a result of such an inspection, one or more sleeping persons may be woken up (i.e., induced to proceed with their life as described by the program).

We restrict ourselves to such exclusion rules for simultaneous eaters that

condition 1: if V is a permissible set of simultaneous eaters, so is any subset of V

condition 2: each person occurs in at least one permissible set of simultaneous eaters. (Note: if a person occurs in exactly one permissible set of simultaneous eaters, this set contains—on account of condition 1—only himself and no one else.)

From condition 1 it follows that there is no restriction on the set of simultaneous thinkers; as a result the inspection EXIT will never have the consequence that the person invoking it will be put to sleep. As a result, persons can only be sleeping on account of having invoked the inspection ENTRY and the act of admitting person i to the table can be associated with the waking up of person i. (A little bit more precise: if during the inspection ENTRY as invoked by person i the decision to admit him to the table is *not* taken, he is put to sleep, otherwise he is allowed to proceed. If in any other inspection the decision to admit person i to the table is taken (person i must be sleeping and) person i will be woken up).

Furthermore we restrict ourselves to the case that

condition 3: for each person the action "eat" will take a finite period of time (larger than some positive lower bound and smaller than some finite upper bound); this in contrast to the action "think" that may take an infinite period of time.

In the simplest strategy no inspection will leave a person sleeping whose admittance to the table is allowed as far as the occupancy of the table is concerned. Alas, such a strategy may have the so-called "danger of individual starvation," i.e., although all individual eating actions take only a finite period of time, a person may be kept hungry for the rest of his days. (The classical configuration showing this phenomenon is the Problem of the Dinig Quintuple. Here five places are arranged cyclically around a round table and each of five persons has his own place at the table. The restriction is that no two neighbors may be eating simultaneously. The rule will then be that every person is admitted to the table as soon as he is hungry and none of his two neighbors is eating. In this particular example this rule leaves no choice, i.e., when I leave the table the decisions whether my lefthand neighbor and my righthand neighbor have to be admitted to the table are independent of each other. In this example my two neighbors can starve me to death, viz., when my eating lefthand neighbor never leaves the table before my righthand neighbor is eating and vice versa. If the remaining two persons remain thinking, access to the table will never be denied to my neighbors and with me hungry the process can continue forever.) The moral of the story is that if we are looking for strategies without the danger of individual starvation, we must in general be willing to consider allocation strategies in which hungry persons will be denied access to the table in spite of the circumstance that the occupancy of the table is such that they could be admitted to the table without causing violation of the given simultaneity restrictions. Our interest in strategies without the danger of individual starvation was aroused by the sobering experience that quite a few intuitive efforts to exorcize this danger led to algorithms that turned out to be quite ineffective because they could lead to deadlock situations. The remaining part of this paper deals with a general characterization of strategies that do not contain the danger of individual starvation. We shall restrict ourselves to strategies where the decision to admit persons to the table will be taken for one person at a time; from our analysis it will follow then that our characterization can be given independent of the specific simultaneity restrictions (provided of course they satisfy our stated conditions 1 and 2).

We start by proving a theorem, in which we consider the following (possible) properties of a strategy.

property A: the existence of at least one sleeping person implies at least one person who is eating or leaving the table

property B: for any person i it can be guaranteed that during a period of his hungriness the decision to admit someone else to the table will not be taken more than N_i times, where N_i is a given, finite upper bound for person i.

Our theorem asserts that when conditions 1, 2 and 3 are fulfilled, properties A and B are the necessary and sufficient conditions for any strategy in order not to contain the danger of individual starvation.

The necessity of property A follows from the inadmissibility of the situation in which one or more persons are sleeping while all remaining ones (if any) are thinking. The thinking ones may go on thinking forever, as a result no new inspections will be evoked and the sleeping ones remain hungry for an infinite period of time.

We say that the danger of individual starvation is absent when the hungriness of any person will never last longer than a given, finite period of time. The minimum time taken by the act of eating imposes an upper bound on the personal frequency with which any given person can be admitted to the table; the total number of persons is M and therefore there is an upper bound on the total frequency with which someone is admitted to the table. Therefore the number of admissions during a period of hungriness of person i must always be less than a fixed, finite value: property B is necessary in the sense that a set of fixed, finite N_i's exists such that it is satisfied.

Next we show that the conditions are sufficient. When person i becomes hungry—by invoking ENTRY—we have to show that his hungriness will only last a finite period of time. If in the course of that very inspection he is admitted to the table, it is true (for inspections take only a finite period of time), otherwise he goes to sleep. At the end of that inspection at least one person is eating (on account of property A). From the fact that the action "eat" takes only a finite period of time, the persons now eating will have finished doing so and will have left the table within a finite period of time. From this and property A it follows that within a finite period of time a new person will have been admitted to the table. The assumption that person i remains hungry forever implies that the lucky person must have been someone else, i.e., within a finite period of time the number of times it has been decided during hungriness of person i that someone else is admitted to the table is increased by one. Then the argument can be repeated and within a finite period of time the number of times someone else is admitted to the table would exceed N_i, contrary to our property B. Therefore person i will not remain hungry forever.

Having established that properties A and B are necessary and sufficient for the absence of the danger of individual starvation, we are now in a position to characterize all strategies satisfying them with *a priori* given bounds N_i. For this purpose we associate with each hungry person a counter called "*ac*" (short for "allowance count"). Whenever person i becomes hungry, his *ac* is added to the set of *ac*'s with the initial value$=N_i$; whenever it is decided that a person is admitted to the table, his *ac* is taken away from the set of *ac*'s and all remaining *ac*'s are decreased by one. Property B is guaranteed to hold when no *ac* becomes negative.

We call the set of *ac*'s "safe" when for all $k \geq 0$ holds that at most k *ac*'s have a value$<k$. Note that also the empty set is safe. (Another formulation of safety is that it must be possible to order the *ac*'s, if present, in such a fashion that the first $ac \geq 0$, the second $ac \geq 1$, the third $ac \geq 2$, etc.) Such a safe set has four important properties.

Property 1: No safe set contains a negative element (substitute $k=0$ in the first definition).

Property 2: If removal of an element from the set is accompanied by a decrease of the remaining elements by one, each non-empty safe set contains at least one element that can be removed such that the remaining set is again safe: for this purpose it is sufficient—although one has often greater freedom—to choose one of the smallest values.

Property 3: In the case of an unsafe set, let K be the minimum value of k, such that more than k elements have a value less than k. Addition of a new element to an unsafe set will never make it into a safe one, nor will it lead to an increase of K.

Property 4: In the case of an unsafe set, K (as defined in the previous paragraph) is an upper bound for the number of times that an element can be removed (again each removal being accompanied by a decrease of the remaining elements by 1) before negative values occur.

Properties 3 and 4 tell us that an unsafe set of *ac*'s is bound to lead to negative *ac*'s before it is empty. Therefore safety of the set of *ac*'s must be maintained if we wish to guarantee property B. This imposes a lower bound on the initial values of the *ac*'s, i.e., the N_i. With M processes, at most $M-1$ will be sleeping (property A), if we impose

$$N_i \geq M-2$$

we can guarantee that, given a safe set of *ac*'s, the addition of a new *ac* will never lead to unsafety.

We can now characterize all strategies satisfying properties A and B. We call a person "admissible" if the following three conditions all hold

(1) he must be hungry

(2) his addition to the set V of eating persons would not cause violation of the simultaneity restrictions

(3) his removal from the set of hungry persons would leave a safe set of *ac*'s. We now characterize *all* strategies enjoying our (necessary and sufficient) properties A and B in terms of a *general permission* and a *specific obligation.*

Each inspection ENTRY or EXIT has the general permission to decide (zero or more times) to admit an admissible person to the table. However, those inspections that would violate property A in the case of zero admissions have the specific obligation to admit at least one person to the table. They are the ENTRY while there are no eating persons and the EXIT in which a person is the last to leave the table while there are sleeping persons. In both cases conditions 1 and 2 and property 2 of safe sets guarantee the existence of at least one admissible person.

It is clear that any such strategy will satisfy properties A and B, it is also clear that any other strategy will have to be rejected: if the general permission is violated, an erroneous admission to the table takes place or we end up with either deadlock or violation of property B, if the specific obligation is not fulfilled property A is violated. In this sense we have characterized *all* strategies satisfying properties A and B.

CONCLUDING REMARKS

For a very specific reason the result obtained seems significant. When one is making an operating system one is faced with "absolute requirements" (of a rather logical nature) on the one hand and "desires" (not necessarily all compatible with each other) on the other. In the early design phase of the Multiprogramming System we had the hope that all allocation strategies could be factored in the sense that first we could produce the code that would ensure non-violation of the absolute requirements, in which then all sorts of strategic routines could be plugged in, the idea being that a change of strategic routines could influence the desirability of the systems behavior but could never lead to violation of the absolute requirements. In the later design stages we have not been able to reach that goal: we turned up with allocation strategies for which we could prove that the absolute requirements would never be violated, but each new proposed strategy required a new proof of this fact. The origin of this failure was our inability at that time to give a constructive characterization of *all* possible strategies that were guaranteed to meet our absolute requirements. This paper shows that—at least in the case of the chosen absolute requirements—such a characterization can be given in terms of permissions and obligations and in such a way that it has been proved that the obligation can always be fulfilled. The question under which other circumstances such characterizations can be given is now open for investigation.

ACKNOWLEDGMENTS

The author wishes to express his great indebtedness to A. Martin and W. H. J. Feijen, for it is due to their persistence, in a common effort to clear up our thinking about starvation, that I was guided towards the approach described in this paper.

On modeling program behavior

by PETER J. DENNING

Princeton University
Princeton, New Jersey

INTRODUCTION

This is a paper about the history of the working set model for program behavior. It traces briefly the origins and bases of the idea and some of the results subsequently obtained. The physical context is a hierarchical memory system consisting of a severely limited quantity of main (directly-addressable) storage and an essentially unlimited quantity of secondary (backup) storage. In this context, the intuitive notion of "working information" as the set of words which are (or should be) loaded in main memory at any given time in order that a program may operate efficiently is as old as programming itself.[1] The sharply increased interest in program models since the mid-1960s is a direct consequence of the widening use of virtual memory and multiprogramming techniques, which have shifted the responsibility of memory management from programmers to machines. I am assuming here that the purpose of memory management is ensuring that an active program's working information is present in main memory, and the purpose of a program model is providing a basis for determining a program's working information at a given time and predicting what it will be at a future time.

The intuitive notion calls for "working information" to be defined as machine-independent as possible, so that there can be an "absolute" measure of a program's memory demand. Moreover, the definition should be dynamic since we wish ultimately to derive adaptive memory management policies from it. In my own efforts to formalize the intuitive notion, I adopted the spirit of an approach suggested as early as 1965, according to which a program's "working set" at a given time consists of those objects which must be loaded in main memory in order to guarantee a given level of processing efficiency.[19] It seemed to me that an ideal definition should, either explicitly or implicitly, specify a priority listing on a program's information objects at each moment of time; then, given the desired level of processing efficiency and the physical characteristics of the system (e.g., the ratios of speeds between various levels of memory, or the capacities of various levels of memory), one should be able to compute, at any given time, an integer k such that the k objects of highest priority constitute the program's working set at that time. Because a direct formalization of this idea did not appear immediately amenable to analysis, I settled instead on a definition of "working set" as a collection of recently referenced objects.[11,12] As will be seen, this alternative definition is equivalent to the former one under realistic assumptions about programs.

A useful definition of working set should, in addition to the above, satisfy two properties. First, it should be based on easily observable properties of program behavior. As suggested in Figure 1, the stream of addresses (the *address trace*) generated by a processor is perhaps the most easily observed aspect of dynamic program behavior. Now, a given program's instruction and data code is ordinarily divided into blocks of various sizes, each block being identified by a number and consisting of words with contiguous addresses. Since memory allocation policies deal with blocks, not words, as the units of allocation, there is no loss of generality in supposing that a string of block numbers (the *reference string*) represents observable program behavior. Specifically, if $a_1a_2 \ldots a_t \ldots$ is an address trace in which a_t is the address referenced at time t in the time frame of the program (program time is measured discretely, $t=1, 2, 3, \ldots$), and r_t is the number of the block containing address a_t, the reference string is $r_1r_2 \ldots r_t \ldots$. In the discussion to follow, I shall assume that the blocks of a program are all of the same size (i.e., paging is used); this is purely a matter of convenience, as generalizations to variable block size are straightforward. Under this assumption, a reference string is a sequence of page numbers.

Second, the definition of working set should be based

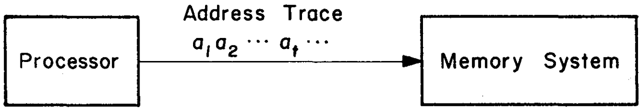

Figure 1—Address trace

on information about a program's observed past and not on information about its future—i.e., the working set at time t should depend only on $r_1 r_2 \ldots r_t$ and not on $r_{t+1} r_{t+2} \ldots$. I imposed this requirement because I wanted a program model which would guide a choice of memory management policy in the absence of prior knowledge of program behavior (e.g., programmer or compiler advice or predictions[1]), since experience suggests that prior knowledge is either inordinately expensive to obtain or is unreliable. I was not attempting to deny that, if reliable prior information is present, it can and should be used to improve an estimate of a program's working set; I wanted only to avoid making prior information a fundamental assumption of the model.

A DEFINITION OF WORKING SET

With these general notions about how "working set" should be defined, one can proceed to develop the definition itself. As will be seen, the viability of the "most recently referenced pages" definition depends on the property of *locality* (known also as "locality of reference") which is exhibited to varying degrees by all practical programs.[2,3,5–8,12,13,15,17,24,26] The property of locality can be summarized as three statements:

L1. A program distributes its references nonuniformly over its pages, some pages being favored over others.
L2. The density of references to a given page tends to change slowly in time.
L3. Two reference string segments are highly correlated when the interval between them is small, and tend to become uncorrelated as the interval between them becomes large.

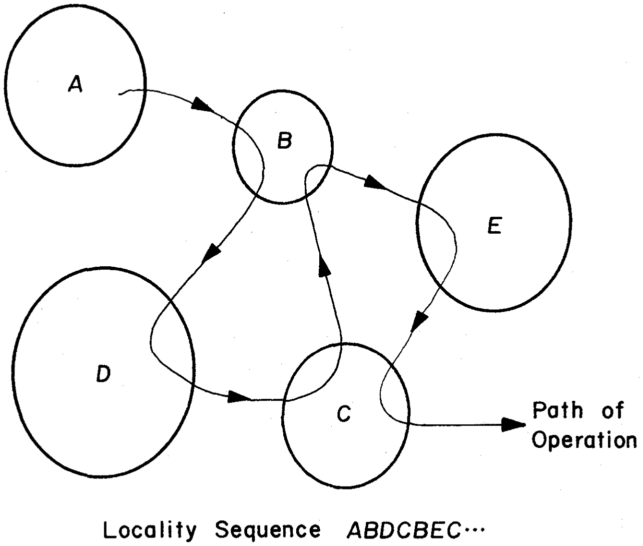
These properties are abstractions of commonly observed phenomena: programs tend to reference pages unequally, they tend to cluster references to certain pages in short time intervals, they can be run efficiently in memory spaces considerably smaller than the program size.[2,21,26] Locality derives from the behavior and style of programmers: they tend to use sequential and looping control structures frequently, they tend to group data into content-related blocks, and they tend to concentrate on small parts of large problems for moderately long intervals.[5–7,15,24,26] The degree to which locality is exhibited is strongly a function of programming style—i.e., algorithm strategy and data organization;[5–7,26] it is reported that high degrees of locality can often be achieved at a cost of under 5 percent of total programming costs.[26] As will be seen below, the definition of working set as a collection of recently referenced pages improves as an estimator of a program's working information as the degree of locality increases.

Based on the foregoing ideas, one can formulate a model for locality. Suppose P is the set of pages of a given program. Associated with the given program is a collection of *localities*, each a distinct subset of P; we denote them by $A, B, C, \ldots$. Two localities may overlap. As suggested in Figure 2, one may imagine that the executing program traces a path of operation through its localities; the path defines a sequence of localities, e.g., in Fig. 2 it is

$$L_1 L_2 L_3 \ldots L_i \ldots = A\ B\ D\ C\ B\ E\ C \ldots$$

Now, let t_i denote the length of time (the *residence time*) the program spends in the ith locality L_i of the locality sequence; while the path is in locality L_i, the program generates a reference substring of length t_i, consisting of pages from L_i only. As an example, consider a program with pages $P = \{1, 2, \ldots, 6\}$ and three localities

$$A = \{1, 2, 3\} \qquad B = \{4, 5, 6\} \qquad C = \{1, 2, 6\}$$



Locality Sequence *ABDCBEC*···

Figure 2—Locality

Suppose the locality sequence is $L_1L_2L_3=ABC$ and the residence times are $t_1t_2t_3=656$. A reference string consistent with these conditions is

$$\underbrace{1\,3\,2\,1\,2\,3}_{A}\quad\underbrace{6\,4\,5\,6\,4}_{B}\quad\underbrace{6\,1\,2\,6\,2\,1}_{C} \qquad (1)$$

Based on the property of locality, one would expect that the residence times tend to be long and that neighboring localities (on the path of operation) tend to overlap.

Ideally, a program's working set at any given time should comprise exactly the pages from the current locality at that time. In practice (at least without the services of a Delphic Oracle) the working set will be an estimate of locality based on observations of the recent past reference string. Accordingly, if $r_1r_2\ldots r_t\ldots$ is a reference string, we define the *working set* $W(t, T)$ at time t to be the set of distinct pages referenced among the T most recently referenced pages, i.e., among $r_{t-T+1}\ldots r_t$. If $t<T$, $W(t, T)$ consists of the distinct pages among $r_1r_2\ldots r_t$ and if $t<0$, $W(t, T)$ is empty. The parameter T is called the *window size,* since $W(t, T)$ can be regarded as the contents of a window looking backward at the reference string. The working sets for $T=4$ on the reference string (1) given above are shown in Figure 3.

The working set is *correct* when it comprises exactly the pages of the current locality. The correctness depends on the choice of window size T; in general, two conditions would have to be satisfied:

1. T is sufficiently large that every page of a locality is in the working set with high probability.
2. T is comparable to or much less than the average locality residence time, i.e., the probability of the window's containing more than one interlocality transition is small.

Locality	Page	Refs.	1	3	2	1	2	3	6	4	5	6	4	6	1	2	6	2	1
AC	1		x	x	x	x	x	x	x						x	x	x	x	x
AC	2				x	x	x	x	x	x						x	x	x	x
A	3			x	x	x	x	x	x	x	x								
B	4									x	x	x	x	x	x	x			
B	5										x	x	x	x					
BC	6								x	x	x	x	x	x	x	x	x	x	x
Correctness -					x	x	x	x				x	x				x	x	x
Size -			1	2	3	3	3	3	4	4	4	3	3	3	3	4	3	3	3

Figure 3—Working sets for $T = 4$

The higher the degree of locality exhibited by the program, the more likely it is that T can be chosen to satisfy the two conditions, and consequently the larger the fraction of time during which the working set is a correct estimate of current locality. Additional factors influencing the choice of T will be mentioned shortly.

The use of a moving window to estimate locality as discussed above is more a matter of convenience than necessity. In a practical implementation it would be sufficient to associate "use-bits" with pages; a page's use-bit is set when the page is referenced, and is read and reset at the end of each interval of T references. The use-bits found to be set at the end of a T-interval would define a working set, and the working set so measured would be used as an estimator of locality until updated at the end of the subsequent T-interval. Indeed, my original proposal for working sets was based on this idea.[10] The T-intervals can coincide with the time slices used to schedule programs.[9,11,12,22,23,27]

Suppose one postulates a "working set paging algorithm"—i.e., a page replacement algorithm that replaces only the non-working set pages of a program. It can be demonstrated that this algorithm will implement the "principle of optimality" for page replacement (replace the page not expected to be used again for the longest time) provided locality is good.[15] In other words, the use of locality as a basis for memory management is close to being optimal.

THE WORKING SET PRINCIPLE AND THRASHING

The *working set principle* for memory management states that a program may be active (i.e., eligible to receive time slices on a processor) only if its working set is loaded in main memory.[11,12,17] It follows from this statement that the number of active programs is limited by the main memory capacity and the sizes of working sets; indeed, if there are n active programs, the main memory capacity is M pages, and the ith working set $W_i(t, T_i)$ contains w_i pages, the working set principle states that the relation

$$w_1+\cdots+w_n\leq M \qquad (2)$$

must be true with high probability at all times. It follows from this statement that only the pages not in the working set of any active program are subject to removal from main memory; in particular, if every page in memory were a member of a working set, it would be necessary to deactivate some program in order to create candidate pages for removal.

If the working set principle is not followed, it is possible for attempted overcommitment of memory to precipitate *thrashing,* a collapse of system performance, especially when the ratio of speeds between auxiliary and main memory is high.[9,12,13,15,23,27] It is of course possible for the working set principle to be violated without having thrashing; the point is that the principle defines a sufficient condition for avoiding thrashing.[13,15]

An efficient implementation of the principle would employ a compromise between the ideas of demand paging and swapping. Demand paging would be used to acquire pages during a program's active intervals, and swapping would be used to move a working set as a unit at the beginnings and ends of active intervals. Such strategy can be remarkably effective when properly designed.[20]

WORKING SET SIZE AND PAGING RATE

The working set size $w(t, T)$ is the number of pages in the working set $W(t, T)$. The average size for the first k references is

$$s_k(T) = \frac{1}{k} \sum_{t=1}^{k} w(t, T) \tag{3}$$

and the limiting *average size* is

$$s(T) = \lim_{k\to\infty} s_k(T) \tag{4}$$

(The error introduced by using $s(T)$ when in practice one would use $s_k(T)$ for some k is not significant under the assumptions of locality.[17]) Consider a reference string segment $r_1r_2 \ldots r_k$; for this segment, let $q(k)$ denote the number of times r_{t+1} was not in $W(t, T)$, $0 \leq t < k$. The *missing-page rate* is

$$m(T) = \lim_{k\to\infty} \frac{q(k)}{k} \tag{5}$$

so that $m(T)$ measures the average rate at which pages are entering the working set. Note that $m(T)$ is an upper bound on the page-fault rate of a single program in a system using the working set principle of memory management, for a page may leave the working set and subsequently return without leaving main memory in the meantime.

The important properties of $s(T)$ are summarized in Figure 4. The curve $s(T)$ is upper-bounded by the smaller of T and N, where N is the size of the program; $s(T)$ is nondecreasing in T, i.e., $s(T) \leq s(T+1)$; $s(T)$ is concave downward; and the "slope" of $s(T)$ is the missing-page rate:

$$s(T+1) - s(T) = m(T) \tag{6}$$

Finally, $m(T)$ is nonincreasing, i.e., $m(T) \geq m(T+1)$. The proof of (6) is straightforward: note that

$$w(t+1, T+1) = w(t, T) + \Delta w \tag{7}$$

where Δw is 1 if the next reference r_{t+1} is not in $W(t, T)$ and 0 otherwise, i.e., Δw is 1 if and only if the next page referenced is missing. Observe that the expected value of Δw is $\overline{\Delta w} = m(T)$. Taking expectations on both sides of (7), one finds

$$s(T+1) = s(T) + \overline{\Delta w} = s(T) + m(T) \tag{8}$$

which is equivalent to (6). A complete discussion of these properties, together with proofs, can be found in Reference 17. Experimental verification is presented in Reference 25. Further relations between $s(T)$ and $m(T)$ and page "interreference-interval distributions" can be found in Reference 17.

PRACTICAL IMPLEMENTATIONS OF WORKING SET POLICIES

There is a close kinship between the working set model and LRU (least-recently-used) paging, a kinship which can be used to approximate the working set model in systems where implementing a window T is impractical. The LRU paging algorithm is a demand-paging algorithm for managing a main memory space held fixed at k pages; at each page fault the least-recently-used page is replaced to make way for the page entering memory, so that the memory always contains the k most recently used pages. By comparison, a working set

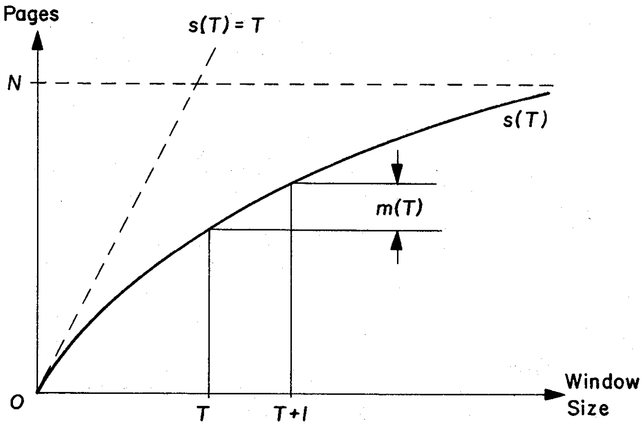


Figure 4—Mean working set size

$W(t, T)$ always contains $w(t, T)$ most recently used pages, where $w(t, T)$ is variable. It follows immediately that the $s(T)$ and $m(T)$ curves of a program can be used to estimate the page-fault rate $F(k)$ of the LRU algorithm in a k-page memory; see Figure. 5. A more detailed argument[17] shows that, under general conditions, $F(k) \geq m(T_k)$.

Now, one can imagine implementing a working set policy according to which the window size T is varied dynamically so that the missing-page rate $m(T)$ is controlled to be within a range m_1 to m_2, where $m_1 > m_2$. The importance of such a policy is twofold: not only does it imply each program operates in a known range of processing efficiency, but it allows a system designer to determine bounds on the paging traffic generated by a given statistical mix of active programs. The policy determines a sequence of times $t_0 t_1 t_2 \dots t_i \dots$ such that $T_i = t_i - t_{i-1}$ is the ith value of window size and (t_{i-1}, t_i) is the ith "sampling interval." During the ith sampling interval the program is run under a working set policy with window size T_i, the number p_i of pages entering the working set during that interval is counted, and p_i/T_i serves as an estimate for the missing page rate $m(T_i)$ during that interval. If p_i/T_i exceeds m_1 then T_i was too small and T_{i+1} is set to a value larger than T_i; if p_i/T_i is in the range m_1 to m_2, T_{i+1} is the same as T_i; and if p_i/T_i is smaller than m_2 then T_i is too large and T_{i+1} is set to a value smaller than T_i.

By virtue of the relation between the working set model and LRU paging, one can approximate the foregoing procedure using LRU paging in a memory space whose size is varied from time to time. In this case, T is taken as a fixed sampling interval (e.g., a time slice), p the number of page faults in the previous sampling interval, and p/T the estimate of page fault rate. If p/T exceeds m_1, the program is allocated one additional page of memory during the next sampling interval (this page being filled on demand at the next fault); if p/T is in the range m_1 to m_2, the memory allocation is unchanged; and if p/T is smaller than m_2, the memory allocation is reduced one page during the next sampling interval (the least-recently-used page being removed). This process is repeated for each sampling interval. During each interval the memory space allocation is fixed and LRU paging is employed. At any time the contents of memory serve as an estimate of the working set.

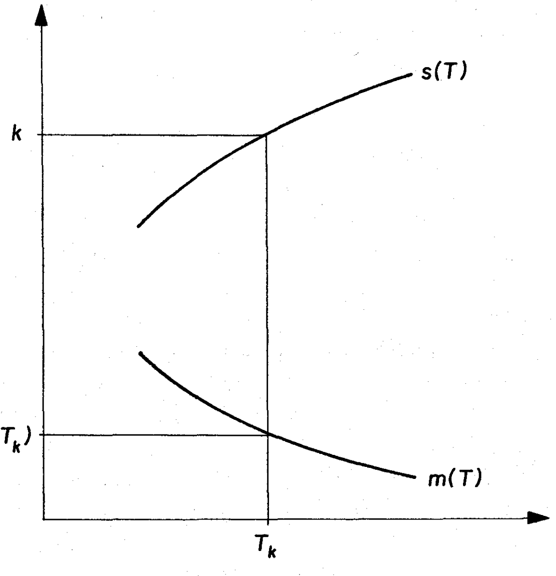

Figure 5—Estimating LRU paging rate

It is important to note that, if the LRU approximation to the working set principle is used in a multiprogrammed memory, a page fault generated by a program causes a page to be replaced from that program's own working set but never from another program's working set. Put another way, the LRU algorithm is applied on a "local" basis but not on a "global" one. Thus a program's missing-page rate depends only on its own behavior and never on that of another program: its working set survives intact despite the paging activities of other programs with which it shares main memory.

DISTRIBUTION OF WORKING SET SIZE

It can be shown[17] that whenever the third property L3 of locality holds—reference substrings tend to become uncorrelated as the interval between them becomes large—the working set size is approximately normally distributed about its mean $s(T)$. Suppose $w(t, T)$ is a working set size process with mean s and variance σ^2. The normal approximation for the distribution of $w(t, T)$ asserts that, for large t,

$$\Pr[w(t, T) \leq x] = \Phi\left(\frac{x-s}{\sigma}\right) \tag{9}$$

where

$$\Phi(x) = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{x} e^{-u^2/2}\, du \tag{10}$$

is the cumulative distribution of a normally distributed random variable with zero mean and unit variance. The ability to consider $w(t, T)$ as a normally distributed random process is of key importance, in view of the enormous literature and theory extant about such processes.[8]

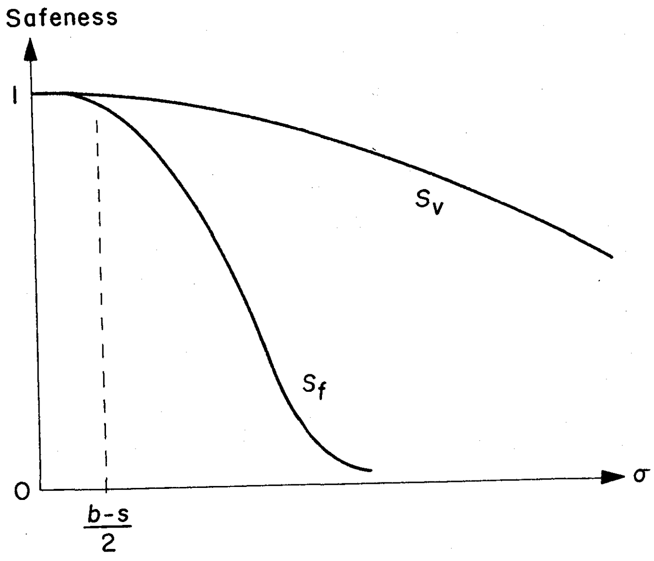

Figure 6—Safeness of fixed and variable partitioning

Two deviations are inherent in the use of the normal approximation to the distribution of working set size: the normal distribution is continuous whereas working set size is discrete, and the normal distribution is defined for negative values. The first deviation is not significant for programs whose working set size varies over a wide enough range of values, and the second is not significant for most parameter values (s and σ) of interest.

The normal approximation has been found remarkably accurate when the correlation property (L3) of locality holds.[8] If this property fails to hold (e.g., the program contains a global loop), it will be possible to predict arbitrarily distant future reference patterns on the basis of present ones and significant deviations from the normal approximation will be observed.[25]

FIXED VERSUS VARIABLE PARTITIONING OF MEMORY

The strategies for allocating main memory, under multiprogramming, usually lie near one of two extremes. According to the *fixed partition* strategy, each of the programs sharing the memory is allocated a fixed amount of memory for its private use. According to the *variable partition* strategy, the amount of space allocated to each program depends on its working set size. The principal argument advanced for fixed partitioning is simplicity of implementation; a recent study by Coffman and Ryan, however, suggests that the cost of implementing variable partitioning is more than adequately compensated by the saving in memory requirement.[8]

Under the assumption that n programs whose memory demands are normally distributed working set processes with the same mean s and variance σ^2, Coffman and Ryan compared a fixed partition and a variable partition strategy with respect to a "safeness factor" as a performance measure (the safeness factor is related to the volume of paging and overall efficiency). In both cases the total mount of main memory was M pages. In the fixed partition case, each program is allocated a block of b pages and the total memory capacity is $M=nb$; a block is considered safe (unsaturated) whenever the instantaneous value of working set size for the program using that block does not exceed b, and the multiprogrammed memory is considered safe whenever all the blocks are safe at the same time. In the variable partition case, each program is allocated an amount of space equal to its working set size; this system is considered safe if the sum of the working set sizes does not exceed the memory capacity M. The values of S_f, the safeness factor for fixed partitioning, and S_v, the safeness factor for variable partitioning, are readily determined under the assumption of normally distributed working set size. The results are suggested in Figure 6. Whenever the variance σ^2 of working set size is small enough so that the block size b is at least $s+2\sigma$ [equivalently, σ is less than $(b-s)/2$], the two strategies are competitive; but when σ becomes large, the variable partition strategy is considerably safer than the fixed partition strategy.

Under the assumption of variable partitioning and a working set memory management policy, it is possible to specify the equipment configuration (relative amounts of processor and memory resources) of a computer system.[14]

CONCLUSIONS

Originally introduced as a means of understanding the vagaries of multiprogrammed memory management, the working set model has proved useful both as an aid for guiding one's intuition in understanding program behavior, and as a basis for analyses and simulations of memory problems. To summarize: it has led to a sharpening of the notions "working information" and "locality of reference"; it has aided in the development of multiprogrammed memory management strategies which guarantee each program a given level of efficiency and which prevent thrashing; it has quantified the relationship between memory demand and paging rate; it has led to better understanding of paging algorithm behavior in both demand and prepaging modes; and it has enabled preliminary analysis of fixed *v.* variable partitioning of multiprogrammed memories and of system equipment configurations. Approximations to the working set principle have been used successfully in many contemporary systems both large and small, demonstrating the viability of the model: systems reporting success include the RCA Spectra 70/46,[9,23,27] certain TSS/360 installations,[18] the TENEX system for the PDP-10,[4] and MULTICS. Many systems have used, successfully, approximations to the working set model, and at least one is including hardware capable of implementing the moving-window definition of working set.[22]

Many extensions to the model are possible and worthy of future investigation. For example, the working set can be defined as the set of most recently used blocks of program code, the assumption of fixed sizes pages being eliminated. Or, it may be useful in some situations to partition the working set into two disjoint subsets, the instruction working set and the data working set, and to implement the working set principle separately for both these working subsets. Or, none of the foregoing considerations has allowed for the possibility of sharing—overlapping working sets—in certain cases the effects of sharing have been quantified, a notable reduction in total memory demand being observed.[12]

Magnetic disks for bulk storage—Past and future

by JOHN M. HARKER and HSU CHANG

IBM Systems Development Division
San Jose, California

INTRODUCTION

In the early days of electronic data processing, new application requirements arose that could not be met adequately by batch processing, a mode dictated by the sequential nature of card and tape input-output equipment. Users needed a device to store and directly access relatively large amounts of data on-line. The first such products, IBM's RAMAC disk file and Sperry Rand's Randex drum, partially answered these needs. However, their use could be justified only for storage of highly active data due to their limited capacity and high cost compared to off-line tape storage.

The subsequent introduction of the interchangeable disk pack lowered disk storage costs and offered a means of supplementing on-line disk capacity with shelf storage of infrequently used data. Systems designed with this component, in combination with programming support for skip sequential processing and other new features, made disk-oriented data processing commonplace by the middle of the 1960s. During the past five years, the acceptance of the disk pack has continued to be a major factor in the explosive growth of disk storage. While important developments have also taken place in fixed media disk devices, the total on-line capacity of disk pack devices today is more than several hundred times that of fixed media files and drums.

A compounding of four other factors had a substantial influence on the success of the disk pack and the rapid growth of disk storage during this period. First, the total data processing base expanded at a very high rate following delivery of the IBM System/360 in 1965. Second, the introduction of IBM's multidrive 2314 disk facility made hundreds of megabytes of on-line storage practical at a cost per byte significantly below that of previous disk pack devices. Third, large programming operating systems became widespread, permitting a user to conveniently incorporate disk processing in his system configuration without knowledge of the device characteristics or programming requirements. Last, remotely operated time-sharing networks and the evolving capability of both hardware and systems programs to handle multiple jobs efficiently put a high premium on having direct access to a large data bank. Not to be overlooked, the operating systems themselves required an increasing amount of on-line storage capacity, typically 25 megabytes at a large installation.

In this systems-oriented environment, the disk pack still performs a vital function in system reliability by assuring that data availability is not jeopardized by the failure of a single drive. However, the use of disk packs as a way of loading and unloading user jobs can be expected to diminish at installations with extensive operating systems since these systems view the peripheral hardware as a resource which is allocated and scheduled without operator intervention. For efficient system usage, a single user's data sets are frequently spread among several packs (or "volumes") of storage and may be interspersed with data associated with other user jobs.

The gradual shift in data management from user to system began with the increase in disk pack capacity from approximately 7 megabytes in the IBM 2311 disk drive to 30 megabytes in an IBM 2314 drive. This trend will accelerate as users move to new disk devices with considerably larger capacity such as the 100-megabyte disk pack in the IBM 3330 drive (Figure 1).

Still another important development over the past few years is an increase in the number of disk device manufacturers whose resources and competition can stimulate further advances.

To see where these trends will lead, it is necessary to understand what key technology developments can be expected, and then put them in the context of future system requirements. Since present disk storage devices rest on a technology base of magnetic recording, primary emphasis will be placed on this technology and its potential for further progress. Alternative tech-

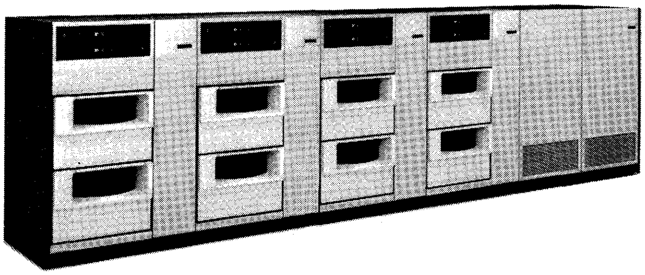

Figure 1—For computer installations in the '70s, the central processor will perform arithmetic and logic operations at speeds measured in billionths of a second, and it must draw upon vast amounts of data stored in magnetic disk units. The IBM 3330 disk storage holds 200,000,000 bytes of information and through its associated control unit, the IBM 3830, feeds data to a processor at a rate of 806,000 bytes per second

nologies now emerging will be briefly assessed. The resulting predictions are, of course, individual and not corporate, but hopefully the ideas have been drawn more from objective observations and published fact than from personal bias.

HARDWARE CAPABILITIES

While a disk file is an intricate piece of machinery, its basic capability rests upon a few key components in addition to the storage disk. The magnetic transducers record and read magnetic patterns representing the information. An actuator moves the transducers over a large number of tracks of recorded information, permitting the economy of access to a large volume of information. The switching circuits enable many transducers to share drivers and sense amplifiers for write and read operations and to share a control unit for processing signals and interfacing the disk file with a data processing system.

In analyzing the cost and performance of a disk file, areal storage density is the key parameter to consider. This stems from the fact that disk files have an inexpensive storage medium but expensive auxiliary components, and only yield a low cost per bit when the auxiliary components are shared by as many bits as possible. Higher areal density also improves performance parameters such as the data rate, access time and amount of data per access.

Along with capacity increase, disk storage devices have improved steadily in reliability and versatility. The successive generations of disk files and their control units have acquired capabilities such as on-line diagnostics, independent device servicing, rotational position sensing and command retry.

Nonetheless, the trend toward a lower and lower cost (e.g., a decrease in rental from $23/megabyte/month for the 2314 facility in 1967 to $8/megabyte/month for the 3330 disk facility in 1971) continues unimpeded because the advantages of density improvements far offset the costs associated with better component and device performance. However, density improvements will not readily enable us to produce small capacity files at significantly lower cost per byte because the cost of auxiliary hardware cannot be spread over a large enough volume of data.

To understand what is desirable and possible for future disk development, we must examine the critical parameters that control areal density—the product of linear density (bits per inch along a track) and track density.

Let us turn first to linear density which, in magnetic terms, is the number of flux changes per inch. This factor is primarily controlled by geometrically related parameters. That is, the head gap determines the minimum bit dimension that can be resolved, and the storage medium thickness and head width determine the maximum available flux. Also, our ability to keep the head gap in close proximity with the medium determines the efficiency of magnetic coupling between the two and insures better resolution by minimizing the interaction of magnetic fields from adjacent flux transitions.

In track density the limiting factor is our ability to accurately position the read-write head within a fraction of the track width. An error in positioning can cause either erasure of an adjacent track or failure to erase completely a previously written record. On readback, either case will reduce the maximum possible signal-to-noise ratio (S/N).

The common design practice is to maintain a position tolerance within 20 percent of the track width.* Early systems used mechanical detents. In the newer machines, the recording head is positioned either by a signal read from one of the recording surfaces as in the IBM 3330 drive or from an external servo reference as in the Information Storage Systems 715 drive and similar disk devices. These techniques have permitted the use of densities reaching 200 tracks per inch.

To improve the positioning tolerance in future systems will probably require servo techniques that actually use the data track itself to provide an appropriate error signal. This perhaps could be accomplished by including appropriate servo data in the basic recording code or by interspersed patterns along the track, at the price of a sacrifice in linear density.

* Because of the many individual tolerances, the actual allowable misregistrations for a particular machine is normally expressed in statistical terms.

On balance, linear density appears to be more amenable to improvement than track density. Increased linear density when compensated by reduced head-to-medium spacing could maintain the same signal, while increased track density would always be accompanied by a loss of signal for a given number of turns. Moreover, as the track is decreased below the present .005-inch width, significant problems in the accuracy of both static and dynamic mechanical positioning of the head will be encountered because of limitations in servo bandwidth, spindle bearing noise, thermal gradients, and similar mechanical factors.

Now, let us examine in more detail the components affecting linear density.

Recording medium

A particulate coating is commonly used for the recording medium. Magnetic particles dispersed in a binder have proved to be tolerant to impact and wear. This system allows us to separate the problem of obtaining the desired magnetic particle characteristics from the problem of obtaining the desired mechanical durability, smoothness, and uniformity in the binder. Consistent with the improved resolution of the recording system, the storage medium thickness has been reduced in successive improvements from 1000 microinches in the earliest disk files to below 100 microinches at present.

While some further improvement is possible, we appear to be reaching the limit of our ability to form a uniform thin coating with adequate loading and dispersion of particles of the proper magnetic materials. Further density increase may require a medium thickness below 20 microinches. The simultaneous requirements of such a thin medium for efficient magnetic coupling and of high magnetization for maintaining an adequate signal seem to be better answered by continuous magnetic films.[1] However, in such media the problems of producing desirable magnetic properties and a durable physical surface must be solved simultaneously. Magnetically, they must provide stable storage, adequate signal and low surface noise. Mechanically, they must withstand the wear from intermittent contact between the disk and the head. From evidence to date, a considerable development effort will be required to achieve a technology as consistent and reliable as current particulate coatings.

Read-write transducers

With write and read transducers, the current practice is to use a ferrite ring head with a glass gap. We can obtain an accurate and well-defined gap with a 40 to 80-microinch length, a 400 to 1000-microinch height, and magnetic pole pieces infinitely long relative to the gap length. Long pole pieces are a consequence of fabrication techniques to obtain flatness economically. Accurate control of gap height is essential since it provides a shunt path for the magnetomotive force and sense flux, respectively, during write and read.

When compared to gap, spacing, and track width, the head as a whole is a bulky structure. While smaller ferrite structures can be produced, current machining practices are a serious limitation to significant size reduction.

One of the fallouts from magnetic film memory technology is a fabrication technique which could be used to form miniaturized magnetic read-write heads.[2] The technique allows us to deposit magnetic-conductor-insulator multilayers and to shape miniaturized structures by photolithography and various etching processes, making it possible to produce narrow gaps for higher linear resolution and narrow width for high track resolution. Also inherent in the fabrication process is the ability to produce economically a multiplicity of elements. They could either be sliced from a large wafer into many chips for individual use or used as a group to provide an array of heads for fixed head files.

Structures of greater complexity than that required for head arrays have been deposited directly onto a silicon wafer in the fabrication of thin film magnetic memories.[3] This suggests the possibility of an array of magnetic heads optimally packaged with the semiconductor selection matrix and sense amplifiers on the same silicon chip. Such heads have quiescent magnetization parallel to the disk surface to avoid undesirable disturbance, high magnetization for an efficient write field, and high permeability at high frequency for efficient coupling during reading.

Head-to-medium spacing

The mechanical access device in the most recent disk files consists of a servo-regulated actuator which moves an air-bearing slider that, in turn, carries the read-write heads. The key design consideration here is the control of head-to-medium spacing.

Smooth, flat surfaces for the head carrier and the medium are essential to the control of head-to-medium spacing. Machining, polishing, and buffing techniques have been developed to consistently produce surfaces with roughness within an arithmetic average of a few microinches. Smooth surfaces prevent contact and ensure operation in a state where there is hydrodynamic lubrication by the air film carried at the boundary layer of the disk.

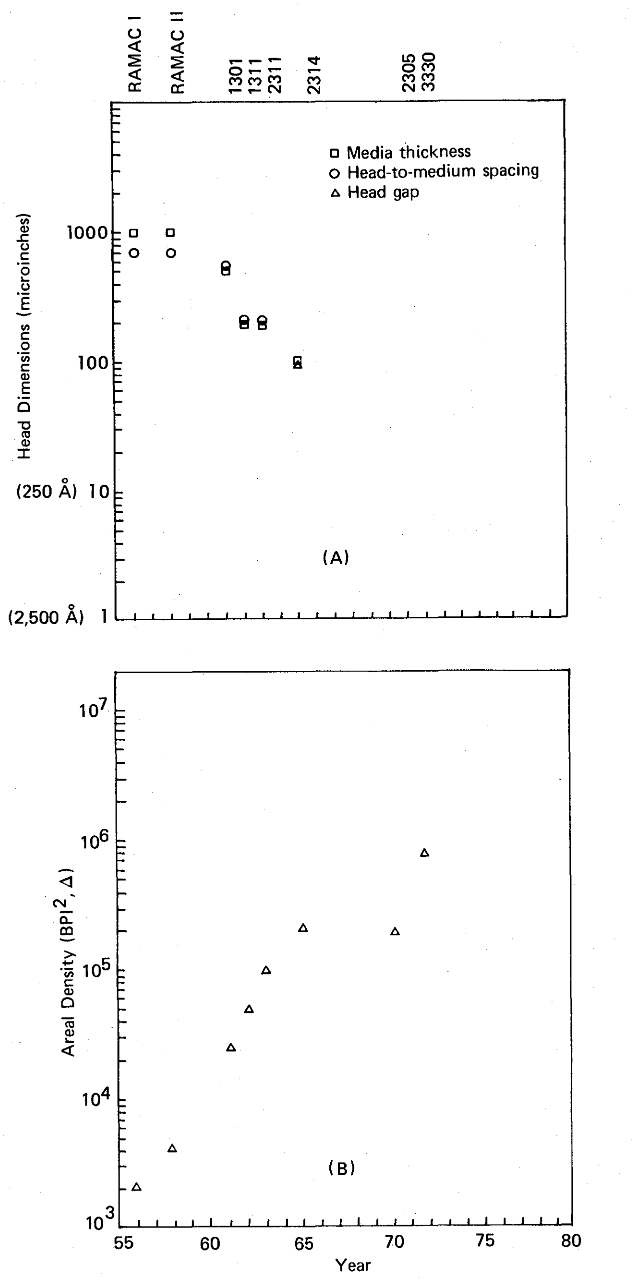

Figure 2—With successive models of disk files, (A) the head gap, medium thickness and head-to-medium spacing continued to decrease, (B) to achieve higher areal storage density

High resolution in future disk files will require considerable reduction in head-to-medium spacing. The air flow will still retain the properties of a continuous fluid medium apart from the regions near the surface where slip flow will occur. The validity of continuous flow will be a function of the Knudsen number, which is the ratio of the mean free path of the air to the spacing. As long as this ratio is less than unity, the continuous flow assumption will hold and hydrodynamic lubrication will not present any limitation. Since the mean free path of air is 2.5 microinches at atmospheric pressure, it is estimated that no hydrodynamic limitation will be encountered at spacings above five microinches.

Reduction of the spacing will also require a proportional reduction in the area of the bearings used to support the magnetic transducer. Such a reduction in area would be accompanied by much lower loads than those needed for air bearings at present.

The preceding discussion alludes to a general relationship between recording density and geometrical parameters of components. Indeed, as shown in Figure 2, successive generations of magnetic disks indicate that areal density has been increased by scaling down three key geometrical parameters: head gap, medium-to-head spacing, and medium thickness.

Reading, which is the inductive sensing of the recorded magnetic pattern in a disk, is essentially a linear phenomenon. If all geometrical parameters in the three-dimensional space are scaled up or down, while the magnetic material (specifically, the magnetization) is unchanged, the field distribution and field magnitude do not change.[4] Since the signal voltage is directly proportional to flux ([field] [length]^2) and inversely proportional to time duration ([length]/[rotational speed]), the signal voltage per unit track width per turn of read head ([field]/[rotational speed]) stays constant. The signal is also directly proportional to storage medium magnetization. Typically, for an iron-oxide disk medium at a rotational speed of 3600 rpm, a signal voltage of 10 microvolts per mil of track width and per turn of read head is obtainable.

The dimensions for the key geometrical parameters at various areal densities could be extrapolated if one set of values were known. Using the IBM 2314 as a reference, at 2×10^3 bits per inch linear density (2×10^5 bits per square inch areal density), the head gap, medium thickness, and head-to-medium spacing are, respectively, 100-100-80 microinches. Extrapolating the linear density of the 2314 file (2200 bits per inch) by a factor of 10 would reduce these parameters to 10-10-8 microinches.

Obviously a 10-microinch (2500 Å) gap is not easily achievable with the conventional ferrite technology. The problem is compounded when narrow track width is also pursued for higher track density. Thin film heads offer one solution for producing such narrow gaps. The thin recording medium required would be difficult to achieve with particulate binder coatings. However, a continuous film medium could provide a film of the required thickness with the higher magnetization needed to maximize the signal output. Typical saturation flux density for cobalt nickel film is 10,000 gauss, while that for iron-oxide disks is 450 gauss.[1]

This analysis demonstrates that the per-turn per-unit track width signal can be maintained or even improved at high linear density if we are willing to pay the price of implementing exacting geometrical dimensions and developing new materials and fabrication techniques. It should be emphasized, however, that the total signal is likely to decrease by a factor of 10 with the projected higher areal density since a miniaturized head can only accommodate fewer turns of windings than before, and higher track density requires narrower head width.

For increased areal density in the near future, better detection circuits are needed in addition to improvements in recording components and mechanical tolerances. Further density improvement will be accompanied by the signal decreasing toward the intrinsic noise levels of both the storage media and the electronic devices.

Signal-to-noise ratio

In viewing the disk file as a transmission channel, we encounter many sources of degradation in the optimal available signal-to-noise (S/N) ratio. Track misregistration detracts from the written signal and adds unerased old recording to the noise. Head-to-disk-spacing variation affects the pulse crowding phenomena. Lack of uniformity in the distribution (size and orientation) of magnetic particles as well as foreign inclusions and voids in the binder system cause extra and missing bits. Up to now, these noises have been the principal sources of error, and most of the engineering design and process quality-control efforts have been aimed at avoiding and minimizing them.

However, with the high degree of miniaturization, the intrinsic random noises will assume a significant role. They include the so-called storage medium "shot" noises and thermal noises associated with the input impedances of the sense amplifiers and the winding resistances of the read heads. The signal voltage induced in the read head is composed of the individual voltages produced by the discrete magnetic particles embedded in the binder. Their discreteness and inhomogeneity result in a random noise which is analogous to those associated with the emission of discrete electrons in vacuum tubes.

While the system noises arising from mechanical misregistration or environmental pickups can be designed to an acceptably low level, the intrinsic random noises cannot be prevented. We can only insist on an adequate S/N to ensure a sufficiently low probability of failure or sufficiently long mean time between failures (MTBF).

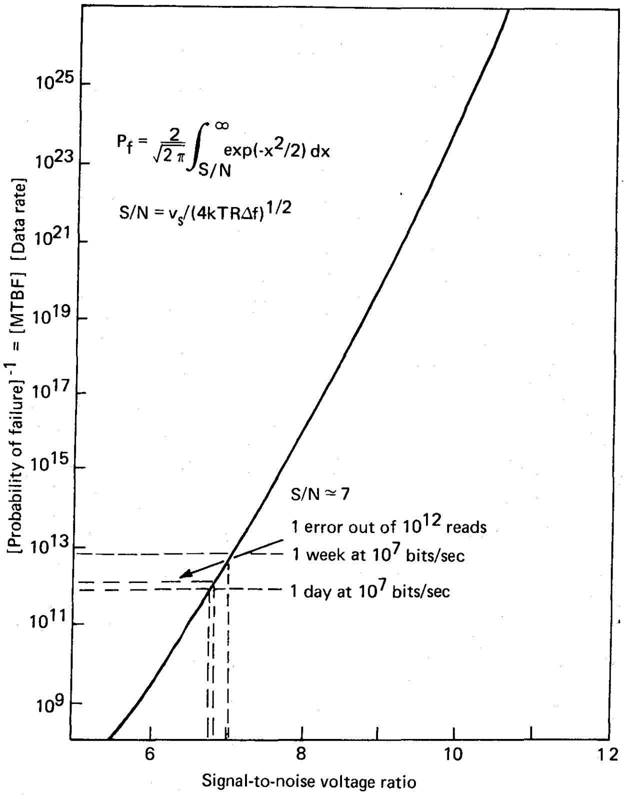

Figure 3—Mean-time-between failures as a function of signal-to-noise voltage ratio

A very striking feature of the intrinsic noises is the extremely nonlinear relationship between the MTBF and the S/N. For example, when the S/N is reduced from 10 to 5 (a factor of 2), the MTBF suffers a reduction by 16 orders of magnitude! Thus, it is imperative to have an ample margin for the S/N in order to safeguard a satisfactory MTBF or to ensure an acceptably low error rate.

To achieve an error rate of one error out of 10^{12} reads, an S/N of 7 is required (Figure 3). A signal of a few tens of microvolts per mil turn at linear densities between 10 and 20 kilobits per inch can be obtained by using improved magnetic components. If a 10-turn read head and .002-inch track width are assumed, the signal at the preamplifier is a few hundreds microvolt. Presently, preamplifiers have a thermal noise of about 50 microvolts at a frequently bandwidth of 15 MHz at room temperature. The noise voltage (V = square root of $4kTR\Delta f$) as seen by the sense amplifier is a function of the amplifier bandwidth. As increased data rate (resulting from higher linear density) requires wider bandwidth, the noise increases. For example, the same intrinsic noise source which gives 50 microvolts at 15-MHz bandwidth would give 130 microvolts at 100-MHz bandwidth. Obviously, the present preamplifiers are inadequate for the future high density magnetic disk recording. To maintain the S/N at 7, the thermal noise should not exceed 30 to 70 microvolts at a bandwidth of 100 MHz.

The typical medium shot noise from a state-of-the-art particulate disk is a few microvolts per mil turn. For a 10-turn head, the medium noise is amplified to tens of microvolts per mil at the input of the sense amplifier. To reduce the shot noises in particulate media, particles must be made smaller and more homogeneous. Fine polycrystalline continuous thin film media may also be helpful.

The thermal noises can also be lowered by reducing sense amplifier input impedance. Moreover, since the errors due to random noises are transient and recoverable, a track can be reread to correct the errors, provided that reread occurs infrequently.

Coding

So far, we have implicitly equated bits per inch with flux reversals per inch. This implies a data coding that requires one bit per flux reversal, but codes are possible which achieve greater than one bit per flux change. Current products use coding schemes (NRZI, FM, MFM) that range from one to two flux changes per bit. The choice of such codes is usually dictated by a balance between spatial resolution and timing tolerance of clocking and data detection. Codes that offer as much as two bits per flux change require clocking capability which must maintain synchronization within a small fraction of a bit time over many bit periods. Extremely narrow pulses also are needed to minimize peak shift caused by adjacent bit interference. At a 10-MHz data rate, this requires timings in the nanosecond range and is difficult to achieve economically in normal commercial environments, due to variations in disk speeds, temperature, and other factors.

This tradeoff, compounded with the extreme nonlinear error dependence on the overall system S/N makes it unlikely that practical recording devices will greatly improve upon a one-to-one relation between flux reversals and bits stored.

DEVICE CHARACTERISTICS

So far, only factors most relevant to increasing areal density have been examined. Let us now consider device characteristics which include actuator access time, latency time, data rate and volume of data per access.

The access time is limited by the mechanical design of the actuator and the servomechanisms. The latency time is half the period of rotation. The data rate is the product of linear density, track length and angular velocity. The volume of data per access is the product of tracks per cylinder (number of heads) and bits per track.

Thus, an increase in linear density improves two of the four performance parameters since it increases both the data rate and the volume of data per access. However, these improvements have an upper limit. We know that the linear density is increased at the sacrifice of S/N due to signal decrease as well as bandwidth increase. This leads to increased error rate (or probability for failure). The MTBF suffers both from the data rate increase and failure probability increase. Since the thermal and shot noises are random, the errors will be transient and recoverable; we could and would attempt occasional reread. However, when the MTBF approaches the period of rotation, continuous reread will be needed and we have reached an untenable situation.

In addition to density improvement, there are other avenues to performance improvement. It has been demonstrated in fixed head files that the access time can be eliminated. In one fixed head file (Burroughs Model 9375-3), 12,420 heads are used to serve 40 fixed data surfaces. Currently, such files are significantly more costly than moving head files of the same capacity, but again the application of thin film technology could substantially reduce this premium, at least at modest capacities.

Magnetic thin-film head arrays are composed of fewer layers of materials[2] and a smaller number of magnetic elements (typically tens of heads) compared to a film memory array (typically 10^3 to 10^5 bytes). Thus, the existing fabrication techniques as advanced by the film memory development, together with the necessary improvements in the disk surface and a mechanical slider to hold an array of heads, could produce integrated head arrays. When combined with a semiconductor selection matrix, an economical solution to reduce access time substantially may well be possible.

The latency time seems to be a different matter. Each track contains more than 10^5 bits at present, which will increase to more than 10^6 bits in the future. To be competitive with electronic random access memories which can directly access many small blocks (hundreds to thousands of bits), thousands of integrated head arrays with associated sliders and selection matrices would be needed. Obviously, this would be an inferior answer for applications requiring short latency time, and we can expect disks to continue to serve optimally as storage for relatively long records. At its best, the disk file may approach the performance of a shift register electronic memory, but it will still fall short of the performance of an electronic random access memory.

Improvement of the cost per bit through capacity increase need not be accompanied by high data rates entailing expensive electronics. By lowering the rotational speed, the economy of large volume can be obtained while holding the data rate constant. However, this would result in a proportionate increase in latency, offsetting the current effort to decrease access time and improve system throughput.

In summary, over the next decade, there is the potential to improve linear density by a factor of 5 to 10, and the track density by a factor of 2 to 4. Beyond that, the cell sizes will be limited by intrinsic noises, and the cost of further improvement would outweigh its gains.

To achieve these improvements, new technologies will have to become practical. Reaching these goals will require significant changes in basic processes, the resources of a vigorous competitive industry, and probably will take most of the decade to evolve.

ALTERNATIVE TECHNOLOGIES

The continual demand for more on-line bulk storage has attracted new technologies to contend for the magnetic disk market. While these technologies are based on interesting physical phenomena and enthusiastic predictions, their merit as future products must be measured in terms of both economical viability and technical capability.

The economical assessment of any totally new technology should cover the development cost for both hardware and programming, and address whether the possible return will justify the investment. The latter will be influenced by the range of products to which the new technology can be applied. The assessment of hardware costs should include not only the development of new storage materials, but associated component technologies and system interface. Programming costs would include the impact of both system and user programs. Most difficult of all, if basic changes in current system architecture are required, the burden of justifying a total system development falls on the new technology.

It is useful to summarize the advantages and disadvantages of magnetic disk systems with a view toward the difficulties and opportunities for introducing alternative technologies into the market place. The reversibility of magnetic recording permits updating records in place, and its remanence ensures nonvolatile storage. Concurrent development of systems configuration and disk files has resulted in considerable interdependence of operating systems and disk processing. This and heavy user investment in disk-oriented programming will discourage dramatic departure from current hardware concepts. Off-line storage capability gives the user unlimited private programs and data sets, along with the flexibility to use different computing systems. As an on-line storage device, the disk drive offers large data volume per access, has 10-millisecond access time, provides very fast data rates, and includes considerable logic and system capabilities through the channel and control unit electronics. At present, the disk file offers the largest on-line direct-access storage capacity (10^6 to 10^8 bytes, and growing beyond 10^9 bytes) at the lowest cost per bit. The technology on which such files are based is still capable of more than 10 times improvement in storage density, and hence commensurate improvement in both capacity and cost per bit.

Magnetic disk technology does have basic limitations. Unlike solid state memories, its cost advantage cannot be as easily extended to low capacity storage. It does not appear that substantially reducing latency by faster rotation or more transducers will be economical. Magnetic disk recording does not permit local mixture of memory and logic as does semiconductor technology. Finally, due to its mechanical nature, the disk file consumes space and power and requires maintenance. While these limitations do not detract significantly from the merits of the disk file for the majority of its present bulk-storage applications, they do offer opportunities for new technologies in special applications such as in space, or in minicomputers, and in computers with new architecture and operating systems.

Concentrating on bulk storage, we limit our comments to three leading alternative technologies: beam-addressable files,[5] LSI semiconductor arrays[6] and magnetic bubbles.[7]

Beam-addressable files use the speed and flexibility of optical techniques which rapidly move a light beam to access the stored data rather than mechanically moving the read-write device to the storage media as required in current disk storage. However, the problem faced by optical accessing methods is finding materials that are sufficiently sensitive to allow writing with very low energy levels, and which, in turn, provide enough energy to allow high speed readout with an acceptable S/N.

Photographic materials can satisfy both requirements. They have been used successfully, for example, in the trillion-bit memory of the IBM 1360 Photo-digital Storage System. Designed for specialized applications. the system's nonreversible film memory would seriously inhibit its extension to a more dynamic on-line environment. Systems which employ high energy lasers to vaporize holes in metallic coatings and other similar technologies face the same problems.

The most commonly proposed reversible beam-addressed file technologies are based on thermal writing and magneto-optic reading by a steerable laser beam. This approach, configured as a disk file, is attractive in concept. It shares with conventional disk equipment the simplicity of a homogeneous, stable, but reversible storage medium. At the same time, the beam technology offers the possibility of eliminating mechanical accessing mechanisms.

In practice, there are serious drawbacks. The magneto-optical read and thermal write transducers require the development of a storage medium with large magneto-optic effects. Although such materials exist (e.g., MnBi for room temperature operation, EuO or Fe-doped EuO for low temperature operation), they are by no means optimized nor do they have an established materials technology comparable to particulate oxide media or permalloy magnetic films.

Moreover, at present, nonmechanical deflectors can only steer a light beam to a limited number of recording tracks, and a simple solution to the technical problems involved does not appear to be immediately at hand. An alternative to this scheme utilizes mirror rotation in combination with a matrix-controlled laser array to select a track, and mechanical rotation to scan the track. Another drawback is that the dc bias field cannot be easily switched on and off, thus necessitating two rotations to effect rewrite.

However, the projected storage density (and thus, roughly cost per bit) of a magneto-optic file is comparable, but not significantly superior, to that for conventional magnetic recording. This factor, along with the current state of materials development and the mechanical-accessing feature suggests that the magneto-optical file is not likely to replace conventional magnetic files unless the latter fail to reach their projected improvement in areal density.

The semiconductor industry is well established and broad-based. Semiconductor components have found their applications in the memory hierarchy, ranging from the CPU to cache and main memory. Developments in FET devices and charge-coupled devices have further heightened the hope that they might become sufficiently cheap to replace disk files.

Since cost is the central issue, let us consider if there is a tangible technical basis for predicting whether semiconductor costs will approach magnetic disk costs. Basically, magnetic disks are only expected to perform the storage function, while the semiconductor storage cell must enable selection and transmission as well. Consequently, semiconductor devices have much more stringent materials requirements, and many elements have to be electrically connected.

The high quality single crystals, the high-resolution photolithography, and the many processing steps which tend to compound failures are not likely to lead to a cost even close to that of the disk file for bulk storage. However, it is quite reasonable to expect that solid state memories may eventually catch up with the low-capacity end of the disk files, namely the 10^6 to 10^7-byte fixed-head files. The cost per byte at that capacity level, whether for semiconductors or magnetic disks, is at least 100 times higher than that for the large-capacity disk files.

The magnetic bubble technology has shown impressive progress. It appears to have found materials for high-density storage, thin film techniques to facilitate fabrication, and processing steps similar to those well established for the semiconductor technology. But as far as cost is concerned, the comments concerning semiconductors apply equally well to the magnetic bubble technology. Perhaps the simpler structure, resulting in simpler processing steps, will give magnetic bubbles a cost advantage over semiconductors, but this still should be far above the cost of large disk files.

Undoubtedly, there are some intrinsic properties which could be explored for significantly new file configurations. For example, magnetic bubbles exhibit capabilities for both logic and nonvolatile storage. The logic capability enables on-chip decoding and amplification, and offers the potential of removing the demarcation line between storage unit and control unit. The nonvolatile storage capability allows both on-line and off-line stable storage.

In conclusion, the magneto-optical file is configured for bulk storage, but it still lacks satisfactory storage media and accessing devices. The photo-digital file (non-reversible media) implies a drastically different programming system and architecture. The semiconductor and magnetic-bubble memories do have a sound technology foundation, but their present configurations and cost projection are only suitable for large memories (10^6 to 10^7 bytes), but not for bulk storage (10^7 to 10^9 bytes).

PAST AND FUTURE HIERARCHIES

Having explored what technical capability can be expected, let us switch the frame of reference to that of a systems designer and look at what will be desirable and useful in the future development of disk storage.

In the past, storage has consisted of high-speed semiconductor memories, lower speed ferrite cores, fixed head disks or drums, movable head disk files and magnetic tape units.

As a sweeping generalization, to a system designer any form of hierarchy of storage is an undesirable compromise. Where possible, all the memory associated with a data processing system should be available in a single configuration with an access time comparable to the logical processing speed of the system. While in practice this is economically unrealizable, the fewer the levels of storage the better because each level produces a new set of problems and a new set of complexities.

In the past when the user worked with relatively simple problems that were well structured, stable and few in number, he could be expected to deal with the problem of knowing where his data was stored. He was also acquainted with something of the characteristics of the devices that were being used so that he could adapt his program to make efficient use of these devices.

Having user programs manage storage in such a manner implies that no significant change in the system can occur without impacting both user and systems programs. However, the life of an applications program needs to be easily extendable across several generations of hardware and operating systems.

Further in the future, there will be a multiplicity of users with less and less sophistication, as well as stored data sets for common usage whose characteristics the users do not understand, or even wish to understand, and cannot predict. Therefore, programming operating systems have evolved which perform a data management function and make the hierarchy of storage devices "transparent" to the users. This process started with the very primitive I/O subroutines of the '50s and proliferated in the mid-60s to include a wide variety of access methods and supervisory scheduling functions. These now are beginning to include virtual memory techniques and entire data handling subsystems such as Honeywell's Integrated Data Store and IBM's Information Management System. In addition, the increasing importance of shared data and the necessary associated security procedures will require new centralized storage management functions.

On the other hand, the management of bulk on-line storage has always been a critical issue in determining systems performance. Although substantial success has been achieved in transparently managing data movement between semiconductor buffers and main memory, similar techniques applied to data transfer between main memory and disk storage have achieved only limited success. The problem is that efficient management of today's on-line and off-line storage demands considerable attention to block size, sequentiality and patterns of periodic access. And the direct extension of these techniques to still another level of bulk storage is far from obvious as there is gap in storage management procedures between what we need to do and what we know how to do.

With this background, let us consider the hierarchy of storage defined previously and the impact of evolving technology on at least its exterior configuration.

Over the next 10 years, two main factors in addition to improvements in disk technology will be evident in computer storage development. First, there will be a substantial cost reduction in semiconductor memory or an alternative such as magnetic bubbles. Neither, however, is very likely to approach disks on a cost-per-bit basis. Second, extremely large capacity on-line magnetic tape devices will become available, such as the Ampex Terabit Memory System or other systems of mechanically accessed tape reels. Although we will see increasing variation in the possible characteristics of such large capacity storage devices, they will probably all characteristically have a lower cost per bit than disks during this decade and substantially poorer random access capabilities.

The cost reduction in semiconductor memory, or its equivalent, may result in its supplanting ferrite cores, fixed head disks and drums by the 1980s. Moreover, as these large capacity memories commonly reach 10^6 to 10^8 bytes, more jobs will be processed concurrently and more of the data required for a single job will be held in main memory. In this case, the present access time to a disk store can be tolerated, and pressure to improve this parameter will diminish in favor of an emphasis on cost, capacity, reliability and packaging advantages.

A more interesting question is the relationship of tapes and disks in future on-line storage systems.

A tape-oriented system might be envisioned as a three-level hierarchy, consisting of a very large main memory (10^7 to 10^8 bytes), a moderate-sized disk system, plus a tape based mass store.

In using this system we are confronted with the significantly increased difficulty of managing such a hierarchy at exactly the time when system, rather than user, management of storage is becoming more and more important. Looking up an entry in last year's ledger should not cause any substantial portion of that ledger to be staged to disk. On the other hand, because of the slow random access rate possible with the tape-based device, it is clear that, when a data set becomes active, independent requests to that data set must be limited to a few, if anything like the efficiency of current systems is to be maintained.

Such tape-based devices could reduce the need for capacity in disk storage. However, maintaining an equivalent rate of systems activity would substantially increase the requirement for accesses to each unit of disk storage since a smaller number of drives must handle all previous memory disk transfers plus the added accesses caused by tape-to-disk transfers. Thus, the cost savings in the disk component of the system may be less than expected.

As a result, it appears that the limitation of access rate in tape-based devices, however mechanized, will offset their lower cost unless a very low percentage of the accesses directed to the data base require access to that portion stored on tape.

These predictions do not imply that a tape-based library will not play an important role in future systems as an archival or I/O device. What they do imply is that such a device will not impede the growth of disk file capacity for on-line storage.

CONCLUSION

In summary, the picture is one of a continuing evolutionary development of present disk file technology with at least an order of magnitude increase in storage density as well as total storage volume, and a corresponding decrease in the cost per byte stored.

In a future hierarchy, the upper limits of solid state memory capacity imposed by cost considerations will move to the 10^7-byte range, either by continued development of silicon technology or the introduction of a new technology such as magnetic bubbles. However, above 10^8 bytes there still will be at least one and probably two orders of magnitude of cost-per-byte difference between solid state memories and large magnetic disk files. Thus, both will coexist.

The increased size and higher data rates of electronic memories will also tend to increase the need for blocking of records, permitting increased efficiency in the use of disk storage space. The very high data rate that will be possible and necessary as a consequence of further disk developments will make the interchangeability of disk packs more a feature that insures data availability than a typical means of moving data into and out of an active system data base.

Therefore, the role of disk storage will become more and more the maintenance of current on-line data with lower performance tape libraries performing an archival function.

Given the momentum of magnetic disk technology and the availability of new materials and fabrication technologies to provide a significant increase in density, it is unlikely that any other technology will displace magnetic recording in the coming decade as a principal data storage media for the industry. For some other technology to displace it, probably the alternative method would have to provide functions we do not foresee rather than merely a more economical or efficient means of storage.

Ultra-large storage systems using flexible media, past, present and future

by WILLIAM A. GROSS

Ampex Corporation
Redwood City, California

INTRODUCTION

This paper aims to survey past and present, and predict possible future ultra-large digital memory storage systems It is easy to describe what exists, but difficult to present meaningful predictions. To cope with this objective, characteristics of systems that *can* be available in 1976 and 1981 will be described and explained. Since it is probable that not all of these will be available, the necessary and sufficient conditions have to be identified. These conditions are qualitatively reviewed by discussing the development process of systems such as ultra-large storage systems.

The functional need for ultra-large storage systems has arisen because the power of computers, the complexity and amount of processing done, and the back-up memory sizes have continued to grow. Each year more data processing managers find their tape libraries and stables of disc files getting out of hand. An on-line, but slower access memory is required to fill this new memory hierarchy niche.

In this paper the characteristics of ultra-large storage systems and the boundary between such systems and large storage systems are defined. After reviewing the development process, identifying physical, engineering, software, and system implication, technological considerations relevant to ultra-large storage systems are detailed. Then possible bit-by-bit and holographic storage systems are described and realizable properties predicted. The sufficient condition required for existence of these systems is funding of the development and production. There are too many vagaries in patterns to predict this. The paper does aim to set the stage for rational decision making. Decisions yet to be made will determine which of the possible systems will be produced, and when.

DEFINITION

An ultra-large digital storage system is defined by function and size. It fills a new position in the memory hierarchy of large computer systems, by replacing off-line data stores, and placing the entire back-up storage on-line. Since ultra-large storage systems back up tape transports and disc files, the size will vary with time. In 1972 ultra-large digital storage systems place on-line 10^{11}-10^{12} bits with access time to any data set in approximately 1-10 sec. In ten years the largest size used is likely to approach 10^{14} bits. The lower bound of memory size will be about three to ten times the storage capacity of the largest commonly used disc file units (or competitive storage systems such as may exist if large bubble memories become practical).

Ultra-large memories are systems in their own right and can be operated in stand-alone modes. More than one CPU can be connected to an ultra-large storage system without changing any of the computers' internal software operating systems. Successful systems will have both hard and soft wiring, a minimum of moving parts, and be very reliable. Flexibilities should permit simultaneous writing, erasing, reading and searching. Though data can be stored off-line for archival purposes, it appears likely that operating data will be kept on-line. The high packing density (up to three orders of magnitude fewer reels required) and low shelf storage cost (about 10^{-6} cents per bit) may induce the user to duplicate some data for shelf archives.

An assessment of existing computer systems, and trends leads to specifications of ultra-large storage system performance objectives today, and in five and ten years. The smallest sizes of ultra-large storage systems, $5(10^{11})$ bits in 1971, 10^{12} bits in 1976, and $5(10^{12})$ bits in 1981 are likely to have to sell for about

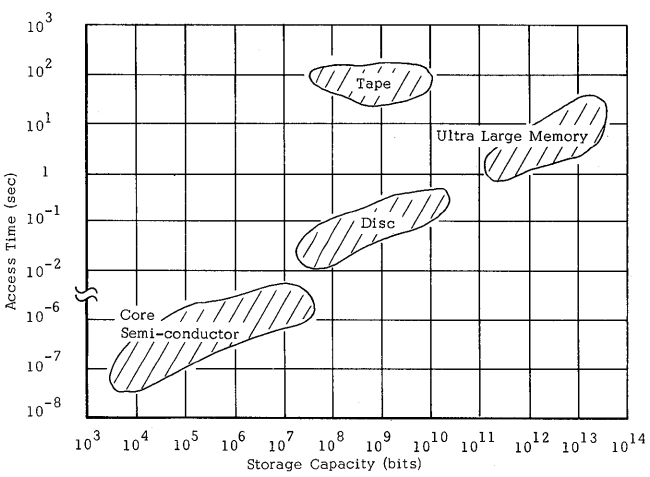

Figure 1—Storage capacity vs. access time for memories in the computer system hierarchy

one million dollars each. The largest size should be about ten times larger, and the cost less than three times as much as for the smallest system. Data accuracy (uncorrectable readout error rate) should be at least 10^{-10} in 1971, $5(10^{-11})$ in 1976, and 10^{-11} in 1976. Throughput will have to be at least 5 Mbps, i.e., $5(10^6)$ bits per second, in 1971, 10 Mbps in 1976, and 15 Mbps in 1981. Because of the mechanical access required, average access is likely to be about fifteen seconds throughout this period. Cost per bit off-line should be less than 10^{-6} cents per bit (with the storage medium fully used) throughout 1971-1981. Systems, of course, must be very reliable. Because of the size of the systems, capability of graceful degradation is useful.

These characteristics, when plotted on cost/size/access time charts as in Figures 1 and 2, clearly indicate the hierarchical position with respect to other memories.

Functionally, writing and storage of vast amounts of data, like 10^{12} bits, and accurate readout for very low costs appear to require storage in a volume. I believe that the system objectives described cannot be met in this time frame by storage in a solid volume; therefore, it is necessary to build up a volume, sheet by sheet, as in a scroll, or book. Hence, technologies reviewed here, relate only to recording on flexible media which may be stored on reels or in bins.

Assuming data accuracy, and retrieval times to be satisfactory,* storage of 10^{12} bits at a data density of 10^6 bits per square inch (as in magnetic recording in 1971) requires 10^6 square inches, or about one sixth of an acre. To avoid substantial mechanical storage, a storage system of less than 1000 square inches would be required. For 10^{12} bits, this requires 10^9 bits per square inch. Though electron beam writing with this density is possible, and readout from small areas can be demonstrated, readout under the specifications required is not practical within this time frame, and, in fact, may not be achievable. Ultra-large storage systems are therefore likely to require mechanical movement and accessing of substantial areas of flexible media.

BOUNDARY BETWEEN LARGE AND ULTRA-LARGE STORAGE SYSTEMS

As observed, the boundary between ultra-large, i.e., flexible media stores, and large, i.e., disc file stores, will move with time and with system application. Harker's companion paper[1] reviews the present state of disc files, and predicts the characteristics of disc file units in ten years. Not knowing his assessment at the time of this writing (Sept., 1971), I will predict a one order of magnitude increase in disc packing density, perhaps using magneto-optic readout techniques from plated discs. In ten years, therefore, it should be practical to use disc files to store 10^{11} bits, and the boundary between large and ultra-large storage systems would move from the 10^{10}-10^{11} bit region of today to 10^{11}-10^{12} bits in 1981.

PROCESS OF ULTRA-LARGE STORAGE SYSTEM DEVELOPMENT

A viable memory storage system, or for that matter, any technological device or system must have passed

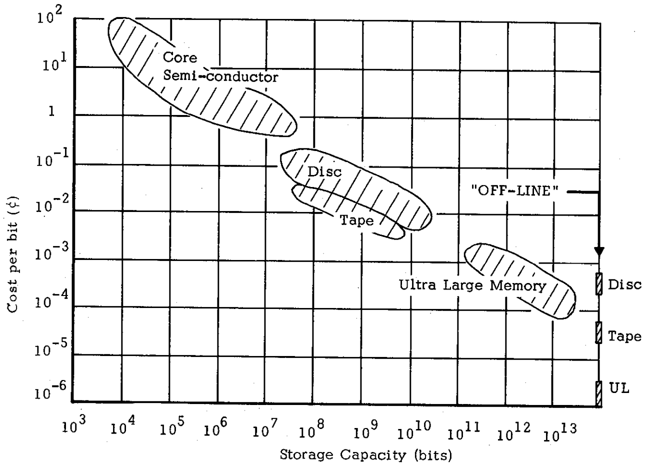

Figure 2—Storage capacity vs. cost per bit for memories in the computer system hierarchy

* It is important to note that storage density should always be specified together with data accuracy, and access times and data rates, because of the substantial tradeoffs which occur between these factors. Sometimes high density storage is specified, and the low realizable data accuracy may not be mentioned or even understood.

several necessary conditions imposed by physics, engineering hardware and software, architecture, economics, and the market (e.g., timing). Each of these factors is reviewed in this section identifying its function in the development process. Understanding them is a prerequisite to either making or reviewing predictions.

1. *Physics*: The fundamentals of physics, and materials, *including the imperfections attainable in practice*, must be such that the desired properties are achievable *with substantial margin.* For memory systems, a first step is commonly to demonstrate that sample bits of data can be recorded and their existence determined by some convenient means; techniques for practical readout being speculated. I call this step *physical feasibility*. The specific demonstration may cost from $5000 to $50,000.
2. *Engineering, Hardware and Software*: Design and repeatable production of reliable devices or systems must be economically achievable in large numbers. Operation must be economical, and occur in commonly available environments without unplanned downtime. There are many engineering implications, a few of which are worth noting.

   a. First, we must often develop processes for producing improved materials and improved fabrication methods. Different processes and methods are likely to have to be developed for each order of magnitude increase in final production.

   b. Second, both materials and designs must be such that required performance, economy, reliability and lifetime are possible. In the case of memory systems, three performance criteria must *simultaneously* be achieved with substantial margin to allow for production and usage variations: data packing density, write/readout error rate, and time considerations (data rate, access time, write/readout cycle time). Most physics feasibility demonstrations (1) involve techniques and materials in which *only* two of the above three criteria can be met. Unless there is likelihood that techniques for meeting the third criterion can be met, the study should be promptly dropped.

   c. Third, the design should approach elegance as closely as possible. By elegance is meant a sort of canonical (optimum in the sense that necessary functions are well met and superfluities are absent) design in which the machine or system is well adapted to people (the users) and in which there are the fewest number of parts, the least amount of material used, and the least amount of power required for operation.

   d. Fourth, the design should minimize both initial cost and long-term operating costs. Wide tolerances on mechanical parts made of durable materials not subject to fatigue or state change failures are desirable. There should be little, if any, contact between parts to minimize wear. Strip files have had difficulties with objectives (c) and (d). All models produced have had reliability problems; none is now being produced.

   e. An *engineering model*, costing perhaps ten to one hundred times the cost of the physics feasibility model (1) has to be built to give confidence that the engineering considerations such as (a)-(d) can be achieved.

   f. If satisfactory performance is demonstrated an *engineering prototype* needs to be built. It may cost from one hundred to one thousand times the cost of the physics feasibility model. The engineering prototype will probably include hardware, firmware, and software development as well as system studies relating to potential applications.

   g. *Software studies and development*, and *systems planning* need to be part of the engineering effort from the inception so that timely, canonical and least expensive development can be approached. Otherwise, major redesign will be required as a minimum, and more likely, too much of the design will be frozen and an optimum configuration not possible.

   h. Finally, a *manufacturing prototype*, costing approximately the same as the engineering prototype, and *documentation*, costing as much as the entire technical effort, is required to prepare for production. It has been my experience, during fifteen years in the data processing industry, that seven to ten years and seven to ten million dollars is a ballpark estimate of the cost required to move a system, such as an ultra-large storage system from conception to completion and delivery of the first production system.

3. *Architecture*: Computer architecture has changed substantially in the last fifteen years. There has been a continual growth, in computer systems, of software size, complexity, hierarchies of

memories, communications, peripherals, and corresponding decreases in many unit costs. The evolution both toward being easier to use (better adapted to people), toward greater variety, and toward increasing maximum on-line size appears likely to continue for more than the next fifteen years. It is this latter growth which establishes the growing market for ultra-large memory storage systems. To use such big memory systems, however, requires that they fit into users' information systems. Computer architecture is presently provided by OEM's. More sophisticated users are beginning to develop their own architecture, and increasingly more will in the future. Both general and special architectures will evolve during the next decade. Many of them will include ultra-large storage systems.

Design of an ultra-large storage system should be such that evolution to larger sizes over the next decade or so is possible without significant impact upon the users' operating systems: There should be negligible changes in software or system organization required. Specifically, any ultra-large storage system produced today should be such that more than order-of-magnitude increases in storage size can be accomplished through the next 5-, 10-, and 15- year intervals without requiring significant software and system changes.

4. *Economics*: The admission price for a new product has to be paid. It has been observed that this price for ultra-large storage systems is likely to run to 10 million dollars. Systems worth many times the admission price have to be sold to justify the time value of the money invested. The market estimate of those funding the development is part of the economic gate. Other parts are estimates of production costs and sales price.

   For a new ultra-large storage system to be produced by 1976, a good part of the admission price must have already been paid, and the rest of it assured.

5. *Timing*. Timing of a new product is always critical. The optimum time is bounded by *too early* (applicable technology not sufficiently developed, market need not yet developed) and by *too late* (market established and being supplied, and price reductions under way). Expecting development of an ultra-large storage system to take more than five years, *a new system can be expected in 1976 only if an engineering model has already been built.*

TECHNOLOGY CONSIDERATIONS LIKELY TO IMPACT THE NEXT DECADE

Material, electrical, mechanical, and magnetic technologies both permit construction of ultra-large storage systems, and limit their performance. The last section discussed some of the process of memory system innovation. This section lists some of the more significant technological considerations required in making predictions.

1. *Materials*: New recording technologies usually require novel storage media. In fact, invention of a new medium often triggers the first feasibility demonstration of a potential new storage process. Unfortunately, though, the quality of existing memory storage media is so good, as a result of *thousands* of man years of development, that *it is extremely difficult for any new approach to achieve the cost/performance improvement required for the resulting system to be successful.*

   The only practical ultra-large memory storage media now in use are silver halide film and magnetic particle tape. They are comparatively reliable, defect-free, and low in production cost. Other media appropriate for ultra-large storage systems have not yet proved themselves. Evolutionary improvements in both silver halide and magnetic tape will continue to be made.

   Both silver halide and magnetic tape, upon analysis, show substantial life as affirmed by National Bureau of Standards tests. After a hundred years we will be in a better position to tell how the mylar backing, which appears to be the controlling factor, holds up. There is good reason to believe that, since 10 year life has been shown, much more life than that can be expected. No storage medium has been certified to have permanent life.

   Silver halide tape used in microfilm applications has the advantage that it does not require much positional accuracy for data retrieval; both silver halide and magnetic tape, used for digital bit-by-bit storage, do. The National Archives finds that it must rewind stored computer tapes using longitudinal track recording every two years. The reason is that temperature variations of even ±5°F lead to tension changes, particularly in the inner one-third of stored tape on reels. The problem with 800 bpi tape is that the transports do not have self-clocking and can cope with very little tape stretching. (The 1600 bpi transports do have self-clocking and can cope with more stretching.)

Experience with transverse recorded magnetic tape is completely different. Transports seem easily able to servo to the two-inch long tracks even after substantial abuse including years of storage in wide temperature ranging environments. In fact, some of the earliest video tapes recorded 15 years ago can be played back with no recognizable loss in signal quality.

The National Bureau of Standards has investigated samples of storage media supplied for the hole-burning Unicon* (which will be described later). Their study revealed that resolution has been accomplished and that holes were produced without apparently damaging the mylar substrate. So long as nothing happens to the plating during the passage of time, the life, like that of silver halide and magnetic tape should be at least 10 years, and probably much more.

2. *Electrical*: Continuing improvements in cost-performance-life-complexity of integrated circuits is leading to increasing use of IC's replacing engineer-designed circuits. Furthermore, built in mini-computers permit use of soft wiring (internal computer control), instead of hard wiring (conventional circuits using conventional circuit elements), and firmware (use of ROM's within soft wired systems). The consequence is increasingly sophisticated final systems providing improvements in performance, cost, and flexibility of use. (Ironically, improvements in IC cost/performance result in corresponding improvements in all hierarchy levels of memories, including that of cores, which IC's are attempting to surpass by cost/performance improvements.)
3. *Mechanical*: Reliability problems and breakdowns seem invariably to be due to mechanical and/or material failure. Comparatively few seem to have recognized this. As has been implied, getting out information is vastly more difficult than putting it into most storage systems. In fact, my experience has led me to observe that the development cost to prove readout capability is likely to be two orders of magnitude greater than the cost to demonstrate recording. Most searches for funding for new storage techniques have to take place between these phases.

Practical reproducibility of production parts, and most importantly, accurate positioning of the readout transducer limit the performance of electro-mechanical storage systems to much lower storage capacity than physical and material considerations would permit with perfect mechanical parts and positional control. In fact, it is well-known, but sometimes ignored, that laboratory performance predicted or even achieved in feasibility demonstrations is often more than an order of magnitude better than can be reliably achieved in an operating system.

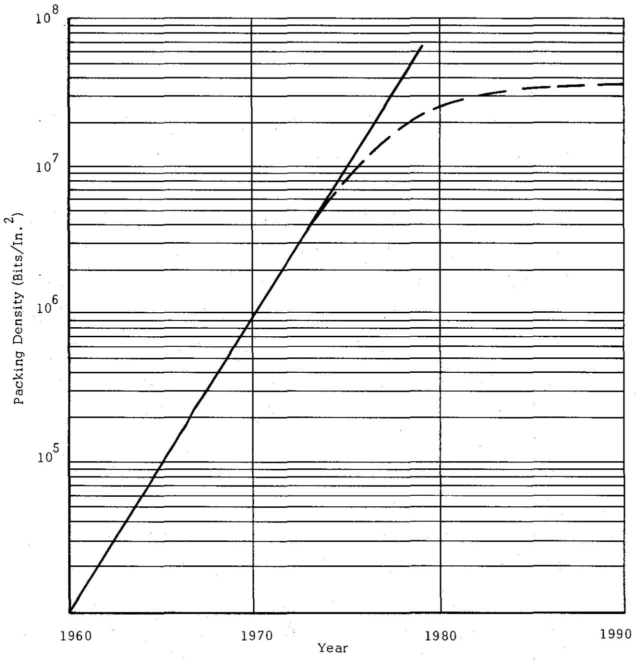

Figure 3—Area packing density, past experience and estimate of what is realizable in commercial products in the future

Conventional, longitudinally tracked magnetic tape transports are a case in point. For economic reasons, and because of the byte-across convention, tape skew has limited linear packing density to 1600 bits per inch. Instrumentation transports, however, not limited by byte requirements, record and reproduce over 25,000 bits per inch. The ultimate achievable in practice appears to be about 40,000 bpi, although the magnetic limit is about 100,000 bpi.

Packing density is limited by mechanical position reproducibility for readout, machine to machine. The limits are comparable for both flexible and rigid storage media. The storage density, attainable in mechanically accessed systems whether with rigid or flexible substrates, and regardless of the recording medium, appears to be fundamentally limited by mechanical and material considerations. Figure 3 illustrates how

* Trademark

this density has improved over the last decade, and how I believe it will level off. The figure applies to both bit-by-bit and holographic techniques.

Some[2,3,4,5,6] have used, or proposed, electron beam and laser beam systems with extremely high packing densities to overcome mechanical limitations. Figure 3 still seems to apply, but for different reasons. These will be discussed later in the section on beam access.

4. *Magnetic*: Magneto-electric effects as in core memories, and magneto-electromechanical effects as in disc files and tape transports are used for large memories today. It appears that magneto-electromechanical effects will be used for large and ultra-large storage systems for the foreseeable future. It has already been observed that magnetic tape can store information at vastly greater packing density than we will ever be able to deposit and retrieve it. The other magnetic limitation is in the transducer, the magnetic head. The inductor heads now used become lossy at high frequencies and are generally impractical for use above 15 MHz. This places an upper bound upon single channel data rates.

   There have been many efforts, such as the magneto-resistive head,[7] to produce practical non-inductive, monolithic heads. None, however, has proven to be practical to date. The appearance of a monolithic head stack which can write and read with equivalent performance, but at one-tenth the cost, would result in substantial changes in the design of large and ultra-large storage system memory elements. In the meanwhile, inductor heads will increasingly be made of hot-pressed ferrites for three reasons: superior wear, yield in production, and magnetic performance.

REVIEW AND PREDICTION OF SYSTEM PERFORMANCE

Assessing possible developments in memory technology is of major interest to many groups in addition to the technologists and marketers. Among these are the system designers, senior corporate managements, and venture capitalists. Eshenfelder,[5] Weil,[6] Hoagland,[8] and Best[9] have written papers containing useful survey assessments for ultra-large storage systems which have appeared in the last five years. The technologies and systems I will review fall into two classes: discrete bit and holographic. Discrete bit systems have been, are, and may be:

1. Magnetic-oxide magnetic tape, erasable.
2. Plated tape for magneto-optic read, erasable.
3. Photographic, silver halide tape, using electron or laser beam write and read, permanent.
4. Metallized tape, electron, or laser beam hole-burning write, and readout, permanent.

Holographic systems may be:

1. Photographic, silver halide tape, laser beam write and read, permanent.
2. Plated tape for magneto-optic read, erasable.

Each of the preceding will be reviewed, necessarily in a limited fashion. It is important to note that the predictions for 5 and 10 years from now are not predictions of what will exist, but of what is possible physically, engineering-wise, and system-wise. Whether they are developed, produced, and offered for sale depends upon whether developments are funded.

A. *Discrete Bit Systems*

1. *Magnetic-Oxide Magnetic Tape, Erasable*

Magnetic tape storage fundamentals have been so thoroughly reviewed in the literature[8,10] and somewhat here, that I will focus upon storage systems. Performance data are listed in Table I.

a. *1966*. The IBM 2321[11] Data Cell was introduced in April, 1964. It was the first significant ultra-large storage system to be placed on the market. Like preceding strip-file memories, it suffered from reliability problems. Competing disc files have superseded it. Error rate is not specified; errors are detected by the system and reported to the CPU. Access time is an approximate average.

b. *1971*. The only available magnetic-oxide ultra-large storage system in 1971 is the Ampex TBM,* or Terabit Memory.[12] (Tera is the standard designation for 10^{12}.) The system uses the transverse recording technique developed 15 years ago for video recorders, and widely used since then. Innovations include system design permitting easy growth to both larger size and to new generations without changing software, graceful degradation, and parallel channels for

simultaneous reading, writing, and 1000 ips search. This appears to be the only system available in the next few years which meets all of the specifications listed at the beginning of the paper. Most parts of the first system have been delivered, and customer acceptance tests are scheduled for March, 1972.

A storage system meeting some of the specifications[13] is said to be under development in IBM. It is a three-inch wide multitape loop. In the absence of specific information, I can only speculate that the system will aim to produce automated tape libraries having up to, say 10^{11} bit storage capacity. Tape loops can be stored in chambers, accessed pneumatically, then rotated at high speed for writing, reading, and erasing. Reliability problems associated with the extremely large number of rotational cycles requires, i.e., tape edge damage, and splices (if used) will have to be solved. If produced, and reliability is demonstrated, this large storage system would impact the lower bound of the ultra-large storage market. It remains to be seen whether achievement of the projected performance is possible with a reliable system.

c. *1976*. Packing density, and, therefore, total capacity of the TBM* can be doubled in five years, and the data rate increased to match increasing capability of central processors.

The tape loop, if successful, should also double capacity by about 1977. If tape loops become established, any competitive large-storage systems will have to leapfrog in cost/performance in order to be used. Ultra-large storage systems will continue to be required for larger files.

d. *1981*. By 1981 the TBM* cost/performance can increase as shown in Table I. If tape loops are successful, they would continue to meet needs at the low end of the ultra-large storage system market. Tape loop packing density is likely to remain under one million bits per square inch because of registration difficulties.

2. *Plated Tape, Laser Record, Magneto-Optic Readout, Erasable*

At this point it is useful to refer to Table II which was prepared mostly by Irving Wolf. The table shows that one material, cobalt-phosphorous is practical to be plated upon a flexible substrate. That material, and three others, manganese bismuth, manganese antimony, and manganese aluminum germanium are candidates for plating on rigid substrates and may impact the lower end of the ultra-large storage market. It appears unlikely that the europium oxide media, though it requires less power for switching, can be produced which can operate practically at room temperature; the market is not likely to accept a system requiring cryogenic operating temperatures. These technologies have been widely discussed. For example, Eshenfelder[5] has prepared a useful

* Trademark

TABLE II

POTENTIAL MEDIA FOR MAGNETOOPTIC MEMORIES

MATERIAL	ADVANTAGES	DISADVANTAGES	CURRENT STATUS	POTENTIAL
Iron Silicide	(1) Curie Point ~110°C (2) Large Magnetooptic rotation(F)	(1) Anisotropy in Plane of Film (2) Room temperature coercivity (95 Oe)is low for high density storage	Exploratory	Further materials work required.
Europium Oxide	(1) Good 2F/α (figure of merit, α is absorption coefficient) (2) Can be prepared on variety of substitutes (3) Low Δ T (4) Low power requirement	Low operating temperature (77°K) due to low Curie Point	Feasibility of Technique demonstrated	Practicality yet to be demonstrated, further materials work required
Iron Doped Europium Oxide	(1) Similar to EuO magnetooptically	(1) Operating temperature (~180°K) low (2) Low coercivity	Exploratory	Practicality yet to be demonstrated, further materials work required
Europium Sulfide	(1) Stability (2) Ease of fabrication (3) Large M.O. rotation	Very low operating temperature (< 50°K)	Exploratory	Needs further work
* Manganese Bismuth	(1) Good 2F/α (2) High coercivity (3) Anisotropy perpendicular to plane (4) Demonstrated 10^8bit/in^2 density in material (5) Can be used in either Kerr or Faraday modes.	(1) Phase transition near Curie Point, 360°C (2) Fabrication complicated for mass production (3) Δ T = 350°C (4) Impractical for flexible media (5) Performance function of substrate (6) Requires high peak power (7) Efficiency about 0.01%.	Development of feasibility machine	Useful for high modulus substrate storage, card, disc, etc. Practicality yet to be demonstrated. Possible use in holographic mode, though 10KW instantaneous power required for 10^4bit page.
Manganese Arsenide	Low transition temperature (40°C)	(1) 2F/α lower than MnBi. (2) Recording properties unreported (3) Complicated preparation required.	Exploratory	Further materials work required.
*Manganese Antimony	(1) Good range of write temperature (2) Better media reliability than MnBi.	2F/α less than 50% of MnBi.	Very early. Exploratory. Films yet to be developed.	Further materials work required.
Gadolinium Iron Garnet	(1) Low ΔT (2) Low power requirement	(1) Single crystal material. (2) Relatively high media cost (3) Optical absorption < MnBi EuO.	Early exploratory	Practical media techniques yet to be developed. Could b^ put on discs.
* Cobalt- ** Phosphorous	(1) Simple plating process capable of mass production (2) Only material shown feasible for flexible substrate.	(1) Low M.O. rotation (2) Special readout technique required.	Write, read in engineering model demonstrated.	10^{13} bit mass memories on tape or 10^{10} -10^{11} bit disc memories. Possible use in holographic mode.
Manganese Aluminum Germanium	(1) Curie Point ~ 450°C (2) May be feasible for flexible substrate.	α ~ 0.1	Exploratory	Needs further work.

* Appears to be practical for discs.
** Appears to be practical for tape systems.

review. Treves,[14] Smith,[15] Stoffel and Schneider,[16] Fan and Grenier,[17] Aagard, et al.,[18] Wider et al.,[19] and Sherwood et al.[20] provide additional information.

a. *1966-1971. No magneto-optic systems available.*

b. *1976.* Since engineering feasibility of a magneto-optic system using cobalt-phosphorous on mylar, has been demonstrated, it seems evident that a system can be made available to the market if further development is funded. Performance, as indicated in Table I would be comparable or superior to that of the magnetic tape system available then. A significant advantage of magneto-optic systems is that it appears to be practical to achieve packing densities about ten times higher than is now practical with magnetic tape systems. Secondly, there is no contact between the write/read transducer and the medium. Major disadvantages are the handling of the media, the reliable positioning of the write and read photon (laser) beams, and availability of reliable lasers of the required power at appropriate costs. The demands placed upon mechanical positioning controls to take advantage of the higher packing density potential are severe particularly with respect to long failure-free life. There is a fundamental limit to storage density imposed by the diffraction limit of the wavelength of light used. If all elements were perfect, including hundreds of square feet of defect-free storage surface, and $f/1$ lenses used, one bit per wavelength stored with no gap between bits would achieve about $2(10^9)$ bits per square inch. Practical considerations, exclusive of the errors imposed by the storage surface, limit achievable storage densities to about $3(10^7)$ bits per square inch. *This practical limit applies to all of the light actuated memory systems.* Electron beam systems, yet to be described can ideally achieve higher packing densities because the wavelength of the electron beam is about 1/5000 that of light beams. Here, too, practical considerations limit packing density to about the same level.

c. *1981.* If magneto-optic systems are developed for 1976 availability, and they prove to be practical in use, then enough improvements are possible that, if funded, a system having the performance indicated in Table I is possible by 1981.

3. *Photographic, Silver Halide Tape, Using Electron or Laser Beam Write and Read, Permanent*

The technology required for electron and photon beam write/read systems for recording on silver halide media has been developed. Kuehler and Kerby[21] reported on the IBM 1360, flying spot scanner read system. Bousky and Diermann[2] and Pass and Wood[22] reported on electron and laser beam analog recorders for instrumentation purposes. Generally, electron beam systems permit the highest data rate. Although, electron beams can record at the highest packing density, engineering limitations associated with accurately positioning the readout beam onto a flexible medium dictate much lower packing densities; they become comparable to those of magnetic recording systems.

Electron beam systems require operating in vacuum, and laser beam systems require complex light deflection components. Nevertheless, there has been substantial user experience with both kinds of systems for storing analog information.

a. *1966.* No electron or laser beam systems were available.

b. *1971.* In 1965 the IBM 1360[23] was contracted to be built. From 1967 to date five units have been delivered. Penny et al.[24] described the use of such a system, and Burnham[25] the medium. IBM produced systems under contract, but is not offering them for sale, presumably because of profit (production cost, market, reliability) considerations.

Times are different for write, which is by an electron beam in a vacuum, and read, which is by a flying spot scanner. Wet development is automatic. Data is stored on chips which are accessed in pneumatic tubes and stored in cells, which in turn, are stored in trays. Costs shown are estimated.

c. *1976, 1981.* Data given in Table I for these years reflect the performance characteristics achievable by laser systems if their development is funded. Since the media is not erasable, and off-line processing is required, *it seems unlikely that such digital systems will be produced.* Analog systems, however, will probably continue to be produced.

4. *Metallized Tape, Electron or Laser Beam Hole-Burning Write, and Readout, Permanent.*

Dove described a hole-burning storage system in 1964, obtained a patent in 1965, and described the technology recently.[4] He predicted physical feasibility of 10^9 bits per square inch storage capacity, and identified the problems of (1) plated media cracking due to differential coefficients of expansion of the plating and substrate, and (2) preferential expansion due to fabrication. Engineering considerations limit packing density to not much more than 10^7 bits per square inch.

a. *1966.* No system available.

b. *1971.* Precision Instruments announced the Unicon,* a metallized tape hole-burning system in 1969. Dell[26] most recently described the laser beam system which accesses strips of tape from a file and wraps them around either of two rotating drums. The system, though data is not erasable, does permit adding data in spaces not previously written upon. It does not permit graceful degradation. Customer acceptance tests are scheduled for November, 1971. Although the recording material is much more expensive than magnetic tape, the higher packing density yields per bit costs comparable to conventional tapes. Microinch level position accuracy, mechanical part upon mechanical part, is required to achieve the stated error rate. Table I lists the announced performance.

c. *1976-1981.* If Unicon* systems are delivered, have sufficient reliability, and are able to

* Trademark

* Trademark

achieve satisfactory error rates (there are drop-in problems in which dust, or imperfections lead the readout system to read ones rather than zeros), improvements are likely to be made. Since the announced system contains packing density near to the practical optical limit, packing density is unlikely to be improved, and, in fact, may have to be reduced in order to improve error rate. Improvements are most likely to occur in data rates, error rates, and in larger file storage. Performances that seem possible are shown in Table I.

B. *Holographic Systems*

1. *Photographic, Silver Halide Tape, Laser Beam Write and Read, Permanent.*

Anderson[27] presented the most comprehensive review of holographic digital storage, erasable and permanent, on surfaces and in volumes. He observed that, though densities exceeding 10^6 bits per square inch can be written, and readout occurs without critical alignment and tight mechanical tolerances, in situ read and write, but not erase is presently practical. It appears to be practical to develop 10^8 bit data blocks with throughput exceeding $500(10^6)$ bits per second and random access less than 2 microseconds to photo diode readout arrays. In the distant future, it may be possible to write and read out 10^{11} bits in a volume, though selective erasure may not be attainable. Readers are referred also to Briggs,[28] Chen and Tufte,[3] Eshenfelder,[5] and Rajchman.[29]

Problems remaining to be solved relate to developing capability for maintaining mechanical and dimensional stability on a flexible medium or adapting optical or electronic circuits to compensate for imperfections, and inventing and developing suitable light valves, page composers, lasers, deflectors, and photodetectors. Because of the first of these, it appears likely that holographic storage will first be achieved on plates. If developed, it is likely the dimensional stability and alignment problems will probably dictate somewhat lower packing density than is achievable on rigid surfaces. Estimates of what is achievable in a system most likely to become available in 1977/1978, if development is funded, are shown in Table I. If the problems can be solved so that performance comparable to storage on rigid surfaces is achievable, then systems with 25 times the storage capacity and correspondingly larger sizes and lower costs will be achieved. The highest packing density of any system should be achievable, and this would then be the most practical nonerasable store.

2. *Plated Tape, Magneto-optic, Erasable.*

If present applied research efforts continue, it is possible that a satisfactory medium which permits in situ write, read, and erase may be developed within 5 to 10 years. If so, if problems listed above are solved, and if funded, a system with performance described in Table I might be ready by 1981. Again, first applications are more likely to be large memories on rigid surfaces. If the dimensional stability problems are solved to permit storage comparable to that on rigid surfaces, a storage system such as this would probably be the most satisfactory of all proposed. However, there are too many ifs to believe this will happen much before 1981; it may not occur until a few years later.

CONCLUSIONS

Ultra-large digital storage systems will probably continue to be predominantly magnetic tape, inductor-head write/read systems through the next ten years. System improvements are practical and should serve to make it impractical for competing technologies to be developed to the point where they can provide significant competition. For example, electron beam systems with extremely high packing densities are likely to be impractical and not developed because of beam control problems. Holographic storage systems, while practical for fiche-like permanent storage systems, are limited by dimensional and positioning problems, and by the likelihood that an appropriate erasable medium may not be developed soon enough within this time period for such a system to become available. The erasable holographic storage system appears to have the greatest potential for the second 10 year period.

Two ultra-large storage systems have been produced, one erasable (TBM*) the other a permanent store (Unicon*). Time will tell the practicality of these systems.

New devices for sequential access memory

by F. H. BLECHER

Bell Telephone Laboratories, Incorporated
Murray Hill, New Jersey

ABSTRACT

Two classes of devices are seriously challenging the electromechanical disk file for bulk storage applications—magnetic bubble and charge-transfer. These devices can be used for sequential access memory and feature solid-state reliability, small size and potential low costs.

Magnetic bubble devices consist of a thin layer of uniaxial magnetic material imbedded in a bias magnetic field. The easy direction of magnetization is perpendicular to the surface of the thin layer and is in the same direction as the bias field. There is a range of bias fields for which regions of magnetization exist in the uniaxial material with a magnetic polarity opposite to that of the bias field. These regions of reverse magnetization have the form of right circular cylinders and are known as magnetic bubble domains or simply bubbles. The bubble is a stable entity that can be propagated by use of current carrying conductors on the surface of the thin magnetic layer or by the application of an in-plane rotating magnetic field which is used to magnetize small permalloy features on the surface of the magnetic layer (field access).

Rare earth garnet magnetic materials are now available in very thin layers (2 to 5 μm) with the necessary anisotropy and magnetization to produce extremely small bubble domains (4 to 10 μm diameter), and with very few defects to impede domain motion ($\sim$2 cm^{-2}). These materials should make possible storage densities of the order of several million bits per square inch. In this talk, the design of bubble circuits using single conductor current propagation is discussed with particular application to a multi-megabit bubble file.

Two semiconductor devices are available which serve as dynamic-shift registers. One is of a functional nature and is called charge-coupled device (CCD). This device operates on the principle of charge transfer along the interface between a semiconductor and an insulating layer. The charges are moved by appropriately controlling the potential of metal electrodes placed on the surface of the insulator. The other semiconductor device is an integrated version of the IGFET bucket-brigade shift register. Recent developments in both of these technologies are discussed with application to large sequential access memories.

Two direct methods for reconstructing pictures from their projections—A comparative study

by GABOR T. HERMAN

State University of New York
Buffalo, New York

INTRODUCTION

There are situations in the natural sciences and medicine (e.g., in electron microscopy or X-ray photography) in which it is desirable to estimate the gray levels of a picture at individual points from the sums of the gray levels along straight lines (projections) at a few angles. Usually, in such situations, the picture is far from determined and the problem is to find the "most representative" picture of the class of pictures which have the given projections.

In recent years, there has been a very active interest in this problem. A number of algorithms have been proposed for solving it. The algorithms are applicable in a large and varied number of fields. This is perhaps best demonstrated by the reference list, where we see that such algorithms have been published or discussed in journals on computer science, theoretical biology, molecular biology, cellular biology, biophysics, medical and biological engineering, roentgenology, radiology, chemistry, optics, crystallography, physics, electrical engineering, as well as in general science journals. The most important use of the algorithms is the reconstruction of objects (e.g., biological macromolecules, viruses, protein crystals or parts of the human body) from electronmicrographs or X-ray photographs.

Most of the effort in this area has so far been concentrated in developing algorithms and in applying these algorithms for actual reconstructions. So far, there has been only limited attention paid to the relative merits of the algorithms. The present paper is a report on the first of a series of comparative studies of various algorithms for reconstructing pictures from their projections. The two techniques that we shall compare are one of the algebraic reconstruction techniques (ART) of Gordon, Bender & Herman (1970) and a summation technique, which has been independently discovered by a number of people, but the most detailed previous study of which has been given by Vainshtein (1971a, b).

Both these techniques are direct techniques in the sense that the reconstruction is being done entirely in real space (density space), without the use of Fourier transforms. This is worth pointing out, since the first applicable method for reconstructing pictures from their projections (discovered independently by DeRosier & Klug [1968] and Tretiak, Eden & Simon [1969]) depended on the fact that the Fourier transform of a projection is a section of the Fourier transform of the picture. Thus, reconstruction was achieved by taking Fourier transforms of the projections, interpolating in Fourier space to get an approximation of the Fourier transform of the picture, and then taking an inverse Fourier transform to get an approximation of the picture itself. Detailed descriptions of such techniques were given by Crowther, DeRosier & Klug (1970) and Ramachandran (1971).

Crowther, DeRosier & Klug (1970) state that "for general particles and methods of data collection, the method of density space reconstruction is computationally impracticable on presently available computers." However, they appear to be wrong on this point. Both the methods discussed in this paper have been implemented, and precise timings will be given on a number of examples to show that they are not computationally impracticable. Even more interestingly, expanding the mathematics on which the Fourier techniques are based, Ramachandran & Lakshminarayanan (1971a, b) succeeded to produce another direct method, called the convolution method, for the reconstruction of pictures from their projections. They demonstrate on a number of idealized pictures that their technique is faster than the Fourier techniques and that it also gives a better reconstruction. Detailed comparative studies between ART, the convolution method and the Fourier techniques are presently under way, and will be reported on in later publications.

In the next section, we shall briefly describe the problem of reconstruction of objects from their projections and discuss the criteria we shall use for evaluating algorithms for solving this problem. This is the first exhaustive discussion of such criteria, it will form the basis of later comparative studies as well. The following two sections will give brief descriptions of ART and the summation method, respectively. In particular, we shall give a version of the summation method which is superior to previously published versions. In the final section, we shall give a report on the results of our experiments.

A basic difference between the two techniques is that the summation method takes a fixed length of time to run, while ART is an iterative technique such that its result can be improved by repeated iterations. One iteration of ART costs about the same as the summation technique. In rough terms, the results of our experiments indicate the following.

If the number of projections is small, one iteration of ART seems to perform somewhat worse than the summation method. As the number of projections increases, the relative performance of one iteration of ART as opposed to the summation method improves, and eventually it produces superior results. The break even point seems to be at eight projections. However, by repeated iterations, the performance of ART can be improved and it eventually surpasses the summation method in all our experiments. The improvement in ART is especially impressive with eight or more projections. In such cases, we obtain, with five iterations of ART, results which are far superior to the results of the summation method.

METHOD OF COMPARISON

First we wish to describe briefly the problem of reconstructing pictures from their projections. A more detailed description of the problem can be found, for example, in Frieder & Herman (1971).

We assume that f is a function of two real variables such that $f(x, y) = 0$ outside a square region in the first quadrant of a rectangular coordinate system (see Figure 1). Further, we assume $0 \leq f(x, y) \leq 1$, everywhere. Following Rosenfeld (1969), we shall call a function with such properties a *picture function*. ($f(x, y) = 0$ means white, $f(x, y) = 1$ means black, with other *gray levels* in between.)

Let θ be an angle, $-90° < \theta \leq 90°$, and suppose that l is a line making an angle θ with the positive x axis. Suppose, further, that l is divided into equal line segments and that we draw lines perpendicular to l from the points separating these segments. Thus, we get a number of infinite bands, partitioning the (x, y)-plane. We shall refer to these bands as the *rays* of the *projection* associated with θ. Suppose there are r_θ rays which actually intersect the rectangle. For $1 \leq k \leq r_\theta$, let $R_{f,k,\theta}$ denote the integral of $f(x, y)$ in the k'th band which intersects the rectangle. (The integral need only be carried out in the shaded region in Figure 1, since $f(x, y) = 0$ elsewhere.) We shall refer to $R_{f,1,\theta}, \ldots, R_{f,r_\theta,\theta}$ as the *ray-sums* of the projection associated with θ.

The problem of reconstructing pictures from their projections can now be stated as follows.

Give an algorithm which, given

(1) the position of the square region within which $f(x, y) \neq 0$;
(2) angles $\theta_1, \theta_2, \ldots, \theta_m$, together with the widths and position of rays of the projections associated with these angles;
(3) the ray-sums of the projections associated with $\theta_1, \theta_2, \ldots, \theta_m$;

will produce a function f' which is a good approximation of f.

One can only hope for an approximation, since it has been proved, even for the limiting case when the ray

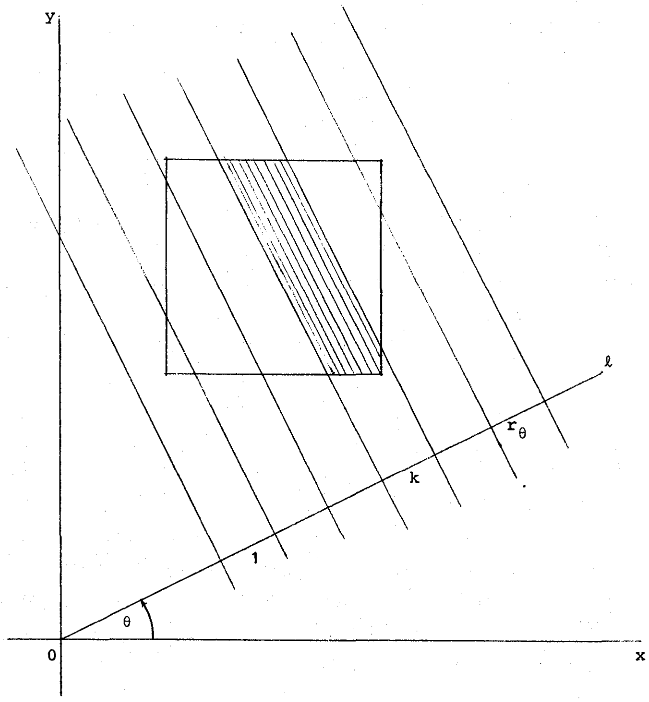

Figure 1

widths tend to zero, that a non-trivial picture cannot be uniquely determined from its projections (Frieder & Herman [1971], Theorem 1). The algorithm ought to be such that for pictures that we are likely to be interested in, they will provide a good enough approximation. This idea is discussed in some detail by Frieder & Herman (1971). For the purpose of the present paper, the following should suffice.

As will be seen in the next two sections, reconstruction algorithms tend to be somewhat heuristic. Hence, an analytical estimate of their performance is somewhat difficult to obtain. Even if there was a method to do it, we would be faced with the problem that the functions f, to which the algorithms may be applied in practice, form a small but not clearly defined subset of the set of all picture functions f. Hence, analytical methods, which give equal weight to all picture functions, may give much worse estimates than what one would obtain in practice. Therefore, it appears reasonable to evaluate and compare reconstruction techniques on the basis of their performance on selected typical pictures and test patterns. This is, indeed, what we are going to do in this paper.

Since our algorithms are to be implemented on a digital computer, it is reasonable to demand that the output f' be a digitized quantized picture function (Rosenfeld [1969], Section 1.1). Indeed, in all our examples, f' will be defined on a 64×64 matrix, and can assume as many values between 0 and 1 as the accuracy of the computer allows. In pictorial representation, we shall use only 16 equally spaced gray levels between 0 and 1, inclusive.

For convenience, we shall use as test data only picture functions which are of the same kind, i.e., 64×64 digitized pictures with 16 equally spaced quantized gray levels. When working out the ray-sums, we shall sum the values of $f(x, y)$ at those points which lie within the ray. At first sight, it may appear that this may change the problem in an essential way, but we shall show in the Appendix that this is not so.

In all our experiments, the rays are defined in such a way, that it is true for at least one edge of the 64×64 matrix that each of the points on that edge is a midpoint of a ray. The reasons for this are discussed in Frieder & Herman (1971) and, more briefly, in the Appendix.

We have decided to use four test patterns (Plate A). The first two of these are binary valued picture functions (black and white) which have been used by Vainshtein in his demonstrations of the summation method. (A1 comes from Vainshtein [1971a] and A2 from Vainshtein [1971b].) We are not aware of any other previously published test patterns on which the summation method was demonstrated. The situation is better concerning ART, Gordon, Bender & Herman (1970), Herman & Rowland (1971) and Bellman, Bender, Gordon & Rowe (1971), all contain a number of test patterns showing the operation of ART. We have decided to use two of these for the present comparative study, both half-tone (i.e., all 16 gray levels occur in them). One is the face of a little girl, Judy (A3), the other is the photograph of some stomata (A4). The first of these has been used by Gordon, Bender & Herman (1970) and Gordon & Herman (1971), the second has been used by Herman & Rowland (1971). Since in previous studies these pictures were not digitized at 64×64 points, we kept the previous digitization (49×49 and 50×50 points) and inserted them into a white frame. This makes comparison with previously published tests concerning these patterns easier.

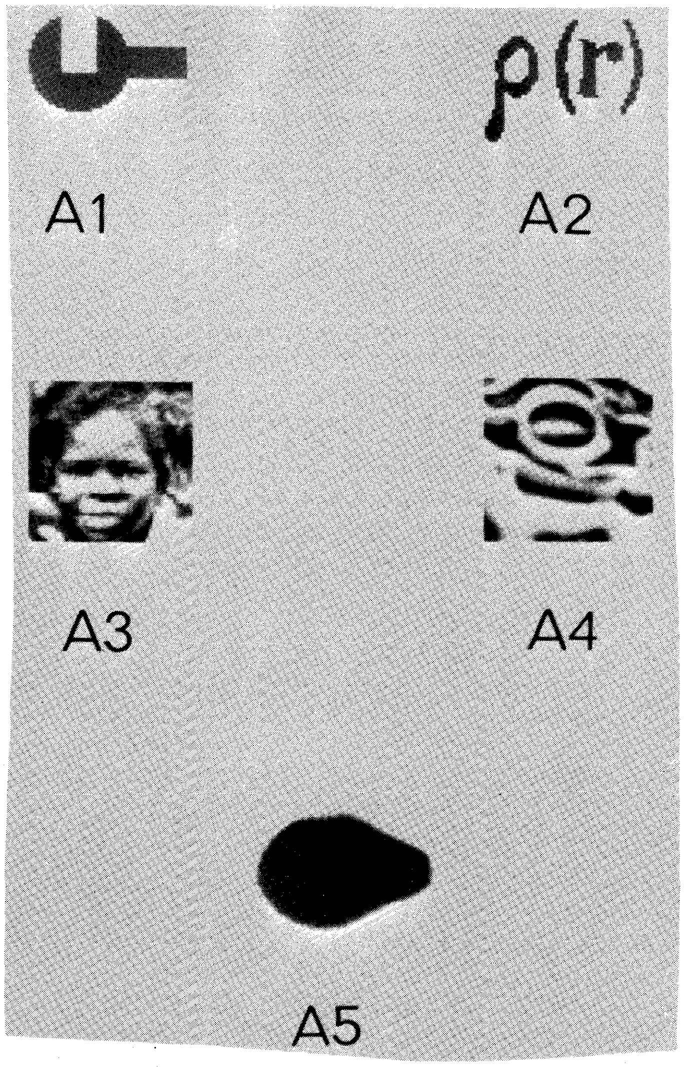

Plate A

For each of the four pictures, we have carried out reconstruction operations using four different sets of projection angles. The first three sets have been used by Vainshtein in his demonstration of the summation method. In all three sets the projection angles are equally spaced between −90° and +90° (with 90° being one of the angles), and there are 4, 8 and 30 angles, respectively. We used these sets of angles, so that our results can be directly compared with the results of Vainshtein (1971a, b).

The fourth set of projection angles comes from a small range. This is particularly important in electronmicroscopic applications, because of the restricted range of the tilting stage. We have, in fact, used the same set of projection angles that have been used by Bender, Bellman & Gordon (1970) in their reconstruction (using ART) of ribosomes from electronmicrographs. We have rotated these angles so that none of them is near 0° or 90°. The reason for this is that both ART and the summation technique would tend to give unusually good results if the edges in a test pattern (like A1) are parallel to one of the projection angles. The fourth set of projection angles which we used was actually 35°, 44°, 62°, 80°, 98° (=−82°) and 116° (=−64°). Thus, all these views come from a range of 81° as opposed to a full range of 180°.

Four pictures, with four sets of projections each, provide us with 16 reconstructions to be carried out with each of the techniques we are investigating. Then we are faced with the problem of evaluating the success of the reconstructions. There is no standard way of doing this. We have decided to use four different sets of criteria: overall nearness of the original and reconstructed pictures, resolution of fine detail, visual evaluation, and cost of reconstruction. We shall now discuss these criteria in some detail.

Overall nearness

(1) Gordon, Bender & Herman (1970) and Gordon & Herman (1971) used the root mean square distance δ as a measure of the overall nearness of the original and reconstructed pictures.

$$\delta=\left[\frac{1}{n^2}\sum_{i=1}^{n}\sum_{j=1}^{n}\left(f(x_{i,j},y_{i,j})-f'(x_{i,j},y_{i,j})\right)^2\right]^{1/2},$$

where $x_{i,j}$ and $y_{i,j}$ are the x and y coordinates of the (i,j)'th point in the $n\times n$ matrix. The validity of such a measure has been questioned by Crowther & Klug (1971), but the discussion by Frieder & Herman (1971, especially Theorem 2) shows that δ is a very reasonable measure for the overall performance of a reconstruction technique.

(2) Ramachandran & Lakshminarayanan (1971a, b) use another measure R of overall nearness in their comparison of the Fourier techniques with their convolution method. This is adopted from X-ray crystallography, and we shall work it out as well as the δ measure for all our experiments.

$$R=\frac{\sum_{i=1}^{n}\sum_{j=1}^{n}\left|f(x_{i,j},y_{i,j})-f'(x_{i,j},y_{i,j})\right|}{\sum_{i=1}^{n}\sum_{j=1}^{n}f(x_{i,j},y_{i,j})}.$$

Thus, R is the mean relative error of the reconstruction.

(3) For a number of applications one wants to make the assumption that f' is a binary valued picture function. This is obviously so if we know that f is binary valued. Even if f is not binary valued, we may wish to contour f' to get some idea of the overall shape of the object which is in the picture f. Let

$$\bar{f}(x,y)=\begin{cases}1, & \text{if } f(x,y)\geq 0.5,\\ 0, & \text{if } f(x,y)<0.5,\end{cases}$$

and let $\bar{f}'$ be similarly defined. We shall refer to $\bar{f}$ and $\bar{f}'$ as the contoured versions of f and f'. (Naturally, for a binary valued picture function f, $f=\bar{f}$.) We shall also work out the mean relative error, $\bar{R}$, for the contoured versions of f and f'.

$$\bar{R}=\frac{\sum_{i=1}^{n}\sum_{j=1}^{n}\left|\bar{f}(x_{i,j},y_{i,j})-\bar{f}'(x_{i,j},y_{i,j})\right|}{\sum_{i=1}^{n}\sum_{j=1}^{n}\bar{f}(x_{i,j},y_{i,j})}.$$

The measure $\bar{R}$ has also been used by Chang & Shelton (1971) in comparing two algorithms for binary pattern reconstructions.

(4) A property of the output of a reconstruction should be that it is consistent with the information available to the algorithm. In other words, the ray-sums of the reconstructed picture should be the same as the ray-sums of the original. Even though there are algorithms which achieve this (Gordon & Herman [1971], and, for binary valued pictures only, Chang [1970], Chang & Shelton [1971]), they usually tend to be slow for practical applications. Both ART and the summation technique will produce pictures where the ray-sums will only approximate the given data. One appropriate measure of the overall nearness of the reconstruction is the root mean square distance ρ

between the ray-sums on which the reconstruction is based and the ray-sums of the reconstructed picture.

$$\rho=\left[\frac{1}{\sum_{l=1}^{m} r_{\theta_l}}\sum_{l=1}^{m}\sum_{k=1}^{r_{\theta_l}}(R_{f,k,\theta_l}-R_{f',k,\theta_l})^2\right]^{1/2},$$

where m is the number of projections and R_{f',k,θ_l} denotes the ray-sum in the k'th ray of the l'th projection for the reconstructed picture f'.

(5) A simple way of deciding the overall success of a reconstruction is to ask whether the reconstructed pattern resolves the original. Based on a suggestion of Harris (1964), Frieder & Herman (1971) used the following criterion for answering this question. A reconstruction resolves a picture, if the output is nearer (in the sense of δ) to the original than to uniform gray. Since the mean gray level of input and output is the same both for ART and for the summation technique, the distance from uniform gray of the output is nothing but the standard deviation of the output. In our experiments, we shall say that the output of the reconstruction resolves the original if, and only if, the standard deviation of the output is greater than δ.

Resolution in fine detail

The major objection of Crowther & Klug (1971) to δ as a measure of difference between the reconstruction and the original is that "it reaches a low value once the large scale features are correct and is relatively insensitive to errors in the fine details." As it was pointed out by Frieder & Herman (1971), this objection is not quite valid. However, it is reasonable to ask what is the guaranteed maximum error in the average grayness of a region of certain size in the reconstructed picture. With this idea in mind, Frieder & Herman (1971) introduced the notion of (a, l, ϵ)-resolution. They said that two picture functions f and g with $4a^2$ non-zero area (a, l, ϵ)-resolve each other if, for every square region of size l^2, the mean grayness of the pictures in that region differs by less than ϵ.

The problem with (a, l, ϵ)-resolution is that it is difficult to calculate. For example, if we wanted to find the minimal ϵ such that an original and a reconstructed 64×64 picture $(32, 8, \epsilon)$-resolve each other, we would have to work out the mean gray value of nearly 6000 regions, each with 64 points. We have therefore devised another method, which is a good approximation to (a, l, ϵ)-resolution, but which is computationally much simpler.

For $0\leq l\leq 6$, let

$$\epsilon(l)=\max_{\substack{0\leq i\leq(64/2^l)-1\\ 0\leq j\leq(64/2^l)-1}}\left[\frac{1}{2^{2l}}\left|\sum_{1\leq m\leq 2^l,1\leq n\leq 2^l}\left[f(x_{i\cdot 2^l+m}, y_{i\cdot 2^l+n})-f'(x_{i\cdot 2^l+m}, y_{i\cdot 2^l+n})\right]\right|\right]$$

In other words, $\epsilon(l)$ is the maximum difference between f and f', when they are both digitized as $(64/2^l)\times(64/2^l)$ pictures. Thus, $\epsilon(0)$ is the maximum difference between the values at any point of f and f', while $\epsilon(6)$ is the difference between the mean gray values of f and f'. For every l, $\epsilon(l)$ indicates the point by point reliability of the reconstruction when both the original and the reconstructed picture are digitized as $(64/2^l)\times(64/2^l)$ pictures. For example, if $\epsilon(2)=.01$, and the gray level in the 16×16 digitized version of the reconstructed picture is .253 at a certain point, then we know that the gray level in the 16×16 digitized version of the original is between .243 and .263.

The notion expressed above is easily generalized for test patterns which are digitized as $2^k\times 2^k$ matrices, for any k. Also, $\epsilon(l)$ is computationally easy to calculate, it only requires a repeated increase of the roughness of digitization by a factor of two.

For each of our experiments, we shall give the values of $\epsilon(0), \epsilon(1), \ldots, \epsilon(5)$. $\epsilon(6)$ is always zero.

An alternative way of representing our results regarding resolution in fine detail is to state the size of detail which is reliable within a certain error. For any $\epsilon>0$, $l(\epsilon)$ will denote the maximum number n, such that n is a power of two and the $n\times n$ digitization of the original and the reconstructed pictures differ by less than ϵ at all points. Thus, $l(0.1)=32$ will mean that the original and the reconstructed pictures digitized at 32×32 points will differ at each point by less than 0.1, but if they are digitized at 64×64 points, then they differ by more than 0.1 at least at one point. So, $l(\epsilon)$ is roughly the resolution of the reconstruction if the error tolerance is ϵ. For each of our experiments, we shall work out $l(0.01)$, $l(0.02)$, $l(0.05)$, $l(0.10)$, $l(0.25)$ and $l(0.50)$. Clearly, there is no point in calculating $l(\epsilon)$ for $\epsilon>0.5$.

Visual evaluation

The methods mentioned in (a) and (b) above include all computationally possible ways of measuring the success of reconstructions which are known to us. We left out measuring resolution by the use of Fourier transforms (see (a, l, ϵ)-resolution in Fourier space in the paper by Frieder & Herman (1971)), because of its computational difficulty, and its inappropriateness for comparing two direct methods. Even though the mathematical measures we used should provide quite conclusive evidence of the relative merits of two reconstruction techniques, there has not yet been enough experience with them to know the correlation between the values of the measures and visual acceptability of the reconstruction. For this reason, we shall give for each of our experiments the reconstructed picture, which can then be compared with the original. When the test-pattern is a binary valued picture function, we shall also give the contoured version of the reconstructed picture.

Cost of reconstruction

This is obviously an important measure. In practical applications, especially three-dimensional reconstruction, one has to carry out a large number of reconstructions, and cost can be a prohibitive factor.

To insure that our cost comparisons are valid, we have incorporated both ART and the summation method in the same general program written in FORTRAN. They make use of the same set of service subroutines, e.g., the one for finding out which points lie in a particular ray.

Time, rather than cost is given, since it is easier to obtain. However, cost appears to be a more stable measure between installations. Since all experiments have been run on a CDC 6400, at a cost of $475 per hour, the reader can easily work out the actual cost of the runs. (Rate may vary from installation to installation.) Run time is given in seconds.

DESCRIPTION OF ART

The method we shall describe now is one of the algebraic reconstruction techniques of Gordon, Bender & Herman (1970), the one which was called in that paper the direct additive method. Other papers relevant to this method are Bender, Bellman & Gordon (1970), Crowther & Klug (1971), Bellman, Bender, Gordon & Rowe (1971), Frieder & Herman (1971) and Herman & Rowland (1971).

The basic idea of the method is the following. Starting from a blank picture, the ray-sums of all the projections are satisfied one after the other by distributing the difference between the desired ray-sum and the actual ray-sum equally amongst all the points in the ray. While satisfying the ray-sums of a particular projection, the process usually disturbs the ray-sums of previously satisfied projections. However, as we repeatedly go through satisfying all the projections, the disturbances get smaller and smaller, and eventually the method converges to a picture which satisfies all the projections. Because we start with a uniform blank, and while satisfying each of the projections we make as uniform changes as possible, the final product tends to be as smooth as a picture satisfying the given projections can possibly be. For practical applications, this seems to be a desirable property of a reconstruction algorithm. Roughly speaking, our reconstructed picture will show only features which are forced upon it by the projections, rather than features which are introduced by the reconstruction process.

Mathematically, let f' be the partially reconstructed picture just before we wish to satisfy the projection associated with the angle θ. Let $(x_{i,j}, y_{i,j})$ lie on the k'th ray of that projection, and let $N_{k,\theta}$ be the number of points on that ray. Then f' is changed into f'' by the rule

$$f''(x_{i,j}, y_{i,j}) = f'(x_{i,j}, y_{i,j}) + (R_{f,k,\theta} - R_{f',k,\theta})/N_{k,\theta}.$$

If the value of f'' obtained in this way is negative, it is rounded to zero, if its value is greater than one, it is rounded to one.

The process of satisfying all projections one after the other exactly once is referred to as one *iteration*. The accuracy of ART increases with the number of iterations, and we report on the results of experiments after 1, 5 and 25 iterations.

DESCRIPTION OF THE SUMMATION METHOD

This method has been described by Vainshtein (1971a, b), Gordon, Bender & Herman (1970), Gaarder & Herman (1971), Ramachandran & Lakshminarayanan (1971b). The most detailed discussion of its properties is contained in the work of Vainshtein (1971a, b).

Roughly speaking, the idea is to distribute each of the ray-sums equally amongst all the points in the corresponding ray. If there are m projections, this will result in a picture whose total density is m times what it should be. We therefore subtract from the value at each point $(m-1)d$, where d is the mean density of the picture. (The mean density can be worked out from the ray-sums.) Rounding negative values to zero and values greater than one to one, we get our first approximation to the input.

This procedure has a lot to recommend it. It is conceptually and computationally simple. It can be implemented by a photo-summation device without the use of a digital computer. It seems to provide us with a smooth picture. In fact, if the projections and rays satisfy certain conditions, the result of the algorithm will be a picture which satisfies the projections and for which the variance of gray levels is smaller than for any other picture satisfying the projections (see Gaarder & Herman [1971]).

However, the algorithm has some rather peculiar properties which make it often useless in practice. It appears that as a result of rounding to zero and one, the average density of the picture increases. Hence, we get, with 30 projections, the picture in A5 corresponding to the test pattern in A1. Vainshtein (1971a) recommends that the output should be contoured at a level so that the total density of input and output are the same. However, this advice can only be followed for binary-valued picture functions. To improve the quality of the output for arbitrary picture functions, we carried out the following process.

First of all, if a ray-sum is zero, we know that the value of the function at all points on that ray is zero. The first step in our modified algorithm is to mark all points which lie on rays with ray-sums equal to zero.

Then we carry out the process described above, but equally distributing the ray-sums only amongst the unmarked points in the ray. After subtracting $(m-1)d$ from the value at each point, we round all negative values to zero.

At this stage, the mean density $\bar{d}$ of the reconstructed picture will usually be greater than d. So we multiply the value of the reconstructed function at each point by $d/\bar{d}$, making the mean density of the reconstruction equal to that of the original. We should at this point round all values greater than 1 to 1, but there was no need for this in any of the 16 experiments that we tried.

We found that this modified summation method gave much better results than the simpler technique described at the beginning of the section. For example, for the test-pattern A1 and 30 projections, we get the following comparisons.

	δ	$\epsilon(0)$	$\epsilon(2)$	$\epsilon(4)$	time
simple method	0.32	1.0	1.0	0.44	11.25
modified method	0.18	0.75	0.57	0.09	12.92

Clearly, the large improvement is well worth the small additional cost. In all the experiments reported on in the next section, we used the modified summation method.

A final comment. ART and the summation method have been referred to (Crowther & Klug [1971]) as "very similar." The descriptions above clearly indicate that this is not so, and, as can be seen from the next section, the power of the two methods is quite different. It is therefore invalid to draw conclusions about the behavior of one of these methods from the observed behavior of the other one. The two methods could be combined in an iterative summation method, where after each iteration the difference between the desired ray-sums and actual ray-sums is simultaneously equally distributed amongst the points on the rays. This method should give similar results to ART, but it requires a considerably larger memory in a digital computer implementation.

RESULTS OF THE EXPERIMENTS

We summarize the results of our experiments in the following tables. Table I contains results on δ, R, $\bar{R}$, ρ, whether the reconstruction resolves the original, and time, t. Table II contains $\epsilon(0)$, $\epsilon(1)$, $\epsilon(2)$, $\epsilon(3)$, $\epsilon(4)$ and $\epsilon(5)$. Table III contains $l(0.01)$, $l(0.02)$, $l(0.05)$, $l(0.10)$, $l(0.25)$ and $l(0.50)$. These are marked as 1 percent, 2 percent, 5 percent, 10 percent, 25 percent, and 50 percent in the table.

In all the tables, the numbers 4, 8, 30 and 6 on the top refer to the number of projections. The first three sets are equally spaced, while the last set consists of the angles 35°, 44°, 62°, 80°, 98° and 116°.

The vertical arrangement of the four numbers in each of the entries of the table refer to the result by the summation method, followed by the results by ART after 1, 5 and 25 iterations.

As can be seen from these tables, if the number of projections is small, one iteration of ART seems to perform somewhat worse than the summation method. As the number of projections increases, the relative performance of one iteration of ART as opposed to the summation method improves, and eventually it produces superior results. The break-even point seems to be at eight projections. However, by repeated iterations, the performance of ART can be improved and it eventually surpasses the summation method in all our experiments. The improvement in ART is especially impressive with eight or more projections. In such cases, we obtain, with five iterations of ART, results which are far superior to the results of the summation method. These conclusions are clearly demonstrated on the plates showing the reconstructed pictures.

Plate B contains reconstructions of the wrench (A1), Plate C contains reconstructions of $\rho(R)$ (A2), Plate D contains reconstructions of Judy (A3), and Plate E contains reconstructions of the stomata (A4). Plates F and G contain the contoured versions of the reconstructions of the wrench and $\rho(R)$.

In all plates, the first row gives the reconstructions based on 4 equally spaced projections, the second row gives the reconstructions based on 8 equally spaced projections, the third row gives the reconstructions based on 30 equally spaced projections and the fourth row gives the reconstructions based on the 6 projections from the 81° range. Within each row, the first picture is the result obtained by the summation method, which is followed by the results obtained by ART after 1, 5 and 25 iterations, respectively.

There are a number of observations worth making regarding the results of our experiments.

First of all, the basic measures δ and R give, with hardly any exceptions, the same ordering between different experiments for the same picture. There seems to be little reason to use the one rather than the other. The orderings based on these measures are also in very strong correspondence with the orderings based on any of the resolution measures.

Another interesting point is that there is no instance when a picture reconstructed by ART does not resolve the original after five iterations.

The third observation is in reference to Table III. Very little information can be gained from a digitization with fewer than 8×8 points. In all our experiments the summation method produced a picture whose 8×8 version differs from the 8×8 original at some point by at least 0.1. In fact, for the wrench (A1), even 30 projections can only produce a picture, where the difference between the 8×8 pictures is more than .25, at least at one point.

It has been claimed for ART (Frieder & Herman [1971]) that for an $n \times n$ resolution it requires approximately n equally spaced projections. Table III bears

Plate D

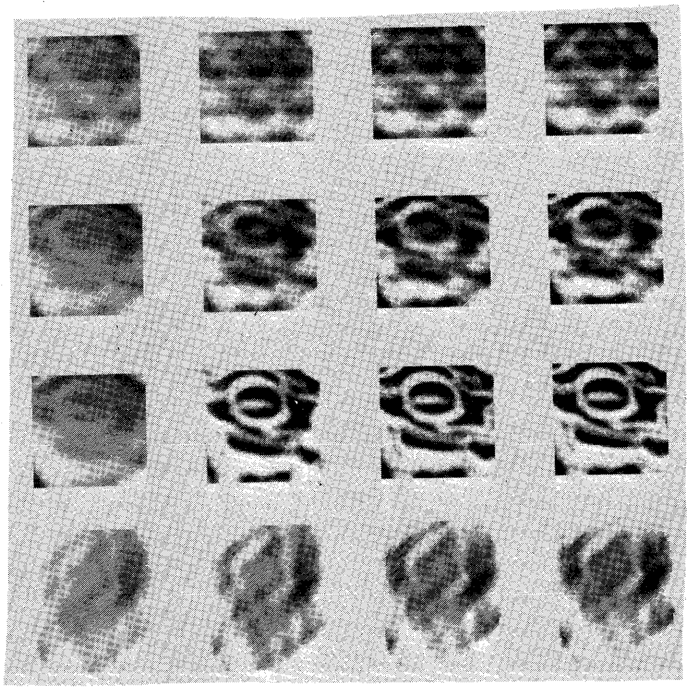

Plate E

this out. For the binary valued pictures with n equally spaced projections the error at $n \times n$ resolution is less than 0.05 at all points, while for the half-tone pictures it is less than 0.1. (This is after 25 iterations, sometimes sooner.)

For the case of 30 projections, for all four test patterns, the error at each point in the 64×64 reconstructed picture after 25 iterations of ART is less than .175, and in the case of the binary valued pictures it is actually less than .015 (see Table II).

For perfect contouring we need an error which is less than .5 at each point. Thus, we see that contoured 16×16 reconstructions of all the pictures are perfect, with all four sets of angles, when ART is used with 25 iterations. For the summation method, the same statement holds only for 4×4 reconstructions.

At two points, our results do not strictly correspond to results in earlier publications.

The first of these is the bad quality of the contoured output of the summation method (Plates F and G). The contoured output obtained by Vainshtein (1971a) in the same experiment appears to be superior. The reason for this difference is that Vainshtein contoured at a level which will make the contoured input and output to have the same density, while we made the half-tone output to have the same density as the input, and then contoured at .5. The reader can easily judge for himself, from Plates B and C, what the effect of contouring at different levels would have been.

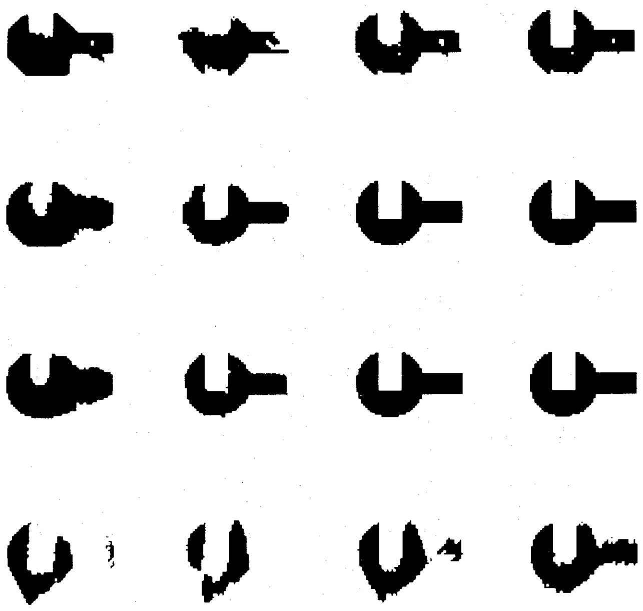

Plate F

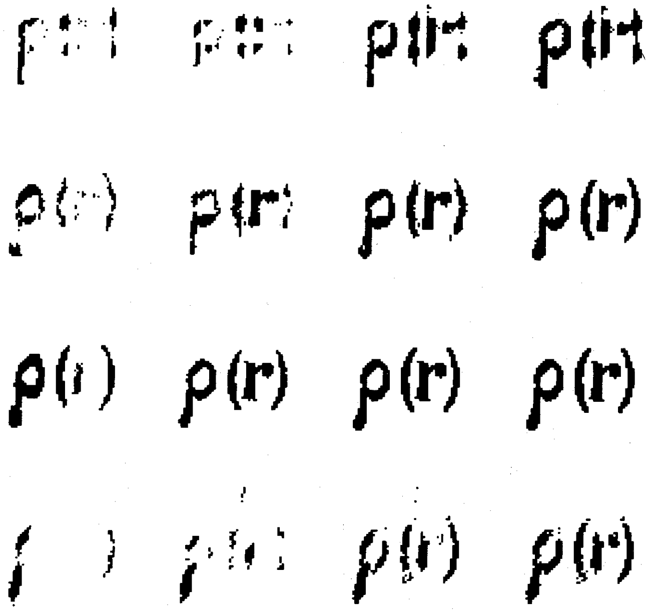

Plate G

The other point concerns the performance of ART on the half-tone pictures using 6 projections from the 81° range. The results appear to be much worse than what have previously been obtained either for Judy (Gordon, Bender & Herman [1970]) or the stomata (Herman & Rowland [1971]). There are two reasons for this. One is that we are putting a fairly wide white frame around the picture. This frame does not contribute to the total density, but the fact that it goes all the way around the picture cannot possibly be detected from projections taken in a small range. Since ART is intended to produce a picture as smooth as possible while satisfying the projections, it will smooth out the picture into that part of the original white frame which is not uniquely determined from the projections. This will also bring with itself a general lowering of density in the middle portion of the picture, causing some distortions in trying to satisfy some of the projections. The second reason for the bad quality of the reconstructions of the stomata, as opposed to earlier experiments with angles within the same range, is that previously all the projection angles clustered around the horizontal, while due to the rotation discussed in Section two, now they cluster around the vertical. The stomata seem to have many horizontal bands, thus, reconstructions from projections from a small horizontal range produce better results, than from a small vertical range. (This is not the case with Judy.) The countermeasure to being a victim of the orientation of the object relative to the small range of views is to average a number of independent reconstructions (see Herman & Rowland [1971]). The following table gives the value of δ when the Judy and the stomata test patterns are reconstructed, with and without a white band around them, with six views from two small ranges, as well as the average in each case. All results are based on ART after 25 iterations.

	Angles −45°, −36°, −18°, 0°, 18°, 36°	Angles 35°, 44°, 62°, 80°, 98°, 116°	Average
Judy 49×49 version	.14	.16	.13
Judy 64×64 version	.19	.19	.16
stomata 50×50 version	.16	.23	.17
stomata 64×64 version	.17	.22	.17

As can be seen from this table, averaging considerably improves the quality of the reconstruction, for the 64×64 pictures. Using a smaller frame can also be helpful in this respect. Thus, the bad results we obtained for half-tone pictures with six projections from a small range can be avoided by a careful choice of the square in which $f(x, y)$ is assumed to be possibly non-zero (it should be as small as possible), or by averaging. Naturally, the same comments apply to the summation method as well.

ACKNOWLEDGMENTS

This research has been supported by NSF Grant GJ998. The author is most grateful to Mr. Stuart Rowland for his constant help with programming and in other matters. The following colleagues have also been helpful both by enlightening discussions and in producing the actual pictures: R. Bender, G. Frieder, R. Gordon and J. Rowe. The pictures have been produced by the courtesy of Optronics International, Chelmsford, Massachusetts.

APPENDIX

Justification of the use of digitized rather than continuous test patterns

A basic assumption of any picture reconstruction process is that the picture is reasonably smooth relative to the size of the ray widths. It is clearly unreasonable to expect an algorithm to reconstruct detail which is much finer than the width of the rays.

Since our digitization was done approximately on the same scale as the ray width (i.e., the distance between two adjacent points in the matrix on which the digitized picture is defined is of the same order of magnitude as the ray-widths), we may conclude that values of the digitized picture at neighboring points are highly correlated. Furthermore, by our smoothness assumption, if we divide the continuous picture into squares with centers at the points of digitization, at all points in the squares the gray value of the picture will be near to the digitized value at the center.

The way we have chosen the position and width of the rays is such that relative positioning of the squares and the rays will be as shown in Figure 2.

In the digitized version, the contribution to the indicated ray in Figure 2 will come from the value at

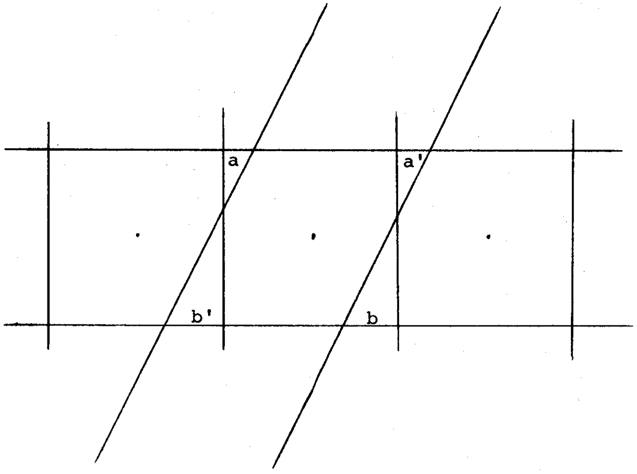

Figure 2

the center of the square, which is supposed to equal the total grayness in the square. In the continuous version, however, regions a and b in the square do not contribute to this ray, while regions a' and b', which are outside the square, do contribute. However, the area of a is the same as that of a' and area of b is the same as that of b'. Hence, if the picture function is smooth relative to the ray widths, the ray-sums of the digitized and continuous versions of the picture are approximately the same.

To demonstrate that this argument works in practice, we took ray-sums of a continuous version of the test pattern in A1, with a genuinely circular boundary. The following shows the order of differences in our measurements when we used the continuous and discrete test patterns. The discrete pattern is not binary valued, rather it is the 64×64 digitization of the continuous pattern with 16 gray levels. All results refer to the experiments with four projections, ART and five iterations.

	δ	R	ρ	$\epsilon(1)$	$\epsilon(3)$	$\epsilon(5)$
continuous test pattern	.1642	.4461	7.515	.5755	.2315	.0168
digitized test pattern	.1633	.4429	7.230	.5658	.2303	.0161

It appears that there is no essential difference between the results of the two experiments. Other tests gave similar results (see, e.g., Herman & Rowland [1971]).

Since the use of digitized test patterns makes experimentation considerably simpler, it seems advisable to use them, rather than continuous test patterns.

PRADIS—An advanced programming system for 3-D-display

and

W. GILOI

University of Minnesota
Minneapolis, Minnesota

SUMMARY

The development of PRADIS was started in early 1968 as a vehicle to implement and evaluate new schemes of man-machine-interaction, data base organization, and hidden-line detection which were being developed in our laboratory. With time it evolved into a rather elaborate programming system for generation, construction, manipulation, and perspective display of arbitrary three-dimensional objects. All relevant object types such as polyhedrons or groups of polyhedrons with convex or concave structure, objects that are described by analytical expression, as well as the most general case of objects that are bounded by arbitrarily curved surfaces can be handled. Different modes of defining and inputting objects and different-hidden-line suppression algorithms have been individually developed and implemented for these various types. Man-machine-communication has been facilitated by defining a simple command language for the user. The execution of any command can be initiated by pointing to the respective instruction in a command menu. Additionally, a keyboard (or the console typewriter) can be used for specification of parameters or the description of objects by analytical equations. Subroutines for scaling, translation, and rotation are part of the system as well as program modules which enable the user to construct three-dimensional objects by drawing two-dimensional views of them.

PRADIS is a modular system designed for implementation on a small to medium scale computer (our system has only 16 K of 24-bit words). Each module of the programming package is a functional entity, linked to other modules by an overlay technique. In the paper, the construction of the programming system and its modules, the different input modes, and the various hidden-line detection procedures are described. Representative pictures illustrate the performance of the system and its intrinsic procedures.

INTRODUCTION

PRADIS is a programming package written in FORTRAN II for the SDS 930 computer. As our configuration has only 16 K of core memory, the whole system has been divided into 16 segments (links). Each segment is a self-sustained entity that takes care of a certain complex of the total set of functions. The various subsystems exchange data via a shared common area.[1]

The first module is a control module that interprets the command language by which a user defines what class of objects he is going to deal with and what input mode he will use. The control module then calls the respective link which provides a data input in the required mode, generates objects, and executes instructions in an interactive mode. By setting certain sense switches, the user finally terminates the job or calls the control module again for further execution of other jobs. Figure 1 gives a simplified block diagram of the entire system which we will discuss more in detail in the following sections.

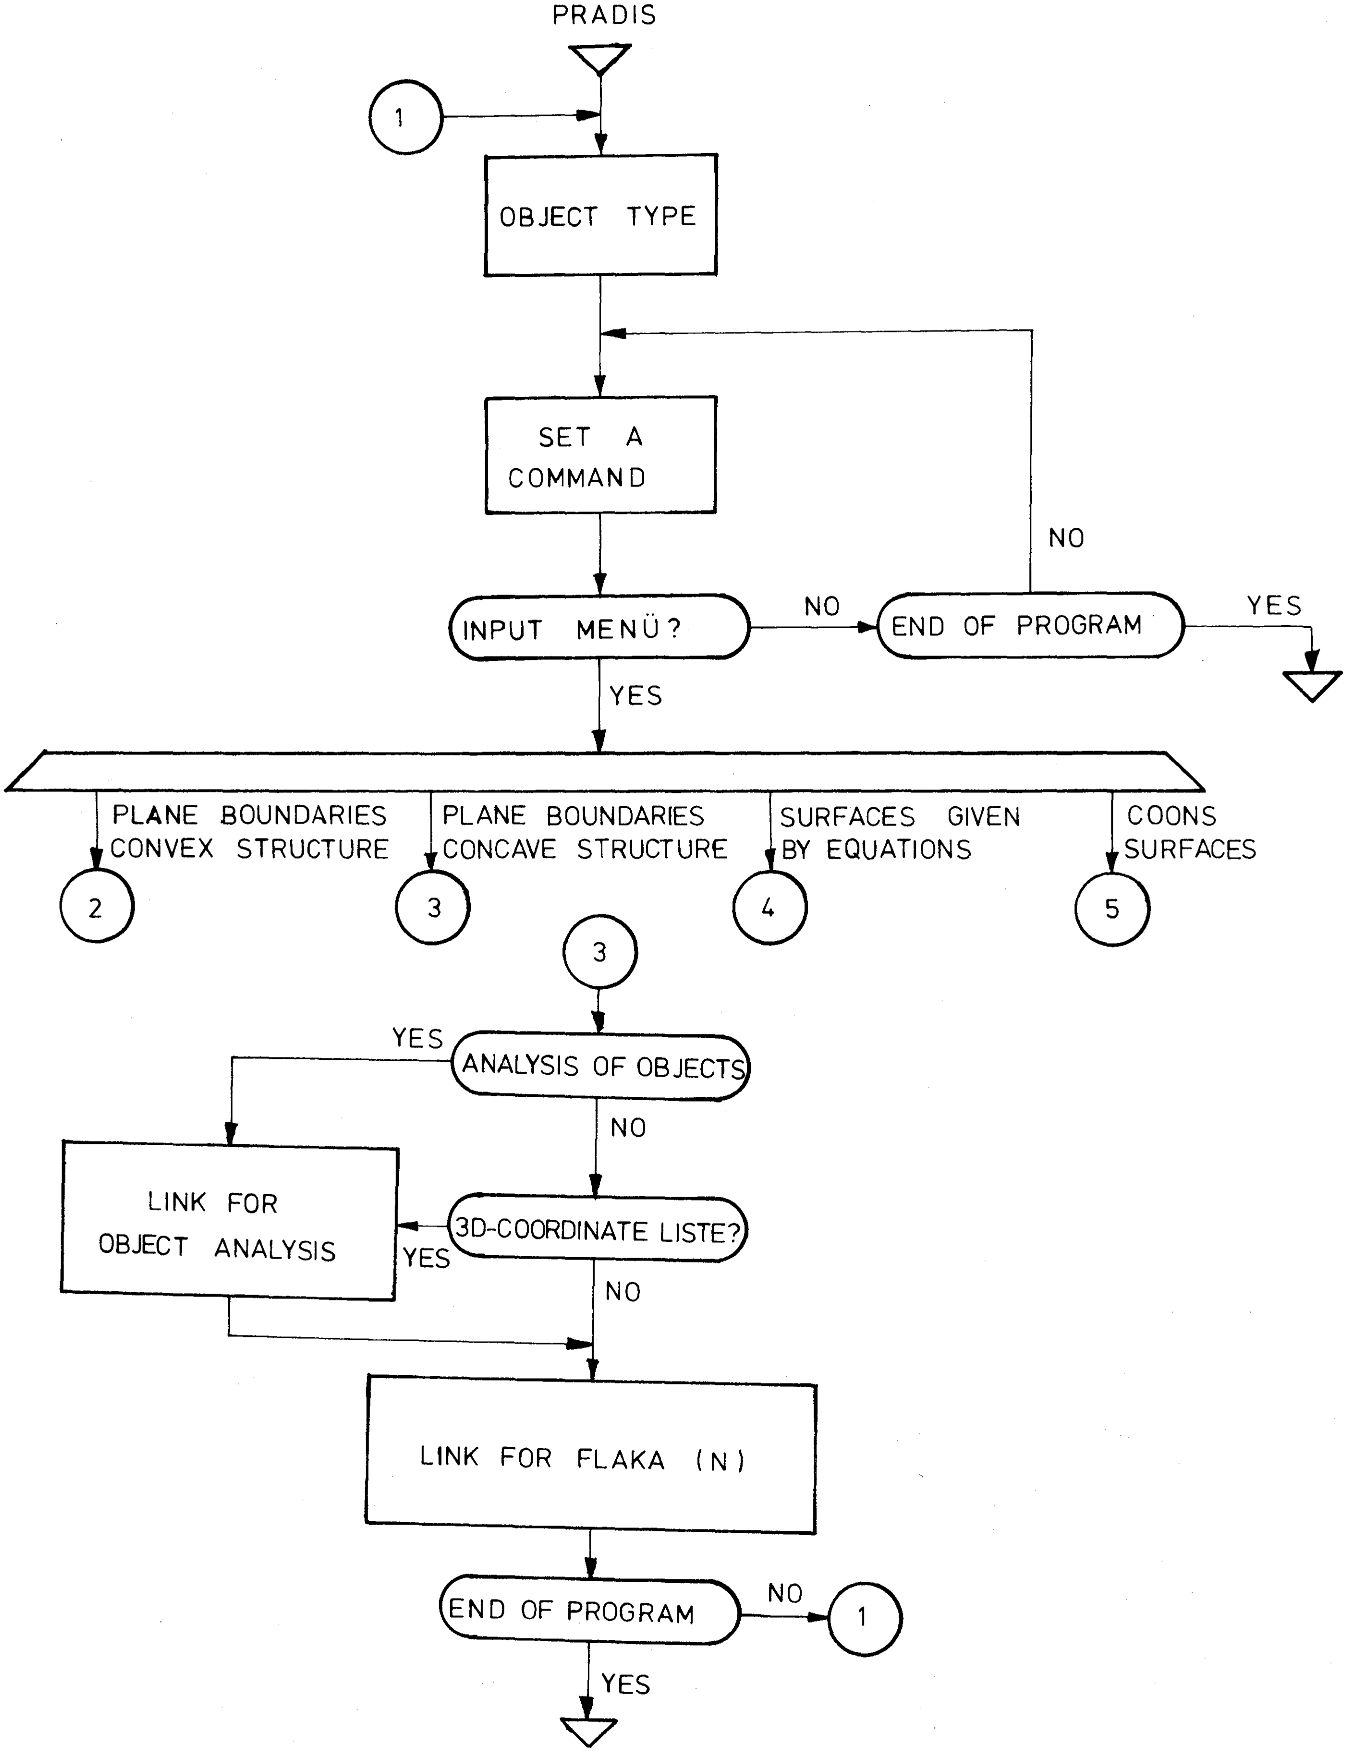

Figure 1a—Block diagram of the system PRADIS

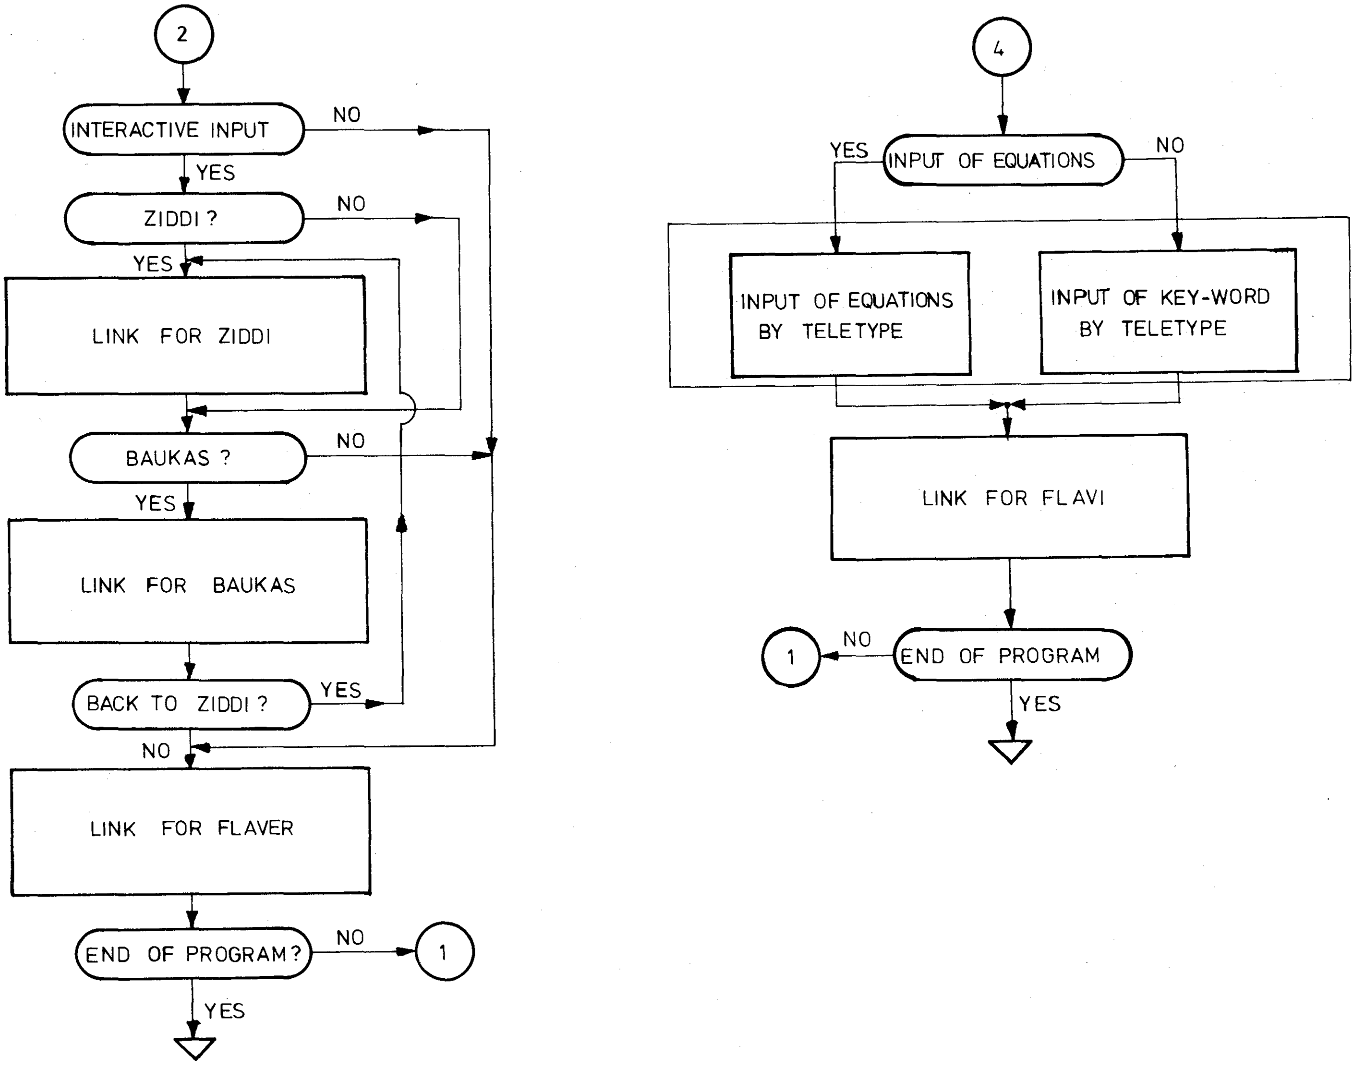

Figure 1b—Block diagram of the system PRADIS

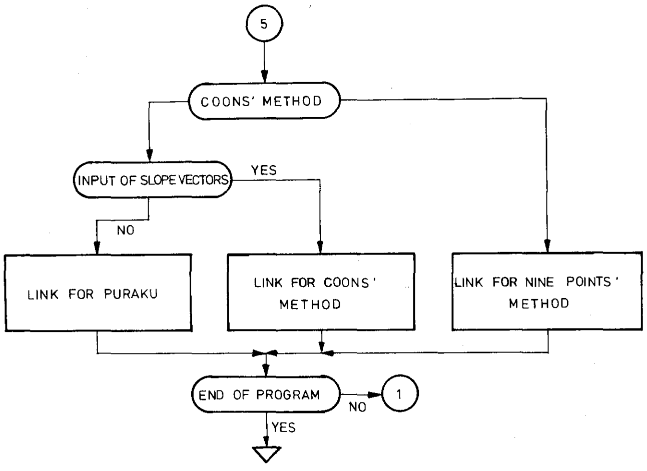

Figure 1c—Block diagram of the system PRADIS

CLASSES OF OBJECTS

The classes of objects that can be selected are:

- Groups of polyhedrons of convex structure (KOVSTR)
- Groups of polyhedrons of concave structure (KOKSTR)
- Groups of objects that are defined by functions of two variables which have to be given in analytical form (FUNGLE)
- Groups of objects described by functions of two variables which are "primitive functions" (i.e., they are stored under a function name in the library) (FUNAME)
- Groups of objects that are neither polyhedrons nor defined by analytical functions but that are composed by "surface patches" as defined by COONS' theory (FLADAR)

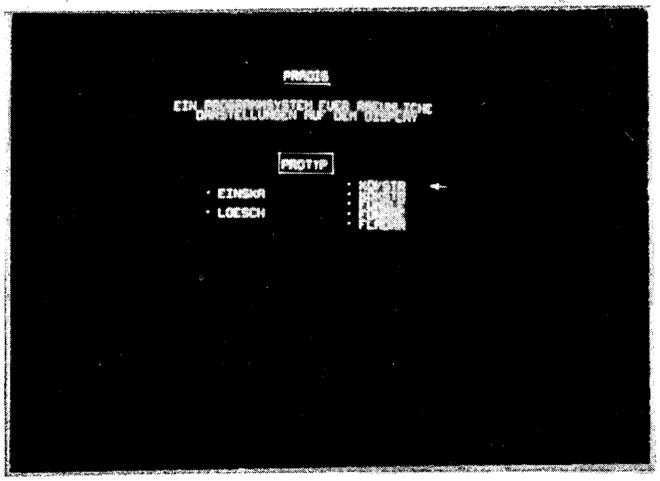

Figure 2—PROTYP—Menu

(In the present version of PRADIS 'FUNGLE' and 'FUNAME' are intrinsically the same module. However, in an extended version they have to be distinguished.)

Figure 2 shows the "menu" or "light-button field" which enables the user to select the required module by pointing first to the PROTYP command and then to a selection instruction. The selected problem type (and the respective module) is indicated by an arrow. An erroneous selection can be corrected by a delete instruction (LOESCH). Otherwise, the next instruction menu is called, depending on the object class the user wants to deal with.

MODES OF INPUT

Each module provides several input modes for the generation and manipulation of objects as shown in Table 1.

Some comments shall be given. ZIDDI and BAUKAS are able to call each other to facilitate the interactive procedure of constructing objects of convex structure. ANKOR, so to speak, is a sort of preprocessor which calls automatically LIDREI after the analysis of the inputted objects has been performed (of course, this step can be skipped by entering LIDREI directly). LIDREI includes as well as BASTRU the 4×4-matrix operation that takes care of scaling, perspective display, and rotation of objects or groups of objects. In either case the hidden lines are evaluated and suppressed. Naturally, the employed hidden-line detection strategies have to be different.

In the case of objects defined by equations the input procedure consists in typing in either the defining equation (FUNGLE) or the functions name (FUNAME).

For the fourth class of objects (i.e., general three-dimensional objects composed by surface patches) we have two optional modes of object definition and input: FLEIN 1 and FLEIN 2. FLEIN 1 provides the definition of general three-dimensional objects following COONS' method; i.e., by putting in the characteristic nodes and slope vectors.

FLEIN 2 is based on the input of nine points for a surface patch definition, providing a much easier way of defining objects. This technique will be described in a later section.

CONSTRUCTION AND DRAWING OF THREE-DIMENSIONAL OBJECTS

To our knowledge, the first program which served that purpose was developed by T. JOHNSON[2] of M.I.T. in connection with the SKETCHPAD project. In this program, an object is represented by three views

TABLE I—Input Modes for the Generation and Manipulation of Objects

object type	input commands	visibility procedure	comment
KOVSTR	ZIDDI BAUKAS BASTRU	FLAVER	Display of objects bounded by plane surfaces with convex structure

FLADAR	FLEIN 1 —— PURAKU TANECK FLEIN 2	FLAVI	Display of objects that are composed by 'surface patches' (Coons)

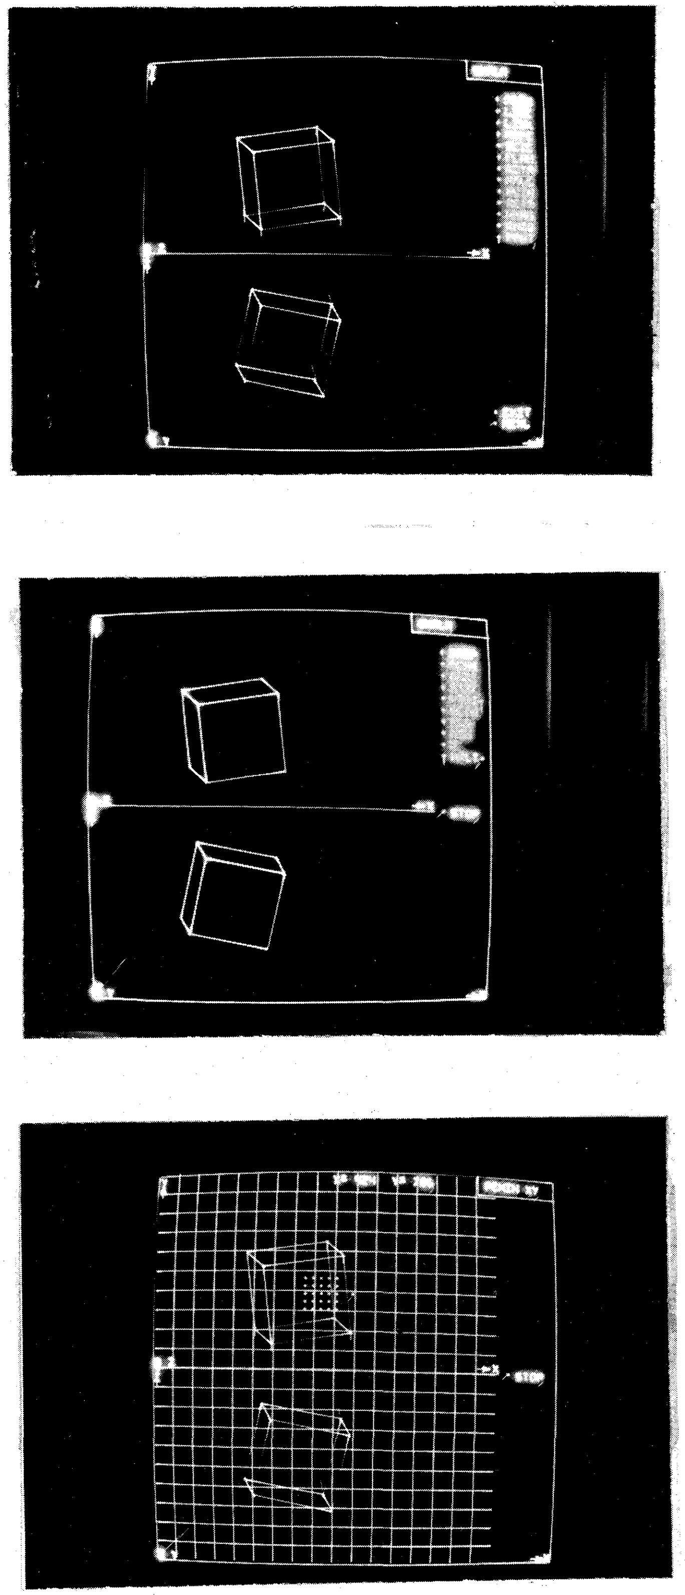

Figure 3—Examples of objects constructed with the aid of ZIDDI

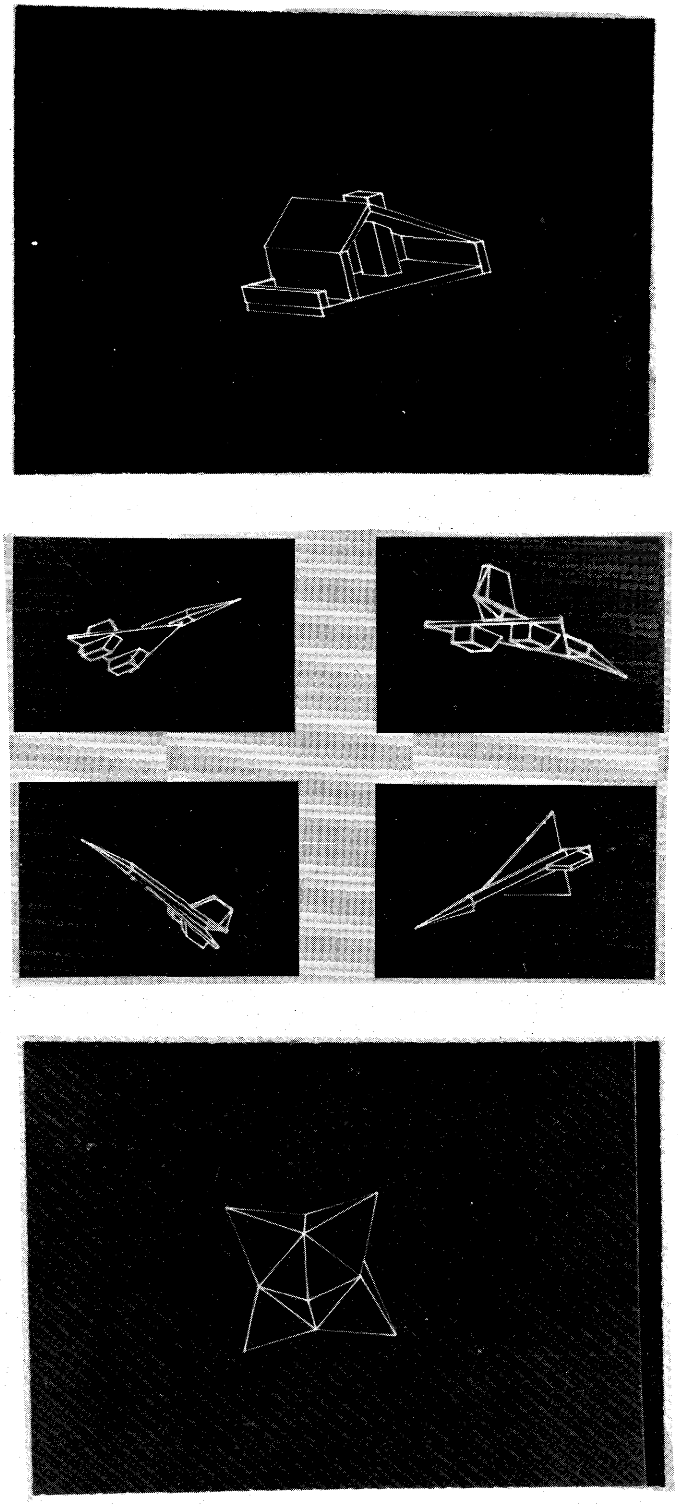

Figure 4—Examples of objects constructed with the aid of ZIDDI

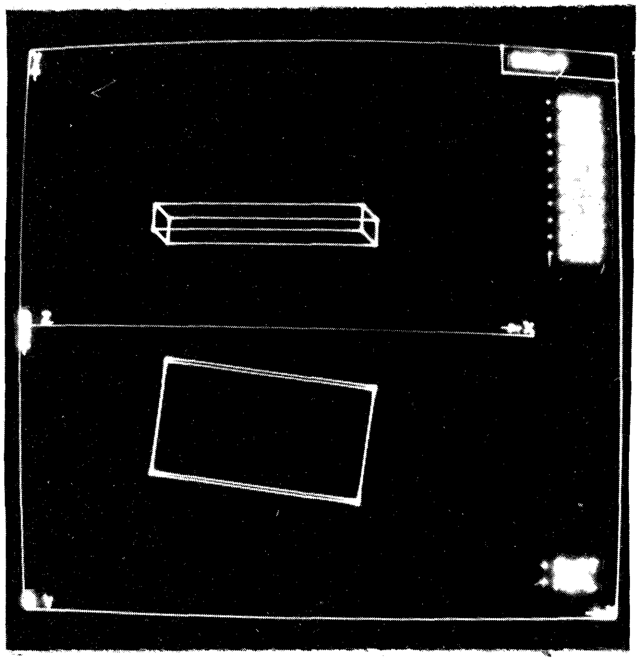
and one section which have to be drawn by light-pen. Recently, two more programs have been reported,[3,4] but they do not offer the generality and flexibility of ZIDDI and BAUKAS.[5]

ZIDDI takes advantage of the man-machine-



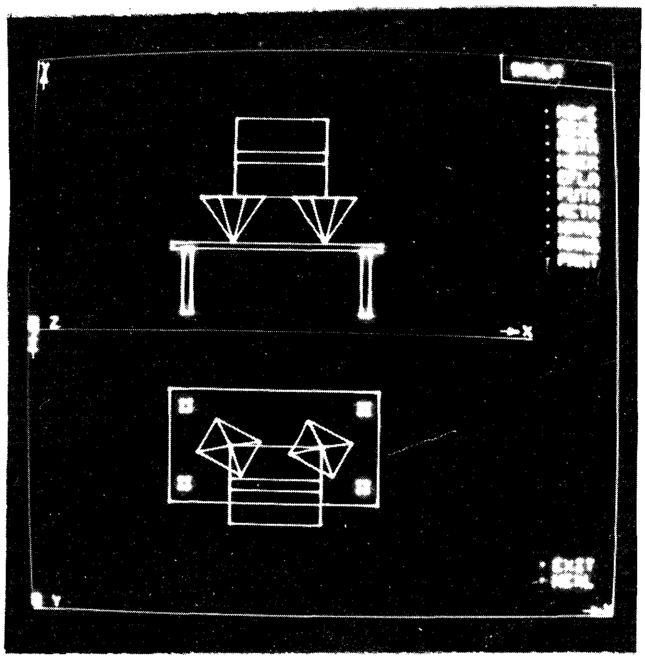


Figure 5—Illustration of BAUKAS

communication by which a display system with light-pen facilitates the task of constructing three-dimensional objects by drawing two-dimensional views. Additionally, the user has a set of powerful commands at hand for executing coordinate transforms and other operations. Using the light-pen, the user marks dots which are subsequently connected by lines. These lines may constitute surfaces which, again, bound bodies. Dots and lines can be arbitrarily added or erased. All coordinate transform procedures (scaling, translation, rotation) can be called by pointing to the respective command in the command menu, and they may be arbitrarily used to generate and modify figures and objects. In space, a point is defined by three Cartesian coordinates x, y, z. However, on the two-dimensional screen of the scope we have only two coordinates. This discrepancy is overcome by defining two areas on the screen: the xy-plane and the xz-plane. Both planes are automatically connected by linking related coordinates (for better accuracy the user can ask the system to display only one of the two planes in double size and to draw an auxiliary grid).

Concave structures are not always uniquely defined by two views, but by rotating them into an appropriate position a unique object definition can be obtained. Some simpler examples of objects that have been constructed with the aid of ZIDDI are shown in Figures 3 and 4.

BAUKAS (from German "Baukasten" = building block) provides the possibility to call primitives which are stored in a font and use them as components of a more complex object. The primitives have been constructed at an earlier time by the aid of ZIDDI. Figure 5 illustrates the way BAUKAS works. A table is going

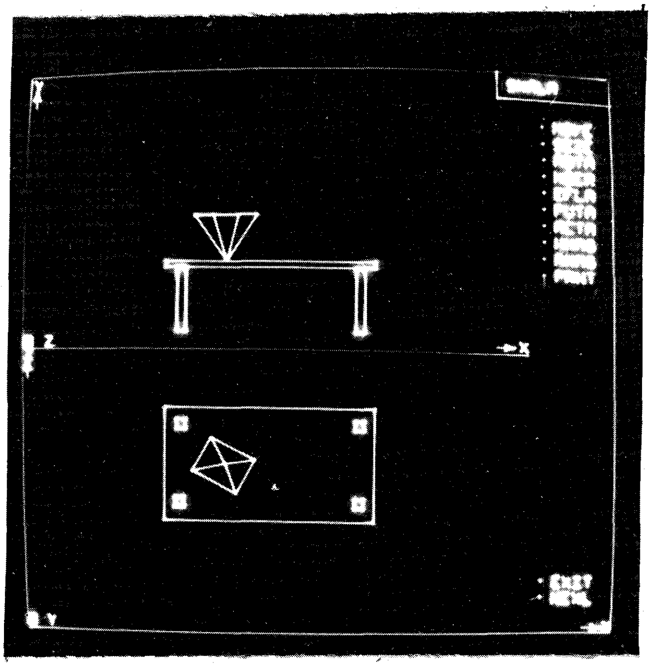

Figure 5 (cont'd)

to be constructed by using cubes as primitives. By deforming the cubes in one way, we get the table-top; by deforming it in a different way, we get the legs. On top of the table we put two other primitives: the pyramids and the cube on top of them. The flexibility of BAUKAS is illustrated by some examples given in Figure 6.

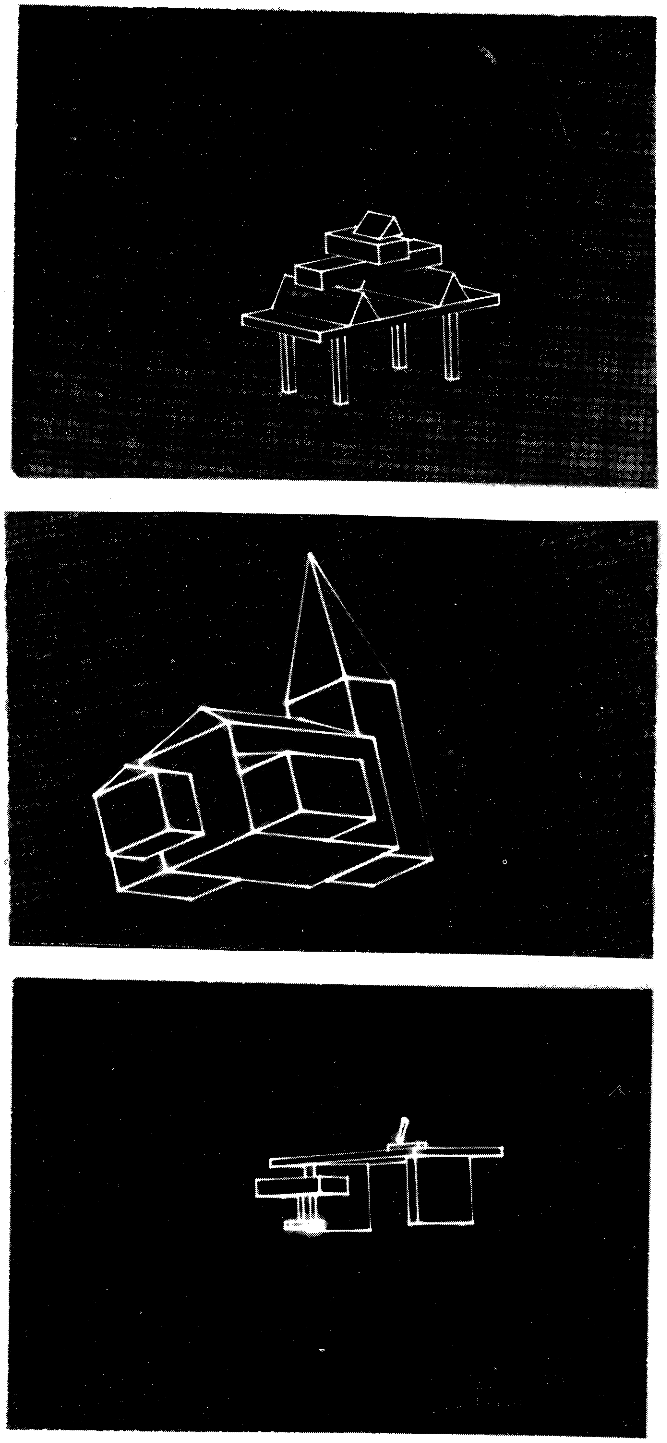

Figure 6—Examples of objects constructed with the aid of BAUKAS

ANALYSIS OF POLYHEDRONS WITH CONCAVE STRUCTURE

Concave objects are those which are bounded by one or more concave surfaces or which have cavities. A group of disconnected objects (with empty space in between) is—as a group—concave, too. It is evident, that in contrast to convex structures some difficulties may arise with respect to establishing unique relations between all points, lines, surfaces, and objects of a structure. However, these difficulties are overcome by the following procedure.[6] Prerequisite for it is, that a list is available which gives the three spatial coordinates of all points, and which marks all connections between them. Such a list may have been put in by the user or it will be generated by the program.

The most general case is that the user has three drawings which show three different (two-dimensional) views of the object. In that case the user has only to provide for each drawing a list of the two coordinate values of all relevant points, together with a second list of all visible connections. The order in which the points are numbered is arbitrary. From these lists the program generates a list of all points in space in the following way: the y-coordinate of a point in the xy-list, for example, is taken, and the yz-list is searched for the same y-coordinate. If the search is successful, the xz-list is searched for a point, whose x- and z-coordinates correspond respectively with the x-coordinate of the point taken from the xy-list and the z-coordinate of the point taken from the yz-list. Triples of x-, y-, and z-values obtained in such a way constitute the coordinates of a (spatial) point of the three-dimensional object. Eventually, the list of all spatial points is sorted with respect to increasing values of x and a running index is assigned to each triple.

The second task is to generate a list of all lines of the three-dimensional objects from the input of their two-dimensional views. A similar search procedure as in the case of the generation of the lists of spatial points is used, i.e., the three lists which belong to the two-dimensional views are searched for certain equivalences. The difference is that now an equivalence is not given by the coordinate values but by their running index. The point is that first of all the arbitrary numbering in the list of all points of the two-dimensional views has to be replaced by the corresponding running index taken from the ordered list of spatial points. In order to make that feasible, the lists of the points of the two-dimen-

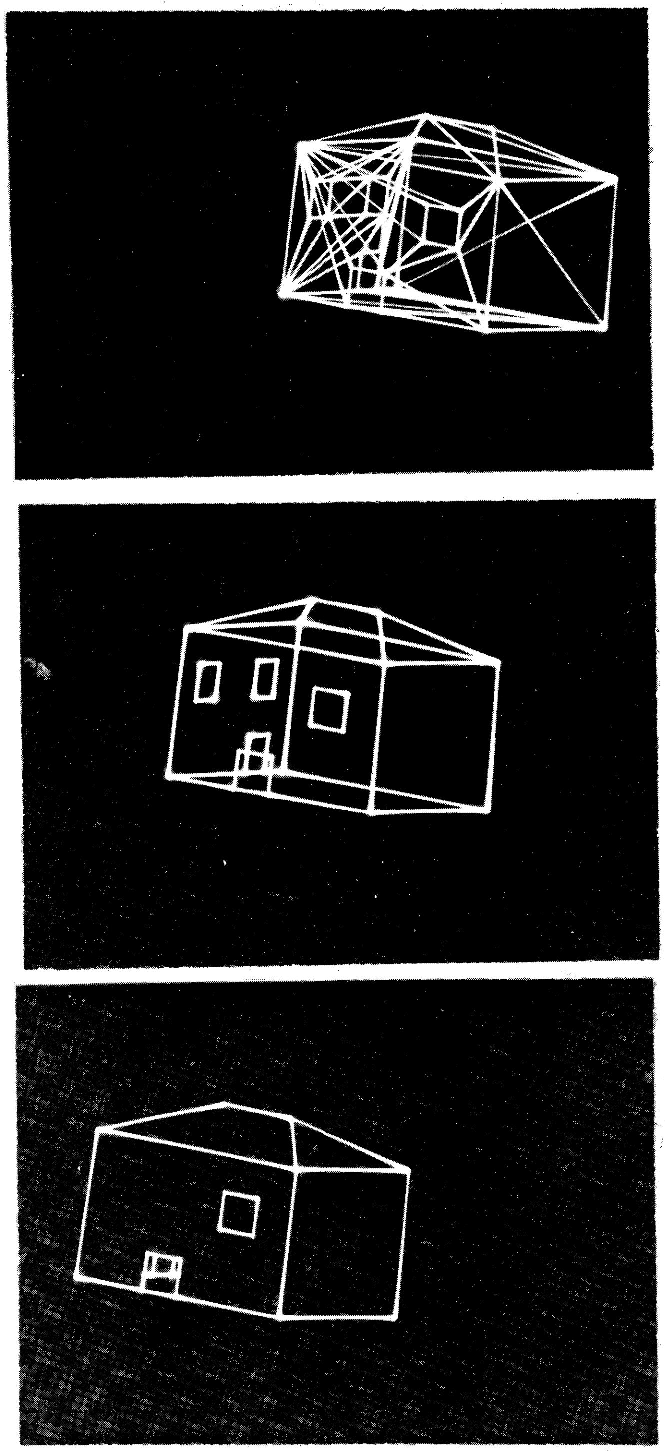

Figure 7—Examples for the results of the object analysis

sional views must at first be augmented by all connections which are existing in the three-dimensional case but not visible in all the two-dimensional views. This procedure is fairly complicated so that it would lead too far afield to explain it in detail. The next figures show some of the results we obtained with this procedure (Figures 7 to 9).

DEFINITION OF OBJECTS BY ANALYTICAL FUNCTIONS

There are three different ways of defining three-dimensional objects by analytical expressions:

(1) the implicit form $F(x, y, z) = 0$
(2) the explicit form $z = f(x, y)$
(3) the parametric form $x = f_1(u, v)$, $y = f_2(u, v)$, $z = f_3(u, v)$.

Though the implicit form is the most simple one, it does not lead to an efficient computer algorithm. The explicit form, on the other hand, does not provide a unique description (e.g., for $z = 0$ we have $f(x, y) = 0$ which does not only define all the points of a plane but all the points on a cylinder). So we have to rely on the parametric form.

In order to facilitate the input procedure, the system enables the user to key-in his equations on the display keyboard (or console typewriter, respectively). After having the equations analyzed and transformed, the system calls an appropriate algorithm for function evaluation. Furthermore, the user will be asked to specify all necessary reference coordinates, scaling factors, and other parameters. Syntactical errors will be detected, and error messages will be output. The respective language which we use is simple; its syntax has been described elsewhere.[7,8]

The typed-in equations are processed in the following steps:

(1) loading into a buffer storage area
(2) equation analysis and coding
(3) assignment of values to the parameteric variables (u, v)
(4) assignment of values to the coordinate variables (x, y, z)
(5) calculation of the right-hand expressions and storage of the obtained results.

In the second step the equations are converted into polish notation, and a push-down stack is set up. An operation matrix defines whether or not an actual operation can be immediately performed on two subsequent variables. The first row denotes the actual operators and the first column their predecessors. The meaning of the numbers in the matrix is

1: Operation cannot be executed. Bring operator into the operator stack.

2: Both operators have same priority. Execute operations.

3: Actual operator has higher priority than predecessor. Execute operation.

4: Erase parentheses (or brackets). If the expression between parentheses (brackets) is a subroutine for function evaluation, it is executed.

5: Recognition of a terminal operator.

6: Invalid combination of operators. Output error message.

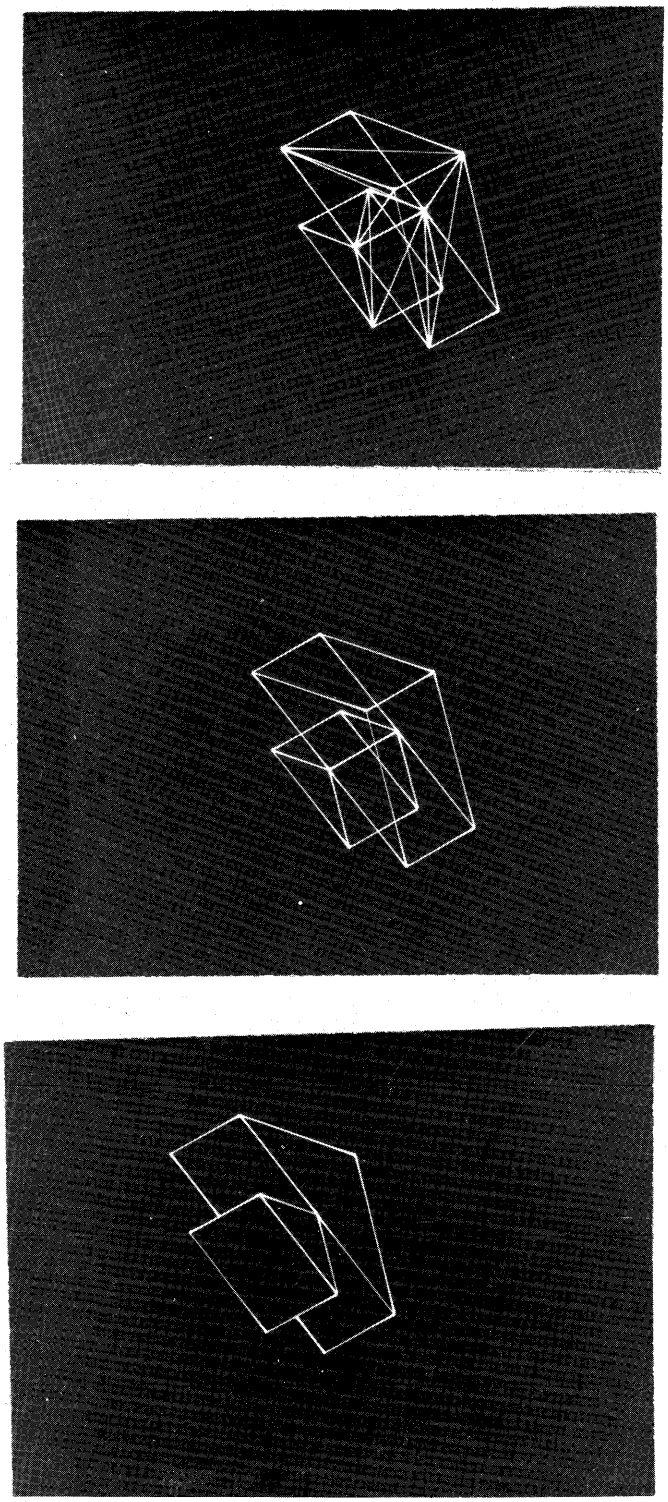

Figure 8—Examples for the results of the object analysis

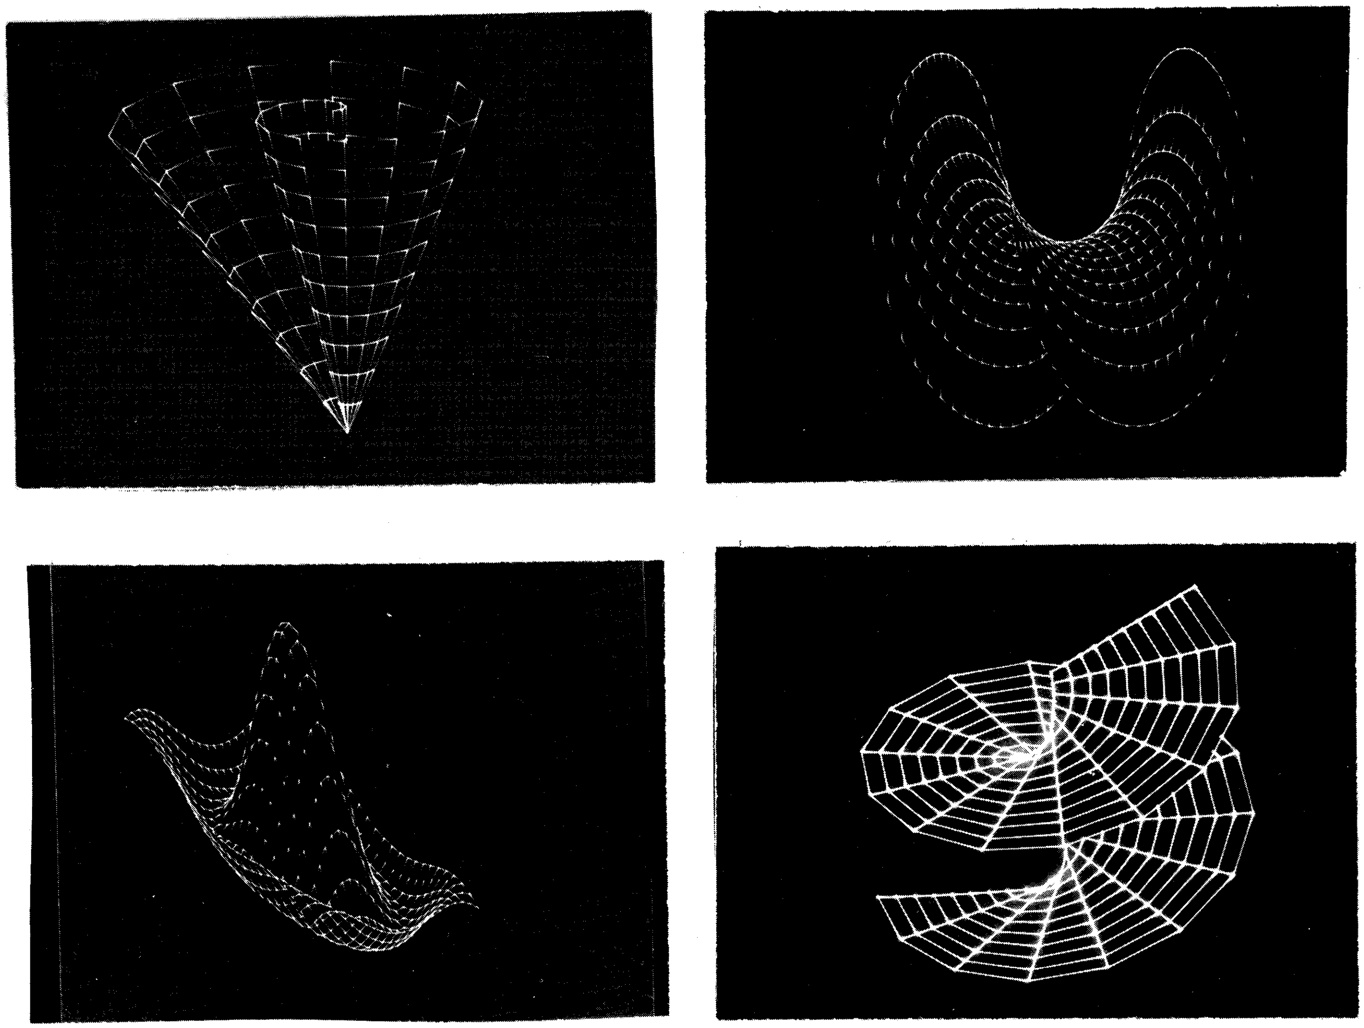

Figure 10—Surfaces generated and displayed with FLAVI

The above outlined analysis program has been written in FORTRAN II which, however, had to be supplemented by bit and character manipulation subroutines. The submodule FLAVI can be applied for hidden line detection and suppression to the thus calculated functions. Figure 10 shows some objects generated in that way.

GENERAL OBJECTS

According to COONS' theory and the nine point modification we have three main modes of defining bounding surfaces of general three-dimensional objects:

(1) The boundary contours have to be specified; blending functions (functions that define how the boundaries are connected by curved surfaces) are defined once and for all.

(2) Four corner points and eight corresponding slope vectors have to be specified for each surface patch; fixed blending functions are given, as in the first method.

(3) For each surface patch nine characteristic points have to be specified. No blending functions are required.

Generation of boundaries by polynomial approximation (FLEIN 1, PURAKU)

The first approach offers the advantage of dealing with larger entities than the "surface patches" in the second and third approach. Each boundary is approximated as an entity by a polynomial approximation. For each contour $n+1$ quintuples have to be specified; n being the degree of the approximation polynomial.

The five values of each quintuple give the three coordinates of a point through which the polynomial passes as well as two parameters for the specification of the two degrees of freedom of the surface. Thus, the degree of partitioning the objects can be lower.

However, the method shows some deficiencies. (One serious deficiency is, for example, that it is not very well suited for an interactive use of the display system but requires rather elaborate preliminary work.) It is left to the user to define the degree of each approximation polynomial; if he is not very familiar with the performance of polynomial approximations, large errors may occur. Of course, the best performance is obtained if the boundaries are conic sections.

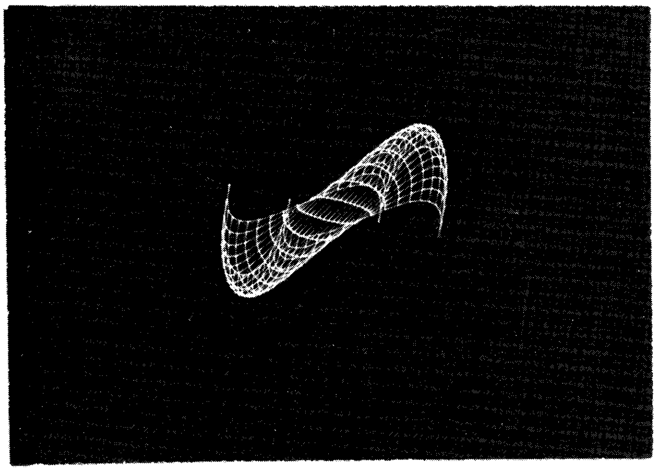

Figure 11—Object defined by COONS' method

COONS' method (FLEIN 1, TANECK)

As mentioned before, for each construction element called "surface patch" of a curved surface we have to specify four corner points and eight corresponding slope vectors, two for each boundary contour. These vectors, of course, are defined in space by specifying their components.[10] In FLEIN 1, the intrinsic blending functions are of third order. Figure 11 shows an example for an object defined in such a way. In order to obtain a smooth representation of an object, it is necessary that the user develops a good feeling of how to specify slope vectors in an optimum way. Hence, the application of this method requires a lot of experience and preliminary work with pencil and paper.

The nine point method (FLEIN 2)

Here, a surface patch is defined by specifying nine characteristic points: the four corner points, four points on the boundaries (one point on each one), and one point in the center of the surface.[11] Figure 12 gives an example: the surface element is a quadrilateral, the center point is on the same level (has the same z-coordinate) as the four corner points, and the points on the boundaries are on a higher level. In Figure 13, in contrast, the center point has been raised to the level of the boundary points.

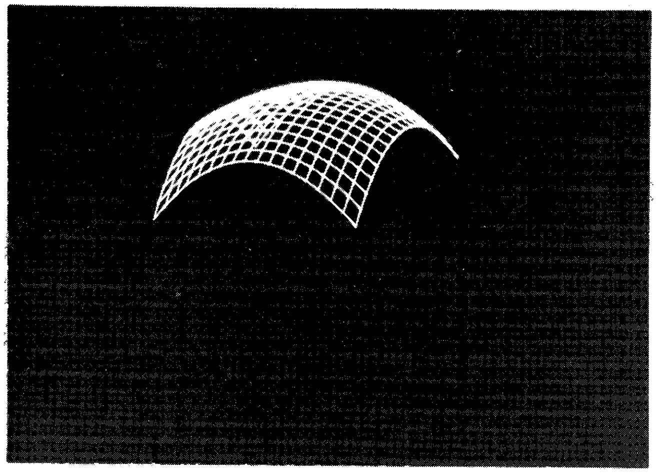

Figure 12—Example for the nine point method of defining a surface patch

The nine point method works better the more information about the objects one has (points of inflexion, boundary, etc.). Boundaries are approximated in an optimum way if they are parabolic. Any time a break point or a point of inflexion occurs, a new surface patch has to be defined. Hence, the nine point method leads to a finer partitioning than COONS' method. Another disadvantage is that it does not guarantee

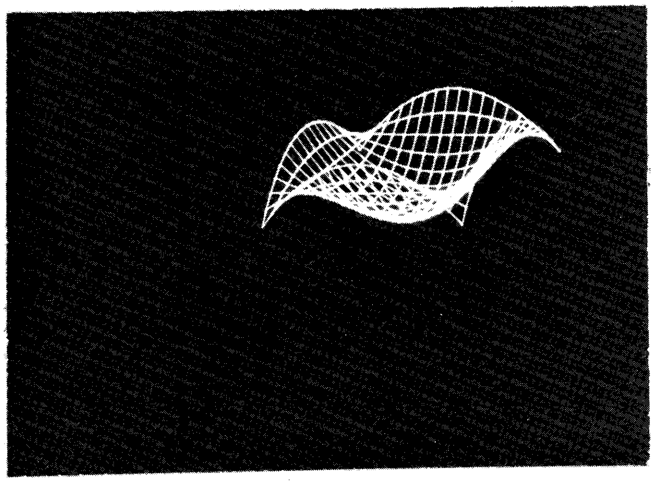

Figure 13—Another example for the nine point method

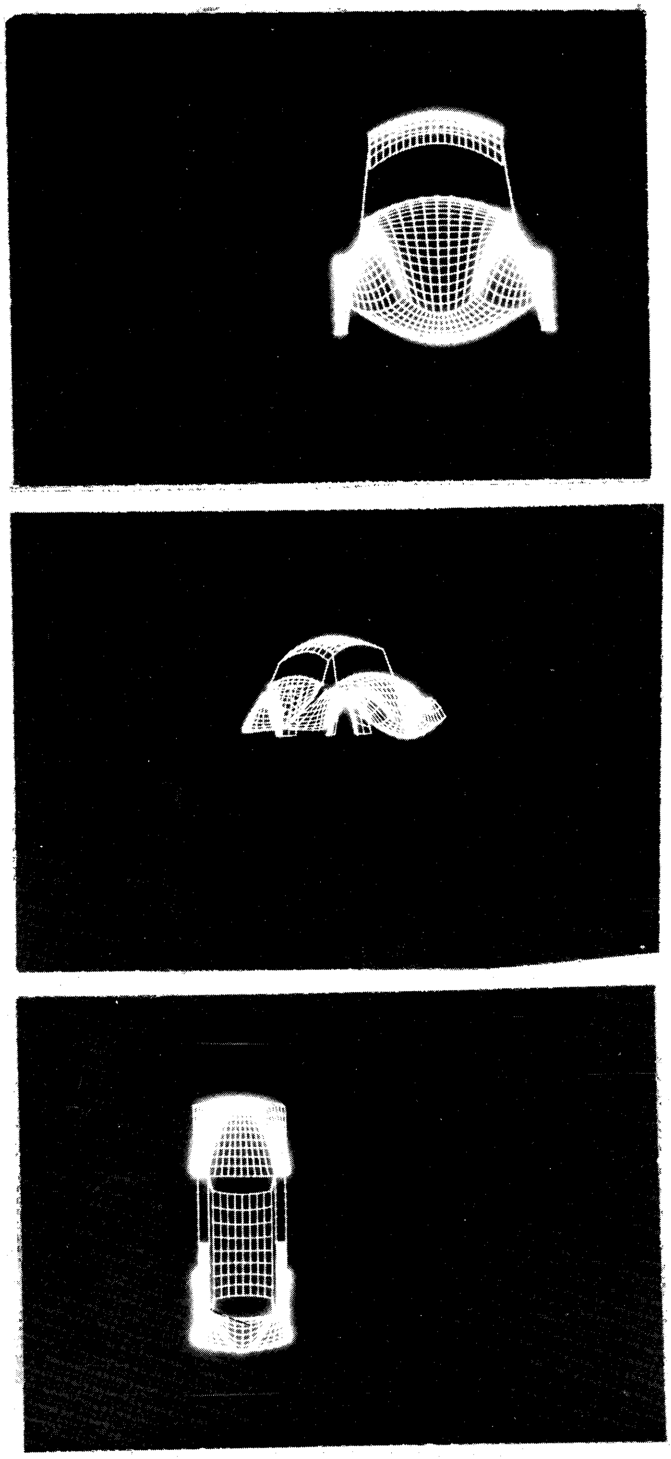

Figure 14—Automobile as an object generated by aid of surface patches

a continuous transition between surface patches. A big advantage, on the other hand, is given by the fact that no blending functions have to be defined and no spatial vectors have to be specified, both requirements expecting very much from the user with respect to his power of imagination.

Additionally, the nine point method requires much less time for preparation and execution of a problem. It is particularly suited for plotters or displays that work incrementally. The man-machine-interaction is excellent. Figure 14 shows as an example the body of a well-known automobile.

COORDINATE TRANSFORMS

PRADIS uses homogeneous coordinates. A coordinate transform is performed by multiplying the matrix of homogeneous point coordinates by the transform matrix TM—as indicated in Figure 15. The transform parameters have to be specified by the user.

VISIBILITY CRITERIA

Visibility criteria enable the program to detect (and erase) hidden lines. For a satisfactory display of three-

$$\underset{\substack{4\times 4\text{-}\\\text{Trans-}\\\text{forma-}\\\text{tion}\\\text{matrix}}}{\begin{bmatrix} \\ \text{TM} \\ \\ \end{bmatrix}} = \underset{\text{Rotation}}{\begin{bmatrix} & & & 0 \\ & \text{RM} & & 0 \\ & & & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}} \cdot \underset{\text{Scale}}{\begin{bmatrix} Sx & & & \\ & Sy & & \\ & & Sz & \\ & & & 1 \end{bmatrix}}$$

$$\cdot \underset{\text{Translation}}{\begin{bmatrix} 1 & & & \\ & 1 & & \\ & & 1 & \\ X_T & Y_T & Z_T & 1 \end{bmatrix}} \cdot \underset{\text{Perspective}}{\begin{bmatrix} 1 & & & 0 \\ & 1 & & 0 \\ & & 0 & -1/c_z \\ & & & 1 \end{bmatrix}}$$

$$[x \quad y \quad z \quad 1]\cdot[\text{TM}]=[x' \quad y' \quad 0 \quad p] \qquad p=1-z'/c_z$$

c_z . . . Centrum of projection

$Y=y'/p$

Figure 15—The 4×4—Transformation matrix

dimensional objects, the hidden line suppression is mandatory. We distinguish between three types of criteria: point tests, surface tests, and combined point/surface tests. In the case of surface tests the primitive which is tested is a surface element as the name indicates. The surface test indicates only, whether or not a line is visible as an entity; i.e., a possible mutual hiding of two surface elements cannot be taken into account. Hence, it is not applicable to concave structures.

Points test partition a line into small segments that are only considered to be visible if none of the arbitrarily selected points on this segment is hidden by a surface element. The point test procedure is generally applicable, however, it requires a prohibitive amount of execution time. Combined point/surface tests try to combine the advantages and avoid the disadvantages of point tests and surface tests.

In PRADIS, we use some new schemes which we developed.[12] The implementation of our hidden line detection algorithms are called FLAVER, FLAKA, and FLAVI. The gist of these three algorithms shall be summarized in the following.

(1) FLAVER—FLAVER uses a hidden line algorithm that is applicable to convex structures. The procedure consists of three main steps. In the first step, the angle between the line-of-sight and the normal line on the surface is calculated resulting in a criterium for totally hidden surfaces. In the second step, a priority is assigned to each one of the remaining surfaces. Thus, the sequence is defined in which the mutual hiding will be determined. This is done in the third step by investigating whether or not the terminating points of a line fall into a surface with higher priority than that of the surface the line belongs to. If only one of the terminating points is hidden, the point of intersection between this line and the surface boundary is determined. This point terminates the visible part of the line. The point is that only surfaces with higher priority than that of the surface the respective line belongs to are to be taken into account, thus saving considerably computation time.[12,13]

(2) FLAKA—FLAKA works on concave structures; i.e., it works in the more general case where the polyhedrons may have cavities and/or a group of disconnected polyhedrons occurs. In this case, the angle between the line-of-sight and the normal line, unfortunately, does not provide a simple criterium for determining whether a surface is visible. This difficulty is overcome by dividing in a preliminary step all the surfaces of a structure into triangles. On these triangles the last two steps of FLAVER can be applied. The partitioning of all surfaces of the structure results in additional lines (if a rectangle is partitioned into two triangles, an additional line is generated which is the rectangle diagonal). Special care has to be taken to suppress these additional lines (therefore, the triangles are of course not visible).

(3) FLAVI—The intrinsic hidden line detection algorithm of FLAVI takes care of objects that are defined by analytical expressions—be these expressions defined by the user in form of equations or generated by the program according to COONS' theory. The procedure works as follows: First of all a Cartesian coordinate grid of 11 by 11 lines is superposed. If the visibility of the point of intersection between $2(\Delta u - \Delta v)$-segments has to be determined, only the surface patches have to be considered that have no empty intersection with the respective grid area. Subsequently, surface patches to be taken into account are partitioned into triangles, and the z-coordinates of these triangles are calculated at values of x and y given by the coordinates of the intersection point. If a triangle has a z-coordinate which is greater than that of the intersection point, it hides that point. If no such triangle exists, the point of intersection is visible. All points of intersection of all lines $u=$constant and $v=$ constant have to be tested in that way. If one of two connected points is visible and the other one hidden, more points located on the connecting contour have to be examined.

ACKNOWLEDGMENTS

The authors are gratefully indebted to Mssrs. Grosskopf, Schulz, Castro, Mahramzadeh, Hunger, Burmeister, Eckert, and Kniepen who contributed by their thesis work under our supervision to the successful implementation of the PRADIS system.

MARS—Missouri Automated Radiology System

by J. L. LEHR, G. S. LODWICK, L. J. GARROTTO, D. J. MANSON and B. F. NICHOLSON

University of Missouri
Columbia, Missouri

The primary role of the radiologist is to examine patients, usually with the help of ionizing radiation, in order to provide information of use in patient care. The radiologist functions as a consultant that is, patients are referred to him by many other physicians, and he delivers information obtained from his special methods of examination back to each patient's referring physician. As a result the radiologist deals with greater numbers of patients than most physicians. Also, he needs to move a great deal of data quickly and accurately.

Radiology is a relatively young field of medicine, and the variety and complexity of examination techniques in the radiologist's aramentarium continue to multiply. Because of this and because he examines more patients each year, the annual increase in demand upon a radiologist's time has been estimated from 15 to 25 percent. Fortunately, however, radiologists are used to living with complicated electronic gear, and the specialty as a whole has shown considerable interest in employing data processing techniques to streamline patient care delivery.

Our own efforts began in 1965 as project RADIATE (Radiologic Diagnoses Instantaneously Accessed and Transmitted Electronically), continued as ODARS (On-line Diagnostic and Reporting System), and have finally been renamed MARS (Missouri Automated Radiology System). It was apparent initially that straightforward computer programs could carry out a variety of business functions such as patient billing or inventory control. However, the most important information flowing through a radiology department is the medical information, i.e., what the radiologist has to say about the patients he examined. The processing of this basic information was the problem we tackled.

Traditionally the radiologist has dictated his consultation after reviewing a patient's films. This dictation is then transcribed, proofread, and finally returned to the referring physician. The problem of capturing this data for a computer can be solved in a variety of ways ranging from keypunching the reports to utilizing typewriters which produce magnetic tape along with typed copy. Such approaches do provide the computer with data to process. Indeed, they provide a large amount of natural language data which requires very sophisticated processing to interpret. Although processing of dictated reports has the superficial advantage of not interfering with traditional methods, it tends to complicate the flow of information rather than facilitating it.

We have chosen a more radical approach for MARS. Instead of dictating his report, the radiologist interacts with the computer via an on-line terminal. He constructs his report by retrieving terms from several large lists, each containing a particular category of term, and stored in direct access files. The retrieval technique is a modified keyword in context approach. The radiologist types in one letter denoting the particular type of term followed by the first four letters of any word in the term. The computer displays a list of all terms associated with this keyword, and the radiologist selects one of these. Three categories of terms are available; examination types, anatomic sites, and diagnoses.

In addition to incorporating phrases retrieved by keyword, the radiologist has additional options in preparing his report. He may select any of a list of commonly employed phrases such as "there has been essentially no change in findings since the previous examination." This particular phrase being the fourth in the list, the radiologist may simply type "P4" to add it to the report. Or, if he does not remember the number, he may simply type "P" to request display of the entire list from which he then makes his selection. Another option available is the incorporation of a pre-coded sequence of statements which are retrieved by typing a three letter abbreviation, or mnemonic. For example, if the radiologist types "CAD," the computer will incorporate into the report a series of statements describing a geriatric chest with calcification in the aortic arch, tortuosity of the descending aorta, and degenerative changes in the thoracic spine. These pre-coded statements frequently make it possible to complete an entire report by typing only a few letters. The approach is obviously quite similar to the use of "canned" reports generated by semi-automatic typewriters. However, the computer system does have the advantage that the radiologist reviews the report on his terminal immediately and, if he wishes, he may easily edit it. For example, if the changes in the spine are unusually marked, he might add an appropriate modifier to the report. Finally, if the radiologist is unable to express himself fully by the options provided, he may type as many additional remarks as he feels are needed.

This method was aimed at solving the basic problem of capturing the radiologist's report in a form which the computer could comprehend. The technique met with criticism for two reasons. First, it altered the traditional form of the radiological consultation. Instead of paragraphs of prose, the referring physician would receive a somewhat terse list of observations and impressions. Second, it required that the radiologist operate a keyboard. Added to the very real problem which would arise if the radiologist were slowed down by using a terminal there is a largely emotional problem which stems from the idea that it is somehow "sissy" for an M.D. to type.

The only way we could see to answer these objections was to put the System to work. Our immediate goal was not to automate all the functions of the department, but to test the hypothesis that the medical information flow could be handled by an on-line system as described. Accordingly we wrote, tested, and rewrote programs. Finally, on April 1, 1970, we locked up the radiologists' dictaphones and began using MARS to process all consultation in our department. Clinical use required not only that the radiologist be able to interact with the computer to define individual reports but also that there be a system for handling the flow of patients through the department. The system we have used can best be described by following the progress of a typical consultation through the department.

A patient presents for examination in the department at a reception area accompanied by a request form filled out and signed by the referring physician. The receptionist informs the computer of the patient's arrival by entering the patient's unit number via a terminal. The computer searches the hospital master disk file for this number and responds by displaying information found there, including the patient's name, date of birth, sex, race and hospital ward or outpatient clinic code. If the information is not on file (as, for example, in the case of a patient not previously seen at the hospital who requires emergency care), it is entered by the receptionist manually. The receptionist then types in the clinical history provided by the referring physician, along with his name. Finally, the examination requested is entered, and the computer stores all of this information in a temporary holding file. A three digit number indicating the location of the record within this file is displayed to the receptionist who writes it on the request form.

The patient is examined and the roentgenograms, along with the patient's previous X-rays and reports and the request form are brought to a radiologist at one of several terminals for interpretation. The radiologist begins by entering the three digit address of the information entered by the receptionist. The computer retrieves the preprocessed patient identification data and displays it on the screen. The radiologist corrects any errors in this data and then completes the report by the method outlined above. Finally the radiologist proofreads the entire report, makes any corrections and then signals the computer that the report is complete. The computer immediately types out a copy of the report on an output terminal located on the patient's ward and, simultaneously, three copies are produced in the department of radiology. One of these copies is affixed to the jacket containing the patient's radiographs; the second is mailed to the referring physician for his convenience; and the third is attached to the request form, presented to the radiologist for signature and returned to the patient's medical record.

All the reports transmitted during the day are kept on a random access disk file and any of them can be reviewed instantly by entering any patient's unit number on a terminal. At night, each report transmitted is permanently stored in a numerically coded form on a large direct access file. From this file any report for any patient can be retrieved for review within a matter of seconds. Also categorical searches can be performed on-line.

In our two years of experience with this system we have learned many things. Primarily we have shown that it is possible to operate a department with an on-line information system. In evaluating MARS we did measure some parameters such as the time spent by patients in the department and the time a radiologist spends reporting a case. We found these to be essentially unchanged from data accumulated before the System went into operation. MARS did, however make a great reduction in the delay between arrival of a patient in the department for examination and delivery of a written consultation. Before MARS this delay averaged 23 hours with about 75 percent of all reports being sent out on the day following the examination. With MARS this delay has been reduced to an average of 10 hours, and 75 percent of all reports are transmitted on the day of the examination. We regard this as a significant improvement in patient care.

Our experience operating MARS has not been uniformly pleasant, however. We have been plagued by unreliable computer services. We have been operating on an IBM 360-50 under O.S. using the Baylor Message Handler for terminal I/O. The system is a busy one with two million bytes of "slow" core, multiple tapes, disks, and a data cell. In addition to a couple of batch partitions, the system handles a variety of on-line applications for other departments in the Medical Center, as well as a good deal of developmental work. With all of this, the time during which MARS has not been available to radiology has averaged slightly over 10 percent of our working day. For the most part, failures are due to system software. The system simply dissolves. Generally it can be restarted in from fifteen to twenty minutes providing our radiologists with an unscheduled coffee break. More serious failures of hardware or software have not been uncommon, however, and when the system is down for an hour or longer we revert to dictation of reports.

We should emphasize that our computer center has a staff of good systems programmers and is headed by an able Director. However, we see certain disadvantages in the very concept of a large central computer. If a radiologist is going to build his practice around an information system, then he will be responsible for the effect that system has on patient care. This responsibility is very difficult to assume unless it is coupled with clearly defined administrative control over the operation of that system. It is difficult to see how this is possible if the radiologist is only one user of a large time sharing computer.

Our experience with MARS on the 360 has convinced us that the concept of on-line management of information flow is valid for a department of radiology. We have been reluctant, however, to fully exploit the possibilities for a more completely automated department on a computer system with the disadvantages outlined above. Finally, we have become quite interested in building a system which can be exported easily to other departments. For these reasons we are in the process of implementing a stand-alone version of MARS on a smaller computer, the PDP-15, using MUMPS, the Massachusetts General Hospital Multi-Programming System.

The basic reporting function of MARS on the PDP-15 is still quite similar to that discussed previously and consists of retrieving from standardized tables those terms to be incorporated into the reports. We have been able to make the retrieval of terms a bit more sophisticated, however. After examining the frequency with which terms were used in some 50,000 reports we found that a relatively small number of terms were used quite frequently. These terms have been assigned unique three-letter mnemonics so that they can be retrieved without bothering to look at other terms which would be retrieved under the keyword search. In addition, the keywords are no longer restricted to four letters. The modifying terms have been expanded, separated into exam, site, and diagnosis categories, and assigned mnemonic codes for retrieval. Also, the definition of "canned" reports has been left to the discretion of the individual radiologist, so that these can be tailored to suit his needs. Finally, the program has been altered so that the radiologist can specify multiple terms with one input string. This frequently makes it possible for him to define an entire report with one turn-around at his terminal.

In addition to these relatively minor changes at the radiologist-computer interface, we are expanding MARS to automate several other departmental functions. For the most part these are the fairly straightforward business-like applications which we ignored previously, and they come as rather natural spin-offs from the medical information system. These applications are, however, extremely important from a cost-effectiveness viewpoint. One application is patient billing. Since the MARS report contains the name of the patient, the examination performed, and the consulting radiologist's name all the information needed to specify the charge is available to the System. It is only necessary to associate with each examination in the table the appropriate fee. The System displays these charges to the radiologist who verifies and/or corrects them just prior to transmitting his report.

In many departments patient billing is handled by another agency, usually a hospital. Under these circumstances the department's responsibility ends at correctly specifying the charge for each patient. If billing is done by hand, a daily listing of charge should suffice. At our hospital, patient billing is done by computer, so that we will provide the charges on magnetic tape. We do expect to develop a more complete billing and accounting system for those departments which elect to handle this function. Our basic concept is to keep computerized ledger sheets on direct access files. For active accounts, this record will contain both itemized charges and a record of payments made. Inactive accounts will be transferred to tape and/or paper files. The goal is to provide a billing system which is responsive to human direction and can make any patient's bill accessible for review and, if necessary, correction on-line.

Another type of information which MARS can provide automatically is a statistical analysis of the department's work load. The rapid growth of services delivered by radiologists means that additional equipment and personnel must be acquired almost continuously. In deciding just what piece of equipment should be purchased next it is obviously valuable to know what types of examinations are being performed most often. We assign a statistical code to each entry in the exam table which defines for the System how we want our utilization counts broken down. When a report is transmitted the appropriate counts are incremented. These figures are stored by the day during any month. At the end of the month totals are printed out, and at the end of the year a monthly breakdown is produced.

Another operation in the department which is amenable to automation is management of the X-ray files. Currently roentgenographic images are stored on large films. All films for a patient are usually stored together in one or more large jackets which in turn are filed according to patient number. Films are pulled from the files either for use within the department or to be loaned to referring physicians for use outside the department, for use in conferences, clinics or in the operating suite. Since the X-rays themselves form a part of the medical record, the radiologist being legally responsible for them, it is obviously essential to have a system for keeping track of who has checked out what films. It is also necessary at times, to send out "overdue" notices. Current films are also pulled for review by referring physicians within the department viewing area. Since these films do not leave the department, it is not necessary to check them out. However, it is not uncommon for a doctor to request films which have been checked out. Under any of these circumstances a harried search through the department, and through multiple scraps of paper ensues. Some tracking of the films within the department is accomplished by logging the patient in and reporting the case. It would be possible to create additional check points to further ameliorate this problem.

Finally, any time a patient is examined in radiology, all of the patient's previous X-rays are pulled for review so that the radiologist may detect for changes in the area examined, or so that he may correlate the findings from examinations of other areas. In order to reduce the delay caused by pulling the old films, MARS transmits a request to the file area as soon as the patient is logged in at the reception area.

One of the ways in which radiologists attempt to meet increasing patient loads is by keeping existing facilities busy through scheduling of examinations. In our department only those examinations which require the participation of a radiologist have been scheduled. In particular, nearly all patients have been simply sent from the clinics to the department without any prior warning. To alleviate this problem we have developed an on-line appointment book. A referring physician, or his secretary, may call the radiology reception area and request that a given exam be scheduled for his patient at a particular time. The System opens the appointment book to the appropriate day, and checks to see what has already been scheduled. If the schedule is tight, the System warns the receptionist who can then attempt to get another time which is more convenient for the patient, his physician, and the department. Each morning the schedule is printed out allowing our personnel to plan how they will meet the projected patient load. A longer range goal for this MARS module is to provide for a constant on-line reevaluation of the work load by the System, which might then make specific recommendations such as assigning individual patients to specific examination rooms.

A potentially great advantage of having a radiologist interacting with a computer is that the machine may be able to assist them interpret the films. There are several possible techniques for this. Perhaps the simplest of these is retrieval of useful medical data. We have a growing file of radiological information arranged hierarchically by organ system, and subdivided by diseases or roentgen findings. This film may be examined on-line by the radiologist while he is reporting. A slightly more complicated method of assisting the radiologist is to provide him with a logical tree for the analysis of certain diagnostic problems. The radiologist is asked a series of questions about the findings on the films and depending upon his answer to each question another appropriate question is asked until he reaches a leaf on the tree. Typically this will be a list of diagnostic possibilities. Another technique which may be employed is that of Bayesian analysis. The radiologist is asked to specify whether certain findings are present on the films, and the System then uses estimates of the frequencies with which these findings occur in various diseases to estimate probabilities for the diagnoses. Such programs are available for the diagnosis of pulmonary nodules, heart disease, and thyroid dysfunctions. The tree branching and Bayes techniques have been combined into a program for the analysis of solitary bone tumors. Many investigators are becoming interested in collecting the type of data required to attack diagnostic problems by means of these techniques.

There is great pressure on the medical profession to produce more patient care with no loss in quality and without further increasing the cost to society. Computer technology holds the promise of helping us to reach that goal. Our efforts in developing MARS have been to automate the practice of radiology. In doing this we have made changes from the traditional practice of our specialty; we feel that we have improved it.

Certainly there is need for further work. The use of computers for training radiologists and radiological technologists has not been thoroughly investigated. Technological advances on the horizon such as high quality microfilm systems for storage of roentgenograms, or electronic equipment to transmit images will both augment the possibilities for automation, and may well require sophisticated data processing systems to have their full impact. Finally, we are beginning to see some practical possibilities for direct computer analysis of the X-rays themselves. The task of demonstrating the feasibility of automated systems, of developing cost-effective systems, and of educating the medical profession to use them effectively should provide a challenge for many years to come.

"Sailing"—An example of computer animation and iconic communication

by STEPHEN M. ZWARG

National Security Agency
Ft. George Meade, Maryland

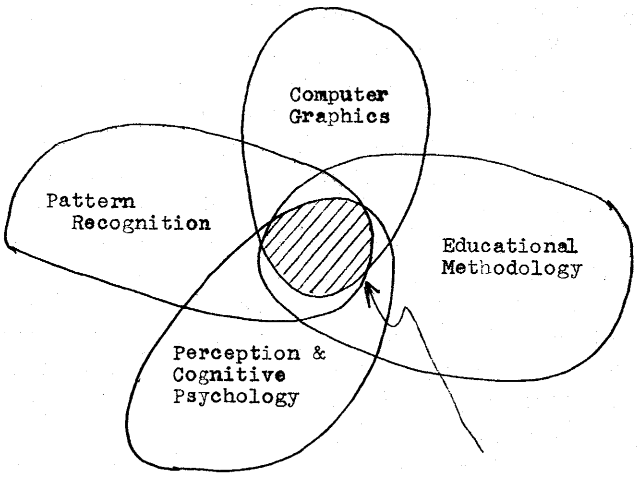
INTRODUCTION

The use of the visual process for the perception and assimilation of ideas is well recognized by educators, psychologists, as well as computer scientists. The popularity of movies and television and the concomitant growth in visual literacy of the viewers of these media are two factors exploited by those who wish to communicate ideas using these media. The world which comes across on the movie or TV screen is the camera's eye view of the visual world (as opposed to our visual field, that which our eyesight and brain perceive of the visual world, or "reality," see Gibson[6]); and as such it is an image of reality. This can include images of beautiful scenery, complex human interactions, or of a printed page illustrating a lecture. Any ideas which are communicated by these devices, while relying upon imagery, tend to inform the viewer by creating the illusion that he is there, so how and why would he act, or they inform him by straightforward strings from some generally accepted language (as in the case of a screen full of text). Bruner, a cognitive theorist, feels that information acquisition proceeds through three stages:[5]

1. Enactive—using personal action
2. Iconic—perceptual organization and integration of images
3. Symbolic—using a language or accepted set of representations

As a child develops he progresses through these three stages. Most of the things we learn in school or from books are by symbolic means. Imagery can back up symbolic and enactive paths of learning with varying degrees of success.

Iconic communication itself, using pictures, figures, or visual images in combination with motion in the cases of movies, cartoons, and TV, is not so well understood as an idea transporter. With the fusion of the abstract symbol manipulative, computational power of the computer and the concrete world of visual imagery (in an animated movie in this case) it was hoped to study the problem of idea expression and perception through images. The motivation for producing a computer animated film was simple—it was a course requirement for a graduate seminar led by Prof. William Huggins at Johns Hopkins University. Titled Iconic Communications, the intent of the course was to produce a movie, and thereby develop and learn the computer related techniques, as well as develop the potential of iconic modes of communication by research in the related areas of: computer graphic systems and devices and data structures; machine perception, pattern recognition, and syntax of pictures; memory, perception, and cognitive psychology; education, geometry, and visual syntax.



Iconic Communications

This sort of interdisciplinary study was interesting as well as very fruitful for those of us in technical fields, such as electrical engineering or computer science, who were looking for new applications or who only vaguely understood present applications of advanced computer graphic technology.

OTHER COMPUTER ANIMATION SYSTEMS

The use of computers for the production of animated movies is not new. Several on-line and off-line methods exist with varying degrees of interactive capability. Baecker[3,4] at M.I.T. produced the GENESYS system, making use of the TX-2 computer and graphics system, which permitted the animator/operator to specify on the graphic screen (1) images to be moved about as well as (2) schedules by which they were to be moved. All of this was done on-line and little or no programming was necessary by the animator. The images used were anything that the user could draw, alleviating him from tediously specifying coordinate input. The feedback of results was immediate. One result of taking programming away from the user was that the computer spent its time keeping track of the animator's on-line doodlings instead of offering computational or problem solving power directly toward what to do with these doodlings. The specification of pictures and their driving functions was very good for simple and fast cases but not really suitable for an extended animated effort. Spending a short amount of time to produce a short sequence tended to make the effect of the image short-lived.

Others, including Anderson[1,2] and Knowlton[8,9] spent their time developing elaborate list processing languages and stacking data structures (as in CAMP and BEFLIX). These specialized languages required much understanding on the part of the animator but his facility for taking advantage of the computer's computational power rose correspondingly. The usual technique was to write the program in the specialized movie language, run it on a computer graphics terminal, film it, and then postprocess the film to add color or special effects. Some strikingly beautiful films were produced by Knowlton at Bell Labs and are available on loan from there. Not much attention was paid in these efforts to what images were used or what ideas should be communicated. Visual effects were sufficient to prove the technology.

More recently, at the University of Pennsylvania's Moore School, Talbot, et al.,[9] have attempted to fuse the on-line interactive approach to movie specification with the remote computational power of a large computer for the final movie production. They also developed a specialized hierarchical language (with a formal Backus Naur syntax specification) for the animator to specify his pictures, motion, scenes, and movie segments. The on-line activity consisted of drawing on the DEC-338 scope, working in one of the picture definition modes mentioned above, and then reviewing the rough construction of the movie immediately. When the animator was satisfied with his rough draft he entered transmission mode and the outline of the movie was sent to a remote IBM 360/65. There the draft of the movie was translated into the final movie generation commands to drive a SC-4020 microfilm plotter. The main point was to be able to review movie production at any stage as well as to specify everything on-line. Data entry was again a problem, figure manipulation awkward, and no concentration was made on types of images, what their effects and relationships should be and how to get ideas across. The preoccupation with hardware and syntax specification has obfuscated idea communication.

THE MOGUL SYSTEM

Our animation system at Johns Hopkins possesses all the so-called drawbacks. It is not on-line, no expensive graphics equipment is available, only a second generation IBM 7094 computer. Turn around for the finished movie is slow since no SC-4020 plotter is owned either. Tapes must be sent someplace that has one, delaying things by several weeks. Short term feedback of a coarse nature is available from the computer's line printer, and outputs can be had within an hour or so, typical of a batch operation. The draw package used by animators, entitled MOGUL—Movie Oriented Graphical Utility Language[7] and developed by Prof. Huggins, Tom Hoffman, and Jerry Yochelson, is a FORTRAN based system and requires that the user understand that widely known language. As such, though, the user has at his command all the computational routines he can program. Data input for animator specified images in two or three dimensions is as easy as FORTRAN allows. The time invested in learning how to program and working out movie scenes on graph paper is well invested, however, and may even overcome all the previously mentioned handicaps, or at least show that lack of equipment is not always a handicap. Those of us with programming experience enjoyed the ability to work with an animation system in a familiar language. The preciseness of a computer language (but not the restriction of a special purpose language) and the slight delay in feedback of results made us be more sure of what we wanted to see, and eliminated the draw it and play it right back looseness of on-line systems. We found that for at least 75 percent of the movie's preparation the immediate feedback is not necessary if we had a good idea (through time spent on a storyboard and basic visual techniques) of how the movie should go. Admittedly the final polishing up would have been easier with immediate checks, but costs prohibited this.

THE IDEA OF THE SAILING MOVIE

Since all of my spare time during the summer is spent on the water, when asked to make a film about an idea, the one which naturally occurred to me was that of a sailboat making its way around a race course, thereby demonstrating basic sailboat aerodynamics. The first step in my animation effort was to lay out a storyboard. This is the sequence of key scenes in the movie along with a brief explanation of what is happening. Briefly the storyboard of the "Sailing" movie goes like this (see Figures 4-9, also an intermediate version 16mm film of "Sailing" and several other students' works is available).[11] An outline of a boat with mast and sail appears, centered on the screen. The boat representation is similar to those found in sailing text and rulebooks, reinforcing its familiarity. The boat then shrinks as a race course appears. The course consists of three flag buoys and wind arrow, pointing from left to right. The boat shrinks to normal size and begins sailing around the course. The boat tacks up the first leg, illustrating the relative position of boat and sail necessary for movement against the wind. The boat reaches down the second leg, jibes, and reaches down the third leg, with the sail farther out moving faster than on the first leg. Midway up the first leg again the boat grows, buoys disappear but wind arrow remains. The next sequence attempts to demonstrate the aerodynamic principles of a sail in terms of force vectors and parallelograms of forces. Three arrows grow out of the center of the sail representing forces acting on the sail. One is parallel to the wind arrow, the sum of forces developed by the wind; the other two are perpendicular and parallel to the surface of the sail, the components. The component perpendicular to the surface of the sail in turn has components parallel and perpendicular to the axis of the boat. The first of these will drive the boat forward while the latter will drive it sideways. With a keel or centerboard the sideways force is largely resisted. The forward driving force acting on the boat then results. Arrows in the forward and sideways directions are drawn. Two force rectangles are now on the screen. They grow and shrink simultaneously with the wind arrow to illustrate that forces developed are proportional to wind velocity. The various component arrows grow and shrink and change direction as the sail is overtrimmed and overeased, illustrating the optimum position of trim—that point at which the forward driving arrow is longest.

Arrows disappear. Boat shrinks back to normal size and continues on its second lap around the now appearing racecourse. After reaching leg three it slowly shrinks to nothing and heads toward the edge of its world.

DEVELOPMENT OF GENERAL ANIMATION TECHNIQUES

One of the goals of the movie experience was to develop some general rules, heuristics, or theories upon which future work could be based. At least we could find out some things not to do. One of the greatest difficulties concerned the use of symbols or images to express ideas. Which are "correct," "good," or "effective," etc? What is the criterion (or grammar) for judging visual images? How does one even make graphic an idea without moving from the iconic to the symbolic level of communication? The medium is hard line black and white to start with. Using any sort of standardized symbols or representations immediately brings on a whole set of preconceptions (or ignorances) and prejudices on the part of the viewer, and if these are not complementary to the idea being shown they can sidetrack the communication process. In the case of the sailboat, I felt that anyone who thought of sailing rulebooks when he saw my sailboat would be thinking of rules and principles, and that was what I was trying to show so it was a useful image.

The use of text or mathematical languages was also discussed. We felt that any reliance upon text should be minimized. Words or letters only detracted from the intent to stay at the iconic level. When used for emphasis, reinforcement, or clarification, however, text has a place. Similarly, mathematical symbols or any other formal symbolic language more often than not gets in the way of the showing, if not also the conceptualizing of visual explanations. Languages are useful here only in the knowledge that they can be called upon sometimes to write down the process being shown. The literacy of the audience with respect to the language being shown (or not shown) must also be considered.

One thing that had to be well worked out in advance and which was a continual cause of surprise after finally viewing the movie was the layout of images or occupancy of the screen. Given a full, two dimensional square or three by four rectangle for a screen we were acutely aware of empty spaces. The full screen has to be used for motion and action for full spatial effect, but by no means should it be filled with clutter. One of the main advantages of the medium is that it is completely

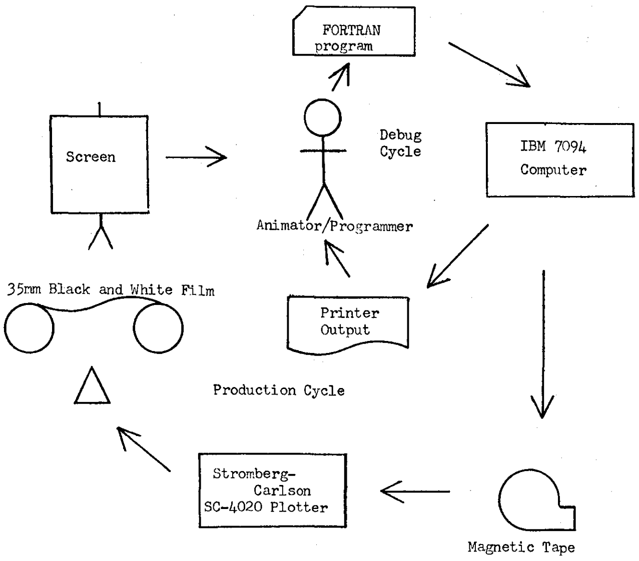


Figure 1—Steps to produce an animated movie

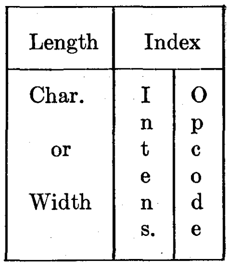
bare bones, stripped of all extraneous detail, and this should be used to best advantage by retaining a simplicity of imagery bordering on paucity. The center of the screen is the key spot for any important activity or attention getting. Split screen or simultaneous occurrences divide attention and effectiveness.

Abstractions and relationships are difficult to portray. The choice of images, their size, relative position, order of appearance and movement all can suggest functions, relationships, and dependencies. There is the difficulty of avoiding coincidental though erroneous suggestions of relations versus the valid suggestions of intended relations. Does the fact that one object precedes another on the screen or that it is larger than another indicate that it is more important? If one event happens before another does it imply cause and effect or time sequence? Questions like this have to be considered for individual cases to be sure that the animator's intentions are being realized. Importance is often indicated by size, positioning at the center, illumination (blinking), and motion. The relationship of cause and effect was never satisfactorily protrayed. In one film the anthropomorphic symbol of a detached hand had to be introduced to cause a switch to be thrown.

The obvious capability of a movie for showing motion cannot be too strongly stressed. Without background sensory cues, however, some sort of frame of reference has to be established to inform the viewer of his or an object's motion. A world of lines, edges, and boundaries is being dealt with, not one of textures and surfaces. Motion of objects within the screen boundaries can mean all sorts of things. The capability of the computer to calculate regular paths also adds to the possibilities. If two objects move simultaneously, or in some synchronized fashion, or with the same pattern an obvious relationship suggestion is being put forward. One problem engendered by the capability of (and the expectation of) motion in the movie is that of bringing images on and off the screen. Should they just appear, pop on, or should they grow or should they come on from the left (or right)? For the illustration of static concepts this is more of a worry than for cases where motion on and off the screen can seem natural.

Timing is the other major tool the animator has to work with, but it is also the most difficult to handle properly. Difficulties in the proper use of the screen area can be resolved using the line printer output, but timing problems never are fully resolved until the completed movie is seen. This is one instance where a preliminary viewing of the movie on a graphics terminal would be useful so that timing could be improved without making a whole other movie. Slowing down the action is one way to illustrate importance, up to the point where things become painfully obvious. Speeding up activity moves the viewer over less important or intermediate material. Judging what fast and slow are is difficult, though, and we really had to see a boring thing happening for an interminable time to understand what too slow was. One rule of thumb we started with to judge how long a sequence should take was to equate the timing with how long a verbal explanation would take. Motion of an object relative to stationary objects or at a faster speed than other objects is one way to command attention. Repetition of action, even with slight variations, is important for facilitation understanding of difficult material. The redundancy of presentation should increase with the complexity of the visual material. It is in the production of repetitive sequences of highly redundant though complex material that the computer comes into its own. Hand animation requires each intermediate frame of a cartoon to be drawn while a computer can painlessly calculate endless



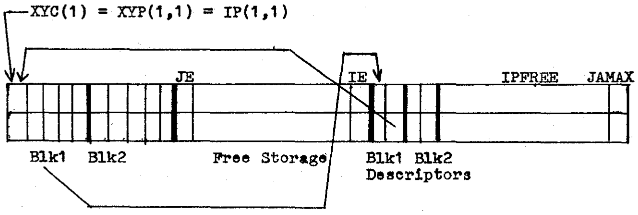
Length	Index	
Char. or Width	Intens.	Opcode

Figure 2—Block descriptor format

numbers of slightly varying scenes. Pauses in activity are very useful as punctuation, giving the viewer time to digest what he has just seen rather than overwhelming him with too much action in too short a time. Fades, holds in action, and jumps to new scenes also serve useful punctuation purposes, each with different effects.

THE MOGUL DRAW PACKAGE

The sequence of steps we followed to produce animated movies is illustrated in Figure 1. The basic tools the animator has are his skills as a FORTRAN programmer, the ability to draw points and lines between them furnished by the MOGUL system, the computer, and the final film medium. The MOGUL system was developed mostly out of our experience in Dr. Huggins' seminar and contains those elements of programming which were always needed for film production, hopefully freeing the animator to deal with image entities and motions rather than coordinate details. It is a structured set of functions built of the compiler level FORTRAN programming language. Those interested in the complete system should refer to Tom Hoffman's paper.[7] Only the salient features of it will be presented.



```
Directory variables:

     IPFREE---pointer to list of free descriptor pairs

     IE    ---highest index of XYC not occupied by block points

     JE    ---lowest index of XYC not occupied by block points

     JAMAX ---maximum dimension of XYC
```

Figure 3—Storage of block information

MOGUL actually consists of three sections. The first and largest is the set of drawing functions, the DRAW package, which enables the animator to create images, manipulate them, and set up operation codes to be interpreted when the images are to be drawn. The second section is the executive portion, MOGI, which keeps track of frame numbers and screen dimensions. The user defines the dimensions of the two dimensional real plane in which he is going to draw things, e.g., a square grid of 1024 points running from 0.0 to 1023.0 in both x and y directions; then MOGI windows any coordinates outside of this area. When output on some sort of device is called for, MOGI normalizes coordinates and then calls on some device driving program. MOGI also administers the mode of movie generation, debugging or production. The third section, the Device Driver section of MOGUL contains the device dependent output code to translate from the normalized coordinates of MOGI and command a printer, microfilm plotter, or scope to produce visual images. The animator's program is actually a subroutine called MOVIE which is called from MAIND, the first program entered. MAIND initializes the system, calls MOVIE, then finalizes the system and returns to the IBSYS Monitor. The user must return himself (via a RETURN statement) to MAIND to terminate his job properly.

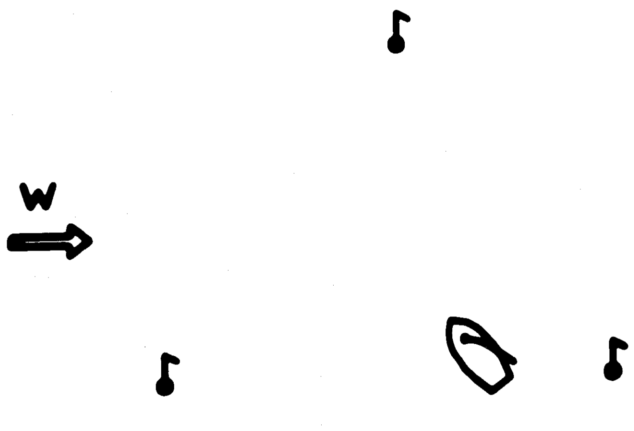


Figure 4—Boat sailing up first leg of racecourse

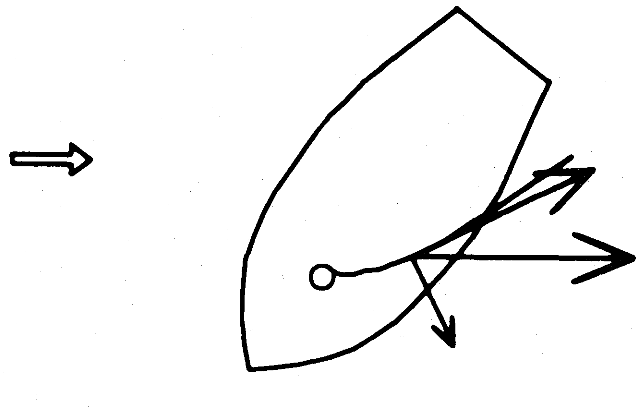

Figure 5—Decomposition of first force vector

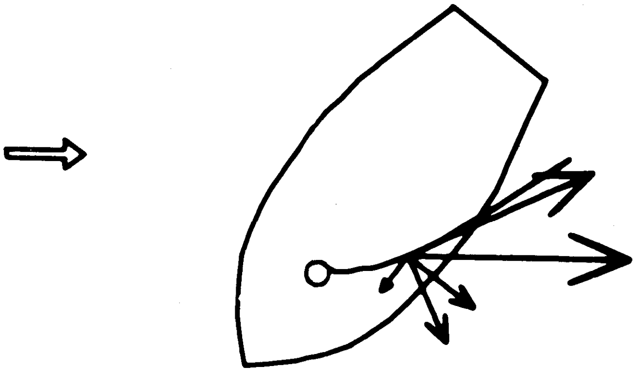

Figure 6—All force vectors depicted

The screen is a partition of the two dimensional real plane with the limits of the partition defined by user specified parameters. The routine is:

CALL SETAX (ZLL, ZUR)

or

CALL SETAX (XLL, YLL, XUR, YUR)

where (XLL, YLL) and (XUR, YUR) are the coordinates of the lower left and upper right corners of the window enclosing the usable screen area. The screen can also be considered a complex plane with points whose coordinates are given by a real (x) part and a complex (y) part. Thus ZLL represents the lower left and ZUR the upper right points just mentioned, and

ZLL = CMPLX(XLL, YLL)

ZUR = CMPLX(XUR, YUR)

Any object which appears on the plane is a collection of x and y coordinate points with lines drawn between them. An object is then a $2 \times N$ real array or block, with the first row being the x coordinates and the second row being the y coordinates, or a $1 \times N$ complex array with the real part equal to the x coordinate and the complex part equal to the y coordinate of a point. Blocks have associated with them names, e.g., Boat, Sail, etc., somewhat indicative of what the coordinate points represent. This name of the block contains a pointer to the location of directory information describing the block. The "value" of the real FORTRAN variable Block is the index of the array XYC where the directory information for Block resides. Included in the directory is the length of the block; its index (a pointer to the location of the block's coordinates in the array XYC); the opcode which specifies whether no lines,

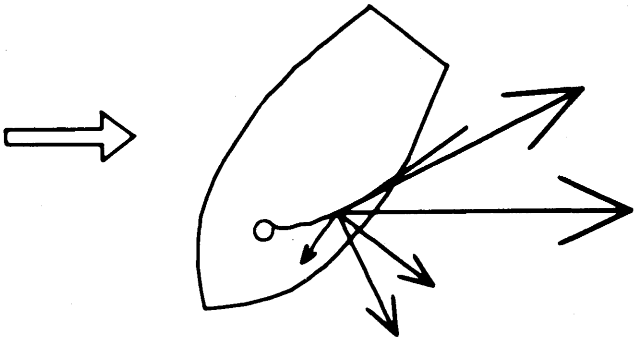

Figure 7—Force vectors and wind arrow enlarged

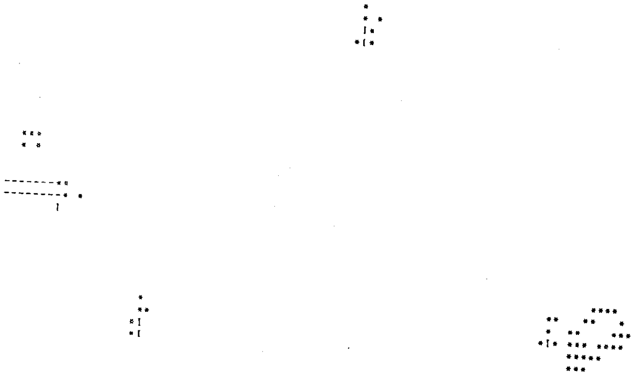

Figure 8—Line printer output showing racecourse

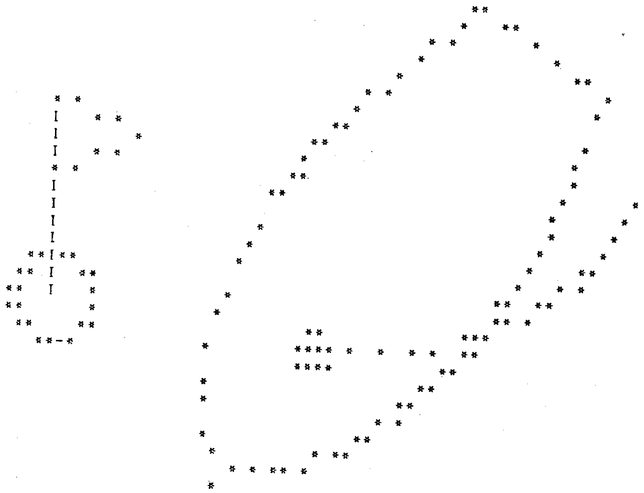

Figure 9—Line printer output, closeup of boat and buoy

disconnected lines, or connected lines should be drawn between points, or where characters should go; the width of lines; and the intensity of plotting. Everything on the screen is specified by a block, facilitating the use of general manipulation routines which always operate on blocks. Only by the opcode of a block is the interpretation of its contents determined.

Storage is considered to be a one dimensional contiguous complex array, and all blocks and descriptors are stored in this array. The array has three equivalent names: XYC, XYP, and IP, depending on whether one likes to work with complex numbers, real numbers, or integers, respectively, as coordinates. In the lower end of XYC go the block contents. In the upper end go the block descriptors. Creations, length adjustments, and deletions of blocks are administered using the index variables of XYC. XYC is declared in a COMMON statement, making it available to any subroutine of the animator.

Figure 2 shows the contents of the directory for a block. Figure 3 depicts the allocation of storage for block information.

Storage for blocks is allocated and all housekeeping of pointers is taken care of by the following functions:

CALL CREATE (N, BLK)

or

BLK=CREATE (N, BLK)

—makes space for a block of size N and sets BLK equal to the pointer to the block directory. The value equals the returned pointer.

BLK=SETUP (N, TYPE)

—creates a block big enough to contain N things of type TYPE, where TYPE can be connected lines (N−1 points needed), disconnected lines (2N points), or characters. Other directory information is set and the value of the function equals the pointer to the block.

CALL COPY (FROM, TO)

or

TO=COPY (FROM, O)

—copies the block FROM into the block TO, adjusting the length of TO if necessary. Directory information is copied also.

Blocks are erased and their space returned to free storage by:

CALL DELETE (BLK1, BLK2, . . . , BLKn)

As can be seen block functions can be effected either by subroutine calls or by function calls which return a value. There are cases in writing a movie program where both are useful, though consistency in calls is to be preferred to avoid errors. Primitive functions are available to set or return the value of block directory information if this is necessary.

Objects to be drawn can be specified in two ways. Either the animator plots his drawing on graph paper and then enters the point coordinates, or he specifies some function to calculate the points. The "Sailing" movie uses both methods. For example the boat and sail were entered as points from a drawing on graph paper, while the mast and buoy were calculated from an equation for the points on a circle. Thus, blocks must be prepared to receive data in several ways. Data can be loaded point by point into a block with the following sequence:

CALL BUILD (BLK)

—initializes the function COORD to begin placing data into BLK beginning at the first column of BLK.

CALL COORD (Z)

or

CALL COORD (X, Y)

—places the complex coordinate Z or the real coordinates X, Y into the next column of BLK.

A whole array of coordinates can be loaded into a block using:

CALL LOAD (I, N, XY, BLK)

or

BLK=LOAD (I, N, XY, BLK)

—loads N coordinates from the complex array XY into BLK beginning at the I column. The second usage returns the pointer to BLK as its value.

Once objects to be displayed have been created and assigned to blocks, the animator must decide what to do with them. Scaling and translation are the two main manipulations he may perform, and these are done by applying arithmetic operations to blocks (which in fact contain complex, real, or integer numbers, depending upon interpretation). Complex variables and complex arithmetic permit handling of two dimensional data with one statement. Scaling is done by a series of complex multiplications of block points by a complex scale factor. Translation is done by adding a complex translation factor to every block point.

CALL SCALE (SFACT, FROM, TO)

or

TO=SCALE (SFACT, FROM, O)

—scales the block FROM by the complex scale factor SFACT and places the results in TO

```
CALL TRANS (TFACT, FROM, TO)
```

or

```
TO=TRANS (TFACT, FROM, O)
```

—translates the block FROM by the complex translation factor TFACT and places the results in TO

```
CALL SCLTRN (SFACT, TFACT, FROM, TO)
```

or

```
TO=SCLTRN (SFACT, TFACT, FROM, O)
```

—scales and translates

With the use of a scale factor defined as follows:

```
SFACT=CMPLX(FACTR, 0.0)
          *CMPLX(COS(ANGLE), SIN(ANGLE))
       =MAG (FACTR)*ROTD(ANGLE)
```

an object will be FACTR times larger and rotated by ANGLE degrees from its former position. MAG and ROTD are defined as above in MOGUL. Neither scaling and translating operations change the data in the block FROM. Scaling of an object occurs about the origin about which the object was defined. If the origin is the origin of the screen coordinates rotations and magnifications will be with respect to this point. A more useful convention is to define all objects with an origin within them so regular rotation and scaling will result. Translation occurs with respect to the object's previous position.

Objects are drawn using the following routines:

```
CALL DRAW (BLK1, BLK2, . . . , BLKn)
```

—causes the output of the n blocks to the Device Driver program where they are drawn according to their directory information.

```
CALL DRAWST(SF1, TF1, BLK1, SF2, TF2,
        BLK2, . . . , SFn, TFn, BLKn)
```

—causes the scaling by SFi, translation by TFi, and drawing of a copy of BLKi. The copy is then deleted leaving BLKi intact. Argument list is one or more triplets.

To roll the film between frames, one logically calls:

```
CALL ROLL
```

—advances film 1 frame.

or

```
CALL ROLL (NFRMS)
```

—advances film NFRMS frames.

ASSEMBLING A MOVIE

Working from his storyboard, the animator knows what objects he wants to display when. Once he has entered or calculated the point coordinates of an object in his program he must specify the dynamics of the object. The usual method for doing this in FORTRAN based MOGUL is with DO loops, where the scale and translation factors change incrementally with the iterations in the loop. This is fine if only one object is being displayed or if all the objects are scaled and translated with the same factors. When different sized objects or different motions are required there must be nested loops or different factors for each. A movie is then a series of DO loops where each loop describes some sequence of frames and contains the following basic elements:

```
    DO 10 I=1, NFRMS
    ——
    SFACT (I)=——
    TFACT (I)=——
    ——
    CALL DRAWST (SFACT(I), TFACT(I),
      BLOCK)
    ——
    CALL ROLL
10  CONTINUE
```

The computer is doing the job of interpolating and specifying all the intermediate frames here, where in conventional animation each frame has to be specified individually. Even commercial animation studios are getting away from this frame by frame drudgery, though, by using over and over certain stock positions, motions, and expressions for characters. The result is somewhat crude and jerky animation. One should really see the old Walt Disney full length animations to appreciate the Rolls Royce versus the Chevrolet approach to animation which is apparent now. Of course no one can pay 750 artists fifty cents an hour anymore either.

DO loops progress at a linear rate and all motions are not necessarily linear. Variable increments in translation factors must then be calculated. Another difficulty arises in the drawing of an object composed of various smaller objects. Other than by nesting subroutine calls or drawing each component separately in its assembled position, the big object cannot be drawn all at once as one large block. There is no hierarchy for nesting blocks composed of other blocks. In the "Sailing" movie the boat consisted of a hull, a mast, and a sail all of which had to move and rotate as an entity. A subroutine was defined which in turn called all these component blocks and then drew them with the specified parameters.

All of the objects which appear in the film are defined as prototypes. Some I drew myself, such as the boat, arrows, and basic sail. Others, such as the wind modified sail and the mast (a circle) result from calculations. The prototype blocks all have an origin within them. For manipulations either the implicit scaled and translated copy produced in DRAWST or an explicit scaled and translated copy of the prototypes is used to retain the original models.

CONCLUSIONS

The final movie which I produced for the seminar was really only an intermediate version, since the MOGUL system was not complete then. However, it illustrates all the points I wished to make, and only a few bugs and the inconvenience of not having all the DRAW functions sets it apart from the latest version. After watching it and watching others' reactions to it I am satisfied that it is getting some of the ideas across I wanted. The film did reveal to me that I must have had an audience in mind which had some sailing knowledge. Many more of the little points were picked up by these people than by those with no sailing background. The latter saw an interesting little boat move about the screen, but without any sympathy for the problems of sailing they missed the basic points of tacking into the wind and correct sail trimming. The strongest point of the film (and possibly, the medium) is its absolute attention getting capability as well as the elimination of all extraneous background material.

There are limitations to this method of communication. Computer animation has many of the strengths of a computer directed system but the artist as animator is farther removed from his final product. Though he is spared the necessity of drawing many slightly varying drawings and though he can calculate, modify, and display phenomena not observable or feasible in the natural world, he cannot express the artistic technique or capability that would be evident if he were holding the pen. Rather than an artist, an artist-programmer-psychologist-computer scientist is required. The attempts mentioned earlier to provide online animation facilities to those uninitiated in the ways of computers only debilitates the capabilities of both parties. Advantage should be taken of the requirement that the animator have some technical knowledge of the system as well as some awareness of the problems involved in iconic communications. Perhaps a simple enough language or computer will be developed some day which will enable an animator to think out and then immediately create his cartoon sequence. At the moment I think this is not true, nor is it necessarily a bad thing either. The preciseness of computers actually aids in formalizing the images to be used in a communications process.

The results for iconic communications I think are just beginning. The visual medium is good, but it takes too long to get thoughts displayed just right. Other than generalized heuristics there is no formal syntax or set of models which can help a potential image communicator. Measurement of the effectiveness of idea transmission, validity of images used, relationships portrayed, all these subjects still pose many questions. Thoughts have been entertained to match up the computer with a TV screen and dump digital information in a video format onto black and white or color monitors. Technically feasible (and marketed) the concept may lower the cost and time involved in producing animations, as well as bring the manifestation of computer generated images closer to home.

Computer description and recognition of printed Chinese characters

by WILLIAM STALLINGS

Honeywell Information Systems Inc.
Waltham, Massachusetts

INTRODUCTION

An approach to pattern recognition

An increasingly important aspect of computer pattern recognition research is automatic pattern description. Investigators have emphasized that pattern analysis should be basic to any pattern recognition scheme.[4,11] Pattern analysis may be defined as the identification of elements of a structure and the description of the relationship among those elements. Chinese characters, by virtue of their regular structure, seem well suited for pattern recognition based upon pattern analysis.

With this point of view, a scheme for automatic pattern recognition has been developed which includes the following tasks:

(1) Description. A systematic scheme for the description of the pictorial structure of the patterns to be recognized is developed.
(2) Analysis. An algorithm is designed which analyzes the structure of the patterns, producing a representation of the structure conforming to the descriptive scheme.
(3) Encoding. From the structural representation of a pattern, a code is generated which uniquely identifies the pattern.

This method has been applied to the recognition of Chinese characters. A program has been written which analyzes Chinese characters; the program produces a data structure which describes a character in terms of basic picture elements and the relationship among them. A procedure has been developed for generating a numeric code from the structural representation. Recognition is achieved by building up a dictionary matching characters with their codes; the code for any new instance of a character can then be looked up in the dictionary.

The methodology of pattern recognition still lacks any solid theoretical foundation. The author feels that progress in this area requires building up a body of effective pattern recognition techniques. It is hoped that the methods and techniques developed in this project on a specific class of patterns will be applicable to other pattern recognition problems.

Specifically, this project deals with a class of patterns which displays a rich structure developed from a small number of basic elements, all of which are relatively simple. The patterns are characterized by the fact that these elements may be combined in many complex ways. Other classes of patterns which fit this description will hopefully benefit from knowledge gained here.

A Chinese reading machine

Two obstacles have hindered the access of interested non-Chinese groups to the vast body of written Chinese produced each year. The first is the difficulty of the language itself. Chinese is very complex and takes so long to master that few Westerners ever learn it well. And second, of course, is the size of the printed output in Chinese. Manual translation is slow and tedious, and can never be relied on to handle more than a tiny fraction of the material.

To make available to Westerners the culture and technology of one-quarter of the human race, some form of automation must be introduced. A Chinese reading machine, which could scan printed Chinese and produce English output, would provide the most desirable means of improvement. Such a machine is a long way down the road, but individual steps which advance toward that goal are to be encouraged.

Considerable work has been done in the area of automatic translation of Chinese.[7,12] These efforts have been only partially successful. Even if a good translation device were available, however, the formidable problem of encoding Chinese characters for input would remain.

One answer to the problem would be the development of a practical Chinese character recognition machine, toward which the effort of this project is directed.* It is hoped that advances in this area would provide additional incentive for work in translation devices. On a more modest scale, a Chinese character recognition device could be used as a type of on-line dictionary to speed up the process of human translation. Even this limited application would be a welcome advance.

THE STRUCTURE OF CHINESE CHARACTERS

Chinese is a pictorial and symbolic language which differs markedly from written Western languages. The characters are of uniform dimension; they are generally square; they are not alphabetic.

The characters possess a great deal of structure and hence are well suited to the method of recognition outlined above. Many regularities of stroke configuration occur. Quite frequently, a character is simply a two-dimensional arrangement of two or more simpler characters. Nevertheless, the system is rich; strokes and collections of strokes are combined in many different ways to produce thousands of different character patterns.

Chinese characters consist of sets of connected strokes. Each stroke is roughly a vertical, horizontal, or diagonal straight line segment. Sets of connected strokes form units hereafter referred to as components. Each character consists of an arrangement of disjoint components. Figure 1 shows a character having three components.

The structure of a Chinese character may therefore be specified on two levels:

(1) A description of the internal structure of each component, and
(2) A description of the arrangement of components in two dimensions.

Components

Two questions needed to be answered when deciding how to describe the internal structure of a component:

(1) What class of objects should be considered as the basic picture element?
(2) What sort of structure should be used to describe the relationship between elements?

Three criteria were used in answering these questions:

(1) The structure should be easy to generate from the original pattern.
(2) It should be easy to generate a unique numeric code from the structure.
(3) The structure should represent the pattern in a natural manner.

A natural method of representing the internal structure of a component would be in terms of strokes. This indeed is the approach taken by several previous recognition schemes.[5,8] These schemes make use of on-line input, in which strokes are drawn one at a time. The difficulty with this approach for *printed* characters is that strokes do overlap and are not easily isolated. Also, the description of the relationship between strokes becomes complex.*

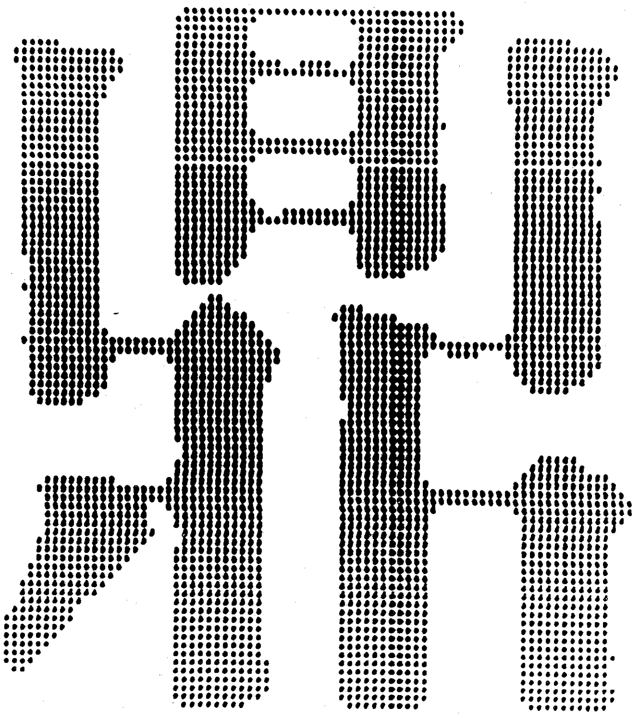

Figure 1—Character with three components

* The author is aware of one previous attempt at the recognition of printed Chinese characters.[1]

* For a discussion of a system for the description of Chinese characters in terms of strokes, see Fujimura and Kagaya.[3] The authors are primarily interested in computer generation of Chinese characters.

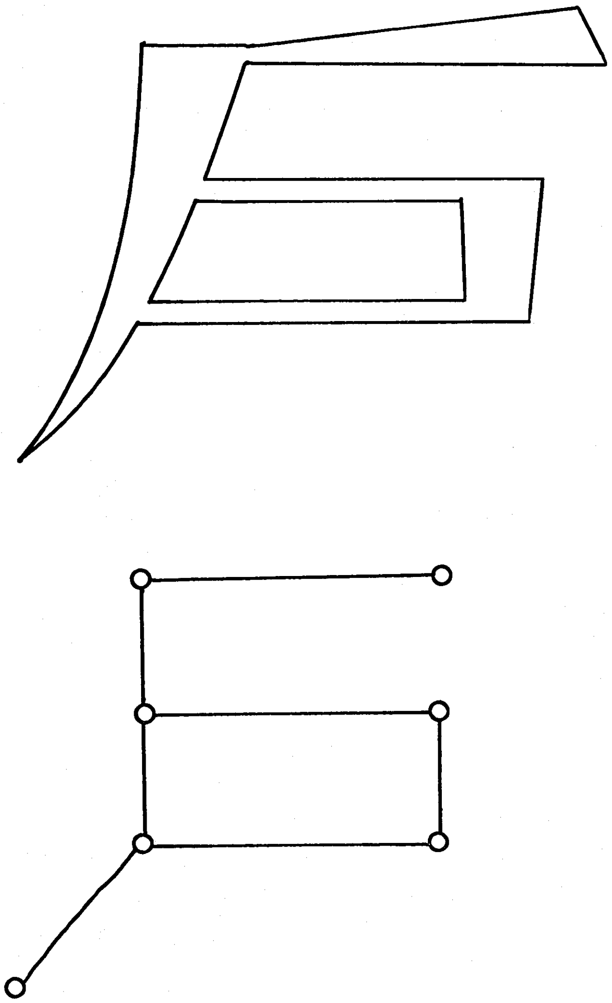

Figure 2—Component and graph

It is more promising to describe components in terms of stroke segments. This can best be understood with reference to Figure 2. As can be seen, a component can be depicted as a graph. The branches of the graph correspond to segments of strokes. These segments are bounded by stroke intersections and ends of strokes.

It will be shown later that this representation satisfies criteria (1) and (2). That it satisfies criterion (3) is fairly clear.

Characters

The arrangement of components in two dimensions to form characters can be described using the concept of frame. Each character is viewed as occupying a hypothetical square. The segmentation of a character into components segments its square accordingly. The square, or frame □, may be segmented in one of three ways: (a) East-West ◫, (b) North-South ⊟, (c) Border-Interior ▣. Each of these segmentations corresponds to a two-component character. For example, 引 would be represented by (a), which decomposes the character into 弓 and |. 台 would be represented by (b). Finally, either partial or complete enclosure, such as 句 and 困 would be represented by (c). Frames for characters composed of more than two components are obtained by embedding (a), (b), or (c) in one of the sub-frames of (a), (b), or (c). The process of embedding is recursive, in that any sub-frame of a derived frame may be used for further embedding. For example, the four-component character of Figure 3 can be described by the frame arrangement of Figure 4a. The frame description can be conveniently represented by a tree, as indicated in Figure 4b.

This description of the arrangement of components is based on the work of Rankin,[10] who introduced the concept of frame-embedding. The definition of component used here is slightly different from that of Rankin. Despite this, Rankin's claim that the three relations used in his scheme are sufficient to describe accurately virtually all characters seems to apply.

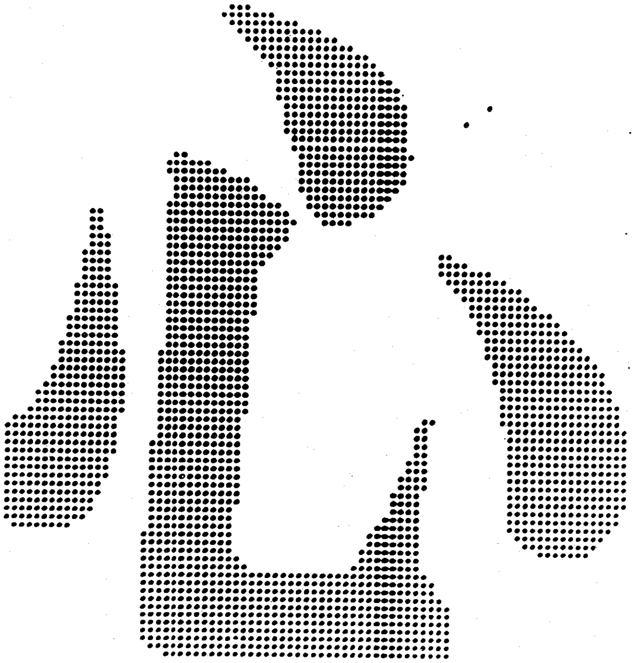

Figure 3—Chinese character

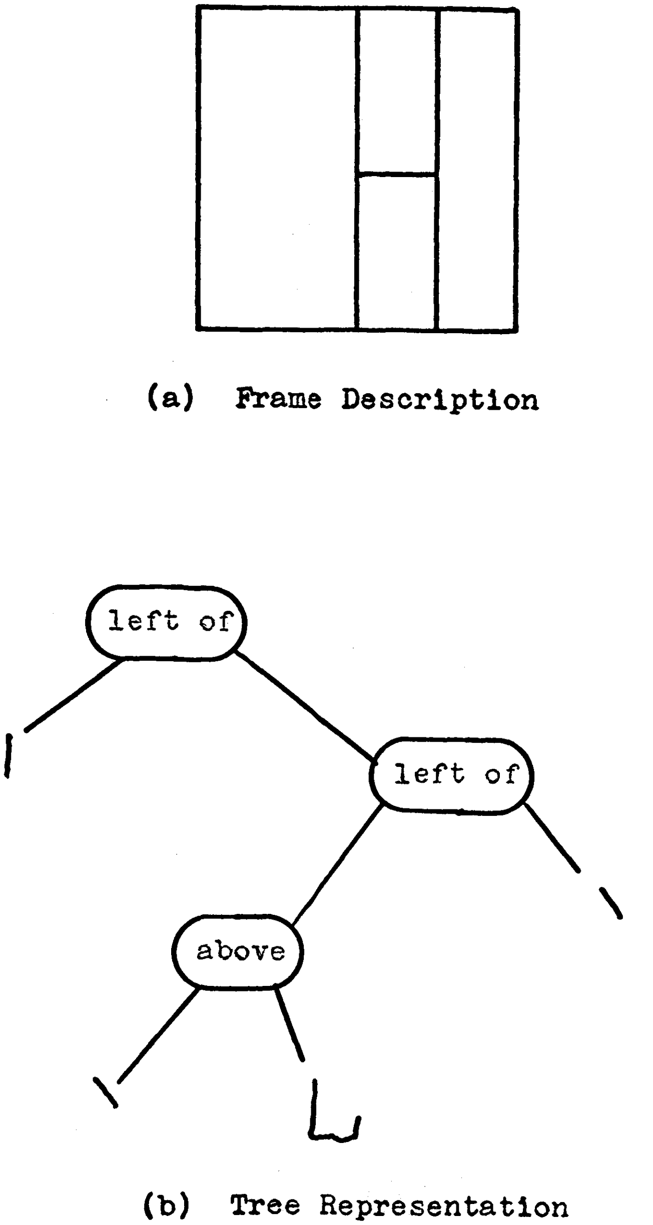

(a) Frame Description

(b) Tree Representation

Figure 4—Frame description and tree representation

INPUT

The program operates on a representation of one character at a time. The representation is in the form of a matrix whose entries have value zero or one corresponding to white or black on the original printed picture.

The device used to obtain the matrix is a flying spot scanner which measures the intensity of light reflected from an opaque sheet of paper at a number of points inside a small area or "window" on the sheet. If the intensity reflected relative to the incident intensity at a point is below a certain threshold, the value one is transmitted for that point (BLACK), otherwise a zero is transmitted (WHITE). The effect is that of placing a grid over the picture and making each square either all black or all white.

A program has been written which operates the scanner and stores the resulting matrix in core. The size of the matrix is 80×80 for a single character. However, both the window size and the sampling rate (the fineness of the grid) may be varied so that characters of varying size can be processed. Additionally, the threshold may be adjusted to achieve the best quality.

Certain functions of the program depend on the fact that there are no gaps or holes in any of the strokes. This is not always the case due to the quality of the printed input. Accordingly, a smoothing operation is performed to fill in the gaps. The resulting matrix is used as the data base for the program.

The digitized form of a character can be displayed on a CRT. Figures 1, 3, 5 and 6 are photographs of such displays.

ANALYSIS OF COMPONENTS

A program has been written to perform the analysis of components. For a given component, the output of the program is a connected graph in which branches correspond to stroke segments and nodes correspond to the endpoints of stroke segments.

The program is quite complex, and will be described in detail in a future paper. A brief outline of the procedure is given here.

The procedure begins by finding an arbitrary stroke segment of a component. This is done by scanning along various rows and columns of the matrix until a stroke is encountered (See Figure 5). This initial stroke segment is the first branch of the graph. Next, the two endpoints of this initial segment are found. This is done by crawling along the stroke in both directions. Crawling is accomplished by following along the boundary points of the stroke using a standard contour-tracing algorithm. The crawling halts either at an intersection of strokes, characterized by encountering a large black area, or at the end of a stroke. Both of these two conditions for halting correspond to a node of the graph being encountered.

Thus, one initial branch and its two nodes are found. The procedure continues in the same manner. For each of the two nodes, all segments leading from it are investigated (by crawling), finding more nodes. Segments leading from each new node are similarly investigated until the entire component has been covered. During the execution of this recursive procedure, the graph of the component is developed as each new node is encountered.

ANALYSIS OF CHARACTERS

The algorithm for analyzing the pictorial structure of a character is in two parts:

1. A collection of connected graphs is produced, one for each component.
2. The relationship among components is determined.

Finding all components

The program described in the previous section must be applied to all the components of a character. Some method must be used for finding each of the components and keeping track of those which have been analyzed.

To do this, the following procedure is employed. As a component is being analyzed, its outline is drawn on a separate pattern. That is, the contour points of a component are filled in on a new pattern as they are encountered during analysis. The auxiliary pattern contains, at any time, the outline of all the components of a character which have been processed.

After a component has been processed, a search is made for a stroke of a new component. If a stroke is found, its boundary points are checked against the auxiliary pattern to determine whether or not this stroke belongs to an already-analyzed component. In this way, new components may be found and analyzed. The procedure halts when no new strokes can be found. The result is to produce a collection of connected graphs.

Figure 6 shows the result of applying the algorithm to the character of Figure 3.

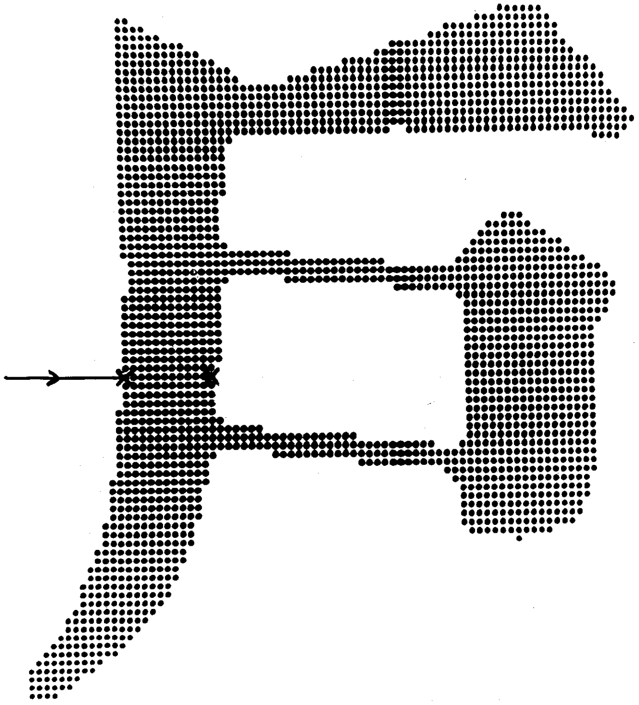

Figure 5—Finding a stroke

Constructing the frame

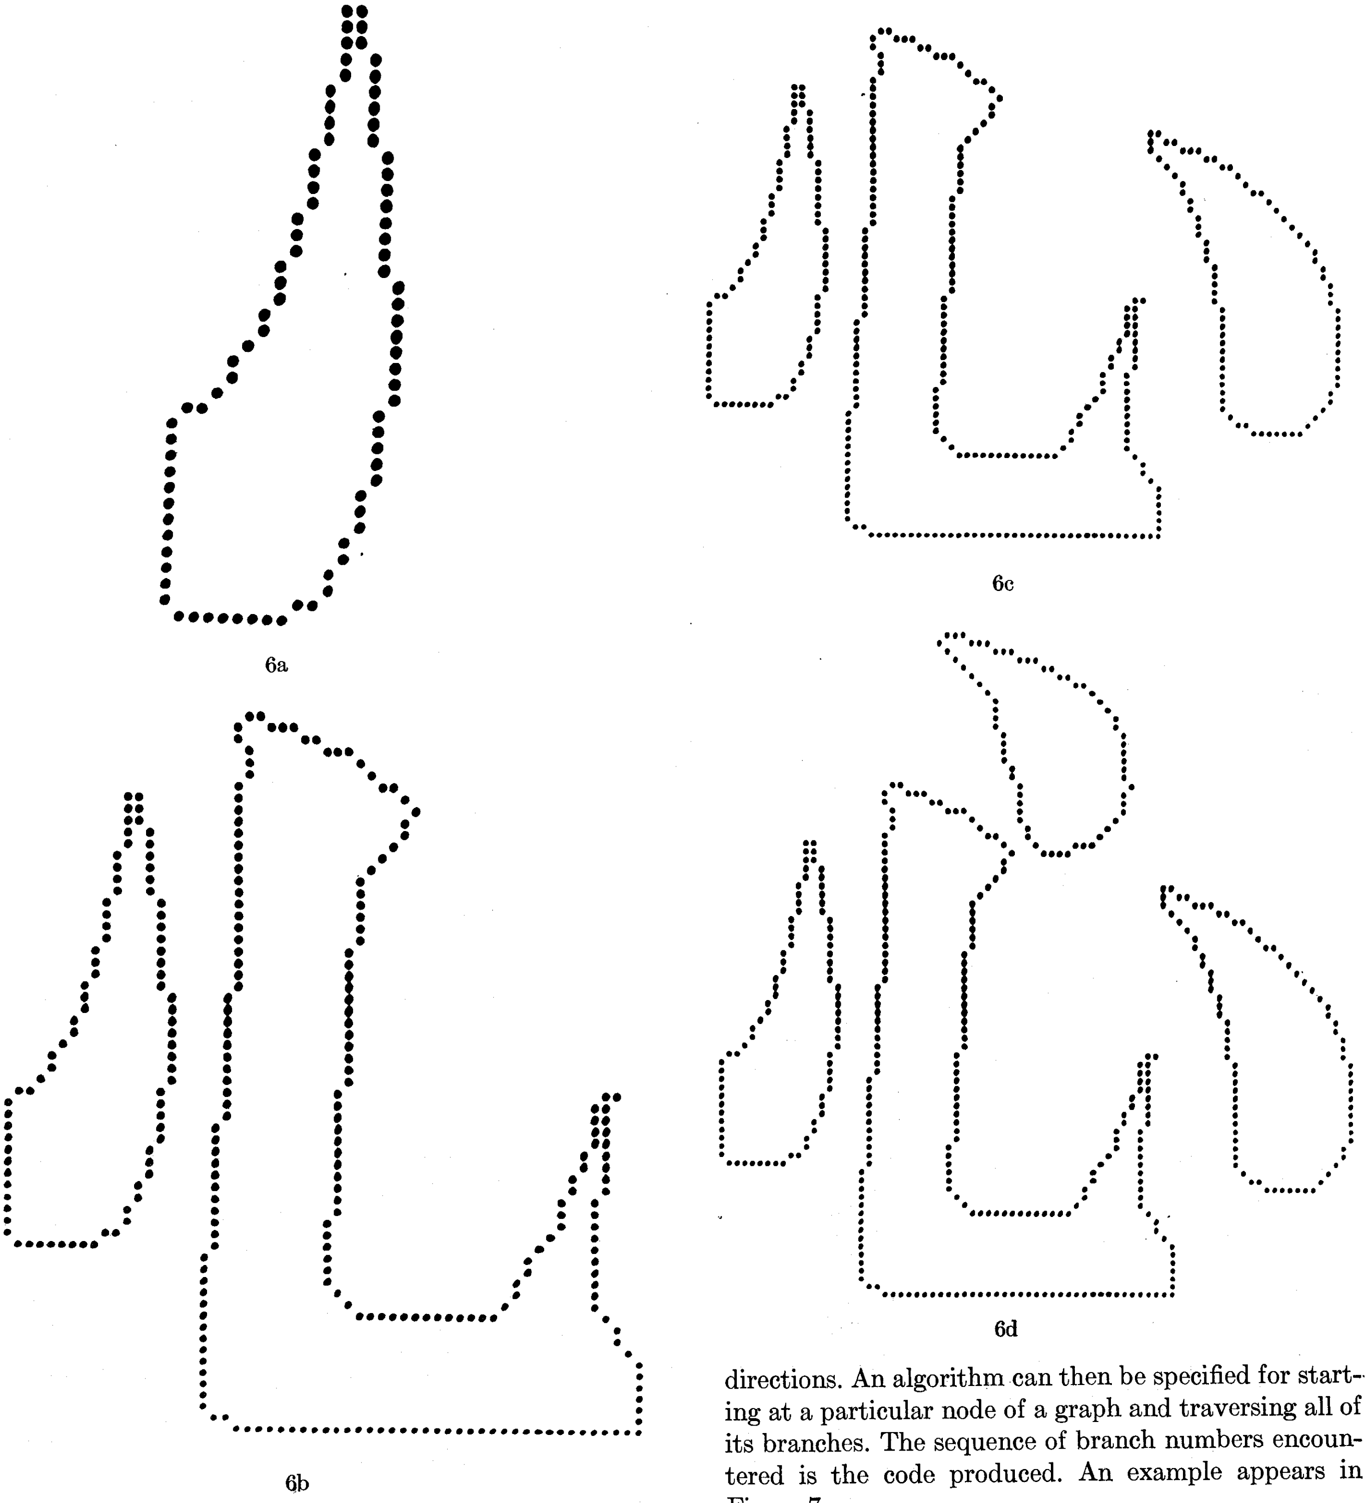
Representation of the frame description of a character is done conveniently by means of a tree. The root node of the tree has as its value one of the three relations indicating how the overall frame is broken into two sub-frames. The two sons represent the structure of the two sub-frames. Terminal elements correspond to components (see Figure 4b).

The method of obtaining such a tree will be briefly described. First, each component in the character is inscribed in a rectangle. This is easy to do since the coordinates of each node are known. The relationship between all possible pairs of components is determined by determining the relationship between their rectangles. The one of the three permitted relationships (East-West, North-South, Border-Interior) which most nearly approximates the true relationship is chosen. Then it is determined if one of the components has the same relation to all other components. This will usually be the case. If so, that component becomes one son of the root node of the tree; the value of the node is the appropriate relation; the other son is a tree representation developed for the remaining components. This sub-tree is determined in the same way.

If no single component is found, a more complicated procedure is used to determine if any two components have the same relation to all others, and so on.

ENCODING OF COMPONENTS

For recognition purposes, a procedure has been developed for generating a numeric code for each character. The first step in this procedure is the generation of a code for each component in a character.



6a

6b

6c

6d

Figure 6—Outline of a character

The code for a component is generated from its graph. To this end, the branches of a graph are labeled at each end. The label on a branch at a node indicates the direction or slope of that branch quantized into eight directions. An algorithm can then be specified for starting at a particular node of a graph and traversing all of its branches. The sequence of branch numbers encountered is the code produced. An example appears in Figure 7.

The algorithm obeys the following rules:

1. Start at the node in the upper left-hand corner of the graph. Exit by the branch with the lowest-valued label. Mark the exiting branch to indicate its having been taken, and write down the branch label.

2. Upon entering a node, check to see if it is being visited for the first time. If so, mark the entering branch to indicate this.
3. Upon leaving a node, if there are available unused directions other than along the first entering branch, choose the one among these with the lowest-valued label. Leave by the first entering branch only as a last resort. Mark the exiting branch to indicate its having been taken and write down the label on the branch.

Since at each node there are just as many exiting branches as entering branches, the procedure can only halt at the starting node. At the starting node, all exiting branches have been used (otherwise the procedure could have been continued), hence all entering branches have been used since there are just as many of these. The same reasoning can be applied to the second node that is visited. The first entering branch is from the starting node and this branch has been covered both ways. But this branch would only have been used for exit from the second node if all other exits had been exhausted. Therefore all branches at the second node have been covered both ways. In this manner, we find that the branches of all nodes visited have been traversed both ways. Since the graph is connected, this means that the whole graph has been covered.

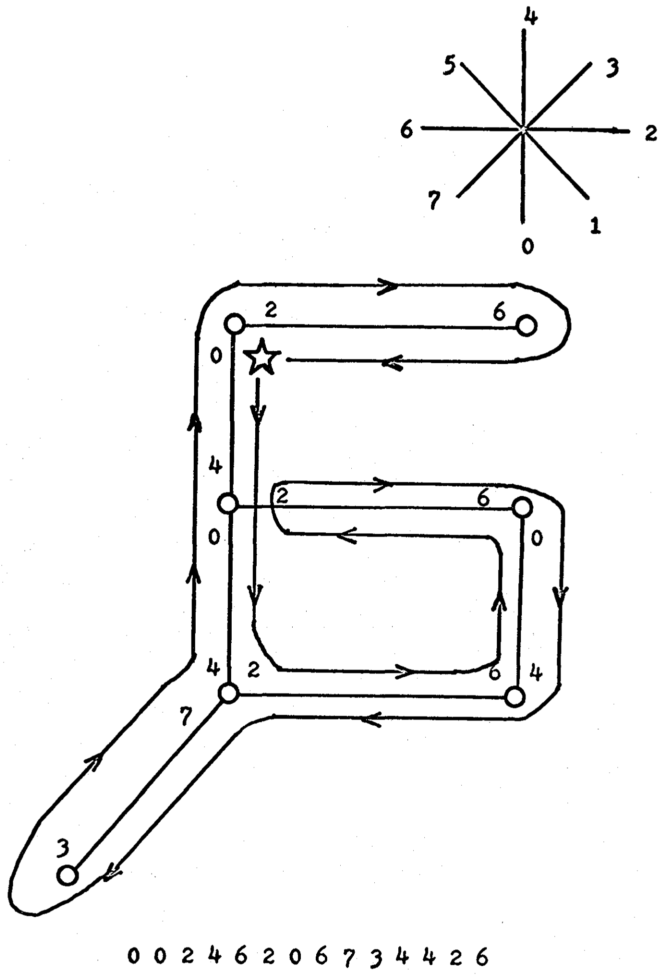


Figure 7—Encoding a graph

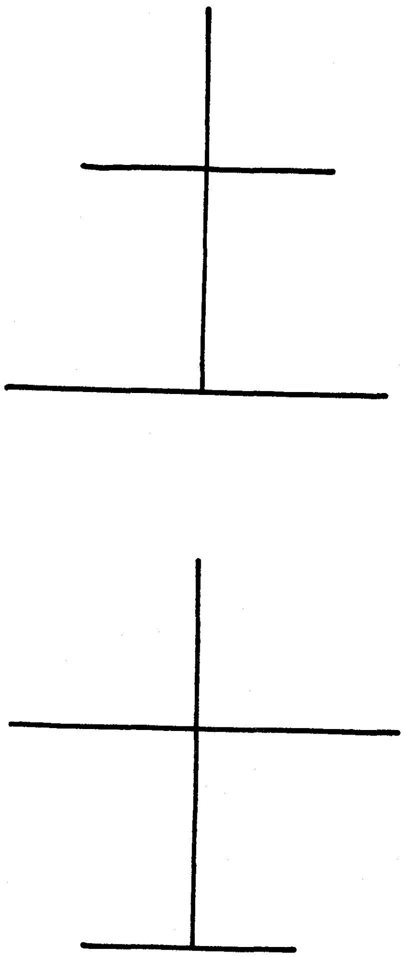

Figure 8—Two characters with same graph

All branches are traversed exactly once in each direction by this procedure, so all labels are picked up. The code consists of the branch labels in the graph written down in the order in which they are encountered.

This algorithm is based on a procedure for traversing graphs described in Ore.[9]

While it is true that this scheme will always generate identical codes for identical (isomorphic with the same labels) graphs, the goal of generating a unique code for each character is not achieved. Two types of difficulties are encountered.

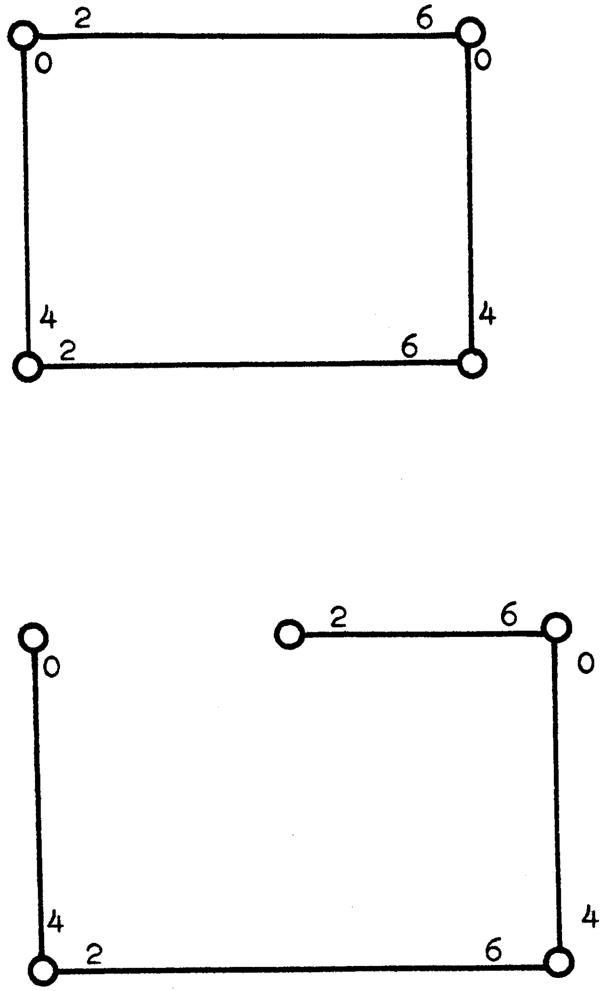

Figure 9—Two graphs with same code

The first is that two characters might generate the same graph, hence the same code. Figure 8 gives an example of such a situation. This situation appears to be very rare, however, and it seems to be no great hindrance to make special cases of these characters.

The second difficulty is that two different graphs might generate the same code. Figure 9 illustrates this situation. The author has been unable to find any pair of characters whose graphs exhibit such a property. Again, this appears to present no great problem.

The method, then, will generate different codes for different characters with only a few exceptions. The algorithm is simple and its execution is quite rapid.

ENCODING OF CHARACTERS

The representation of a character is in the form of a tree. The nodes of the tree are binary relations; the terminal elements correspond to components. Considering the relations as binary operators, the tree can easily be flattened to prefix form. This is done by walking around the tree counterclockwise, starting from the root node, and picking up nodes and terminals the first time they are encountered. As is well-known, the string generated in such a fashion is unique; the tree can readily be reconstructed from it. To generate a *numeric* string, the following code can be used:

0↔terminals (components)
1↔left node
2↔above node
3↔surround node.

Figure 10 shows the generation of code from the tree of Figure 4.

We can consider that the code so generated defines a class of Chinese characters all of which have the same frame description. Therefore, a Chinese character may be specified by first giving its frame description code and then giving the code for each of the components

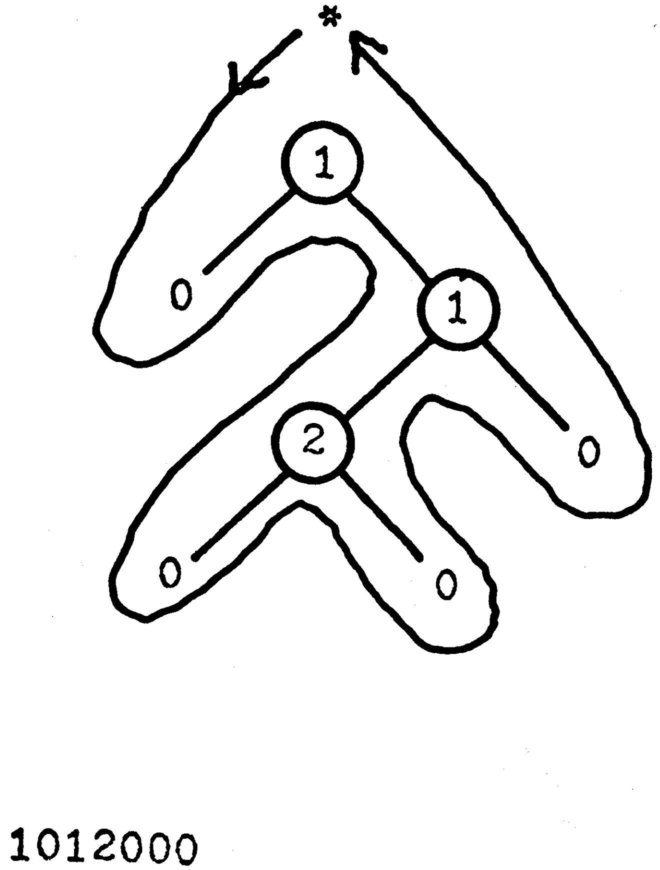

Figure 10—Flattening a tree

that fits into one of the sub-frames. A character having n components will have a code consisting of the concatenation of $n+1$ numbers:

$$N_0, N_1, \ldots, N_n$$

where N_0 is the code generated from the tree and N_1 through N_n are the codes of the components listed according to the order in which the components were encountered in the tree flattening.

RESULTS

The algorithms discussed in this paper have been implemented as a computer program which recognizes printed Chinese characters.

Most of the program is written in FORTRAN. A considerable fraction, however, is written in assembly language. The assembly language routines augment the power of FORTRAN to permit list-processing operations and also to permit FORTRAN subroutines to be called recursively. The combination, while less than ideal, provides for the creation and manipulation of complex data structures in a fairly natural manner.

The program runs on a PDP-9 computer with a core memory of 32K words of 18 bits. The computer also has a large auxiliary disk and magnetic tape storage facilities.

The program has been tested with a number of characters from several different sources. The tests were designed to consider four questions:

1. How successful is the program in analyzing the structure of Chinese characters?
2. Does the program generate consistent codes for characters of the same font? That is, will two instances of the same character from the same source yield the same code?
3. Does the program work for characters from different sources?
4. Do factors such as character size and character complexity affect program performance?

Initial results were obtained from a set of characters obtained from a Taiwan printer. A sample of this set appears in Figure 11. To start, 225 different characters were processed. This was to provide a dictionary for later tests, and to test the pattern analysis capabilities of the program.

The results show a reasonable structural representation produced for about 94 percent of the characters. The failures were all due to a particular component not being analyzed; for all characters the relationship among components was correctly determined. The problems all occurred in the part of the component analysis algorithm concerned with analyzing nodes; i.e., the part which is to find a node and locate all stroke segments leading from it. The routine would sometimes make mistakes if, for example, two nodes were very close together or one node covered a large area. The characters involved were typically quite complex.

Figure 11—Example of character set

From the characters that were successfully analyzed, 25 were chosen for additional testing. Four additional instances of each character from the same source were processed, for a total of 100 new characters.

All new instances of the 25 characters produced reasonable structural representations. For five of the characters, one of the new instances produced a slightly different representation, hence a different code. No character generated more than two codes. In all cases, the discrepancy was caused by the fact that two strokes which were very close in one instance touched in another instance of the same character.

Additional testing was done using two other sources. Characters from issues of a Chinese magazine were used. These were approximately half the size of the characters in the original set. Also, some computer-generated characters[6] were used. These were about double the size of the originals. Both were of about the same style. Fifty instances were taken from each source. The percentage of instances generating the same code as the corresponding character from the original set was 89 percent for the magazine source and 95 percent for the computer source. Discrepancies mostly had to do with stroke segments appearing at somewhat different angles and with strokes touching in one case but not the other.

CONCLUSIONS

Pattern description

A descriptive scheme for the structure of Chinese characters has been proposed and a program for computer analysis conforming to the scheme has been written. The description is on two levels: The internal structure of components, and the relationship among components.

The first level of description is straightforward: a connected part of a character is represented by a graph. This representation is adequate for the description of components; it is reasonable for the human percipient to think of components as graphs.

Analysis on this level works fairly well; difficulty is encountered with some complex characters. Some work has been done on modifying the described approach. The modification consists of "shrinking" a component to a skeleton and obtaining the graph from the skeleton. This procedure is sensitive to contour noise, and it seems that use of this method would result in many components generating several different graphs from different instances.

The second level of description is based on the work of Rankin. With the exception of a very few characters whose components do not fit neatly into the frame description, it is an effective means of describing the structure of Chinese characters in terms of components. The analysis program for this level has been successful for all characters tested.

Pattern recognition

It would be overly optimistic to claim that the results of this thesis prove the feasibility of a hardware Chinese character recognition device. The development of such a device would be an impressive accomplishment. Nevertheless, the author feels that this thesis points the way to such a device by providing a good method for encoding Chinese characters.

There are two separate, but related, problems associated with Chinese character recognition. The first is that complex characters may fail to be encoded, or may generate several codes. The second is that there would need to be a quite large dictionary of characters to handle most material. A college graduate in China is supposed to know about 5000 characters, which gives some indication of what would be needed. The problem of handling a large dictionary arises. This is especially true if many of the characters require more than one code.*

It is likely that a recognition device would be used to process material from mainland China. If this is true, several developments make things look brighter. They result from the desire of the Communist Government to simplify the language.[2] The first is that the Government has recommended the general use of only 2000 characters. A list of these characters has been published. Publishers, being Government-controlled, are under instructions to stay within the total of 2000 as far as possible. Secondly, the Government has simplified a large number of characters. In 1956, a list of 515 simplified characters to be used in lieu of the original complex forms in all publications was released. The average number of strokes per character for the 515 was reduced from 16 to 8. Overall, since 1952 the average number of strokes per character has been reduced from around 13 to around 10 for the 6000 most frequently used characters. The continuing Communist policy of language simplification contributes to the author's opinion that a Chinese character recognition device is a realistic objective.

ACKNOWLEDGMENTS

The author would like to thank Professor Francis Lee of M.I.T., whose guidance and advice were invaluable to this project. The author is also grateful to Professor Thomas Huang of M.I.T. and Professor Herbert Teager of Boston University for their help. This paper is based on a thesis submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Department of Electrical Engineering at the Massachusetts Institute of Technology on August 15, 1971.

* One way to reduce the number of characters requiring more than one code would be to use a stylized font especially designed for use with a character recognition device.

Computer diagnosis of radiographic images*

by S. J. DWYER, III, C. A. HARLOW, D. A. AUSHERMAN and G. S. LODWICK

University of Missouri-Columbia
Columbia, Missouri

INTRODUCTION

The potential of optical scanning equipment and digital computers for assisting or replacing human judgment in medical diagnosis has been recognized by investigators for some time.[1] A number of efforts have been made, with varying degrees of success, in developing automatic techniques for recognizing and classifying blood cells,[2] chromosome analysis and karyotyping,[3] identifying leucocytes,[4] and processing scintigram images[5] obtained in nuclear medicine. These image analysis techniques are now being extended to the clinical specialty of diagnostic radiology where there is an urgent need to provide assistance in handling the several million radiographs read by radiologists each year. The need for computer-aided diagnosis in radiology is becoming increasingly urgent because of the expanding population and the continuing demand for improved quality of medical care. The use of computers in radiology can free the diagnostic radiologist from routine tasks while providing more accurate measurements that lead to consistent and reliable diagnoses.

The most common radiological examination is the conventional chest film. The resultant film is a complex image consisting of a two-dimensional projection of a three-dimensional object, whose structure reflects the absorption of X-rays as recorded on film. Such films commonly offer photographic resolution of 40 line pairs per millimeter. Chest films are commonly called for in routine medical examinations and are used by physicians to determine the health status of the patient. In the case of coal workers' pneumoconiosis ("black lung disease"), chest films are even employed as the basis for determining federal compensation to the individual workers. The chest film examination is employed by the radiologist to ascertain diseases such as lung disease, rheumatic heart disease, congenital and acquired heart disease, skeletal anomalies, and radiation-induced diseases. In addition to the conventional plain films of the chest, other radiant images are employed in radiographic diagnostic techniques, such as a cardiac series, fluoroscopy, image amplification, video tape, and cine radiography. This paper presents the results of an automatic visual system for the diagnosis of heart disease from the conventional radiographic technique employed to form the plain film of the chest.

The basic technique involves the conversion of the chest film to a two-dimensional array of numbers, each number in the array representing the transmittance of light through the film at a particular point on the film. Analysis is then carried out by pattern recognition methods on the digitized image as implemented by the digital computer. Four steps comprise the automatic visual system for diagnosis of heart disease from the chest film.

The first step is the digization of the X-ray image. A specialized camera scans the film which is illuminated from the back, producing an output voltage whose average value is proportional to the amount of light transmitted through a particular point on the X-ray. Each such point is selected by the computer directly controlling the scanner camera. The optical image is thus converted point by point into a two-dimensional array of numbers, each of which represents the "grayness" of the image—that is, the gradation of light and dark on the film—at a particular point.

The second step in the process is that of preprocessing. These techniques are designed to enhance the extraction of selected features and to eliminate irrelevant data in an image. A number of these techniques have proven useful. Gray level histograms are employed to determine if a distribution transformation should be employed. Spatial digital filtering methods utilizing the fast Fourier transform or recursive partial dif-

* This work was partially supported by USPHS Grant GM 17729.

ference equations may be useful. Contrast enhancement is often employed, especially if the digital processed images are to be displayed. Finally, image subtraction is often used to remove irrelevant image information.

The third step is that of feature extraction. The actual selection of an image feature set is a significant problem in itself for which no general theoretical solution exists. One reason for this difficulty is that a set of features required for classification—normal or abnormal samples for a particular disease—is relative not only to the class of images but also to the diagnostic problem under consideration. Also, features needed for one diagnostic problem are useless for another problem. The most difficult portion of an automated image analysis system is that of feature extraction. Techniques which are useful in the feature extraction portion of the process are directional signatures, contour tracing, Fourier transform frequency signatures, template matching, region enumeration techniques, and linguistic methods.

The fourth, and final, step in the process is that of automatic classification. Successful use of pattern recognition techniques requires that all four steps in the process be carefully designed, depending upon the specific problem to be automated. In the case of chest films, classification schemes that have proved useful consist of discrimination functions, both for the normal-abnormal two class problem and for the differential diagnosis—the further division of the abnormal class into subclasses of diseases.

DIGITIZATION OF THE CHEST X-RAY FILMS

Chest films are scanned with a computer-controlled specialized camera that produces an output voltage whose average value is proportional to the amount of light transmitted through a particular point on the X-ray.

The system as depicted in Figure 1 performs three categories of operations: (1) the conversion of images in the form of film transparencies into digital arrays of numbers; (2) the storing of these arrays in an orderly fashion to facilitate retrieval for use by researchers; and (3) the redisplay of these and other picture arrays either to produce a photographic copy or for direct viewing. The conversion of film to numbers is accomplished either by a flying spot scanner (FSS) or an image dissector scanner (IDS) which utilize an image dissector camera in the digitization. Both of these devices operate under the control of a digital computer which also handles the flow of data from scanner to magnetic tape unit.

The digital images are recorded on 800 BPI magnetic tape during the scanning process, becoming permanent entries in the image library. The library consists of digital images stored on IBM-compatible magnetic tape in a special library format that facilitates locating and using every entry in the library. An identification record containing scanning parameters and content information is written at the beginning of each image on a library tape. A library index in punched card form contains identical information and is updated as new images are recorded.

The third function which the system performs is the reconstruction of real images from digital form. Three separate devices accomplish this. The first device is a Hewlett Packard 1300A X-Y display scope with a x-axis input. Second is a Dicomed/30 Image Display, manufactured by Dicomed Corporation of Minneapolis. The third device is a digital image display utilizing a high speed disc memory which is filled at slow data rates, and then dumped at high data rates as video information to a high resolution, high tonal television monitor display. Another distinguishing feature of this device is its interactive capabilities. Through the use of a joystick the operator may extract certain features of the displayed image and enter these into the computer.

Central to the operation of both scanning and display devices, the SEL 840A digital computer acts as controller and information channel for the system. The SEL 840A is a small scale computer with a memory cycle time of 1.75 microseconds and 16K of word memory. A minicomputer could also perform the necessary tasks. An IBM compatible tape drive is necessary for library creation.

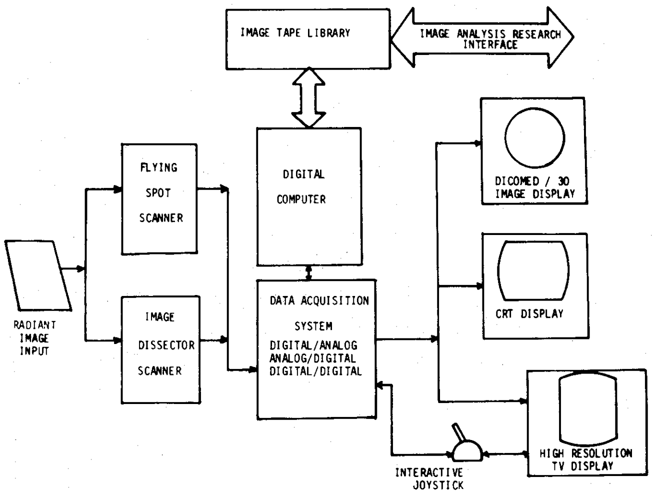

Figure 1—Digital image scanning, storage and display system

Digitization devices

Two digitization devices have been employed in the digitization of chest films—the flying spot scanner (FSS) and the image dissector scanner (IDS).

Flying spot scanner

The flying spot scanner has seen wide use as an image digitizer. Serving as two devices in one, the FSS can also reconstruct hard copy photographic images from digital form. For this reason the FSS is sometimes chosen as both the digitizing and reconstruction instrument in many image analysis applications.

The basic components of an FSS system are shown in Figure 2. When the transmittance at a pair of particular coordinates on the film is to be measured, a dot is illuminated on the CRT at a corresponding location. The position of the dot is controlled by X and Y deflection voltages which are usually generated by digital-to-analog converters. These converters are an integral part of the SEL Computer Data Acquisition System which operates as a peripheral device to the SEL 840A. An image of the computer-positioned dot of light is focused upon the film by the lens. The amount of light passing through the film is measured by a photomultiplier tube positioned behind the film. This signal contains some error due to the fact that the brightness of the dot is not entirely uniform over the surface of the CRT. To account for this error the beam is interrupted by a beam splitter and the intensity of the dot is measured by a second photomultiplier. Both signals from the photomultiplier tubes contain a good deal of electron shot noise. This must be removed by extensive filtering prior to analog-to-digital conversion of the signals. The ration of transmitted signal to reference signal, calculated either digitally or by analog techniques, is the the quantity of interest. This measurement is repeated rapidly for all of the locations in the picture raster.

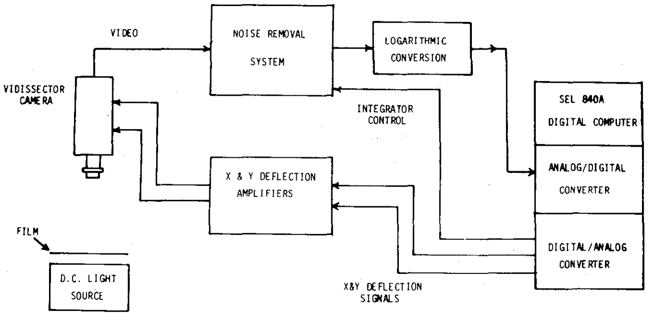

Figure 3—Image dissector scanner system (IDS)

To reconstruct photographs from digital images unexposed film is placed in the FSS and the dot intensity and position are controlled so as to expose the film. The reference photomultiplier measures the amount of exposure that the film is receiving.

Factors affecting the resolution or ability to delineate fine detail of a flying-spot scanner system include CRT spot size, lens resolution, film image contrast and sharpness, and phototube signal-to-noise ratio (SNR). The resolution obtained in an FSS system seems to be proportional to the cost spent in constructing the device. An inexpensive, low resolution FSS has been implemented and will scan 3″ × 3″ film size at a limiting resolution of 256 samples across the film. This has proven quite sufficient for low-resolution image analysis applications. Very high resolution has been attained elsewhere but at a tremendous increase in cost. A disadvantage of the FSS system is that it is difficult to scan large format films such as full size medical radiographs.

Image dissector scanner

The image dissector scanner is the second digitization device utilized. The distinguishing component of the IDS system as depicted in Figure 3 is the vidissector camera, manufactured by International Telephone and Telegraph Industrial Laboratories. The camera employs an image dissector tube to sample the input image.

The image dissector has been described as a photomultiplier with a small electronically movable photocathode area, thus acting as an all-electronic low-inertia microphotometer. The image to be scanned is focused by the camera lens onto a 1.75 inch circular photocathode. Electrons are emitted from the back of the photocathode, forming an electronic image with current density modulated according to the image input. The electron image, focused by magnetic deflection, falls upon an aperture plane, at the other end of the drift tube. The aperture "samples" the image by allowing only a small, well defined area of the electron image to pass through. The sampled photoelectrons are then multiplied by an electron multiplier by a factor of approximately 5 × 10^5. The entire electron image is deflected allowing the aperture to sample different points in the picture.

The input image is a chest radiograph measuring 13½ by 13½ inches and illuminated from behind by a DC powered, high intensity light source. The camera deflection signals are generated by the SEL computer and converted to analog in the SEL data acquisition system. Deflection buffer amplifiers are used to adjust the amplitude and offset of the deflection signals. Eleven bit DAC's are used to allow for scanning rasters of 2048 × 2048 points, although this actually exceeds the resolution of the camera.

The noise current present in the video output of an image dissector camera system can be attributed to random fluctuations of photo-electrons entering the aperture, modified by the statistical noise properties of the electron multiplication process. It is necessary to remove this noise prior to analog-to-digital conversion. This is accomplished by integrating the video signal for a suitable length of time. The resulting signal-to-noise ratio becomes a function of tube construction, input image brightness, and integration time. The integrate time can be selected, but 800 microseconds is a common time. This relatively long integrate time gives a S/N ratio of over 40 DB for a relatively bright input image. This has been verified by digital frequency analysis of the video signal.

The resolving capabilities of an image dissector are determined by the shape and size of the dissecting aperture, usually a circular aperture of diameter 1 mil. This configuration gives a resolution modulation amplitude of 39 percent at 1000/TV lines per inch on the photocathode. The usable diameter of the photocathode is 1.4 inches, given a resolution of 1400 TV lines across the image diagonal.

Logarithmic conversion via a logarithmic video amplifier allows recording of the optical density of a film, rather than transmittance. This is an optional feature, allowing better gray shade condition in the darker areas of a film. An 11 bit analog-to-digital converter is used for the video signal, a more than sufficient number for gray-shade rendition. However, this allows less critical adjustment of the video signal amplitude to insure sufficient quantization levels.

A definite advantage of the IDS system over the FSS system is its ability to scan large format films, such as 14 inch by 14 inch radiographs. With proper optics the IDS can scan small format also. A disadvantage of the IDS system is the inherent non-uniformities in the illuminating light source. Cathode non-uniformity can be typically ± 15 percent over the usable surface, while light source non-uniformity depends upon construction of the source. In the FSS non-uniform CRT response could be compensated for in real time by the reference photomultiplier. For the IDS the correction had to be made by scanning a blank film and then subtracting or dividing each subsequent scan, point by point, by the reference image array. Subtraction was used for density scans, while division must be used for transmittance scans. Figure 4 shows the IDS.

Display devices

Two digital display devices are utilized to examine the processed image—a dark trace storage tube display and a disc memory-TV display.

DICOMED 30 image display

A display device used for examining the processed chest X-ray images is one that is designed and manufactured specifically for displaying digital images (Figure 5).

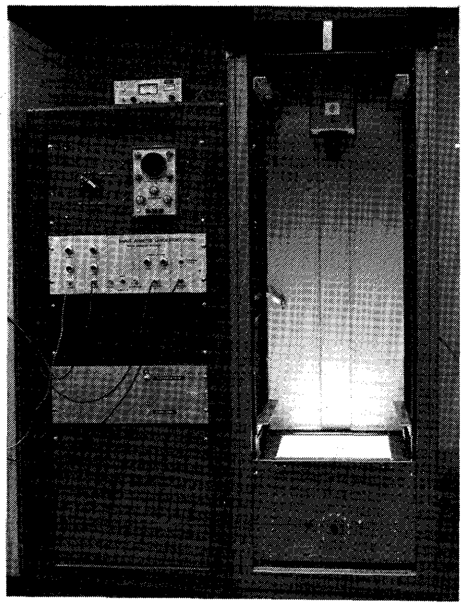

Figure 4—The image dissector scanner system

The DICOMED/30 Image Display is a product of the DICOMED Corporation of Minneapolis, Minnesota. The device interface with the computer is purely digital and is operated like a computer peripheral. The display utilizes a unique type of CRT called a dark trace storage tube which uses a scotophor instead of a phosphor to produce the image. The scotophor is deposited upon the 8 inch viewing surface of the tube. When struck by the electron beam it becomes more opaque and remains so until it is erased by thermal neutralization. This is in contrast with a phosphor CRT which glows only momentarily when it is struck by an electron beam. This almost infinite persistence characteristic of the dark trace storage tube makes it ideal for converting digital images into a usable form. Under program control the DICOMED display "paints" an entire image, one raster point at a time, upon the CRT viewing surface. When illuminated from behind by a viewing light, the CRT face portrays the reconstructed image which remains in full view without need for refreshing by the computer. Thus, with this device, the user can either view the reconstructed image directly or he may desire to make a photograph of it.

The DICOMED display has a set 1024 by 1024 square raster superimposed on the 8 inch circular viewing surface. With digital pictorial data that consists of fewer raster points only a portion of the viewing also need be utilized or, if one wishes, the smaller rasters can be interpolated at display time up to the set 1024 point raster of the display.

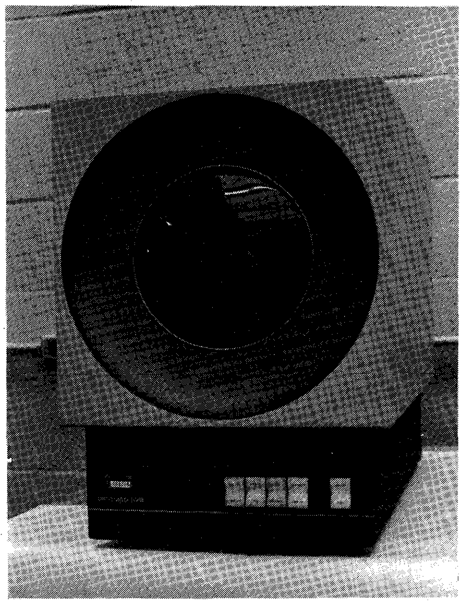

Figure 5—The DICOMED model 30 digital display

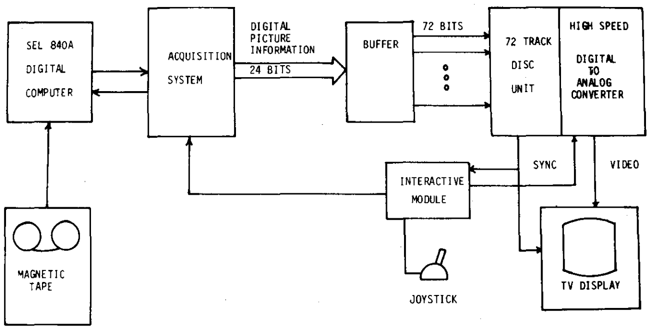

Figure 6—High speed disc image display system

The display and its associated control program can reconstruct an image from magnetic tape in approximately 100 seconds, the time being nearly the same regardless of raster size. The image that is produced has high resolution and can contain up to 64 distinct shades of gray. The contrast ratio of the display is a maximum of 3 to 1 but this can be improved upon when producing "hard copy" by using high contrast film and high contrast paper to print the resulting pictures on. The erasure of images is automatic and takes about 15 seconds to complete one erasure. This is accomplished by heating the scotophor until the scotophor returns to its neutral state. The storage property of the DICOMED Image Display makes it ideal for converting digitally coded pictorial data into a useful form.

*Disc memory-TV display**

Data transfer rates of conventional magnetic tape drives and digital I/O channels are much too slow for flicker-free CRT or TV display of high resolution digital pictures. In the high speed disc-display system, digital picture information is fed to a disc memory at these slow rates, then dumped repeatedly to a television monitor at rates high enough to produce a flicker-free image. The system operates as shown in Figure 6. The image data is read from magnetic tape at interface rates, then dumped via the SEL DAS digital I/O channel into a 72 × 16 bit buffer array. When full, the array is dumped to the disc. The disc is a Data Disc which has parallel read/write capabilities on 72 tracks of 100,000 bits per track. The disc will hold up to three 525 line pictures or one 945 line picture at a time. Once the disc has been filled with the desired picture information, the computer is free to perform other tasks, as the display then acts as a stand-alone facility. The image information is read in parallel by 72 heads, converted to analog form by high speed

* Development supported in part by NSF Grant 20401.

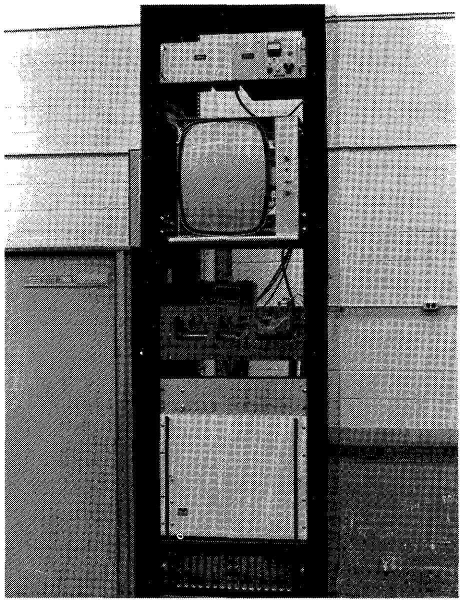

Figure 7—Disc memory-TV display

DAC's, and displayed as an image on the the television monitor at 30 frames per second with interlaced alternate frames, producing a flicker-free image. A control switch determines which of the three 525 line images on the disc is to be displayed.

The television monitor itself has a resolution of 1800 TV lines per picture width, adequate for many applications. The monitor also has a contrast ration of 10 to 1, a substantial improvement over the DICOMED display. Also, picture fill time for a 525 line image is less than 20 seconds compared to 100 seconds for the DICOMED/30 display.

One of the most distinguishing features of this image display system is its interactive capabilities. Although interactive displays are quite common in graphics applications, an interactive high tonal, high resolution image display is a rarity.

This interactive mode is accomplished by using an interactive module which employs a joystick to position a dot of light on the television monitor. The joystick generates X and Y analog voltages which are digitized and compared with the X and Y coordinates being displayed on the monitor. When a match occurs, the image information at the location is ignored and a white dot displayed instead. The X and Y coordinates of the dot may be displayed on a digital readout panel or they may be sent upon command into SEL memory via the digital channel on the data acquisition system. In this manner objects in the image field may be outlined and that outline recorded in computer memory or disc. Another use would be to take measurements of objects in the image. Figure 7 shows the display.

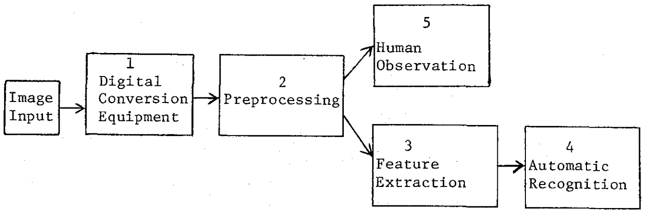
COMPUTER ANALYSIS

Once the image has been converted into an array whose values represent the gray shades in the image, the data are processed on a digital computer for the purpose of identifying and extracting the relevant features of the image. We presently use an IBM 360/50 computer in this processing. It is helpful to consider the structure given in Figure 8 while discussing an image processing system. Stage 1 in this figure has been discussed in the previous section.

In the preprocessing stage, stage 2, one can usually devise methods, such as filtering routines and other preprocessing routines, that are adequate, but not optimal, for the later stages of processing. In some of our studies on chest X-rays we have found that we need no preprocessing. In some of the studies in nuclear medicine a simple averaging technique suffices, which reduces the data to a resolution of 32 × 32 approximating the resolutions of the input camera. Some of the more useful preprocessing techniques will now be discussed.

Distribution linearization

Because image digitization requires that each gray level value be quantized over a finite range (e.g., 6 bits/



1. Digital conversion equipment - The camera and associated analogue to digital conversion equipment required to convert the image into an n x n array of points whose entries give the brightness value of the image.

2. Preprocessing - Programs used to suppress the noise put into the image data by the digital conversion equipment and also programs used to emphasize certain properties in the image that are more important than others for the later stages of analysis.

3. Feature Extraction - The extraction from the image data of information to be used in the automatic recognition of objects in the image. The data emitted from stage 3 of processing should be greatly reduced from that of stage 2 of the processing.

4. Automatic Recognition - The automatic recognition of the important objects in the image by the computer.

5. Human Observation - A human interpretation of an improved image.

Figure 8—Image processing system

picture element), a histogram of the gray level distribution values may be computed.

The gray level histogram (first order probability density function) of most images exhibits a brightness peak which is heavily biased to the dark side of the histogram.[6,7] The digital representation of the radiograph has 256 × 256 brightness values over a 33 × 33 centimeter face, with a sampling frequency in either dimension of .78 lines/mm. The effect of having a large percentage of the 65,536 picture elements (pixels) concentrated into such a narrow portion of the histogram is an image with little visible detail. Many contrast ratios that define edges are simply not displayable. One technique frequently used to correct this is the application of logarithmic conversion of the brightness pixels. This yields pixels which are proportional to image film density rather than brightness.[8] The log operation has the effect of expanding the gray range of the lower brightness pixels while compressing that of the higher brightness pixels. However, because of the shape of the brightness histogram, there is much more contrast expansion than compression.

Because a more rectangular histogram is advantageous, a position invariant, nonlinear histogram equalization technique, similar to the distribution transform in statistics[9], is useful. Since the distribution transformation is only true for continuous variables, some care must be taken to obtain the desired result for the discrete approximation.

Linear filtering

Several techniques for spatial and frequency domain design of spatial digital filters will now be considered.

Digital smoothing is designed to remove noise from images so that later processing will be made easier. Smoothing is usually done by either spatial or frequency domain operations.

One method is to average over a neighborhood in the spatial domain. The basic idea is simply to assign a neighborhood to a point and then change the intensity value of the point by performing an average of all its neighbors.[10] In addition, gradient functions may be set up in various directions in order to test whether or not the averaging process should be performed. An attempt is made to prevent blurring edges or points where significant pictorial information occurs. Noise removal depends intimately upon the nature of the pictures which are being processed. That is, what appears to be noise may be a significant feature in a particular picture.

These averaging methods can also be performed in the frequency domain. One takes the input picture in digitized form and performs the discrete Fourier transform or equivalent methods. The smoothing operations that have been discussed can be performed by removing the high frequencies in the frequency domain. This operation is called low pass filtering. Instead of merely deleting the high frequencies of a picture in order to remove noise, often a selected band of frequencies will be deleted while enough of the high frequencies are left to keep the edges clear.

When an image is low pass filtered, the image contrast is generally unaffected. However, edge detail is effectively removed.[11] Other types of filters can be developed based on a low pass prototype.

Enhancement techniques have an obvious potential for assisting roentgenographic diagnosis. The ability to sharpen detail, for example, and to employ nonisotropic filters to make a hairline fracture more evident, could result in more correct diagnoses, especially when combined with high resolution display equipment for human viewing.

The effect of high pass filtering on an image is to remove the contrast information of the image while outlining edges. The edge outlining effect can be seen most obviously at sharp, high contrast ratio edges. A major application of high pass filters is in the visualization of small, low contrast features superimposed onto uniform backgrounds.[12,13]

A filter which partially suppresses the lower frequency components while enhancing those higher is the high emphasis filter. It should be noted that both the high emphasis and high pass filters create negative brightness pixels. These usually appear as dark bands surrounding the sharper, high contrast ratio edges in an image.

Feature extraction

Feature extraction consists of the extraction of significant features from a background of irrelevant detail. Methods for the enhancement of selected features and elimination of irrelevant detail have just been discussed. In this section, several techniques for the extraction of significant features from an image function will be described.

The selection of an image feature set is a significant problem in itself, and no general theoretical solution exists. One reason for this difficulty is that the set of features required for classification of normal or abnormal samples for a particular disease is relative not only to the class of images but also to the diagnostic problem under consideration. Also, information which is pertinent to one diagnostic problem may be irrelevant to the solution of another problem.

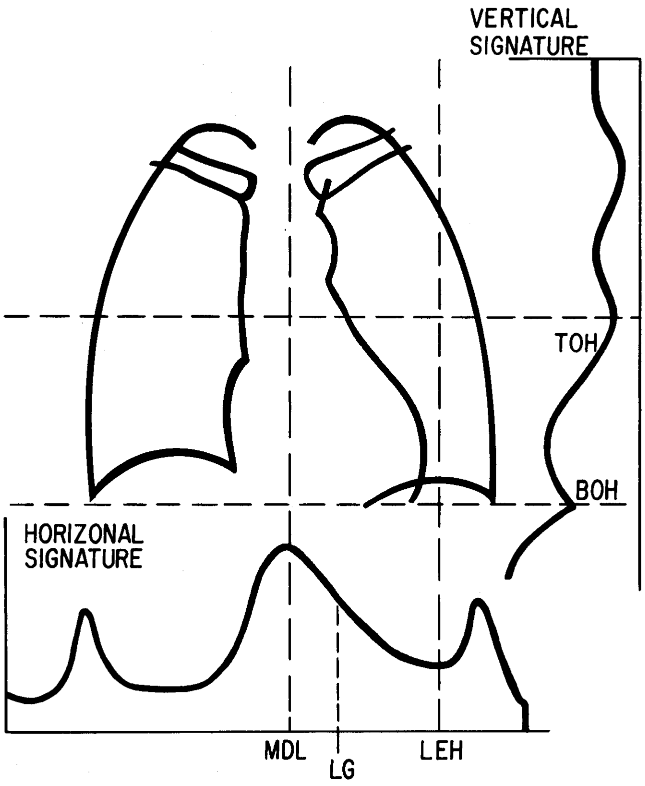


Figure 9—Directional signatures for chest radiograph

Fourier transform frequency signatures

The utility of spatial frequency power-spectrum sampling for automatically classifying patterns in images was demonstrated by Lendaris and Stanley,[14] with particular applications to detecting targets in aerial photographs. The purpose of this section is to consider the applications to biomedical images.

The usefulness of frequency sampling is based on the fact that certain features of an image function may be more distinguishable in the frequency domain than in the spatial domain. Also, a large data reduction may be affected and the features still distinguished.

The frequency signature consists of a set of n samples, where n is the number of sampling areas for a given sampling geometry. Several sampling geometries may be used. An annular ring sampling geometry is suited to the detection of circular objects. A wedge shaped geometry can be used to detect periodic line structures in an image. A horizontal or vertical slit may be used to detect an axis feature. A well-known property of the two-dimensional Fourier transform is that the transform of a circularly symmetric object is also circularly symmetric. Thus, if one is trying to detect circular objects, an annular ring sampling geometry is appropriate. Peaks in this circular sampled signature would correspond to energy at a given radial distance in the transform space.

Template matching

Suppose that an image function of known form which is non-zero only over a finite rectangular region is perturbed by additive noise. The filter which maximizes the ratio of signal power to average noise power at the filter output at some spatial position is called a matched filter.[15] A detection decision may be made by sampling the matched filter output at the position and comparing this value to a threshold. A matched filter detection is not affected by a translation of the signal; however, it is sensitive to rotation. The matched filter is also sensitive to magnification changes. If only a small size variation in the desired signal is expected, then a search through several sizes may be reasonable.

Directional signatures

A simple but powerful technique for locating objects in fixed frame images consists of gray level directional signatures (e.g., Meyers, et al.).[16] A fixed frame image set consists of images of similar objects; for example, chest, head, or leg X-rays. Normalization is a significant but solvable problem. The directional signature consists of a function which is the sum of the gray level pixel values along a line normal to a reference line. The x and y direction signatures for a chest X-ray are shown in Figure 9. Note that major objects such as the clavicle, the lungs, the heart, and the diaphragm, may be located from the signatures. The signature information allows one to "zoom" in on a particular object. After an object has been located, measurements such as size or texture may be made.

Contour tracing

Edge structure is a significant feature in many radiographic images, and motivates the development of computer algorithms for extracting edge information. These programs are often called contour trace programs. A position in a picture where two objects meet will be characterized by a change in the gray shades in the picture array. This has suggested a search for points where the rates of change (deviations) of the picture array PIC (I, J) are large. Once these points are found, some form of logic is then used to connect these points together to form the boundary of the object. There are variations in these techniques including level slicing and contour tracing, but the results tend to remain much the same. This method has several problems. First, due to the noise that will invariably be present in the picture array, contour trace algorithm will tend to give gaps and false spurs. If there are touching and overlapping objects, a contour trace program will tend to switch from one object to another before a boundary of an object is completely traced. Contour trace programs are local algorithms and as such have the following problems: If mistakes are made, such as gaps, they must be corrected later. If there are several objects in the scene, a contour trace algorithm has no way of knowing that it is following a particular object and must be careful not to stray from it. Therefore this technique suffers from the problem of making mistakes which are passed on to the later stages of corrections, namely the pattern recognition stage. Thus, there is the very real problem of errors accumulating through the various processing stages.

Another method that has shown some utility is often called region enumeration. This method tends to be the inverse of contour tracing. In this method a point x = (i,j) in the picture array is located, perhaps by a raster scan, and one desires to identify the points that lie in the same region with x. There will be a property P(y) that one uses to determine if a point y is in the region. First, one finds x; then one examines the 8 neighbors of x. Let y be one of these points. If y has the property P, then y is placed in the region with x, otherwise it is not placed in the region. The process is repeated spreading out from x until all the contiguous points with the property P are placed in the same region. Often the property P will relate to the gray level of the point. For example, does point y have the same picture value as x? Or an average gray value of the region may be kept and y is tested to see if its picture value PIC(y) is close to the average value. Other P's can also be used. There are variations of these techniques in which one uses thresholding with region enumeration. Thus, we see that region enumeration seeks to identify all the points in a region, not the boundary points, and to do this it places points in the region if it is not on the edge of the object, while contour tracing looks for edge points.

The descriptive approach to image analysis

An approach to feature extraction that we usually refer to as the descriptive approach will now be briefly described. Other authors have described related work but have not applied it to radiographs.[17,18,19,20] It is possible that this method can be applied to a number of medical picture classes. Thus far we have applied the method to the analysis of AP chest X-ray with the goal of diagnosing abnormality in the heart and lungs. Since that time, the same program has been applied to AP X-ray of the knee and nuclear medicine images. There are several basic assumptions behind this method.

(1) The analysis of a scene should be top down. That is, one should first analyze the large objects in the scene at the lowest possible resolution and later analyze the finer objects in the scene as details of the large objects.
(2) Feature extraction and pattern recognition must be combined into a reinforcing system, i.e., a system with feedback. That is, feature extraction is not a separate process from pattern recognition; pattern recognition is an integral part of feature extraction and must be included from the beginning.
(3) One must have within the program a comprehensive description of the class of scenes to be analyzed. This description must guide the scene analysis system from beginning to end. The description should be in the form of data to a scene analysis supervisor so that one can readily analyze different scene classes without extensive reprogramming.
(4) Regions enumeration rather than some form of contour trace program should be used in primitive objective identification.
(5) All parameters in the program must be self-adjusting.
(6) The concept of field of vision is important in locating the true boundaries of objects. In many applications one must not only recognize the objects but must also determine the exact boundary of the object. An example is chest X-rays where one needs an accurate contour of the heart in order to diagnose heart disease. We believe that there are advantages in recognizing the fact that a scene is composed of objects that completely fill the area of a scene, i.e., every point in the picture is in some region and one always sees something even though it may be lumped into a catch-all category of background. These objects all fit together in jigsaw fashion to completely fill the space of the scene.

A graphical description seems natural in implementing assumptions 1 and 3. In particular a tree structure very naturally gives a top down description of the scene class. See Figures 10 and 11 for examples. In the program described in Reference 21 each node of the tree represents an object in the picture. The graph is data to the program. Thus when one changes picture

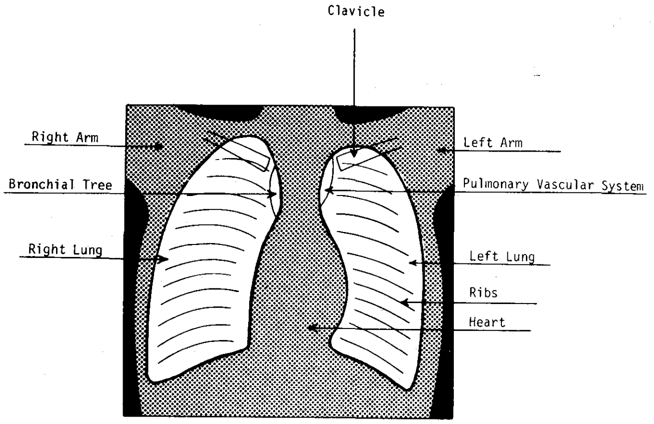

Figure 10—Anteroposterior view of chest

classes, one changes the data which describe the scene class. Attached to each node is a list of attributes for that object and a predicate that describes the objects relation to the other objects in the picture. The attributes might include such facts as:

(a) average gray level
(b) average number of points
(c) shape description such as higher order moments.

An important point to note is that using a top down search for the objects can be located with widely different resolutions. For example, our current version for the chest searches for the level one objects (diaphragm, mediastinum, right lung region, left lung region) at a 16 × 16 resolution.

One does not have to analyze the entire X-ray at once; one should first distinguish these objects from each other. If one desires very accurate descriptions of the borders, one can switch resolutions easily, retaining the information found at the lowest level. When our present program switches resolutions, it merely declassifies the boundary points between objects, then switches resolution and reenters the point classification program which decides to which object the point belongs. Thus, in moving to higher resolutions one merely reshapes the boundary to get an accurate description of the object.

The predicates attached to each node can be very valuable in identifying the objects. Many times an object in a picture has a border that has wide variations in the intensity of the picture function at the border. In places the border may not be visible at all. The predicates are a way to define the boundary of an object when the boundary may not be visible. For example, in Figure 11 consider node 7 and the predicate expressed in PL/1 notation

(L(7)|B(7)|(R(7) & (B(6)|L(6))))|
(U(7) & (B(4)|B(6)|L(6))))|
(L(7) & R(7)))|(U(7) & B(7))

This says that a point x can be put in a region associated with the left arm region only if one of the following conditions holds for the initial regions linked to the node which represents the left arm, Node 7.

(a) Region (7) is to the left of the point. This lets the region 7 grow without hindrance to the edge of the picture.
(b) Region 7 is below the point. Hence, the arm region can move toward the top of the picture without hindrance.
(c) Region 7 is to the right of the point and region 6 is either below or to the left of the point.

The other parts of the predicate are interpreted similarly.

Observe that the left arm region is thus controlled by the left lung region and points cannot be added to the region unless the left lung region lies to its left. Hence, the border is controlled by the predicate which reflects what the picture is of as well as the gray level characteristics of the picture. Figure 12 gives an example output for a program that we have implemented.

A program for the automatic computer diagnosis of rheumatic heart disease has been recently developed at the University of Missouri.[22]

The goal for this study was classification of the heart size from the standard PA chest radiograph into normal or abnormal category. If the cardiac size was judged abnormal, a further sub-classification was

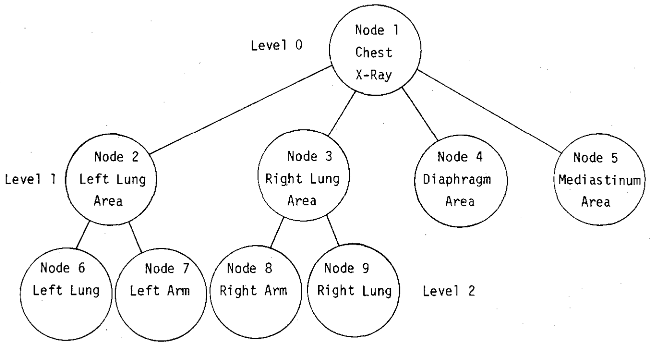

Figure 11—Partial vertical ordering of AP chest X-ray picture

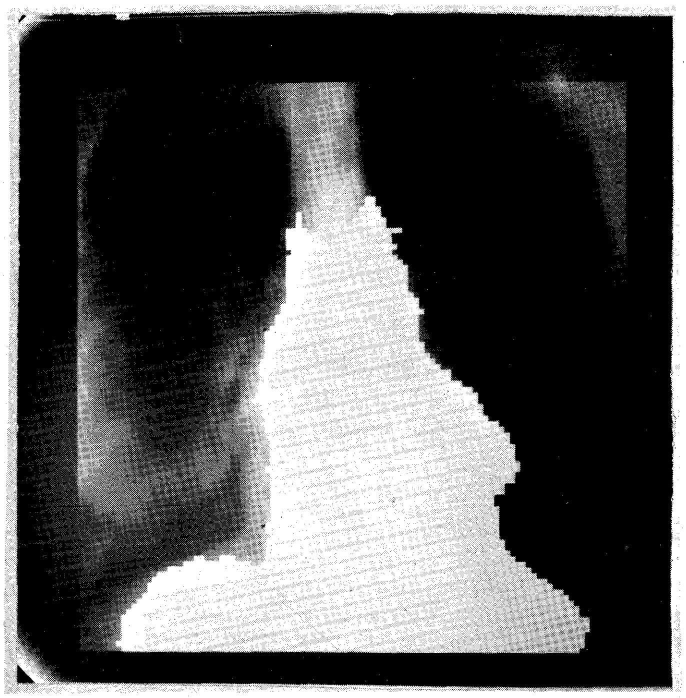

Figure 12a—Node 4—Diaphragm area

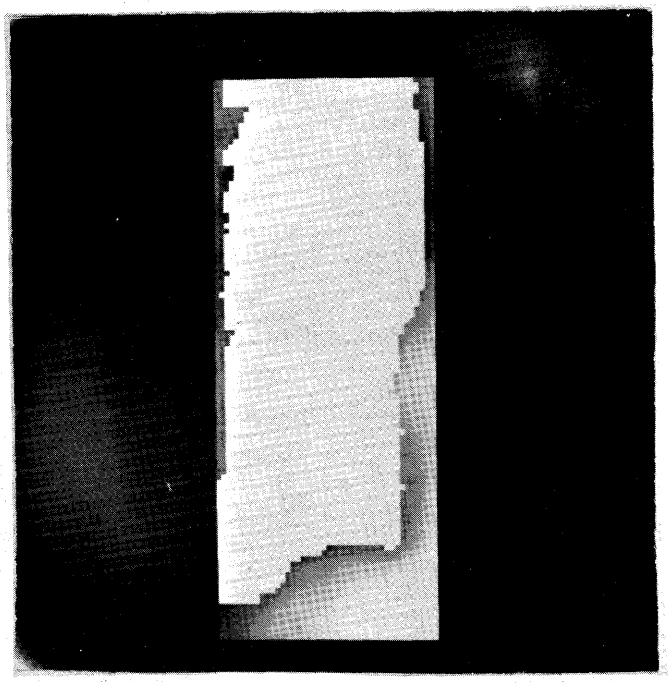

Figure 12c—Node 9—Right lung

accomplished into four separate categories of rheumatic valvular involvement. To test the basic normal-abnormal classification further, some non-rheumatic cardiac abnormalities in adults were also used as test cases. A test set of 279 cases was used. This set included 191 cases of rheumatic heart disease representing all combinations of rheumatic valvular involvement.

All patients in the abnormal group have had right and left heart catheterization and appropriate cinean-

giography to establish the correct diagnosis; 88 normal chest examinations were also selected from patients with no history of cardiac disease, no murmurs, and no cardiac symptoms. These were obtained from routine psychiatric admission chest X-rays and preoperative and employee chest examinations. The normals were selected generally from the age group of 20 to 45 in an attempt to match the age group range of the rheumatic heart disease patients included in the set of abnormals.

The first 135 cases selected as the computer testing and training set were set aside as the radiologist test set library. This separate library includes normals and all categories of rheumatic heart disease, and comprises the basis of comparing the diagnostic accuracy of the computer and the radiologist.

The first step in the feature extraction process was to extract size, contour, and shape of the heart from the standard PA film. This was accomplished by an algorithm that constructs a cardiac rectangle around the heart. The cardiac rectangle is variable in size which is dependent upon the heart size. This cardiac rectangle is obtained by spatial signature analysis.

Once the cardiac rectangle was located, a technique for obtaining the closed cardiac surface was developed. The technique involved thresholding a gray level histogram to produce a one-bit (two level) representation of the chest image within the cardiac rectangle. The algorithm, using a gray level histogram, determines the threshold for converting the extracted cardiac rectangle into a two-bit representation (black and white) image of the heart.

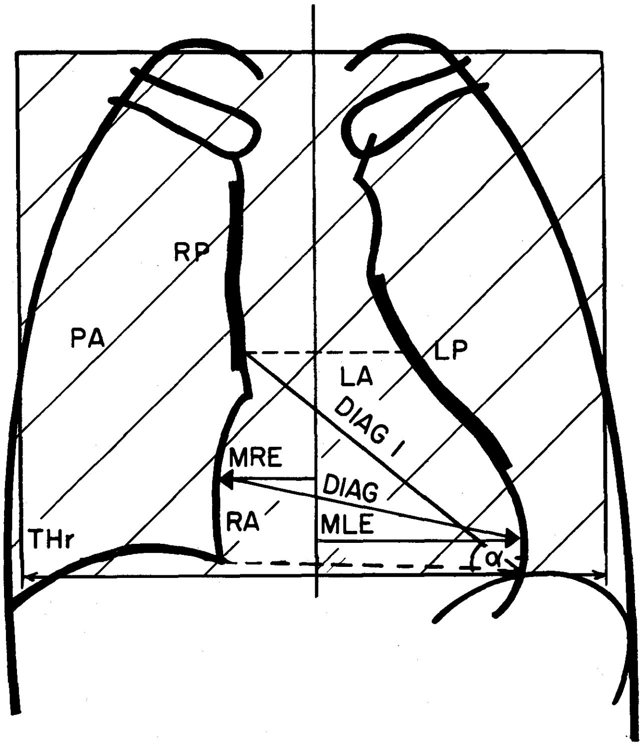

Figure 14—This shows the measurements and two polynomials extracted by the algorithm after the feature extraction phase has been accomplished

The next step was to outline the cardiac contour from this black and white representation. With the left and right outlines determined, the intersection of the right cardiac edge and the diaphragm was determined and a line was drawn from this point across to the intersection of the left cardiac edge with the diaphragm. A line was also drawn to connect the right and left top of heart (TOH) outlines so that the entire heart and portions of the pulmonary arteries are enclosed. A typical example is shown in Figure 13 a-d.

Area and extent measurements are now easily made from this closed contour. At this point, nearly all information from the standard PA chest radiograph needed for the diagnosis and classification of heart disease had been extracted, and the next step was measurement of the heart. The measurements taken are shown in Figure 14.

All cardiac measurements were normalized so that a ratio figure was obtained. The linear measurements were divided by Thr, the thoracic width, and the area measurements were divided by TA, the thoracic area. This allows correction for variation in heart sizes related to the patient's overall size. The same algorithm can also be used for different film input sizes, i.e., standard 14 × 17 inch, 35mm reduction, or chest photofluorograms.

Once these series of heart measurements have been extracted from the cardiac rectangle, this information was used as the basis for first classifying the case as normal or abnormal. If a particular case was abnormal, the classification went further by placing the case into the correct group of rheumatic heart disease.

The diagnoses were divided into 5 classes and the 16 possible combinations of aortic and mitral valve disease were divided into 4 separate groups. The classes considered by the classification scheme were:

Class 1:	Normal
Class 2:	Mitral Stenosis only
Class 3:	Other mitral valve lesions—MSMI; MI only
Class 4:	Aortic and mitral involvement
Class 5:	Aortic involvement—ASAI, AS only, AI only.

Computer classification was accomplished through the use of linear and quadratic discriminant function.[23] This classification method was selected because of its

			Testing	Training	
	Number in Class	Radiologist	Image Analysis Laboratory	Image Analysis Laboratory	BMD
Class 1, Normal	88	83%	88%	94%	94%
Class 2, MS	33	50%	21%	33%	33%
Class 3, MI, MS-MI	21	54%	10%	14%	29%
Class 4, Bivalvular	87	29%	72%	75%	70%
Class 5, Aortic	50	76%	48%	62%	60%
Total	279				
Overall Percent Correct Classification		62%	62%	69%	68%

Figure 15—Rheumatic heart disease classification results

relative simplicity and speed. Initially each part of the classification was processed using both the linear and quadratic discriminant functions. The selection for using a quadratic or linear discriminant function for each group in the final classification scheme was determined by the results: that discriminant function was chosen which gave the best results. If the accuracy was equal for both discriminant functions, the linear discriminant function was selected for the final classification scheme because it required less computer processing time.

In order to estimate the unbiased capabilities of the computer diagnostic classification scheme for the evaluation of new samples, the "jackknifing" test procedure was instituted. This procedure consists of first withdrawing ten percent of the cases from each of the five classes. The remaining ninety percent of the cases in each class with their measurement parameters and polynomials are then used to train the classification scheme. Each case in the withdrawn group is subsequently tested and classified into one of the five diagnostic classes. The withdrawn ten percent of the cases are then replaced into their respective classes, whereupon a different ten percent is withdrawn, tested, and replaced in an identical manner until all the cases have been tested. No case was tested more than once. This is a fair test, since in each case the algorithm had not "seen" the withdrawn test set until asked to make a diagnostic classification. A better test would probably have been to remove one case at a time and test each using the jackknifing procedure until all of the cases had been classified. However, this was not practical because of the large amount of computer time involved.

It would be difficult to judge the value of this automated feature extraction and classification algorithm unless its accuracy could be compared to the diagnostic accuracy of radiologists. For this reason, the following study was instituted.

Ten radiologists were asked to individually diagnose 135 representative cases of the cases evaluated by the computer. This group of radiologists consisted of 7 board certified academic radiologists and three third year residents whose training was nearly completed. Each radiologist was given the PA and lateral views and told that each case was either normal or rheumatic heart disease. He was asked to make a complete radiological diagnosis and record his answers on a form designed for the study. Each case diagnosed was counted as one physician's observation. Information on the forms was then transferred to punched cards and computer programs were written to separate the 639 physician observations collected. Not all of the physicians completed the task of reading all 135 films. A comparison of the physicians' results with the computer results is shown in Figure 15. The Image Analysis Laboratory results are those obtained using the pattern classification method just described. The BMD results are included for comparison.[24]

Overall accuracy was 62 percent for the computer and 62 percent for the group of radiologists. The overall accuracy was computed from the following equation:

$$\text{Overall accuracy} = \frac{\text{Total number correct diagnoses}}{\text{Total number of cases in test group}}$$

This example illustrates that although automatic computer diagnosis is quite different from the other methods, it is competitive and may out-perform them.

The impact of computing on the teaching of mathematics

by WALTER KOETKE

Lexington High School
Lexington, Massachussetts

A discussion of the impact of computing on the teaching of secondary school mathematics must begin with an examination of how modern computing facilities have entered and are entering the schools. The manner in which facilities are obtained often influences the way in which a mathematics program is implemented.

Most secondary schools with computing facilities used by the mathematics department have acquired their facilities in one of two ways. The key to both methods, however, is a motivated, aggressive member of the mathematics department. The reasons for this motivation vary dramatically, but without such an "inside agitator" many schools would yet be without computing facilities.

The first of the two ways by which facilities are initially acquired centers around the manner in which the school conducts its administrative data processing. Several service bureaus that specialize in educational applications have agreed to run a limited number of student programs with very little or no cost to the school. Local industries have been remarkably cooperative in providing limited computer time for the running of student programs. Many schools have had their own computing facilities used for administrative processing for the past 10 to 12 years. These facilities are usually capable of running student programs in a batch processing mode. The second way of acquiring computing facilities for mathematics requires that the school budget additional funds. Although these facilities are more desirable from an educational point of view, the add on cost makes them understandably harder to initiate. Such facilities include purchasing time from either a large commercial time sharing system or from one of several smaller time sharing services dedicated exclusively to serving the educational community. In fact, several secondary schools and small colleges have obtained small time-sharing computers that not only serve their own needs, but also permit them to sell computer time to nearby shcools—usually at a very reasonable rate. Mini-computers supporting multi-user, one language systems are being purchased at an increasing rate. Mini-computer systems that support from one to seven users are now being marketed not only by the major computer corporations, but by many smaller companies who claim to tailor the software and hardware to suit the needs of education. Several batch processing minis are also available with such options as optical card readers that purport to provide the speed of batch processing without the inconvenience of key punching all input.

Having outlined the manner in which computing facilities are obtained, a discussion of the way in which the mathematics department uses these facilities is appropriate. During the past six to eight years many schools have experienced an evolutionary sequence of four distinct applications. Unfortunately, most school systems with newly acquired facilities seem to be beginning the same four step process—without deriving much benefit from the prior experiences of others.

The first of the four steps is to teach programming for its own sake. The main objective of a course is to "learn to program." No specific attempt is made to explore mathematical topics not required to understand the programming language. This first step was a very natural one several years ago when batch processing FORTRAN was the most widely available language in schools, but this step should no longer be necessary with the more user-oriented languages and facilities available today.

The second of the four steps is to teach a course most appropriately titled "computer science." The tcpics of this course usually include a programming language, an introduction to the "insides" of a computer and how it works, and some computer related mathematics. This course is almost always offered as an elective for capable, interested students. The depth of this course is usually directly related to the computer related experience of the teacher. Several acceptable textbooks for secondary school students have been recently published for "computer science" courses.

The third step is that of using the computer as a supplement to the existing mathematics program. Occasional computer related assignments are given that complement the "traditional" mathematics being studied. Students generally have not volunteered for a special elective, but have simply enrolled in a mathematics course that happens to use the computer. This application is often thrust upon a teacher who is only half convinced of the computer's usefulness. This leads to the puzzling dilemma of the teacher's excusing an occasional student who "doesn't like the computer," but the many students who "don't like word problems, or factoring, or solving a series of three or more equations, or . . ." are told that the choice of curriculum is not theirs. The creative teacher, however, has found this supplementary work to provide an excellent opportunity to experiment with many different ideas. The results of such experimentation is one of the factors leading to the now emerging fourth step of this evolutionary process.

The fourth step is that of using the computing facilities as an integral part of the mathematics curriculum. Computer use does not occur only as a supplementary topic or in an elective course, but is an accepted part of the regular mathematics program. This step is just beginning to be achieved in a few school systems. Although this step is the goal of many mathematics departments, supporting textbooks are not yet widely available. This use will, however, develop as the major application in most secondary schools. In this step the computer is used as one of several tools available to the student of mathematics. The computer is used when its application is appropriate and ignored when it is not.

Let's look more closely at how the computer is used as a problem solving tool in this fourth step. The problem solving application is not a drill and practice program used to review rote facts, it is not a computer-assisted instruction application in which the computer presents a pre-programmed lesson, and it is not an application of computer-managed instruction in which the computer is used to log the progress of individual students. Rather, the student is given a mathematics "assignment" just as he is given an assignment if no computing facilities are available. The difference, however, is that the solution to some of the problems may require the use of the computer. In many instances, the student himself must select the problems appropriate for computer solution. When computer use is required, the student must write his own program, enter it into the computer, and complete all required debugging until a solution is obtained. The only "canned program" the student uses is the programming language itself which is the vehicle utilized to solve the mathematical problems. Students in such a course are likely to average writing one or more programs per week. They are, of course, free to write more, but one per week is the number they are required to complete. This type of application is best implemented using some type of interactive terminal. Although batch processing is an acceptable alternative, some important benefits are lost without on-line interaction.

Implementation of the problem solving application seems most successful if terminals are available in a mathematical laboratory rather than a classroom situation. Since a single interactive terminal is most effective when used by one or possibly two students, classroom use is not very efficient unless the terminal is being used as part of a demonstration in connection with some type of projection device. Although some schools have unfortunately experienced occasional incidents of vandalism, an open laboratory in which students are free to schedule their own use of the computer has proved very successful in many installations. Although some type of control is necessary so that many different students can use the facilities, this control should be only that which is absolutely necessary. Ideally the only enforced regulation is one that limits the total time a student is permitted to use the facility. Such a limit not only increases the number of students who can be served, but also forces the student to be "better prepared" when he does use the computer.

How do students using the computer as part of the regular mathematics program learn to program? They should be able to learn the required programming as part of the mathematics course. The programming language used must, therefore, permit the implementation of sophisticated algorithms yet also be very easy for the beginner.

The past 12 to 18 months have reflected school systems acquiring computer facilities at a continuously increasing rate. I suggest that this rate will continue to increase until it "soars" in another 12 to 24 months. There are several reasons for the presently increasing growth rate and the projected increase in this rate. The importance of these reasons varies among school systems, so the order in which these reasons are listed in this paper is not significant.

First is the simple fact that the cost of acquiring computer facilities has been reduced to an acceptable level. More than one school committee has noted that computer facilities can now be acquired for less than the average salary of a teacher, and that's not very much. The reduced cost has been evidenced in the purchase price of mini-computers, the rental of time-shared terminals, and leasing agreements of many batch processing systems. If there is a single most important reason for the increased growth rate, the reduction in price is the most likely suggestion.

A second reason is an increased awareness by both teachers and administrators that computing facilities have become a necessary part of the mathematics program. Although controlled experiments with significant quantitative results demonstrating the value of using the computer are almost non-existent, overwhelming qualitative evaluations ardently support the acquisition of computer facilities. In one of the few quantitative studies seen by the author, students using computer facilities and a control group were given a pre- and post-test in abstract reasoning. The increase in the group mean of the group using the computer was four times that of the control group.

The wider availability of BASIC is the third reason for the increasing growth rate. BASIC is not here defended as the "best" programming language. It is, however, offered as the most appropriate language for present secondary school requirements. Remember that the primary application of the computing facilities is problem solving, not computer science. The computer is to be used as a problem solving tool, thus the programming language itself should not be a problem for the students. Languages such as FORTRAN and APL are themselves problems for most students. The language used must also be well documented, not just in vendor's operating manuals but in the wider literature of mathematics. Languages like FOCAL, CAL and TELCOMP are certainly easy to learn, but they are not often referenced in the literature. BASIC, however, satisfies both of these requirements—it is very easy to learn and commonly referenced in the literature.

A fourth reason for the increasing growth rate is the also increasing number of teachers who want to and are qualified to utilize computing facilities with their mathematics classes. This is partially due to the growing number of good inservice courses being offered in many schools of education. Many new inservice courses are, however, strictly "how to program" classes that do not help teachers implement their new skill in the classroom.

Local school board pressure to "keep up with the competition" who have already acquired computer facilities is the fifth reason. Although this is not a very defensible reason for action, the movement is in the direction of improving education so we should accept rather than condemn it. Such action, however, occasionally results in disastrous experiences when computing facilities are thrust upon unprepared or uninterested teachers.

The sixth and final reason to be listed has not yet happened, but will soon be responsible for giving additional impetus to the growth rate. The fourth and most desirable application of computing facilities was as a tool in the regular curriculum courses. Although this is now being done in some school systems, it is done without the benefit of a single textbook for the students. Such textbooks are, however, now being prepared by several major publishers. When these textbooks are actually marketed in another 12 to 18 months, large numbers of already capable teachers will have the materials for which they've been waiting. This should result in an even greater demand for computing facilities in secondary schools—including those schools that already have modest facilities that are not yet required to serve the majority of mathematics students.

Having examined the manner in which secondary schools acquire computing facilities, the way in which these facilities are used, and the reasons for the continually increasing interest in acquiring such facilities, we will now partially answer the most important question—"Why use the computer in the study of mathematics?"

The history of mathematics shows that the major emphasis of mathematics has shifted from geometry, to algebra, to calculus, to non-Euclidian geometry, and now to algorithms and computation. As the emphasis of mathematics shifts to best serve the needs of society, so also should mathematics education. Topics related to algorithms and computation can no longer be treated as supplementary; they have become a very necessary and important part of the mathematics curriculum.

The history of mathematics also reveals that mathematicians have spent a great deal of time creating ingenious ways to avoid computation. Modern computing facilities have, however, eliminated the need for many of these clever computational aids. Once difficult topics have become quite easy, and many new topics have become very important. Quite simply, the computer has rearranged the priorities of modern mathematics and these new priorities should be reflected in the mathematics classroom. Consider, for example, the "traditional" student of first year algebra and his accrued ability to find the zeroes of a function. He can probably find the zero of any linear function he encounters. If he was in a fast moving class he can even solve quadratic functions—especially those that are factorable. Can he solve other polynomial functions of higher degree? No. Can he solve any other type of function? No—he may not even know that other types of functions exist. If the student is persistent for an additional two to three years, he will eventually learn Newton's method or a similar algorithm that can be used to find the zero of almost any function. The path to this general algorithm is littered with "useful" techniques such as factoring a quartic or even higher degree polynomial to obtain the zeroes. The student in a first year algebra class that has access to computer facilities can study functions and their zeroes in a very different manner. For example, he can locate zeroes of almost any function by searching the domain for a change in either the sign or the slope of the function. This technique will not only reveal the zeroes, but also permit the student to explore maximum and minimum values of a function in an informal yet precise manner. There are of course, many similar examples of now important topics that can only be taught very superficially if at all without access to computing facilities. Listing these topics is not, however, the purpose of this paper. Topics that fall under the general heading of Monte Carlo Methods are fascinating to almost all students. Computing facilities permit the inclusion of some of these now important topics. Probability and statistics cannot only receive increased emphasis with computer use, but realistic problems can be approached rather than superficial models that don't really communicate the meaning of or need for the ideas being studied.

In addition to reflecting some of the priorities of today's mathematics, use of the computer as a problem solving tool helps teach that which is the real purpose of all education—how to think. Although teaching students how to think is the goal of education, there is no course at any grade level in which that is the prime topic, nor is there any methods course in related teaching techniques offered to prospective teachers. Computer facilities will not immediately change this dilemma, but the analytic and algorithmic thought processes are so much a part of programming and related problem solving that students cannot avoid learning them in a well presented course. As one would hope, there is a great deal of qualitative evidence indicating that students do transfer these processes to other disciplines as well. Fortunately, a growing number of mathematics educators have begun to realize that a student's mathematics education should be judged by how he reacts to problems rather than by a list of courses and grades. Computer assisted problem solving and accompanying algorithmic thought help students develop a very sound approach to many types of problem solving in many different disciplines.

Some of the ways in which computer use helps develop analytic and algorithmic thought processes might be clarified by an example. Consider the problem of describing the solution set of a quadratic inequality. A traditional text presents this topic by first listing several specific examples, then asking the student to solve several other specific examples. In a subsequent class, the student is told which of his answers are wrong. A presentation of the same topic with computing facilities available might well begin in the same manner—but it would go further. Students would first be asked to solve a few specific examples using pencil and paper, then asked to write a program that would permit a user to enter any set of values for A, B and C, then print the solution set of the inequality $Ax^2+Bx+C>0$. To write the algorithm for such a program the student would likely have to create and solve many specific examples. He would not bother with the arithmetic exercise of solving examples he knows how to complete. Instead, he could concentrate exclusively on the cases for which he is unsure of the solution set. When testing this program, as with many other programs, the student must "debug" his algorithm. He is not faced with a simple right or wrong situation, but one in which he is likely to be partially right. He must then determine which portion is not correct and the required procedure for correcting it. The entire process of debugging a partially correct algorithm is a realistic valuable experience that is rarely encountered in more traditional courses. Few problems the student will face in any areas of his life will be countered with a solution that is all right or all wrong. The solution will be partially correct and will require repeated debugging.

As computing facilities become available in the large majority of secondary schools, the students, the teachers, and the computing industry itself will feel the effects. The remainder of this paper is devoted to an examination of these effects. Note that some of these effects are already a reality while others are the predictions of the author.

The most immediate and obvious effect upon students is their high degree of motivation. The reason for this motivation changes from student to student. In fact most students seem to sustain their motivation for a shifting set of personal reasons. Skeptics point out that use of computing facilities in a mathematics class does not motivate all students. That is certainly true, but it does motivate most of them. Unfortunately, the same cannot be said for either the content or presentation of most traditional classes. Skeptics also profess that most of the student motivation is simply fascination with a new type of hardware. Although this might well be true at first, the source of student motivation soon shifts to many diverse, more personal reasons. I suggest, however, that even if new hardware were the one and only motivating factor, that's fine. Most teachers are well aware of the fact that motivating students is at least half of their job, and they would be delighted to find any proven method or "machine" that will develop sustained motivation in their classes.

Another effect upon students is that the present "ability grouping" of classes will have to be restructured. Since these groupings often represent present motivation or the results of past motivation, any factor that significantly alters motivation will also alter the groupings. Preliminary evaluations of computer use in mathematics classes indicate that the gap between the "good" and "bad" students is significantly reduced. There are many possible reasons for this. For example, the "good" students are already highly motivated so they do not benefit from that aspect of using the computing facilities.

The study of algorithms and computation permits students to make genuine discoveries. They are able to develop significant new computing algorithms and improve upon those that already exist. Students cannot improve upon the proof of a theorem in plane geometry nor uncover an unknown property of the real numbers. These are unlikely occurrences at any level of mathematical sophistication, and those suggesting that secondary students often make such discoveries kid only themselves. Although a skillful teacher could lead some students to the belief that they have made a discovery—and indeed they often do make personal ones—the discoveries themselves are only contrived and the results are already well-known. In the area of algorithms and modern computation, however, the secondary student is participating in a discipline that is about 20 rather than 2,000 years old. Many students soon learn that they can indeed uncover. flaws in existing algorithms, as well as create new and better ones.

Computing facilities provide many students with a means for exploring previously unexecutable ideas. This benefit of computer use has evidenced itself not only in mathematics but in several other disciplines as well. A favorite student question, "What if . . .?" must go unanswered fewer times when computing facilities are available. More significant than the answer to this question is the fact that the student has the means to answer it himself. In 1970 a high school student discovered the 21st, 22nd, and 23rd perfect numbers. (Perfect numbers are those positive integers that equal the sum of all their divisors excluding the number itself—such as 6 and 28.) Was this student "above average?" Sure he was—so were Pythagoras, Euclid, Fermat, Descartes, Euler, and many other brilliant mathematicians who unsuccessfully sought perfect numbers during the last 2000 years. Is this student the greatest mathematician the world has known? Probably not! He was, however, a creative high school student with access to computing facilities. I feel that the three numbers he discovered and the theorems he created are of less importance than the simple fact that the entire refining process of idea to theory to algorithm to execution to proof to announced results was carried out by a high school student with access to computing facilities. I contend further that such significant work will become an accepted if not expected product of secondary school mathematics during the next decade.

Computing facilities have made and will continue to make secondary school mathematics more relevant and more interesting for students. Pinpointing a single reason for increased interest and relevance cannot be done as these vary widely between students. The simple fact that execution of a program provides the student with immediate reinforcement does much to heighten and sustain his interest. He quickly learns the extent of his success, and if he is well prepared with appropriate test cases, he also receives an immediate, impartial evaluation of his algorithm. Interest is also supported by the student's ability to solve a problem in his own way. No longer will he be told he is wrong because the first few steps of his procedure are not what his teacher expected to find. The student can now complete the entire procedure in his own way, then immediately confirm the validity of his work.

Students find computer related mathematics relevant because they are using what they know is modern technology. They are also able to solve much more complicated problems than the usual oversimplified tasks they are given. In our society of space flight, push button wars, ecological crises, widespread famine, and widespread excess—we cannot afford the luxury of oversimplification. We must be as precise as possible, and where approximation occurs it must be clearly identified and its implications understood. Even the simple concept of percent error is foreign to many traditional mathematics classrooms, yet students want to know and should know about approximation. This is yet another example of the fact that a solution to a real problem is rarely all right or all wrong. An almost right solution, however, may not be of much value unless the "amount of wrongness" can be clearly evaluated. The relevancy of the activity in mathematics classes is also heightened by the fact that students can utilize the computer in other disciplines. Although there is often little application of mathematics when students create simulations for use in science or history, tutorial programs for use in English or foreign language classes, or any of a host of other applications, there is an increased interest in both disciplines. Although the direct application of mathematics may be slight, the application of the algorithmic thought process and the application of problem solving techniques are indeed interdisciplinary. Such student projects are not only very valuable to the student, but quite often the teachers will also become involved in a meaningful interdisciplinary study.

Having examined some of the ways that computing facilities have affected and will affect students, let's now examine the corresponding effects upon teachers. The role of the teacher is altered in several important ways. Most apparent is that the time spent reminding students that they must pursue other studies in addition to mathematics far exceeds the time spent in pursuit of students who are not attempting to complete their work. Quite simply, teachers spend more time convincing students to go home than they do coercing them to do the assigned work.

The teacher's role will become much more that of an advisor rather than that of a lecturer. This new role will place much greater demands upon the teacher, and may be one reason that some teachers have resisted using available computing facilities. The role of advisor means that the teacher must maintain a working knowledge of more mathematics than he is now required to do. Many secondary school mathematics teachers have taught only a single subject—geometry or first year algebra or . . . —for several years. Even though this restricted teaching load may continue, students' pursuit of their own interests and many incidental student questions resulting from assigned programs will not be so restricted. The teacher's knowledge will be inadequate unless it extends well into many areas of mathematics.

Can teachers be expected to know all of the answers? Certainly not, yet this response is not a source of comfort but of discomfort for many teachers. Students using computing facilities remove the security of the teacher who, with his answer key, does indeed have an answer to almost all questions. This artificial security will be undermined even further because of the newness of many computing algorithms. Few teachers believe they are smarter than all of their students—but they have the decided edge of experience. However, when computing facilities are introduced, the edge of experience is removed. There are clearly many teachers who are very uncomfortable in this unfamiliar situation.

A teacher's mathematical background is likely to require some refreshment. One of the reasons for adoption of computing facilities is to reflect the changing emphasis of today's mathematics. The experienced teacher may well find himself in need of several inservice courses to update his own background in mathematics. Topics such as Monte Carlo Methods, Probability and Statistics, Approximations and Error Analysis, as well as Programming itself are some of those that may require additional study. Certainly an extensive, nationwide effort to renew support for inexpensive, convenient inservice education is in order. The positive effects of such an effort were clearly evidenced when similar support was given to the various SMSG mathematics programs. Although an effort of that great a magnitude may not be required, the majority of mathematics teachers do require some type of inservice education and that is no small undertaking. The benefits of these courses should, however, far exceed the possible inconvenience and certain expense of conducting them.

The teacher must also become familiar with a new structure in the courses he is teaching. Of course programming is new and the topics themselves will be somewhat changed and rearranged. Teachers will be able to concentrate on problem solving rather than arithmetic. Any experienced teacher can relate many stories of students becoming so "hung-up" in the arithmetic of a problem that they lose track of what the problem is all about. A traditional course in first year algebra examines polynomials that can be factored as the product of two binomials. The next topic is likely to be algebraic fractions and various techniques for their manipulation. Unfortunately, much of the topic of algebraic fractions is likely to be completely obscured because students approach almost all problems as additional exercises in factoring. Adoption of computing facilities reduces the likelihood of students getting "hung up" on the arithmetic of a problem. One can't resist the observation that problems will no longer have to have answers of 1, 10 or 100 so that the arithmetic can be more readily done by hand.

The teacher will also shift the emphasis of a mathematics course somewhat away from the current stress on structure. The structure of mathematics is indeed important, but that does not mean that the best way to teach the subject is to proceed in an orderly step by step path through this structure. After all, this certainly wasn't the order in which the mathematics was created. The structure will not, of course, be totally ignored, but it will not be emphasized until more advanced courses.

Teachers will also find themselves in a delightful new situation—they will be able to get genuinely excited about the work of their students. Students in mathematics classes using computing facilities can indeed create an exciting algorithm just as an art student can create an exciting sculpture. Clever teachers have appeared enthusiastic when a student solves a problem correctly, just as they have generated a sincere enthusiasm when a particularly "slow" student finally learns a certain technique. They have not, however, often experienced the exhilarating feeling of sharing a student's enthusiasm for something he alone has created. The strongest advocate of an idea is the person who creates it. As the computer permits the student and teacher to share in the development of new ideas, a completely new and very desirable student-teacher relationship will emerge.

Finally, let's examine some of the effects that secondary school computing facilities might have upon the computing industry. Clearly secondary schools represent a new and growing market and thus a new and growing source of profit. The nature of this market, however, is different from most others. The most important single factor in education is cost. Contrary to your feelings as taxpayers, schools do attempt to save money whenever possible. The continuing emphasis on minimizing cost permeates all phases of computer related activities. Although this concern for economy is often very desirable, it often becomes dictatorial. Many competent and valid studies of needed computing facilities have been prepared. The educational pros and cons of several systems are evaluated and closely scrutinized by several diverse committees. And then the decision is made—the school system accepts the least expensive of the proposals.

If a school system adopts computing facilities and has a bad experience with them, this experience is communicated to many, many other schools. Vendors should, therefore, make a special effort to see that the staff of a school is well prepared to utilize the facilities they are marketing. The educational customers of today are surprisingly unsophisticated in comparison to their counterparts in industry. They require a larger than usual amount of "hand-holding" both before and after a sale, and require very solid software and hardware. Although the situation will eventually change, most schools can today only use the software provided by the manufacturer. They do not have the internal capability of tailoring that software to better suit their individual needs.

Other characteristics of the educational market include the fact that the "state of the art" is not an important consideration when hardware is selected. The very latest equipment is a luxury that very few school systems can afford and even fewer systems require. Reliability and durability are far more important than extra speed or exotic features. Most school systems will acquire their computing facilities gradually over a period of several years. Thus vendors must provide very flexible systems that can be expanded with little or no "wasted" expense, yet remain an effective system at each stage of expansion. As has been evidenced previously in this paper, schools are expected to increase their demand for interactive terminals on which students can implement their BASIC programs. The interactive requirement may be altered in some situations, but it is unlikely that BASIC will be replaced during the next few years.

Finally, I hope that one effect upon industry is that more of you get involved in secondary schools. I intend no disrespect for my profession when I state that we need all the help we can get. Offer to teach a special course in your local school system to students, to teachers or both. Assist your school administration and school committee in evaluating various facilities and the benefits they offer. The educational process you support now will repay all of us in the future—and while providing this support you too may have the opportunity to share the real joy of working with today's young people.

Computing in the high school—Past, present and future—And its unreasonable effectiveness in the teaching of mathematics

by WARREN STENBERG

University of Minnesota
Minneapolis, Minnesota

Five years ago computing was trickling into the secondary school scene, but today it's a torrent. Various hardware and software developments over the last two decades have made the computer ever more appropriate for this environment. These developments were: the shared program; the replacement of vacuum tubes by cores; compilers and procedural languages and finally—time sharing. The latest development has been the great reduction in the price of time sharing over the last year.

Six or seven years ago the pattern of computer use in the schools was very different from today. Some schools purchased table top computers with memory too small to contain a compiler so that students programmed in assembler language. (This had some disadvantages which I'll comment on later.) A second pattern saw the teacher carrying the student's program decks to a friendly college or industry to be run in batch mode during off hours. This method had the disadvantage that it took several days to get the three or four runs usually necessary for debugging.

But today we have an entirely different scene. Today it's all time sharing. I illustrate by describing the situation in Minnesota where I have my best access to information. For the last three years we have had time sharing in a few schools in the Twin Cities area on an individual port rental basis. Today every Junior and Senior High School in Minneapolis and St. Paul has at least one console. This also holds true of most of the suburbs. In the outlying areas of the state, time sharing has not as yet made a very strong showing.

After this glimpse at the hardware trends in the schools, it's time to see what the computer is doing there. The types of computer use fall generally into four categories:

1st Computer Assisted Instruction (CAI)
2nd Student use of canned programs including simulation
3rd Student programming
4th Computing courses

(The first three categories involve use of the computer in courses in the traditional curriculum.)

CAI is essentially a programmed textbook with the computer turning the pages. My personal prejudice (shared by many people I have talked to) is to be very skeptical of CAI as a substitute for the teacher in the classroom. But I see a great future for it in the areas of drill, review and remedial work. So far CAI is nonexistent in Minnesota secondary schools. At present the main deterrent to CAI is cost. If the cost factor were eliminated there would still be the impediment of the scarcity of CAI materials. At the University of Minnesota, CAI is extensively used in the beginning German course. The cost per student hour at the console is about one dollar; each student spends about five hours per week at the console. This totals up to $50 per student per 10 week quarter. In addition the hardware (CRT terminals) is exorbitantly expensive. Also the development of the software for this course was about $20,000 not counting the overhead of maintenance of the CAI center at the University of Minnesota. This program would have been impossible without generous foundation support. According to experts of the University of Minnesota, economically feasible CAI depends on two developments: first dramatic hardware improvements—probably replacement of cores by integrated circuits; second, increasing the amount of activity at the terminal end of the system—computer controlled slide projectors, film clips and audio cassette players. Even assuming that the necessary hardware developments will be forthcoming, the development of the course materials will require national dedication to the project and many millions of dollars of financial support. Even in this era of electrifying change, a decade would seem a conservative estimate for the realization of the potential of CAI.

Computer science courses have not as yet played a major role in the computer use in the secondary scene but they now seem to be coming up fast. In Minneapolis three high schools currently have such courses. Next year six schools will have such courses and in two years it is estimated that all the city's high schools will have them. Representatives of the University of Minnesota computer science department believe that within a few years the content of their present first course will be so widely offered in high schools that it will no longer be offered at the University except as a remedial no credit course.

But we are confronted with a very definite problem in connection with this movement of shoving the first computer science course back into the high school. The problem is that no standard curriculum has as yet been developed for these courses. Each teacher is "doing his own thing." A great deal of highly creative course development is taking place with bits and pieces being assembled from various sources; textbooks are generally not used. This is actually a very healthy development but still it creates a problem for the colleges. For they cannot know just what the students passing through these courses know about computing. So there is an urgent need for state departments of education to establish guide-lines or syllabi for computing courses. These should be worked out in collaboration with high school teachers and college computer science departments. These guide-lines should be sufficiently flexible as to encourage the creativity and originality of the individual teachers but they are altogether necessary lest the high school programs go to waste. First steps in this direction are now being taken in Minnesota.

Actually we can foresee three kinds of computing courses in the high school:

(1) *The College Preparatory Course.* This emphasizes algorithms and programming probably with the major stress on mathematical algorithms. It includes subscripted variables, functions and procedures. This course could be an alternative for one semester of mathematics.

(2) *The Engineering Course.* This course would include some algorithms, but the stress would be placed on computer logic and circuitry, binary arithmetic etc. In a lab associated with the course students would construct models of computer components. The course might include a quick pass over some elementary principles of electronics. The course could be used as a substitute for a semester of science.

(3) *The Vocational Course.* This course would consist of data processing techniques, the COBOL language, and an experience with operating a computer. Though primarily conceived for the non-college bound student, the course could be useful for the potential student of business.

The latter two courses are still in the category of pipe dreams since the teaching personnel just does not exist.

So far we have been discussing computing courses in the secondary schools. It's time that we should, turn our attention to the other face of the coin—the use of the computer in the conventional curriculum. This category makes up the great bulk of computer use in the schools at the present time. It is first necessary to recognize the sharp dichotomy between the use of the computer in mathematics courses and the use in other curricular areas. In mathematics courses virtually all computer applications involve the student in constructing his own algorithms and writing his own programs. Outside mathematics the situation is completely reversed. Here the student does no programming himself but works with canned programs where he supplies data or changes the values of parameters and observes the effect on the resulting output. These applications fall generally into the category of simulation or computer games. The programs involved are long and complicated. They will not be worked out by the individual teachers—they will be developed by experts. A teacher using them won't have to know anything about the actual programming—he merely has to be confident that they do what they are supposed to. In other words, the teacher using the computer in non-mathematics courses needs to know next to nothing about computing—only how to call up the program and plug in numbers. Contrariwise, the mathematics teacher has to know enough programming to teach it to his students and to help debug their programs.

On the basis of these observations one might suppose that the non-mathematical use of computers, since it is so much less demanding on the teachers, would be much more widespread than the mathematical use. The exact opposite is actually the case. Why? The reasons for this phenomenon are easily identified. They are:

(1) the non-mathematics teacher assumes that any use of the computer involved vast technical knowledge and this inspires him with fear bordering on terror;

(2) he receives no training in computer use in his college training mainly because the education faculty adopts the same attitude toward computing as he does;
(3) the availability of computer oriented materials outside mathematics is still comparatively sparce;
(4) information about existing materials is not readily accessible to teachers;
(5) the importance of computing is nowhere near as great in other areas as it is in mathematics.

To rectify this situation four measures are necessary:

(1) faculties in schools of education must themselves be educated in the use of the computer in their fields;
(2) teachers' institutes featuring the application of computers outside of mathematics must be promoted;
(3) city school systems must hire specialists in non-mathematical uses of computing who can indoctrinate teachers and keep them informed of current developments;
(4) computer oriented student texts and supplements must be produced.

Basically, developments in this area involve a two-stage process—training the education faculty to train the teachers. For this reason developments will be relatively slow in coming unless the National Science Foundation and the U.S. Office of Education decide to initiate a crash program.

The situation is much brighter in the area of mathematics—the reasons being that the effectiveness of computing in mathematics is quite obvious; a large amount of material is available; and the technological aspects of computing hold relatively less terror for the math teacher. The way in which the math teacher has obtained his training may come as something of a surprise. Up to now it has been almost all in-service rather than pre-service training. NSF summer institutes have played a major role here. But in Minnesota, University sponsored summer institutes and academic year seminars have been even more important. Last summer, 60 Minnesota high school teachers participated in a university sponsored summer seminar. Currently 77 Minneapolis math teachers are participating in an institute jointly sponsored by the Minneapolis school system and the University of Minnesota. Better than half the junior and senior high school math teachers in Minneapolis schools have now had computer training. All math students in this school system will have some exposure to the computer.

In outlying areas of the state as might be expected, we see a much bleaker picture. Where the teachers and schools are widely dispersed, teacher training becomes more difficult and the acquisition of hardware presents a formidable obstacle. These problems can only be solved if the state department of education assumes the initiative in forming cooperative regional networks. Such a regional network has been set up in the junior college system. All of Minnesota's junior colleges now have consoles, a development which came to fruition during the current academic year. (As a footnote it is interesting that Minnesota's junior colleges are exhibiting an interesting counter-trend; the chief customers for computing here are the physics courses—the result of a particularly effective training program for junior college physics teachers.)

In spite of this counter trend, the computer in the high school is closely associated with the mathematics program. One reason for this is that elementary mathematical algorithms involve much less extensive knowledge of programming than non-mathematical algorithms and so provide a convenient vehicle for initiating the student in computing. But this is of relatively minor importance. The more fundamental aspect of this interaction is found in the impact of the algorithmic approach in the clarification of mathematical concepts. In college mathematics this impact seems likely to completely revolutionize the teaching of calculus, linear algebra, ordinary differential equations and numerical analysis. And the impact of the algorithmic approach looms no less dramatically on the secondary mathematics scene, so dramatically in fact that there is the temptation to try to use it everywhere, even in those places where it is inappropriate. The great scientist Eugene Wigner has spoken of the "unreasonable effectiveness of mathematics in the physical sciences." In the title of this talk I have paraphrased Wigner's words to "the unreasonable effectiveness of computing in mathematical pedagogy." And indeed this effectiveness is so great as to seem almost mysterious. Now I will try to uncover some of the clues to this mystery which I catalog below.

PRINCIPAL WAYS IN WHICH COMPUTING AFFECTS MATHEMATICAL PEDAGOGY

- Dynamic vs. Static Approach
- Computing Attitude toward Variables
- Development of Problem Solving Technique

- Affinity between Algorithm Construction and Theorem Proving
- Mathematical Topics which are Algorithmic in Nature
- The "Teaching Effect"
- The Stimulation to do Independent Work
- The Excitement of Being Involved in Modern Technology.

Now let's examine and explain the items in this catalog.

Dynamic vs. static approach

In computer oriented mathematics the emphasis is on "what you do to find it" rather than on "what it is." This particularly applies to definitions and existence theorems which can often be put into an algorithmic setting. I believe that the vast majority of students tend to think dynamically and be stimulated by this more active approach.

The computer attitude toward variables

There is a subtle but important difference between the computer attitude toward variables and the traditional mathematical attitude. Traditionally, a variable is a symbol for which values may be substituted from a certain set called the domain of the variable. In computing a variable is a symbol which at any time has a definite value although this value may change from time to time. In the computing approach the student feels that variables stand for something concrete and definite and thus feels more at home with variables and arithmetic expressions.

The profound importance of this subtle distinction was first brought home to me when I was observing a seventh grade class trying out some SMSG text materials on flow charting. The teacher was quite pessimistic about the prospects for success. He said that seventh grade students could understand arithmetic expressions to the extent of being able to substitute values for the variables to evaluate the expression, but that they could not manipulate with the expressions to find other equivalent forms. It turned out that the students had no difficulty with the material but in fact assimilated it at a prodigious rate. I remember particularly vividly the reaction to the simple over-time algorithm in Figure 1 where the variables stand for wage, rate and time. One student commented that the expression $R\times 40+1.5\times R\times(T-40)$ could be simplified to $R\times(40+1.5\times(T-40))$ which would be more efficient as it would require one less arithmetic operation Another student observed that the expression could be still further simplified to $R\times(1.5\times T-20)$. The class agreed with these simplifications and appreciated the reasons for them. The teacher and I were both quite dazzled by the easy familiarity with arithmetic expressions on the part of these seventh graders with no experience in algebra. And this was on the first day of flow charting with numerical algorithms.

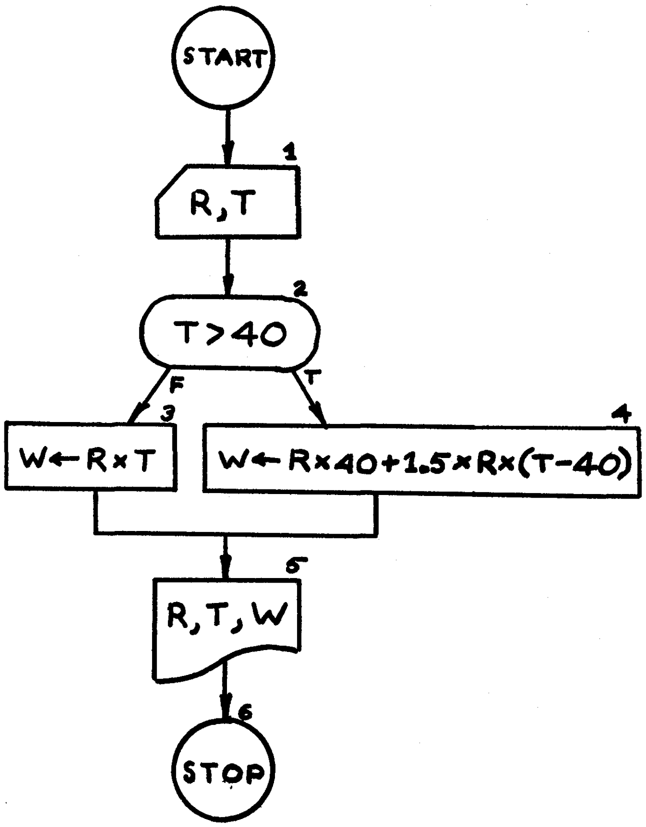

Figure 1—Over-time

One difficulty some students seem to have with mathematics is that arithmetic expressions when they become too complicated have no meaning for them. They see these expressions only as strings of symbols. This applies already to such an expression as the quadratic formula

$$\frac{-B+\sqrt{B^2-4\cdot A\cdot C}}{2\cdot A}$$

In the computing approach they tend to see the expression as being in itself an algorithm for calculating a particular numerical value.

This motivates a remark I'd like to make on computer languages. I have long felt that in more advanced courses applying the computer, such as computer calculus, it is absolutely necessary to use procedural languages like FORTRAN or BASIC. The difficulty with assembler languages is that students get involved in so much detail that they lose sight of the original mathematical ideas. Experiments with teaching computer calculus using assembler languages have borne this out. However, in earlier grade levels where the problem consists of appreciating the meaning of arithmetic expressions the situation is entirely reversed. Here in programming with a prototype assembler language such as SAMOS the student plays the role of a compiler as it were and breaks the expression into its component parts, thus getting a real feeling for the meaning of arithmetic expressions. I hope some experiments will be made to test this pedagogical technique in the seventh or even the sixth grade.

Development of problem solving technique

Most teachers have had the frustrating experience that many students faced with a problem where they can't see the path from beginning to end just can't be made to do anything at all. We just can't seem to get them to pick up a pencil and start writing *something*. Experience with algorithm construction changes all that. Here students learn to find the heart of the algorithm—the fundamental idea—and then to work both ways from the heart. They soon appreciate the futility of trying to start at the beginning and work toward the end. They learn to have patience with their abortive efforts.

Once the student finds a solution, any solution, he stands back and looks for simplifications and improvements. He looks for improvements in the efficiency, the elegance, the clarity of his algorithm. He also looks for additional features he can add to the algorithm, making it do more.

All this is the essence of problem solving and theorem proving in mathematics. The difference is that in the computing setting students take to these activities like a duck to water. The ability to handle hard problems is not confined to the gifted. Many students learn to tackle really difficult algorithms requiring weeks of work, breaking them down into their component parts and putting the pieces back together. As one by-product of teaching computer oriented mathematics we hope to tap this problem solving power and direct it toward solving mathematics problems.

Affinity between algorithm construction and theorem proving

We have already seen in the discussion of problem solving how the mental attitudes necessary for theorem proving are stimulated by the computer viewpoint. But the relation between computing and theorem proving is more than just an analogy. In the computer approach to calculus and linear algebra most of the existence theorems are nothing more than algorithms. "If you can show how to find it you know it exists." This suggests a constructive approach to mathematics as in fact is the case. Although we do not accept all the goals of the intuitionists, we travel a long way down the road with them.

One result of presenting mathematics from a computer approach is that the entire course is reorganized. Although we arrive at essentially the same destination we get there by an entirely different route. The advantage is that the average student will understand more of the theory and the top student will understand it better. There are very definite levels of understanding. It is one thing to follow the steps in a proof. It is another thing to feel it with a sense of inevitability.

These remarks may help to dispel a popular misconception relating to computer oriented math courses. It is widely supposed that in such courses we use calculations as a substitute for theory. In actuality the main function of computing in these courses is to reinforce and promote the understanding of theory.

Mathematical topics which are algorithmic in nature

There are a large number of mathematical topics which are intrinsically of an algorithmic nature. In college mathematics some of these topics are: convergence of sequences, the definite integral, ordinary differential equations, numerical analysis, and practically all of linear algebra. There are also many topics in high school mathematics which lend themselves to algorithmic treatment. Among them are: solutions of systems of equations, the Euclidean algorithm and the fundamental theorem of arithmetic, a wealth of material connected with factoring and primes, area under curves, mathematical induction, sigma notation, square roots by the "divide and average" (Newton's) method. In the traditional ways of teaching these subjects, the algorithmic approach has not been stressed. Most of these subjects have been very poorly understood by students. The algorithmic approach should produce a high level of comprehension. A couple of examples are in order to show why.

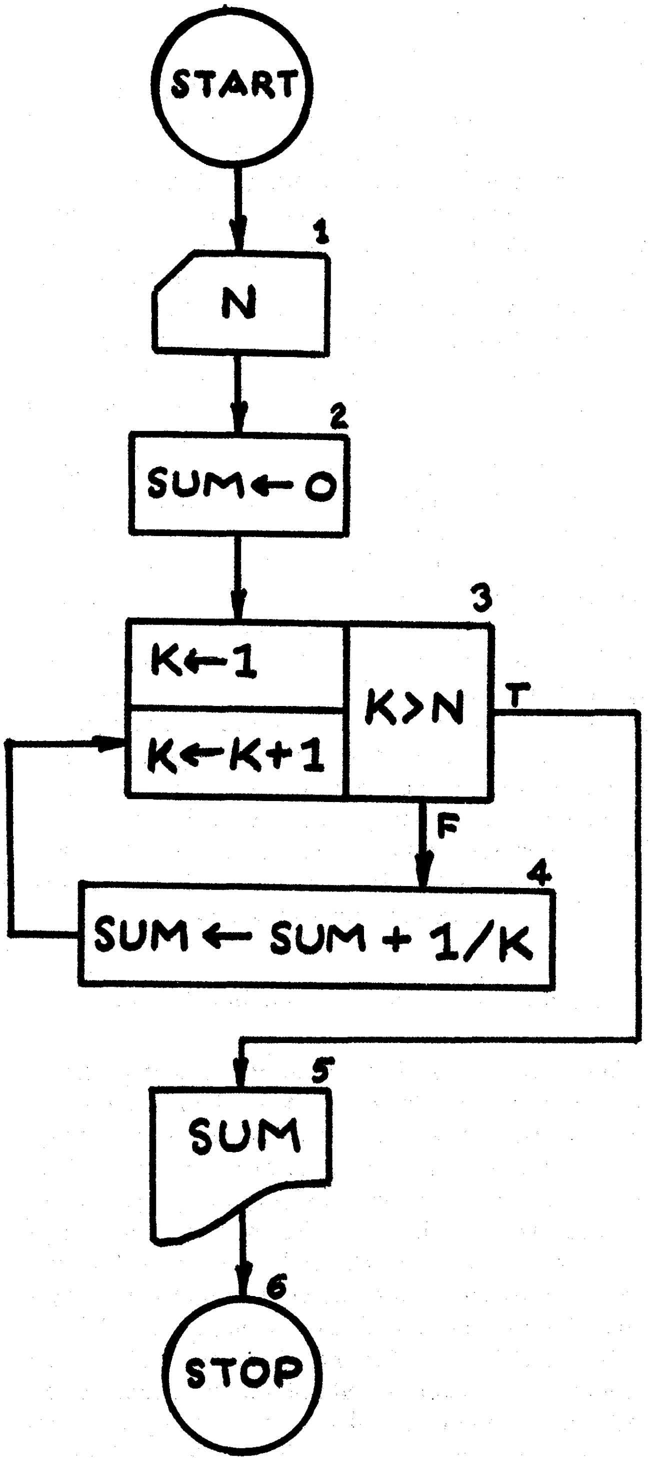

Figure 2—Sigma notation

The sigma notation, as exemplified in

$$\sum_{k=1}^{n} \frac{1}{k}$$

is nothing but a shorthand notation for the algorithm depicted in Figure 2. Students traditionally have a great deal of difficulty with this notation. If you don't believe it, ask your students to find

$$\sum_{k=1}^{100} 1$$

Using the algorithmic approach the student can be asked to trace the flow chart of Figure 2 by hand (with $1/k$ replaced by 1) until he sees what it does.

We see here that our very definition of the sigma notation is as an instruction to perform a calculation rather than as the result of this calculation. This is an example of the dynamic as opposed to the static treatment. Another important point illustrated by the sigma notation algorithm is the concept of a bound or "dummy" variable. The student sees clearly that the final answer has nothing to do with the variable, k. Bound variables as encountered here and as the variable x in the expression

$$\int_a^b f(x)\, dx$$

have always been a stumbling block for students which the algorithmic approach goes a long way toward removing.

For another example of how the algorithmic approach affects the presentation of a mathematical concept we will look at mathematical induction—a disaster area in the math curriculum. Suppose we have a statement with an integer variable n in it. Let's call the statement $P(n)$. Suppose we wish to find the first positive integer n for which the statement is false. This search can be represented by the flow chart of Figure 3. Now further suppose that we know somehow that whenever the statement holds true for one value of n, it will hold true for the next one as well. If this is the case, then once we have passed through the True exit in flow chart box two of Figure 3 we will go through it the next time as well and the next and the next *ad infinitum*. Now is there any way that we could ever leave by the False exit so as to get out of this loop? When this question is asked in class some student will always answer that this could only happen the first time, that is when $n=1$. Thus if we add the hypothesis that the statement is true when $n=1$ we see that we can never branch to a stop; we are in a tight loop; the statement $P(n)$ is true for all positive integer values of n. And this is the principle of mathematical induction.

In the latter example we see a use of a flow chart that will never be converted to a program and run on a computer. We see then that flow charts can have uses quite apart from programming. A recent experiment was performed in Minnesota teaching a mathematics unit to three groups of junior high school students, one with flow charts but no computing, a second with flow charts and computing and a control group taught in the traditional manner. It was found that the flow-charting group showed enormous gains over the control group but that the computing group was not significantly better than the flow-charting group. The scale of this experiment was not large enough to be in any sense definitive. However, the results point out that the main benefit to mathematics lies in the algorithmic approach rather than in having an easy way to get numerical answers. In more advanced courses like calculus and linear algebra the computer is indispensible as we don't feel the necessary conviction until we see the numerical results.

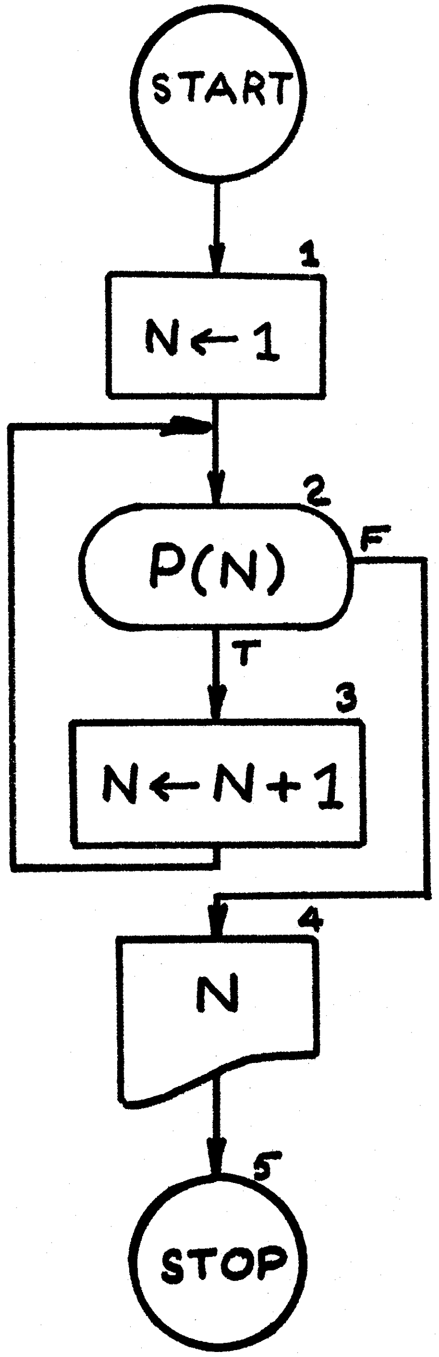

Figure 3—Induction

Computing experience will be of lasting benefit to mathematics students in that they will always have a better understanding of iterative techniques. For example, I have had far better results in teaching Picard's existence theorem in ordinary differential equations (using the successive approximation technique) to students who have been through a computer calculus course.

The "teaching effect"

Every teacher has probably said at some time or another, "You never really learn a subject until you teach it." There is a lot of truth in this. In the computer approach to mathematics the students get the benefit of this sort of experience. For, when he develops an algorithm and writes the program he is essentially teaching the computer to perform the calculation. Actually the student learns much more from this experience than by doing the calculation himself. For his concentration is on the ideas involved in the calculation, where it belongs, and he avoids the tedious arithmetic which is largely counter-productive.

Independent work

Aside from computing I have seen no field of study in which so many students become inspired to invent problems, learn on their own and tackle major projects. This phenomenon has been encapsulized in the phrase "computer bum." Many educators worry lest these students will spend too much time on computing to the neglect of their other studies. However, as I see it, the whole purpose of education is to bring students to the level where they can learn and create independently. We are achieving this desideratum in computing as nowhere else; it should be encouraged and not denigrated. Experts in other disciplines might try to find out why computing is so successful in this respect and try to develop methods of encouraging this sort of resourcefulness in other fields.

The excitement of being involved with modern technology

This item hardly needs any comment except to observe that many educators suppose that it is the only reason for the effectiveness of computing in mathematical pedagogy. Actually it is of relatively minor importance though it is of course a source of stimulation to most (but not all) students and it would be a mistake not to exploit it.

I hope my remarks have shed some light on the present status of the computer in the secondary school—on where it has been and where it is going—and on the reasons for its continuing close association with mathematics in this environment.

Computer-aided design of MOS/LSI circuits

by H. W. VAN BEEK

Texas Instruments, Inc.
Houston, Texas

INTRODUCTION

The functional complexity of MOS/LSI packages has increased exponentially during the past seven years—from a 20-bit shift register with about 130 transistors in 1964 to a one-chip calculator with over 3500 transistors in 1971. This evolution has been realized primarily because of process and engineering advancement in the state of the art. Computer-aided design and layout has played a much smaller part in this development. . . . Why?

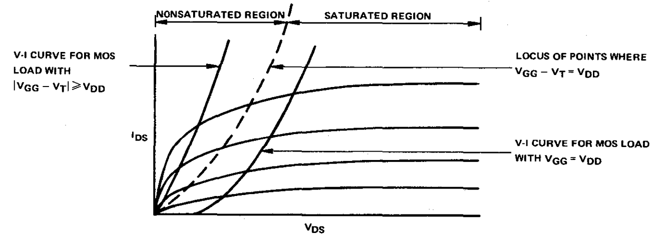
The main reason is that most of the CAD systems developed to date do not provide a viable and economical approach for implementing MOS/LSI designs. Systems currently in use are either too wasteful in silicon "real estate" or require too many error-prone manual operations. In order to achieve greater functional complexities in an MOS/LSI circuit, further development is required in both the simulation and layout of MOS systems. In this paper I will review the current use of CAD tools in both the circuit-analysis and the chip-layout areas. Challenges that must be faced in the future by the programmer in the CAD area will be presented.

COMPONENT LEVEL SIMULATION

The predictability of the MOS transistor in integrated form by means of device equations leads to uncomplicated yet very effective transient-analysis programs.

At Texas Instruments the design engineer uses a parametric circuit analysis program for evaluating cell or gate design based on the standard device equations shown in Figure 1.

It is interesting to note that factors such as speed and power dissipation are directly related to the width and length of the MOS transistor. The program requires as input a wiring node list that describes the interconnection between devices. Process parameters as well as geometrical details of the transistors are data inputs. The designer can also describe particular signal wave-shapes to the program for driving the inputs as well the details of clock signals used for propagating information through his circuit.



NONSATURATED REGION

$$I_D = \frac{\mu\epsilon_o\epsilon_{ox}W}{t_{ox}L}\left[(V_g - V_T)\,V_D - \frac{V_D{}^2}{2}\right]$$

SATURATED REGION

$$\frac{\partial I_D}{\partial V_D} = 0 = \beta(V_g - V_T - V_D)$$

$$\therefore V_D = V_g - V_G$$

$$I_D = \frac{\beta(V_g - V_T)^2}{2}$$

$$gm = \left.\frac{\partial I_D}{\partial V_g}\right|_{V_D} = \beta(V_g - V_T)$$

$$\beta = \frac{\mu\epsilon_o\epsilon_{ox}W}{t_{ox}L}$$

Figure 1—MOS I-V characteristics and basic equations

Transient analysis is performed on the data by generating differential nodal equations, which assume charge balance at each node, and solving these numerically. Prediction and correction techniques are used to select the proper time constants for solving each set of equations.

The program is strictly an analysis tool as opposed to a synthesis medium. Correlation of the computed results compares very favorably with actual results.

The user can specify a tabular listing of absolute and differential node voltages and device currents in addition to a printer plot of voltage versus time.

What is the challenge for software development in this area? I think it is basically that of staying up with the new processes that are coming out of the R & D laboratories and ensuring that the models used for computation remain accurate. The other requirement is to reduce the cost/computer run. Even though the current program executes relatively fast—about 1 minute task time on a 360/65 for a typical problem—it is used so extensively that a 10 percent reduction in run time would represent a sizable monetary savings.

Another aspect is the time required for data preparation by the designer; this, economically speaking, is possibly even more important. With the reduction in cost of simple alphameric CRT display terminals, it becomes feasible to provide each engineering office with such a terminal. The value in this approach, as with other interactive CRT systems, is that during the session at the console you (the programmer) can extract from the engineer his best effort. Input data checking is performed instantly and answers provided when the engineer is most irvolved with solving his problem. This is an extremely important point to keep in mind—software development in this area must be perfectly synchronized with the *modus operandi* of the design engineer. You must anticipate his requirements before he has a change to vocalize them. This implies that you, the programmer, be very conversant in the problem area.

Understanding the problem to be solved for the design engineer is even more important in the area of MOS/LSI chip layout.

COMPUTER AIDS FOR THE LAYOUT OF MOS/LSI CIRCUITS

One of the challenges facing the MOS designer in this area can best be exemplified by discussing a simple but accurate example of a partial system implementation. Logic in the form shown in Figure 2 had been implemented in standard TTL logic; it represented a portion of a larger logic system which was to be converted to MOS.

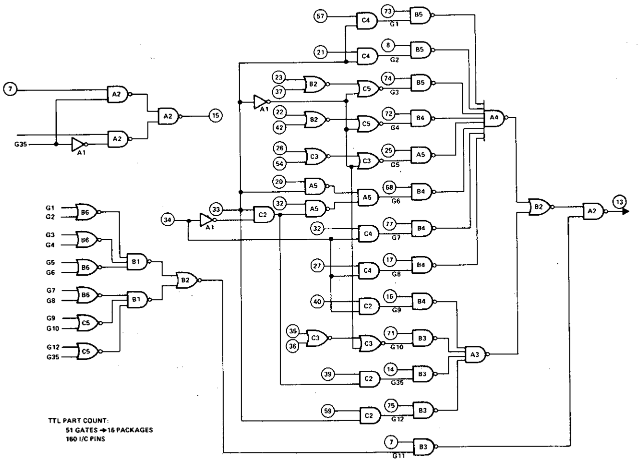


Figure 2—Signal select control logic

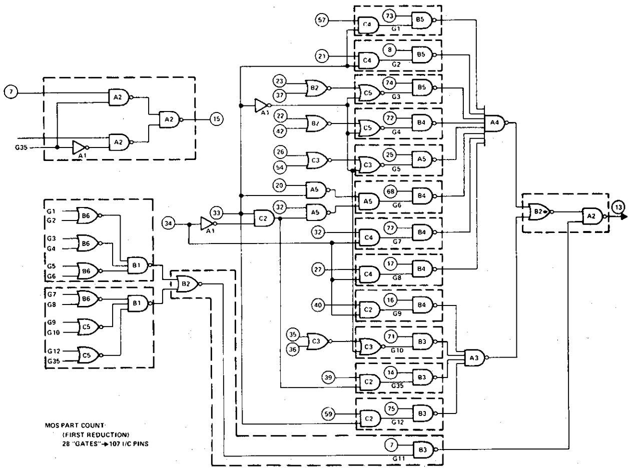

Figure 3—First reduction, signal select control logic

The designer has available to him an automatic P & R (Placement and Routing) program with a substantial number of cells. If he chose this approach he would initially try a one-for-one replacement of the TTL logic diagram with 51 MOS cells. These "library" cells have a standard height of say 12 mils. Assuming an average of three I/O pins per cell and 1.2-mil centerline spacing, we can arrive at an area requirement of 12 mils × 2 pins/cell × 51 cells × 1.2 mils/pin = 12 × 184 mils. This is the area required for the gate (or cells) only, not the intraconnect. For the intraconnect we can assume, for a random logic circuit implemented by means of standard cells, that roughly 20 percent of the area will be occupied by cells and the remaining by intraconnections and bonding pads.

In this particular case the circuit size would be roughly

$$\frac{12 \times 184}{20} \times 100 = 11040$$

square mils or about 100 × 110 mils. The first comment that comes to mind is that the routing algorithm or the designer was not very good at the task. Let's see, however, what the designer can do from this point.

By combining gates that have a fan-out of 1, he can arrive at an arrangement as shown in Figure 3. This approach leads to 28 "standard" cells with a total of 107 I/O pins, resulting in an area requirement of $\approx$7704 square mils or a 31 percent reduction over the first implementation. The designer can continue the "customizing" of cells and maybe achieve a layout equally divided between active and passive area of about 60 × 60 mils.[2]

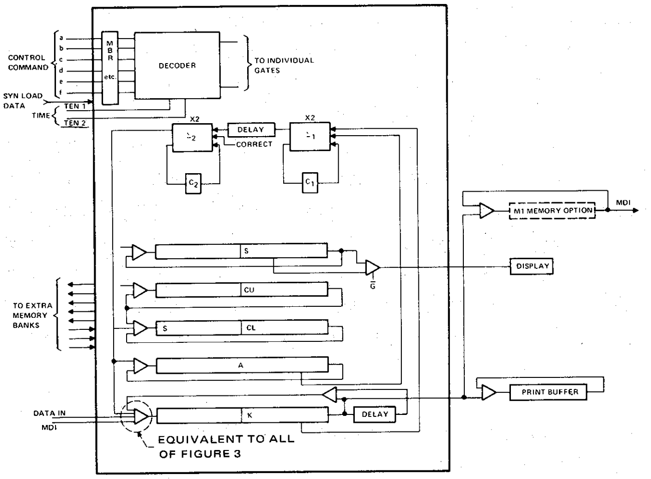

Figure 4—Arithmetic unit

The designer reduced his dependence on the automatic placement and routing program because of the custom design performed, but he now apparently has a small layout. However, this is a false assumption since he only implemented a small percentge of the overall system as shown in Figure 4. Just one small triangle represents all of Figure 3!

Sophisticated system implementation demands a better technique. The designer must be forced to look at the overall logic requirements of the system and break it down into functional blocks. He also must try to make maximum use of the PLA (Programmable Logic Array) or matrix technique since this approach uses the same real estate for active devices as well as for the passive intraconnections to these devices.

The PLA technique is an approach in which system logic equations are broken down into sets of Sum-of-Product terms. Implementation follows by generating Product terms in an AND matrix, and summing these in an OR matrix to produce the desired output (see Figure 5). Memory elements can be added outside the matrices to satisfy time delays and/or storage requirements. Almost all random logic circuits generated at TI contain one or more PLA's for control functions.

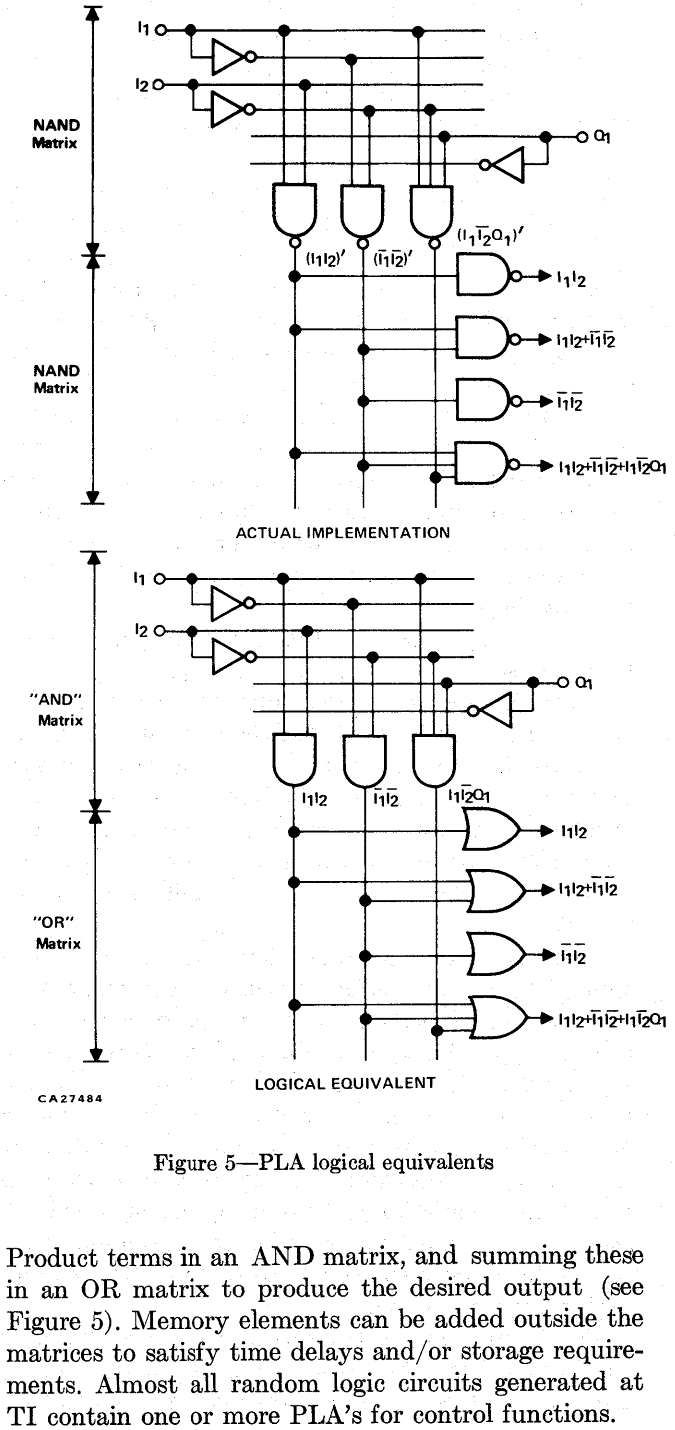

Figure 5—PLA logical equivalents

What is the future then for CAD if we suddenly discard the standard gate or cell approach in favor of a technique that doesn't lend itself to the nicely organized world of fixed-height cell layouts? Is automated placement of cells by means of a program obsolete? I believe that current versions are obsolete for most implementation requirements because of the poor area utilization. The human skill at conceiving an essentially infinite number of possibilities for placing arbitrary size polygons in a minimum area is one that is too costly to implement automatically. For an equivalent logic function the skilled draftsman can always generate a smaller layout than can an automatic placement and routing program.

Let's take a look, however, at the other side of the coin. Future demands on the functional complexity of packaged MOS circuits will increase by leaps and bounds if the past few years are any indication. These pressures will lead to circuit complexities that cannot be handled by only one or two designers, but will require teams of engineers. Even so, the chance for error during the design and layout process will be so great as to make the end product too expensive for the market place. One missed connection or contact on a circuit can cost thousands of dollars in lost time and effort to correct and recycle. An effective means of minimizing errors during the design and layout of a circuit is therefore mandatory.

It is this aspect of CAD that is currently undergoing the greatest evolution. Interactive-graphic systems are now becoming available that allow the designer to lay out his circuit under control of the computer. Data are input to the system by means of a digitizer, graphic tablet, joystick or light-pen. This is an effective manner of reducing the errors that occur in cases where layouts are implemented entirely by hand, because a complex circuit can contain over a quarter million coordinate points!

An interactive-graphic system in use at Texas Instruments lets the user perform his cell placement and the intraconnect between cells, by means of a light-pen-controlled CRT. Major program functions such as signal routing and placing cells are called up by means of a function keyboard. The program has automatic layout rule verification and demands an override command from the operator in order to proceed with the layout. Automatic conductor-spacing routines facilitate the layout of large groups of bused conductors. Only cell outlines are displayed to keep the data handling problem to a minimum.

This system allows the operator a great degree of freedom in doing the work he is most qualified to do, namely the placement of arbitrary-sized cells and their intraconnection. The system meanwhile performs a clerical function—that of encoding the light-pen and function-keyboard commands. The encoded data is in a form suitable for driving digital plotters, and mask-generation equipment.

DATA VERIFICATION

The question that now arises is: "Can we trust that no errors are made in the layout?" The answer is NO, because the user can usually override the system error diagnostics. How do we check his work? A special layout verification program was written to check the final layout just prior to the mask-generation step. It will check all circuit elements against each other for layout rule violations. This task was previously performed by a visual inspection of a digital composite plot of the circuit but the amount of data was becoming so large that errors could and did slip by.

The Critical Clearance program checks both the dimensional consistency of the data input as well as the spacing between figures. This check is performed on data of a particular mask level only. An extension of this program performs a level-to-level check and verifies proper layout rule overlap requirements. Continuity checks are also made to detect open lines or incomplete transistors that might exist in the data deck. A trace-back to the circuit schematic and the original logic description completes the feedback cycle.

FUTURE DIRECTIONS IN MOS/LSI IMPLEMENTATION

Respectable advancements have been achieved in the area of CAD and layout of MOS circuits during the past 5 years, but even so they will not be able to effectively help in our future designs. There still exists a large gap between the abstract aspect of a logic diagram and the concrete point of a circuit layout that is currently filled in with manual and error-prone procedures. To be more specific we must devise a system that accepts logic equations in an existing or new format and provides us with an optimum topological layout. This requires that a component or circuit data base be established with which the designer can interact.

Note that I mentioned a component or circuit data base as opposed to a circuit or logic system data base. I propose that effort be directed toward developing such a data base and that placement and routing algorithms be developed for it. The availability of such a system would allow the MOS designer to bypass the generation of cells for his circuit layout and consequently permit him to generate a circuit directly from his verified logic.

Additional programs that would complement such a system will accomplish the following:

1. Full-circuit parametric evaluation.
2. Minor adjustments to circuit layouts by means of an interactive graphic terminal to accommodate process changes, and
3. Generation of documentation pertaining to the circuit such as bonding diagrams, process flow, parametric test criteria, packaging information, etc.

The above steps currently occupy a sizable portion of the cycle time for completion of a prototype design. The variety of circuits that will be designed during the next few years will bury the component manufacturer unless he takes decisive steps in the aforementioned direction.

The role of simulation in LSI design

by J. J. TEETS

IBM Systems Development Division
Endicott, New York

INTRODUCTION

Forecasts for Large Scale Integration (LSI) indicate that logic gate densities of 1000 gates per chip[1] could possibly be obtained during the next decade. Supposedly, device and circuit innovations could be used to achieve even higher densities. There are, of course, a number of reasons why the industry is not yet manufacturing major LSI hardware on a large scale. One of these reasons is the lack of superior software support for computer-aided design, particularly simulation aids. For LSI, a major increase in logic design verification simulation will be required at the chip level to ensure correctness of design and to minimize the need for chip redesign.

The purpose of this paper is to review what has happened in the last five years, particularly in design verification, and to project what must be accomplished in the next five to ten years in the area of simulation in order to implement the promise of LSI.

REVIEW OF THE LAST FIVE YEARS

This section briefly describes high-level (architectural) and low-level (circuit component) simulators, and then closely examines recent logic level simulators. Logic simulation employs much more detail than high-level simulators and much less detail than circuit simulators. The purpose here is not to demonstrate that these simulators are inadequate for LSI technologies, but to show that each still has a place. The intent is to display a need for multi-mode simulation at the logic level in one user interface.

High-level and low-level simulation

Predictably, there has been and will be high-level simulation studies on various approaches to implementing LSI. Some of the major aspects and tradeoffs evaluated include: (1) replacing third generation systems with LSI, (2) enhancing architectural approaches with LSI scratch pads and main store, (3) microprogramming techniques (both read-only and writable control stores), and (4) considering hardware-software tradeoffs.

An example of an available capability for such high-level studies is the General Purpose Systems Simulator (GPSS).[4] GPSS provides for modelling systems and can collect various statistical measurement quantities such as throughput, resource utilization, queue lengths, busy times, system bottlenecks, etc. The collection of such data is very valuable in evaluating high-level architectures, both hardware and software, in all phases of design.

On the other end of the simulation spectrum is the very detailed low-level (i.e., circuit analysis) simulator. This analysis is at the component junction/resistor level; here the differential equations are solved by numerical methods.

Design verification at the logic level

The requirements of pre-LSI technologies such as RTL, DTL, TTL and recently ECL have led to the development and enhancement of computer-aided design support for simulation, wiring, testing, and packaging of designs. The concept of a central design file, used by all these applications and massaged to satisfaction, is well-known.[3] In this section, the simulation techniques used for technologies leading to LSI are reviewed in some detail to provide a basis for discussing later improvements and extensions required for today and tomorrow.

The techniques used by early logic design verification simulators were of relatively narrow purpose, i.e., they attacked a small set of design problems by using techniques specifically designed for these problems.

There were basically three early types or modes of

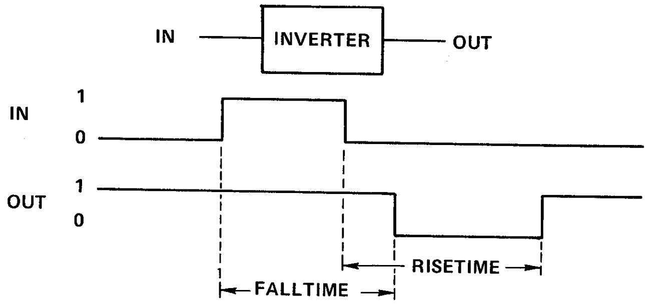

Figure A—2VND simulation

logic simulation that became popular and were implemented (2VND, 2VUD, and 3VZD). All were similar (table driven, handling both sequential and combinational logic) but each was valuable to the designer in a different way.

1. 2-Valued, Nominal Delay Simulation (2VND)[3,9]
   This mode of simulation assumed that the state at any point in the logic at any given time was either "0" or "1". The nominal delay was a gross approximation of the circuit delay (including loading and line delay where appropriate) in the form of a "rise" or "fall" delay, which corresponded to the amount of time taken for the circuit to respond to an input change and change the output state from 0 to 1, or 1 to 0, respectively (see Figure A). When primary inputs to the logic are stimulated, the simulator performs the Boolean function of the blocks driven by the primary inputs. The basic functions performed are shown in Figure D (ignore the "X" and "U" values). For each block whose value is to change, the proper delay is selected and the new block value is propagated after that delay. Propagation continues through the logic until a steady state is reached. When a block's value does not change as a result of an input change, propagation does not occur. This is known as "significant event" simulation and is common to all three simulation techniques being discussed. This mode of simulation, although somewhat gross in timing analysis detail, was very useful in gaining some engineering confidence in the behavior of the early design. This mode was more economical than the "three-valued zero delay simulation (3VZD)."
   One area where this mode fell short, even to the point of misleading the user, can be demonstrated by the following example: the 2VND technique (as used in early simulators) predicted that the response of a TTL inverter whose rise and fall delays were 15 nanoseconds (ns) to an input pulse of width 1 ns, is an output pulse 1 ns wide and 15ns later than the input (Figure B). In fact, however, a TTL gate requires a minimum input width of about 12ns to achieve any output response and would, therefore, completely ignore an input pulse of 1 ns or even 10ns wide (Figure C). Moreover, the technique is not pessimistic as a simulator should be. It allows the user to think that he can count on a narrow pulse to get through a logic gate that is sure, in fact, to ignore it. The point here is that simulators should not tell lies. Pessimism may produce conclusions from simulators which may never exist in real hardware and hence cloud the issue; however, the designers must be alerted to potential problem areas, and then decide for themselves when a real problem exists.

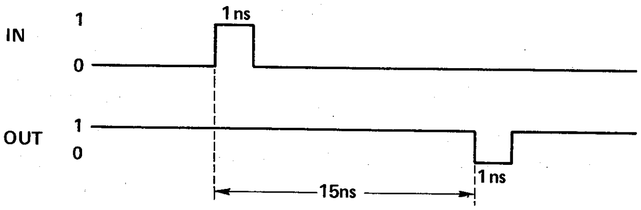

Figure B—2VND prediction of TTL inverter response

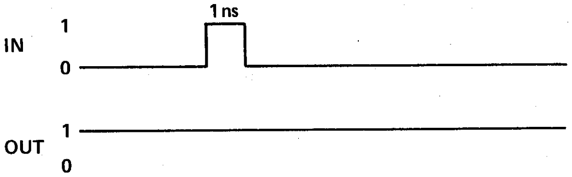

Figure C—Actual response of TTL inverter

2. 2-Valued, Unit Delay Simulation (2VUD)[5]
   This mode is very similar to the 2VND mode, except that the delay of each circuit is the same (one unit), independent of the type of circuit and the direction of change. The contention of this mode is that if one unit of delay is assigned to each logic block (with some exceptions which are assigned a delay of zero), the results of simulation will be sufficiently accurate to serve

a very useful purpose. Furthermore, if a convenient facility is available to add or reduce delays by units, the simulator will be able to closely represent the operation of the actual machine. The applicability of this approximation is dependent on the manner in which the machine was designed. Due to the variation of delays in logic circuits from manufacturing, the designer must allow sufficient tolerance so that all of the manufactured machines can operate identically to the prototype within certain limits of delay variations. Thus, one can consider the unit delay machine merely as one of those variations.

The most important advantage for this simplified timing simulation mode is its speed. It is faster than the other modes and does not require knowledge of nominal delays nor does it require storage for those delays in the simulator. It is subject to shortcomings similar to 2VND in that both modes fail to detect most hazards (subtle timing problems).

3. 3-Valued, Zero Delay Simulation (3VZD)[2, 9]

This mode, the most pessimistic of the three presented, was implemented primarily to detect hazards and races,* as well as to investigate Boolean behavior. All possible timing problems of a design are identified to the designer. This was realized by the introduction of a third value, "X". Any time an input (beginning of course with the primary inputs) changes state, it is forced to pass through X, signifying that the signal is "in transition" or "unknown". When this technique is used, first every primary input that is changing state goes to X, the driven blocks are simulated, and propagation of all blocks to a steady state occurs. The rules for simulating X in a Boolean function are a subset of Figure D, ignoring the "U" for now. After a steady state is reached, the changing inputs go to their final values and again propagation takes place to a steady state (if possible). If a timing problem is a possibility, the value remains X on a block. This indicates a potential hazard involving that block. The possible steady state effects of propagating the hazard are also shown by X values. A facility exists to allow the designer to eliminate some of the simulator's pessimism where races detected by the simulator are known to be noncritical. When used properly, this mode will allow the designer to be confident that all potential timing problems have been identified. However, eliminating pessimism in one part of a design often has unexpected effects on other parts.

Inputs		Outputs			
A	B	AND	OR	EXCLUSIVE-OR	INVERT $\bar{A}$
U	U	U	U	U	U
U	X	U	U	U	U
U	0	0	U	U	U
U	1	U	1	U	U
X	U	U	U	U	X
X	X	X	X	X	X
X	0	0	X	X	X
X	1	X	1	X	X
0	U	0	U	U	1
0	X	0	X	X	1
0	0	0	0	0	1
0	1	0	1	1	1
1	U	U	1	U	0
1	X	X	1	X	0
1	0	0	1	1	0
1	1	1	1	0	0

Figure D—Example of simulator rules
(for all modes, 4-valued)

Because of the two-pass operation described above, this mode of simulation is a little more expensive to use because of the additional computer running time; however, this must be evaluated as a tradeoff against extensive hazard detection capability not available with the other modes.

4. Extensions

Combinations and other variations of the previous three techniques have been used;[6] one of the more useful perhaps was the introduction of a fourth value, "U", which signifies "uninitialized". When a U appears on the input of a block

* If it is possible for the output signals to behave in a manner different than predicted, the circuit is said to contain a *hazard.* When two or more signals are changing together a *race* is said to exist (Eichelberger).

being simulated, it is propagated according to the rules of the simulator (Figure D). At any given steady state condition, the appearance of U's in the logic indicates the absence of initialization data, and therefore, identifies the importance of initial values. This can be very useful when evaluating system reset operations or the effect of incompletely specified input patterns. Two forms of the output from these simulators include: (1) timing charts, which show the reaction (in simulated time) of inputs and outputs of selected blocks, and (2) "snapshots", which display the value of all points in the model at selected times.

Other improvements include extension of 2VND and 2VUD to include both the X and U concepts. Thus, the nominal delay and unit delay modes can be made more useful in the area of hazard detection.

5. The Unfortunate User

Irrespective of the merits of these simulators individually, they had the collective disadvantage of not being mutually compatible. To simulate for more than one purpose (using more than one mode) required considerable, if not total duplication of effort. The problem was compounded because each program had a unique user interface. Thus, the user had to learn several incompatible systems before he could simulate at any desired point in his design cycle. The cost of this additional training and duplication of effort is no longer tolerable, particularly for LSI. It is now essential for different simulation efforts to have maximum commonality in all respects, particularly the user interface. This resulted in the requirement for multi-mode simulation and leads us into present simulator technology.

TODAY AND TOMORROW

Current simulation techniques in the design process

Whatever the size of a design project, there is a general design procedure to be followed. Several stages in that procedure involve simulation and these and other stages may be iterated to feed back information to improve the design. For purposes of discussion, these key stages in design are:

1. Establish system objectives and specifications.
2. Model the system and evaluate it by high-level simulation.
3. Partition the system into units (subsystems) and establish unit specifications.
4. Model the units and compare to specification by simulation.
5. Design units at the implementation level, modelling them for design verification simulation.
6. Compare models from different stages by simulation to ensure the detailed design meets unit and system specifications.
7. Build the system.
8. Check the system against simulation results.

At stages 2, 4, and 6, simulation is employed; however, it is obvious that the level of system being modelled is different at each stage. Moreover, stage 6 simulates several levels together. Hence, multi-level simulation is required for a fully integrated simulation capability.

Another major simulation problem that can and must be solved is that of getting very large models into relatively small computer storages. Previously, users had no option (other than not simulating) except to eliminate bits of their model until it was small enough to fit. This usually caused distress by ending up with functionally awkward pieces and unchecked interfaces between pieces. The solution for this is to partition a model, from the start, into a set of coherent regions (units), each having a well-defined interface with its neighbors (Figure E). These regions may then be simulated together as a system with the simulator automatically handling inter-region transactions by connecting together signals with identical names. An incomplete (or not yet designed) region can be simulated by using manually generated data or higher level models

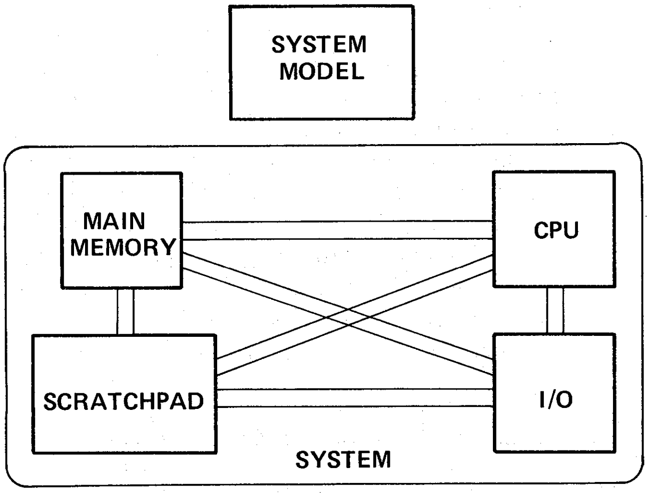

Figure E—System partitioned into regions in place of missing parts which influence the regions modelled at the logic level.

This multi-region concept readily lends itself to techniques for solving the storage problem previously mentioned. One solution is to use a roll-in, roll-out technique to make storage available for active regions. Another solution is to compress the storage requirement (and execution time) of those regions that are being used only to generate interface activity for the benefit of simulating other regions in detail. This compression takes the form of higher level models for the other regions so that the functions can be reproduced at the interface. With this technique, a "multi-level simulation" capability is defined. Merged with a multi-mode capability for those regions modelled at the logic level, an overall capability for system simulation can be provided where the detailed simulation takes place in the area of user interest.

These concepts lead toward the idea of "top-down" design using simulation. In stage 4 of the design, high-level models for the different units may be used to compare specifications of the units against system level specifications by simulation. As stage 5's logic level model becomes available for a given unit, the simulation at stage 6 may take advantage of the higher level models of other units not yet designed in detail. The stimulus (i.e., the input patterns) for the detailed model can be provided by the high-level models surrounding it and can operate concurrently with the high-level models. The high-level model for the region being simulated in detail may be simulated at the same time, and the outputs of both can be fed into a comparator to ensure that the implementation design meets unit and system specifications. This use of the "high-level environment" provides the user a pseudo system simulation at all times, regardless of which unit is being investigated and designed in detail. It also eliminates much of the problem of providing adequate stimulus to the low-level design, which is otherwise a very tedious task.

Thus, the initial and unavoidable need to partition a model can be turned to an advantage. It leads to orderly design, region by region, with thorough checking and evaluation of each unit. In addition, very important advantages, particularly in the LSI design environments, can be addressed in the area of design verification; these include:

1. verify the correctness of design (including comparing high-level to low-level models and comparing different versions of a unit).
2. detect hazards and races which would not be detected by building a hardware model.
3. speed up the design process by using top-down design techniques (which also provide good communication between unit design groups).
4. reduce the overall cost of the design process.

All of the above, particularly the cost factor, are imperative in the LSI design environment.

It has been stated that for LSI, a major increase in logic simulation at the chip level will be required to insure correctness of design and to minimize the need for chip redesign. The engineering change problem is particularly perplexing and still lacks good proposals for its solution. If a chip change is required sufficiently early in an LSI machine project, redesign costs will be incurred although slippage may not occur. During machine test, however, where in the past the practice was to install an immediate fix if possible, slippage as well as redesign costs will accrue; a repeated string of such change cycles is obviously intolerable. Thus, LSI ideally requires error-free design which necessitates simulation aids and capability at a level never required or achieved in the past. Such ultimate goals as self-diagnosing and repairing machines in LSI cannot possibly be achieved without significant advances in design verification and fault simulation capability.

Thus, because of the cost factors and the related problems of system prototype "bring up" (engineering change activity), it appears that the LSI technology is insisting upon much more extensive simulation and paper design before manufacture, and at the same time, a reduction in the overall machine development cycle and cost.

Another salient point that must be made is that it is imperative for fault simulation to be integrated more into the design verification process. If a machine design does not lend itself to system fault diagnosis and component fault detection, then many problems arise. For this reason, the requirements of testing the machine must be fed back into the design process as early as possible. One approach is to use the same stimulus used by the design verification simulators as test patterns for fault simulation. If the patterns detect only a small percentage of faults, then an incomplete job of design verification or an untestable design may be indicated. Quite possibly the answers to testability and diagnosis reside in performing fault simulation as soon as possible after a logic level design is firm, or even during the comparison of alternative design approaches.

The change in engineering design philosophy is largely due to the inadequacies of past diagnostic capability. Tests were derived in the past, in some cases, after the machine had been built. They were, as a consequence, not fully effective in their coverage. The obvious solution is to constrain the initial system and engineering designs by the diagnosis requirements.

An open-ended list of future goals can now be stated for implementation of LSI in the next decade; they include:

1. techniques and software for verifying that system and architectural specifications have in fact been implemented in a machine.
2. highly interactive, terminal oriented, and integrated computer aids for design to reduce user training and turnaround, resulting in usability.
3. advanced and enhanced simulation techniques for verification of designs; particularly multilevel simulation, logic-level simulation, and more effective techniques for timing analysis, at reduced cost.
4. advanced testing capability.
5. a "paper design" capability using software which provides *very* high engineering confidence and paves the way for the reduction or elimination of engineering change activity, at reduced cost and on a shorter design cycle.
6. Automatic input generation (particularly test pattern generation) and automatic output analysis facilities to relieve the burden of the designer.

INTRODUCTION

In large circuits, we are confronted with two problems. First, the modelling of integrated circuit modules using the normal methods of considering each element such as the general circuit analysis program—precise though it may be—can be excessively lengthy and tedious because of the computation time involved and the large storage required.[1,2] On the other hand, since most very large circuits are likely to be active, and therefore non-linear, and since the processes of non-linear analysis are more time-consuming than the corresponding processes of linear analysis, the time required for the inversion of these large matrices would become an even smaller proportion of the total. Though suitable for discrete circuit analysis, this method applied to integrated circuit configurations[3] such as modified TTL and DTL gates leads to complex forms of modelling rendering it inappropriate for use in large systems consisting of hundreds of logic gates. Also, since the models of the elements constituting integrated circuits are more complex in nature than their discrete counterparts, a model leading to accurate predictions of performance will tend to give an excessively lengthy analysis. The choice of models becomes even more critical as the complexity of integrated circuits becomes larger. Even with the recent advances in sparse matrix, adjoint and implicit integration techniques, these methods are not powerful enough to solve the problems associated with large complex logic systems.

Secondly, computer-aided analysis in digital systems commonly involves logic simulation[6,7] and an assessment of propagation delay which is made through the time diagrams for each module available from the manufacturers. However, propagation delay t_{pd} obtained by algebraic methods,[6,7] is imprecise since some important factors governing t_{pd} are not considered. Further, in a logic system the outputs of the modules are delayed and may not be simultaneous even though the inputs are. At high speeds, interconnections introduce significant delays and act as transmission lines; these effects, which cause functional errors and hazards in sequential circuits particularly, are included in the process of simulation.

MACRO-MODELLING

As medium and large scale integration (MSI and LSI) become commercially feasible, the transient simulation and accurate evaluation of t_{pd} in large systems become increasingly important. The need for the accurate prediction of the delays, where complex factors are generally ignored, results from the inability to specify exactly when a given signal will actually make a transition from one state to the other. These delays may also introduce functional errors in the system. Apart from the elemental components and considerations of fan-out, the important factors governing t_{pd} are the rise and fall times of the input function, multiple inputs, short input pulse width, multiple paths, feedback loops and the characteristics of the interconnecting paths. However, to obtain a precise value for t_{pd} and to predict the transient waveform at a given point in a system with multiple interconnecting and feedback paths, a transient Macro-Model is necessary. If the transient behavior of each module under the operating conditions is not precisely known, the actual output logic function obtained may be unrealistic. A novel approach—Macro-Modelling[3,4]—which takes into account all the considerations outlined above and enables a good prediction of waveforms and propagation delays in large integrated digital systems, is based on an analytical formulation of the input-output relationships in transient of the logic module, using the piecewise linear transient device model introduced by Narud et al.[8] Examples of such piecewise linear analytical expressions can be found in References (3) and (8) for a large variety of bipolar and MOST gates.

Koehler[5] alludes to macro-modelling while investigating the effect on propagation delays using quantized tables and taking into consideration the effect of fan-out for the two values of propagation delay for rising and falling edges. He points out the possibility of using empirically-derived expressions for specifying the input-output relationship. Narud, Dertouzous and Jessel[2] have made a good attempt to model an ECL gate by using non-linear input and output current generators and capacitances but their approach has some limitations: the number of gates in the system is restricted to 12 and it is not suitable to analyze systems with saturating bipolar gates or MOST gates as well as interfacing with different kinds of gates. The effect of feedback paths and interconnections causing multiple reflections could not be readily simulated by their method. Macro-modelling in Large Scale Integration (LSI) of digital systems makes use of the periodic nature of a large number of subnetworks. Integrated digital circuits consist normally of a large number of internal nodes—hence variables—whose values need not be known for the evaluation of the overall integrated circuit provided, of course, that their effect is taken into account. Obviously, there are two main aspects of the analysis:

(a) the modelling of different kinds of modules which the system may comprise and
(b) the actual simulation of the whole system.

MACRO-MODELLING IN SIMULATED TIME

The input function is first determined by establishing the dominant input in relation to the other inputs.[4] The dominant input, in the case of saturating multi-input gates, is defined as being the latest arriving and first decaying, or vice versa, dependent on the kind of logic operation performed. For non-saturating gates, a separate integral is solved for each input and the appropriate value is used as the argument in the output function. The dominant input is then subdivided into a given number of fixed time intervals Δt and the output response is computed by successive iteration for each time interval using the analytical input-output relationship for the particular module. The quantized values for the input and output functions at the beginning and end of each interval provide the initial values and slopes (which together form the initial conditions) and must be included in the computation. The simulation is performed by successive iteration of the set of mathematical expressions describing the type of module under consideration. The type of logic module is simulated accurately by an analytical transient input-output relationship—an expression which is analytically derived[2,3,4] and stored for reference. It includes the transfer function of the module as well as a function defining the propagation time. These transient expressions[3,8] are not difficult to obtain using the piecewise linear device model. Each such iteration determines the value of the output for each corresponding equation as a function of the values of the composite inputs. This is illustrated by considering points on the input and output curves (Figure 1) corresponding to time t_i; the time at the beginning of the previous interval is t_{i-1} and $t_i = t_{i-1} + \Delta t$. The value of the output function V_i at t_i is calculated from the corresponding value of the input function I_i and the entire response is obtained by iterated computation. It is important that the current input and output function values (I_i and V_i) as well as the values corresponding to the previous interval (I_{i-1} and V_{i-1}) are made available at the beginning of each interval, since these determine the initial conditions—the initial values and the slopes for each Δt.

Given V_{T1} and V_{T2}, the threshold points associated with the rising and falling input edges, the output response of logic gates may be looked upon as consisting of three main regions:

(i) the region before V_{T1},
(ii) the region between V_{T1} and V_{T2} and
(iii) the region after V_{T2}.

Each main region may consist of one or more subregions. Logic gates normally require one or more subregional expressions[3] to specify their transient response. While each subregion may be considered as a continuous function, the interface point where a subregion begins is defined as a discontinuity. Because of

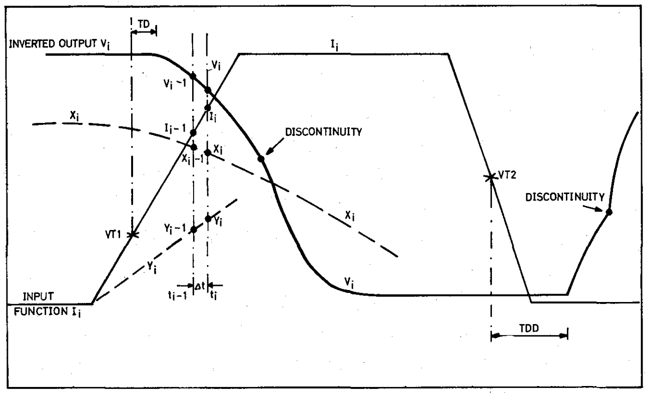

Figure 1—Macro-modelling and waveshaping of continuous expressions for the rise and fall times with discontinuities

the discontinuities associated with the output of these gates, they may be referred to as multiregional gates. Examples of multiregional responses are the modified bipolar and MOST gates.[3] The input-output conditions and transient relationships for each region are different and are considered separately in the simulation. This is consistent with the principle of piecewise linear analysis.[8]

For the output region preceding V_{T1}, an important consideration is the comparison of the slope of the input function at each time interval Δt with the slope of a curve Y_i, which is governed by the internal time constant associated with the gate input.

In general the region between V_{T1} and V_{T2} is governed by TD, a delay time elapsing after V_{T1}, and by the relevant transient relationship of the gate. TD depends on the relationship in time between the rate of rise of the input I_i and the inherent time constant Y_i associated with the gate input. For similar gates, the variation in TD is of little concern, but in a system employing interfacing with different gates, the changes in the value of TD and in the position of V_{T1} must be taken into consideration. Given that I_i is much faster than the internal time constant Y_i, TD is determined by Y_i; whereas, if I_i is slower than Y_i, TD is governed by the input. The required input relationship at interface points is established and the required TD computed. This region is also governed by an intrinsic curve X_i derived from the internal switching characteristics of the gate.[2,8,9] A comparison of the current values (X_i and V_i) at each Δt detects the presence of a discontinuity in the response. The value and slope at the point where a discontinuity occurs are stored as new initial conditions for the next continuous subregion.

The region after V_{T2} which may also be multiregional is governed by TDD, the storage time elapsing after V_{T2}, and the appropriate input-output transient relationship. TDD is an important parameter and governs the output response of t_{pd}. An appraisal of TDD is therefore included in the macro-model.

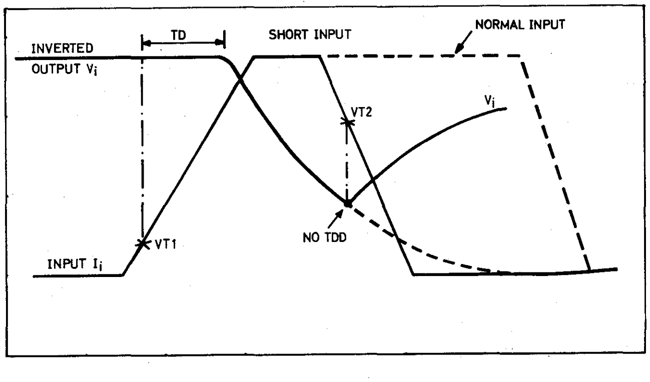

Figure 2—Effect of a short pulse width on the rising response

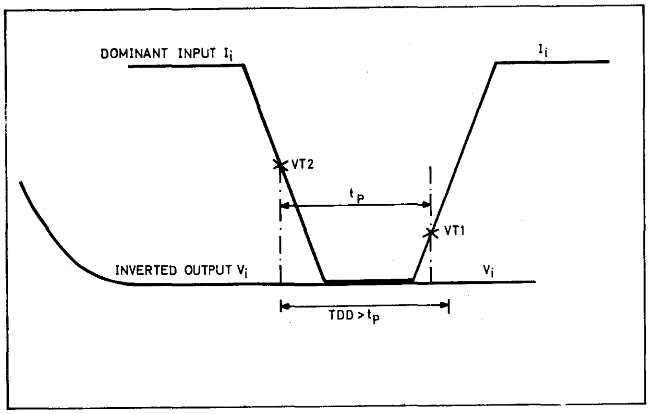

Figure 3—Effect of a short pulse width on the storage time

Assuming that the input waveform consists of reasonably wide pulses, the corresponding output waveform V_i is predicted in a normal manner by considering the parameters TD and TDD for the logic module. If, however, the duration of the input pulse I_i is short and comparable with TD and TDD, then prediction of V_i must be based on the consideration whether the input levels turn the output stage ON or drive it into saturation. It may be seen that this consideration determines whether the output is a pulse waveform or consists of partial pulses or humps. This assessment is made with accuracy by the simulation method, which computes the initial conditions (V_{i-1} and V_{i-2}) at the beginning of each output interval Δt subsequent to an enquiry of the conditions at the input. This is further explained through the waveforms shown in Figures (2), (3) and (4). Figure 2 shows the case when t_p, the pulse width of the dominant input I_i to a gate as measured between the two threshold points V_{T1} and V_{T2}, is small and V_{T2} follows V_{T1} before the output waveform V_i reaches the '0' level. As no storage time (TDD) considerations are involved, it may be seen that the response V_i is only a partial pulse; the settling time at the lower level of the output V_i (before the output starts to rise) is only due to the intrinsic charge in the switching circuit. Figure 3 shows the negative edge of the input I_i and the output V_i of a saturating gate at the '0' level initially. If the transition of the input from V_{T2} to V_{T1} has duration less than TDD, then the output does not change until a time TDD has elapsed after the point V_{T2}. A third case is illustrated by Figure 4 where the time from V_{T2} to V_{T1} (at the lower level of the input I_i) is larger than TDD. In this case the output rises at the end of TDD. If, however, the time

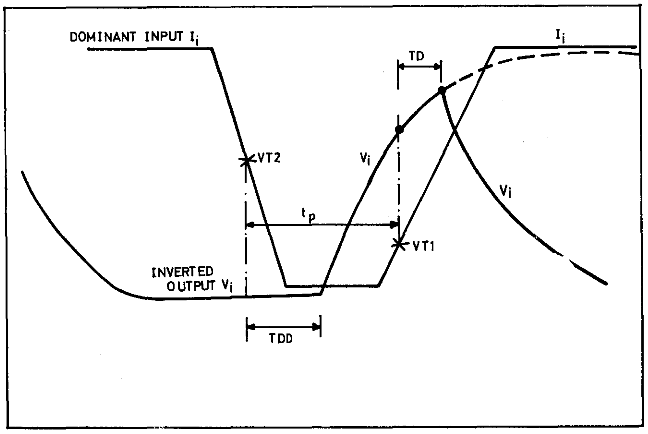

Figure 4—Effect of a short pulse width on the falling response

from V_{T1} to V_{T2} (at the higher level of the input I_i) is short such that the output V_i does not reach the '1' level, then the output continues to rise for a time TD from the point V_{T1} and then starts to fall.

These cases are obviously for inverting gates but the argument applies equally to gates without inversion at the output.

FEEDBACK LOOPS AND FLIP-FLOPS

A sequential circuit can be thought of as a combination of two simple NOR gates connected in a closed loop. The output of each NOR gate drives the input of the other. Actual sequential circuits do not in general behave ideally. Changes in voltages at the outputs of secondaries may not be simultaneous even though their inputs are; at high speeds even short interconnections may introduce significant delays. Unfortunately these various delays do not simply slow down the operation of the circuit, they may introduce functional errors and give rise to hazards. As a result of the inability to specify exactly when a given signal will actually make a transition from one state to the other, Szygenda, Rouse and Thompson[7] associate an ambiguity interval with each signal. The requirement of an ambiguity interval is due to the fact that gates of the same type could have different propagation times; hence the time delay of a gate is represented as a minimum value plus an ambiguity region. The approach in this paper, however, does not require the postulation of ambiguity intervals, since the propagation delays are accurately represented in the Macro-Model developed for each particular gate considered.

The simulation of feedback paths in a system is illustrated by considering Figure 7 in which module 8 forms a feedback loop with module 7. The scanning is started by giving an enabling initial condition to the feedback input of module 7. This may be done by considering the loop open at the beginning of the first time interval t_i; this provides an output for module 7 and hence for module 8. At the beginning of the next time interval, t_{i+1}, the feedback input is then made to take the value of the module 8 output thus giving the corresponding output value for module 7, and the entire output response is obtained by the usual iteration

principle. This in effect may be interpreted as including a delay Δt in the feedback loop. It may be seen that the overall error in propagation time depends upon the ratio $\Delta t/nt_{pd}$ where t_{pd} is the individual delay of n modules constituting the feedback. This principle is easily extended to the simulation of sequential circuits e.g., flip-flops which can be considered as two cross-coupled inverting NOR gates. For inputs originating from a source with a pure delay, the values are those obtained during the previous iterations t_{i-d} determined from the respective values of the actual delay d as a function of time steps. This principle is illustrated in the flow chart of subroutine DELAY as shown in Figure 5.

MODEL IMPLEMENTATION

From the two different modes of handling time and processing events, i.e.,

(i) the next event formulation of a simulation model which is time variable and dependent on the events to be considered subsequently and
(ii) the fixed time step model,

the latter mode approach was chosen. A fixed time step model requires the user to specify a size for the time increment Δt to be used when the model is employed for simulation. In fixed time step simulation all response values are treated as if they all happened simultaneously at the upper end of the interval. Because of this, merely changing the size of the time increment to a large arbitrary value can radically alter the interrelationship of event occurrences.

It is noted that although a time step of any positive magnitude Δt allows the simulation to be executed, the meaning and validity of the results is related to the value of Δt. A very large arbitrary value of Δt may lead to inappropriate initial conditions. The conditions corresponding to a discontinuity or subregion may be left unscanned and the resulting response may have an incorrect subregional waveshape. Δt is chosen to be less than *TD* and *TDD* and is for example 1 or 2 *ns* for gates with switching times of the order of 10 *ns*. On the other hand, a fundamental problem associated with simulation is the time synchronization of model elements. This problem exists because the real network may perform certain phenomena simultaneously while the model must perform these phenomena in a sequential manner.

The simulator MILS (Macro-modelling of Integrated Logic Systems) is based on a "fixed-step" time-increment concept,[11] where a search is done for the next event after the current event has been met and passed.

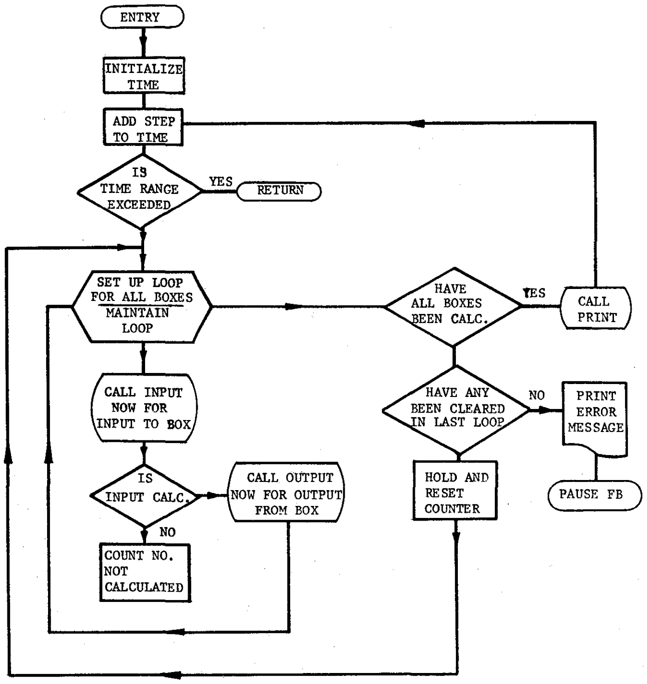

Figure 6—Algorithm illustrating the scanning procedure in simulated time

The actual simulation mechanism used, however, is a special case of this concept; in fact this mechanism can be considered as a special case of the "next-event" [11] principle, since all events do occur simultaneously at the ends of the time intervals and will be processed together until the next time is looked for. There is, however, a definite order in which events occur. This order is procedural[12] and is related to the logical interconnection and physical layout of the system. It is obvious that the card order in the simulation program may not be the same as the order of events occurring and in this respect the program description is non-procedural. In the simulation, each gate or circuit is treated as a box with a sequential number N as well as a type identification number. The description of the modules which may be of different kinds, are previously stored. Input functions, which may occur anywhere in the system, are designated "input-boxes" and included in the simulation with a sequential number. Each unit (or box) has response states at times t_i and t_{i-1}, the latter corresponding to the initial condition and, in general, the response states of boxes of similar or different type numbers need not have the same quantized value. To obtain the response of the system at a certain node, the corresponding discrete value of the input function is obtained and, while time stands still, the output of all the modules are evaluated by scanning in a sequential order. Owing to the topological configuration of a sys-

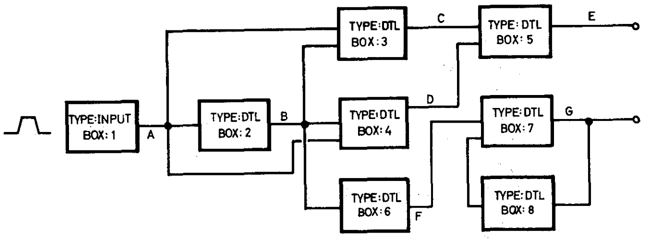

Figure 7—A circuit configuration which has DTL modules and includes a feedback loop; β_0 and F_t were taken as 10 and 500 MHZ respectively

tem, the outputs of some modules may not be available in a sequential scanning in which case the scanning of these modules is repeated with the help of pointers, until all the modules have functioned once. The operation then moves to the next interval, a new value of the input function is introduced, and the corresponding output value evaluated. The entire response is thus obtained by similar scanning. This procedure is illustrated in Figure 6.

Assuming identical box types, the output function V_{n,t_i} of the box n considered at time t_i is dependent on the status J_{n,t_i-1} of the output function. This status is determined from a knowledge of the position of the scanning time t_i with respect to the input function; and J_{n,t_i-1} has different values above V_{T1} and below V_{T2}. The m inputs of box n are first searched—not necessarily in a sequential order—to determine which input is dominant. This depends on the logic operation being performed. This resultant dominant input associated with input k is then designated I_{k,t_i} at t_i and then compared with the previous value I_{k,t_i-1} to determine the slope of the rising and falling input functions. If the j input to a box n is connected directly to an input-box, then the input value will be obtained from the appropriate specified input waveform at time t_i by a simple interpolation technique, but if the j input to box n is not from an input-box then the input value I_{k,t_i} will be extracted from the outputs of the m connecting boxes. If an input is from the output of the same box, this means that there is a feedback loop (see section 4). The previous value of the output function V_{n,t_i-1} is compared with the current value $V_{n,ti}$ to determine the initial conditions at each time interval. An analysis of the configuration shown in Figure 7 which has *DTL* modules and includes a feedback loop (i.e., between modules 7 and 8) was carried out by the simulation technique discussed, and the responses at nodes *A*, *B*, *C*, *D*, *E*, *F* are shown in Figure 8. The response at *G* remains as expected, high. A list of the symbols used in this section is given at the end of the paper.

SYSTEM IMPLEMENTATION

Speed of simulation is an important requirement but may be sacrificed if more accurate results are required through a reduction in Δt. Although an assembler language would result in a little faster execution and less storage requirement, FORTRAN was chosen since it would be easier to implement and is considerably more machine independent.[7] Its use is justified because the method itself is so efficient. The efficiency of this approach is illustrated in the storage and computing time required on Queen's University ICL 1907; 9 K for 300 logic modules, 40 types of logic gates, 10 input waveforms; and 21 mill seconds for the 8 gates configuration of Figure 7. FORTRAN is more compatible when dealing with numerical values in large arithmetic statements—as would be the case when computing the time response in numerical form. PLAN (ICL Machine-Coded Language) or PL/1 has desirable features which could be easily added to support the FORTRAN IV system only in the part of the program not dealing

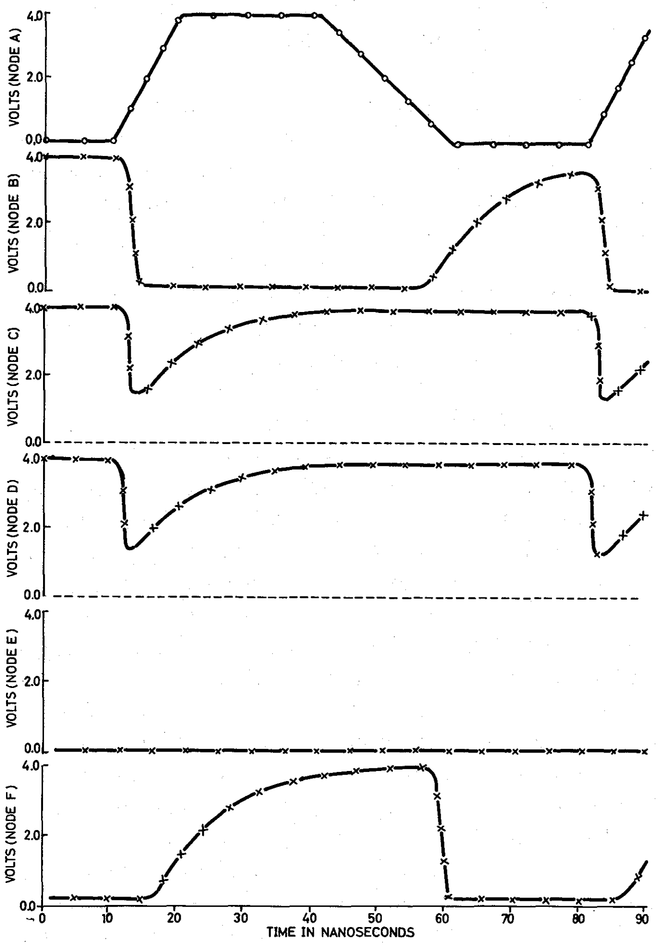

Figure 8

with numerical values especially in the STORE part, hence increasing the efficiency.

However, FORTRAN programs can grow excessively large for two reasons: firstly that they contain a large number of instructions, and secondly that they require a large amount of storage, usually for arrays. Programs which are large for the first reason can usually be overlaid. MILS provides a way of treating the storage in a similar fashion. An area in core can be used to hold the part of a larger storage area that is required at a given time, selected from the larger area held on disc storage. When the part is no longer required it can be written away to the disc storage and the next part can be brought down into core store previously occupied by the first segment. There is no restriction on the order in which sections of storage are accessed. The storage described in this paper is scratched space, i.e., any information stored on it is lost when MILS is terminated. The system uses files on magnetic disc devices to store the information. Files can be on either EDS or FDS (exchangeable disc storage or fixed disc storage) scratch files. A maximum of eight files can be declared at any one time. A file must be declared by a CALL to a subroutine which declares a scratch file of length K elements. One element is required for each real or integer array element. Two elements are required for each complex or double-precision array element; another parameter is for the channel number by which the file is to be referred and must be an integer; a third parameter is for EDS or FDS. The area on the disc is treated as a string of elements numbered from one upwards. It is required to keep track of the start positions of each of its arrays on the disc by means of pointers. This is illustrated by the two subroutines:

```
    CALL STACK (C, K, A)
    CALL ACCESS (C, K, A)
```

where C in the channel number, K is the element number of the first element to be transferred and must be a variable as the value of K will be altered by any of the routines and A is the array name.

X and Y are array elements declared as A(I, J - - - -), A(L, M - - - -). The values given to all dimensions of the array element Y must be greater than or equal to those of X.

Each of these subroutines writes to or reads from the file with channel number C starting at element K. K must be a variable and have a value greater than or equal to 1.

CONCLUSIONS

This formulation technique of an integrated logic module permits the analysis of large networks, consisting of hundreds of logic gates, with complex situations and allows a more accurate prediction of transient performance and propagation delay. The method can be used for studying statistical variations of delays and switching times without employing regressional analysis. The individual elements of the logic module could also be modified for worst case analysis without affecting its macro-appearance. Further, the approach lends itself to predicting the effects of multiple reflections and crosstalk in a system with a given number of interconnecting paths and tap-offs. An analysis of these effects forms an important and interesting part of the overall system simulation. While a large amount of work has been done[3] to simulate these effects, in view of the space and time available, a discussion of this aspect will be outside the scope of this paper.

LIST OF SYMBOLS

I_{k,t_i}	Dominant input function to a box n at time t_i determined from previous boxes' outputs I_i for simplicity
$I_{k,t_{i-1}}$	Dominant input function to a box n at time t_{i-1} $(t_{i-1}=t_i-\Delta t)$ determined from previous boxes' outputs I_{i-1} for simplicity
$J_{n,t_{i-1}}$	Status of the output function at time t_{i-1}
j	Input number considered
k	Dominant input box number
m	Maximum number of inputs to a box
N	The sequential number given to a box
n	The box number being considered excluding all the preceding input boxes $\mid x \mid$ $\mid N-x \mid$
t_i	Current time considered
t_{i-1}	Previous time considered $(t_{i-1}=t_i-\Delta t)$
t_{i-d}	Previous iteration time determined from the respective values of the actual delay d as a function of time steps $(t_{i-d}=t_i-d)$
TD	Delay time above V_{T1}
TDD	Storage time below V_{T2}
V_{n,t_i}	Output function at t_i for the box considered n V_i for simplicity
$V_{n,t_{i-1}}$	Output function at t_{i-1} for the box considered n V_{i-1} for simplicity
V_{T1}	Threshold point for a leading input edge
V_{T2}	Threshold point for a trailing input edge

ACKNOWLEDGMENTS

The author wishes to record his thanks to Professor W. D. Ryan for his inspiration in the development of the macro-modelling technique, to Mr. S. Q. Hossain for his initiation to the interconnection problem, to

Mr. Sam Hogg and the Staff of the University's Computer Laboratory for useful discussions in the design implementation of the simulator and to my wife, Elfriede, who typed the manuscript.

INTRODUCTION

LSI implementation of digital circuitry opens the door to the consideration of dramatically new approaches to the design of system fault diagnosis.[1] New constraints have been added, such as the difficulty of inserting test access points internal to large pieces of circuitry. At the same time, failure modes seem to be changing with bonding lead failures increasing in importance.[2,3] This paper presents an approach that leans heavily on the assumption that adding additional logic to a circuit is of little consequence, whereas it is important to reduce the access provided for testing capability. As the practicality of the proposed approach has not been examined in detail, the concept is primiarly presented to stimulate further study into the special problems and opportunities involved in diagnosis of LSI systems.

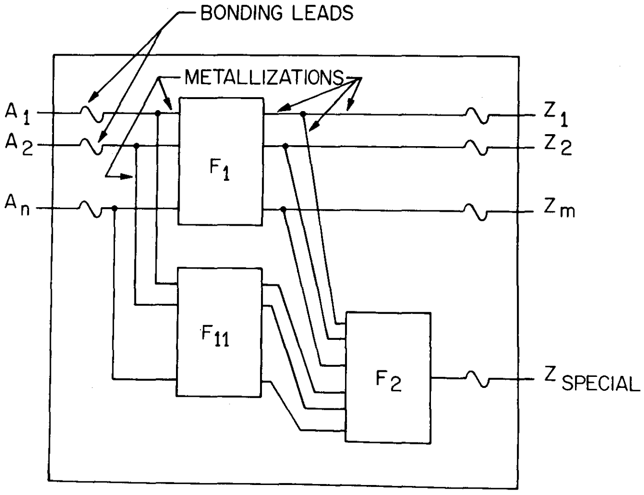
The approach discussed here is to incorporate on each least replaceable unit (LRU) a special combinational test circuit that will identify, by observation of the output alone, any stuck at "0" or "1" input failures to the particular input involved. Such a test circuit is termed an "Ambiguity Resolver" (AR) function, and proof of its existence for any number of inputs will be presented. The identification of a failure to a particular input in general actually only isolates the failure to the bus that is connected to that input because of the propagating tendency of failures on a bus. Thus, all LRU's connected to the bus implicated are equal candidates to have failures on their bus connections. A capability such as provided by AR functions would obviously be of little use in a situation in which buses tend to be common to a group of LRU's. However, when the observable points are restricted to the functional outputs, conventional methods usually do not provide resolution of input/output faults to a unique bus. This feature is conveniently provided by the usage of AR functions.

Let us define some of the terms and clarify the notations used in this article.

DEFINITIONS AND NOTATIONS

Observable Points: points at which the outcome of an applied test procedure can be observed.

* Parts of this paper are excerpts from Dr. Mehta's Ph.D. Thesis. Dr. Messinger of Illinois Institute of Technology served as an academic adviser during the course of the thesis, while Dr. Smith of Bell Telephone Laboratories acted as a thesis adviser. Dr. Mehta is with GTE Automatic Electric Laboratories which also supported the thesis.



F1 : THE BASIC FUNCTION

F11: THE DUPLICATED FUNCTION

F2: A COMPARE FUNCTION

Figure 1—One way to use redundancy

Failure Exclusive Points: a set of points only one of which is affected by any one assumed failure.

Independent Inputs: two inputs are independent iff (if and only if) the logic state of either can be changed without affecting the logic state of the other.

Sensitized Path: a path between a point in a combinational circuit and the output is sensitized if a change of logic conditions at that point results in a change of logic conditions at the output while other inputs are not changed.

Output Vector: the ordered set of (binary) outputs that result from the application of a test procedure (a sequence of tests). The output vector corresponding to no-fault conditions is called the *normal output vector* and is denoted by Σ_n; also Σ_f denotes the output vector for the same test procedure when fault f is present.

Complementary Failures: Stuck-at-0 (s-a-0) and Stuck-at-1 (s-a-1) failures at a particular point (input or output) are called *complementary.*

Least Replaceable Unit (LRU): the smallest subsystem which will be completely replaced if a fault is located at the terminals of, or inside, the subsystem.

Capital letters of the English alphabet are used to denote the inputs and the outputs of a circuit. Usually the early letters (A, B, C) are used for the inputs while the later letters are reserved for the outputs (Z, Y, X, W). Exceptions in these notations are made when dealing with networks to avoid duplicate labeling for connections (buses). Subscripts are used to identify the inputs or the outputs. A distinction is made between the inputs to the circuit (A_i) and the leads which carry these inputs to the circuit. Small letters with identical subscripts (a_i) designate the corresponding leads for any input. Similar notations are used to distinguish the outputs and the output leads. A fault at the input lead is fed back to the input (output of the driving gate) only if it is a propagating fault (i.e., if it affects the entire bus). A lead a_i with a s-a-0 fault, in tables and figures, is denoted by symbol a_i^0; a_i^1 similarly denotes the same lead with a s-a-1 fault.

AMBIGUITY RESOLVER (AR) FUNCTION

Since LSI implementation makes redundant logic economic to use, we examine the possible ways of using redundancy (internal to a LSI circuit) to simplify fault diagnosis of digital systems.

One of the ways to use the redundancy is the conventional approach of duplicate and compare (Figure 1). Two disadvantages prevent this scheme from being attractive. First, the required redundancy is excessive; it takes more than double the circuitry to implement this approach. Second, the approach simplifies the diagnosis of only the internal faults. For the diagnosis of the faults at the bonding leads one has to still resort to other approaches. Unfortunately, a predominant failure mode in systems composed of LSI, that have been in systems which are in operation for awhile, is due to bond failures.[2,3] Therefore, the approach of

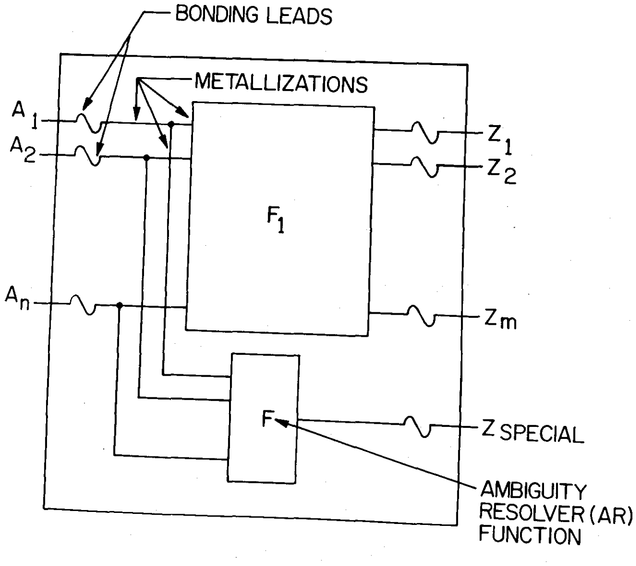


Figure 2—Another way.to use redundancy

Figure 1 does not represent an efficient usage of redundancy.

The proposed approach (Figure 2) consists of a specialized single output test function (F) for simplifying the diagnosis of input faults. These Ambiguity Resolver (AR) functions are combinational logic functions which have the property that input/output faults can be resolved to a unique bus through the observation of the output alone. We will show that such functions exist and that they are simple in comparison to the normal function (F_1). AR functions simplify the fault diagnosis of digital systems implemented with LSI circuits because:

(1) A predominant failure mode in operating IC's is bond failures which result in input/output faults. The AR functions simplify the diagnosis of only the input faults; however, the output faults will become input faults of the driven LRU's and therefore will be diagnosed by their AR functions. It is reasonable to assume that the faults of the unused outputs do not affect the system performance.

(2) AR functions permit resolution of input/output faults to a unique bus. Such resolution is not always available by the use of conventional test procedures when the observable points are restricted to the functional outputs.

(3) Only one point need be observed for diagnosis.

(4) Since the AR function (F) is unrelated to the basic function F_1, its design is completely independent; for example, F_1 may be a sequential function, yet F can be a simple combinational function. Due to this independence, often diagnosis using AR functions requires fewer tests in comparison to a conventional test procedure.

Although the AR approach simplifies fault diagnosis of LSI implemented systems, it is certainly not the complete answer. For example, the AR approach requires testing, and thus does not provide an on-line detection of faults. Also AR function provides neither fault detection nor diagnosis of faults within an LRU. Therefore, in any practical application, the AR approach would probably be augmented with other, more conventional methods.

Since the AR function can be independently designed, in the following sections, we will disregard the basic function. We will concern ourselves only with single output combinational functions which have the AR property. We will assume:

1. Only input/output faults.
2. Only s-a-1, s-a-0 faults.
3. One fault at a time.
4. Access to only the inputs of the function. That is, only the inputs can be controlled externally.
5. Output is the only observable point, i.e., the performance of the function, during the test procedure, can be observed only at the output.

TABLE I—Outcomes of a Test for Complementary Failures at the Input a_k and their Implications

Test	Input Conditions A_1-----A_n	Normal Output	Possibility	a_k^0	a_k^1	Implications for the test
t_i	$\alpha_{1i}\alpha_{2i}$---α_{ni}	σ_i	1	σ_i	σ_i	$\alpha_{ki} = 0$ or 1 fault insensitive
			2	σ_i	$\bar{\sigma}_i$	$\alpha_{ki} = 0$
			3	$\bar{\sigma}_i$	σ_i	$\alpha_{ki} = 1$
			4	$\bar{\sigma}_i$	$\bar{\sigma}_i$	Not realizable

In order to clarify some of the concepts presented here, Section 8 presents an example of the use of AR functions along with a conventional scheme for comparison.

COMPLEMENTARY FAILURES

Understanding the constraints that are imposed on circuits being tested is required before we can go into a discussion of the existence of AR functions. An important constraint is on the allowable outputs for complementary input failures.

Consider a test t_i that applies the input $\alpha_{1i}\alpha_{2i} \ldots \alpha_{ni}$ to a circuit, and consider a particular input lead a_k (see Table I). If the output of the circuit is σ_i under the test t_i, then the output can be either σ_i or $\bar{\sigma}_i$ for a_k s-a-0 and similarly for a_k s-a-1. If the output is σ_i for a_k both s-a-0 and s-a-1, then the output is fault insensitive to a_k. If the output is $\bar{\sigma}_i$ for a_k s-a-0 and σ_i for a_k s-a-1, then it is clear that a_k must have a "1" input for this test t_i. A similar story is true for output σ_i for a_k s-a-0 and $\bar{\sigma}_i$ for a_k s-a-1 (a_k has a "0" input). However, it is not possible to have an output $\bar{\sigma}_i$ for both kinds of failures because this would imply that $\bar{\sigma}_i$ is always the output for a_k with either 0 or 1 input, which contradicts the original assumption. Theorems 1 and 2 state the results just given, which are proved elsewhere in detail.[7] They are given below because the results will be used later.

Theorem 1:

The outcome of a test t_i cannot be different from normal case under both a s-a-0 and a s-a-1 failure at the same input.

Theorem 2:

If the outcome of the test t_i is different from the normal case for the fault f_i, then the outcome of the test t_i for the complementary failure is identical to the normal case.

Finally, each detectable failure must produce a non-normal output for at least one of the tests. For that test, by Theorem 2, the complementary failure must have normal output. Therefore', the resulting output vectors for complementary failures cannot be the same. Thus, although this is not necessary for localization of input faults to a unique bus, complementary failures of AR function will always be distinguishable. Having established this, we are now in a position to formally define the AR function.

DEFINITION AND PROPERTIES OF AR FUNCTIONS

Definition: An n-input AR function is a combinational function of n variables with a single output with the following properties:

1. All faults are detectable, i.e., there exists a test procedure T containing p tests such that $1 \leq p \leq 2^n$ and $\Sigma_n \neq \Sigma_{f_i}$ for any fault f_i.
2. All faults produce unique output vectors for the test procedure T, i.e., $\Sigma_{f_i} = \Sigma_{f_j}$ iff $f_i = f_j$.

Any such set of p tests will be referred to as *Test Pattern* of the AR function (under the fault assumptions made earlier).

Some elementary properties are easily derived from the basic definition of the AR function. Clearly, the output faults yield either an all 0's (s-a-0) or an all 1's (s-a-1) output vector. Also, the normal output vector for the test pattern has to be non-zero and non-all 1's since output faults are to produce non-normal output vectors. Finally, each input fault must yield a unique, non-zero and non-all 1's output vector.

Theorem 3:

If the permissible failure modes include complementary faults at the inputs and at the outputs, then the complement of the normal output vector for an AR function is different from the resulting output vectors for all permissible failures.

Proof:

Since the normal output vector is non-zero, non-all 1's, the complement of the normal output vector ($\Sigma_{\bar{n}}$) is also non-zero, non-all 1's. Thus $\Sigma_{\bar{n}}$ is different from the resulting output vectors for the output faults.

Next assume that the resulting output vector for an input fault f_i is identical to $\Sigma_{\bar{n}}$. This implies that the outcome for each test t_j $(1 \leq j \leq p)$ for the fault f_i is different from the normal case. Now consider the complementary failure $\bar{f}_i$. By Theorem 1, for any test t_j the outcome for both failures at the same input cannot have different performance from the normal. Therefore (by Theorem 2), the outcome for each test t_j $(1 \leq j \leq p)$ for the fault $\bar{f}_i$ must be identical to the normal case. Thus the resulting output vector for the fault $\bar{f}_i$ for the test pattern T will be identical to the normal case. But this is a contradiction since the fault $\bar{f}_i$ during the test pattern T must produce a unique output vector *different* from the normal case. Thus the resulting output vector of an input fault of an AR function also cannot be identical to $\Sigma_{\bar{n}}$. (Q.E.D.)

Next we examine other properties of AR functions which will permit synthesis of new AR functions from

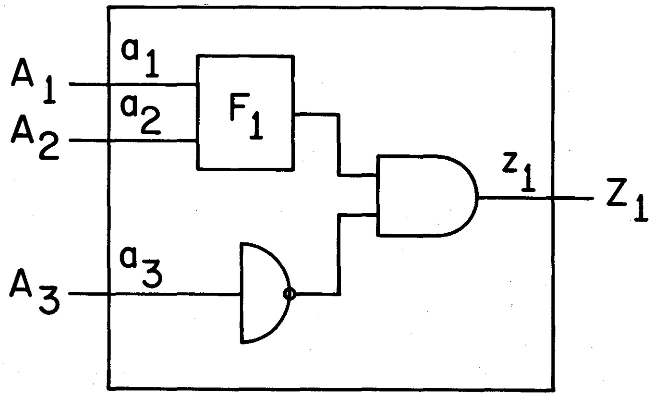

Figure 3a—Not conformal because faults at a_3 violate condition 1

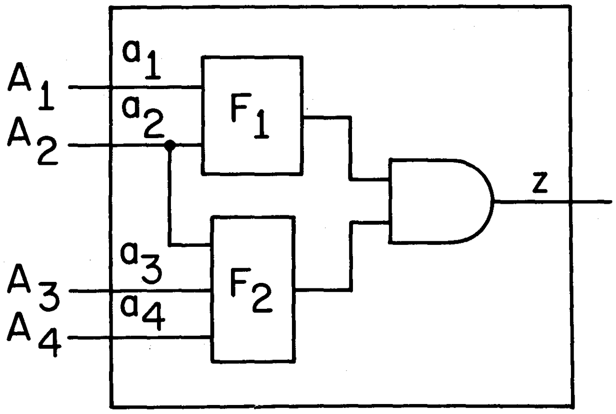

Figure 3b—Not conformal because faults at a_2 violate condition 1

the available AR functions. It will be shown that the resulting functions have the AR property when certain structural constraints are observed. The concept of conformal structure, introduced next, provides one convenient way to produce new AR functions. It should be noted, however, that although conformal structures, as defined below, have the AR property, structures having the AR property need not be conformal.

Definition:

When a one output combinational function is generated by the use of AR functions and logic gates, the resulting structure is *conformal* iff

1. Each input failure of the resulting function results in a permissible input failure at one, and only one, of the AR functions,
2. No two input failures of the resulting function result in an identical input failure condition at any AR function,

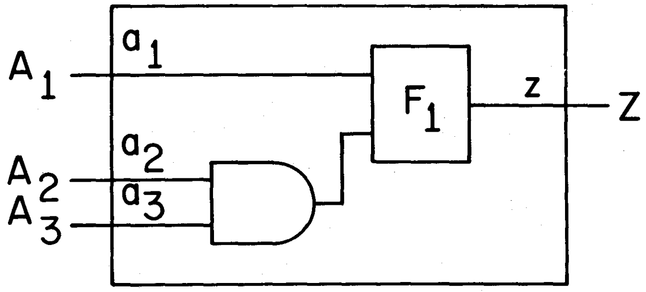

Figure 3c—Not conformal because s-a-0 faults at a_2 and a_3 violate condition 2

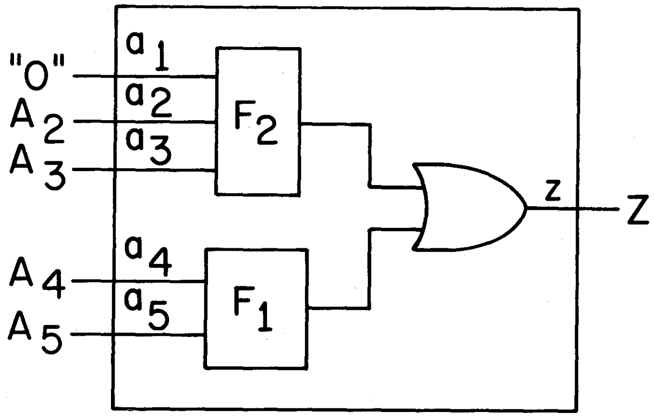

Figure 3d—Not conformal because the test pattern for F_2 may not be possible (condition 3)

3. Application of the test pattern for each AR function is possible by control of the inputs of the resulting function, and
4. For the output of each AR function, a sensitized path to the output of the resulting function exists.

Figure 3, where F_1 and F_2 are AR functions, illustrates a number of structures which are not conformal for one or more reasons.

The motivation for the use of various conditions in the above definition can be intuitively explained at this point. Condition 1 insures that each input fault can be made distinguishable from the other faults by the test pattern of one of the AR functions. The second part of the condition ("only one") prevents one input fault

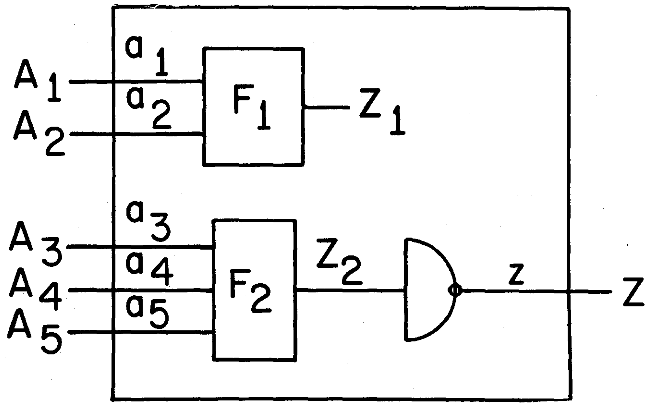

Figure 3e—Not conformal because the output Z_1 violates condition 4

from affecting more than one AR function. The resulting output vectors of each AR function need a sensitized path to the final output to be observable under normal, as well as under various failure conditions. One of the ways to provide such a path is to maintain a unique combination of the inputs at the remaining AR functions (which provides a sensitized path) during the testing of each AR function. Following this procedure, in addition, permits distinguishability of the input faults of one AR function from the input faults of other AR functions as we will see. If an input fault of the resulting structure affected more than one AR function, this procedure may not be possible in all cases. Condition 2 prevents multiple input failures from having identical output vectors, thereby permitting the required localization. Condition 3 assures the ability to apply test patterns to various AR functions, and the condition 4 makes the resulting output vector available at the final output of the resulting structure.

Having established some structural constraints and some intuitive basis for them, we proceed to prove the AR property of conformal structures.

Theorem 4:

A conformal structure implemented with AR functions and logic gates results in an AR function.

Proof:

Let $F_1, F_2, \cdots F_n$ be the n AR functions used in the conformal structure. We will refer to these functions as component AR functions. Let Z_i be the output of the function F_i and let Z be the output of the resulting function F with conformal structure.

To prove the AR property of the resulting conformal structure, we will show the existence of a test procedure which provides the distinguishability of the input/output faults of F.

As the structure is conformal, each input fault of the resulting structure results in a permissible input fault at one (and only one) AR function. Thus the set of input faults of the resulting structure is a subset of the input faults of the component AR functions. Also due to the second condition of conformality, these input faults of F produce unique input faults at the component AR functions. Thus if the input faults of the component AR functions are distinguishable, then the input faults of the resulting function are also distinguishable.

Consider a test procedure wherein we apply the test pattern to each component AR function, one after another, by control of some of the inputs while maintaining the remaining inputs at some logic conditions so as to provide a sensitized path to the output Z throughout the test pattern. The conformality of the structure accounts for the feasibility of such a test procedure. We will show that this test procedure provides the required distinguishability.

To show the distinguishability, we will follow these steps. First we will show that input faults of any F_i are distinguishable from the other input faults of the same AR function. Next we will show that these faults are distinguishable from the faults at the output Z. Then we will show the distinguishability of these faults from the input faults of the other AR functions. Note that the distinguishability is symmetric, i.e., if a is distinguishable from b, then b is distinguishable from a. Therefore, the distinguishability of the output (Z) faults from the input faults of the resulting structure is easily established. Finally, we will show the distinguishability of the output faults from each other.

During the test procedure, the test pattern T_i is applied to F_i, and a sensitized path to the final output for the output Z_i is provided. As F_i is an AR function, its input faults produce unique non-normal output vectors at Z_i for the test pattern T_i which due to the availability of the sensitized path are transmitted to the output Z. (The normal output at Z may be the same as, or could be the complement of, the output at Z_i during the test pattern T_i as sensitization does not guarantee the polarity of the output. But as the uniqueness is what we are concerned with, and as uniqueness is preserved under complementation, we do not worry about the polarity.) Note that due to the conformality of the structure during the test pattern T_i only permissible faults (s-a-0 or s-a-1) exist at the inputs of the function F_i. Further, as we consider only a single failure, when we are considering the distinguishability of the two input faults of F_i, the path sensitization can be assumed to be failure free. Thus the input faults of F_i produce unique output vectors at the output Z_i, which in turn, produce unique output vectors at the output Z. Therefore, the input faults of F_i are distinguishable from the other input faults of the same AR function F_i, when test pattern T_i is applied as a part of the proposed test procedure by observing Z. Also, as the resulting output vector at the output Z for each input fault is different from normal, the input faults are detectable.

Now consider the distinguishability of the input faults of the function F_i from the output faults at the output Z. Observe that when the test pattern T_i is applied, as a part of the test procedure, the observed output vector for the faults at the output Z will be either all

0's or all 1's. While the input fault of the function F_i results in a non-normal, non-zero, non all 1's output vector at the output Z_i, and will be transmitted to the output Z due to availability of a sensitized path. Also as all the properties (non-normal, non-zero, non all 1's) of the output vector are preserved even under complementation, the resulting output vectors at the output Z, for the input faults of the AR function F_i, are non-normal, non-zero and non all 1's. Therefore, the input faults of F_i are distinguishable from the faults at the output Z when the test pattern T_i is applied.

Now consider the distinguishability of the input faults of one AR function, say F_i, from those at the inputs of the other AR functions, say F_j where $i \neq j$. The two AR functions, F_i and F_j, do have independent inputs* due to condition 1 of the conformal structure. Therefore, during the testing of F_i by the test pattern T_i, to provide a sensitized path a single combination of the inputs of F_j can be used throughout the test pattern T_i. The input faults of the function F_j would result in one of four cases during the test pattern T_i.

1. It does not affect the final output.
2. It makes the final output a complement of what should be (changes the polarity of sensitization), i.e., fails all tests in T_i.
3. Makes the final output a logic 0 for all tests.
4. Makes the final output a logic 1 for all tests.

In the first case, the resulting output is normal; in the second case, it is always the complement of the normal; in the third and the fourth cases it is at a permanent logic condition for the test pattern T_i. Since the input faults of F_i, on the other hand, result in unique, non-normal, non-zero, non all 1's output vectors, they are distinguishable from the input faults of F_j in cases 1, 3, and 4. Further, by Theorem 3, the complement of the normal output vector cannot be the same as any output vector for the input faults. Therefore, the input faults of the functions F_i and F_j are distinguishable.

As we repeat the procedure for each AR function, each input fault of every component AR function will be distinguishable from other input faults and from the output faults at Z.

Finally, as the property of distinguishability is symmetric, the output faults are distinguishable from the input faults. Also as the output faults produce an all 0's or all 1's output vector and as normal output vector has a logic 0 and a logic 1 element, the output faults are detectable and distinguishable from one another.

Therefore, as the test procedure considered, provides unique, non-normal, output vectors for various faults, the resulting conformal structure has the AR property and the test procedure is its test pattern. (Q.E.D.)

It becomes apparent that the formulation of conformal structure provides us with a great flexibility in generating new AR functions. Of these, three are worthy of specific mention.

Corollary 1: The *complement* of an AR function is an AR function.

Corollary 2: The AND function of AR functions is an AR function if the resulting structure is conformal.

Corollary 3: The OR function of AR functions is an AR function if the resulting structure is conformal.

EXISTENCE OF A GENERAL N-INPUT AR FUNCTION

There are a number of ways by which we can prove the existence of an n-input AR function, for any n. For instance, it is easy to show that a parity network* with any number of inputs has the AR property. However, for three or more inputs other functions, apparently less complex, also exhibit the AR property. We, therefore, will create simple two- and three-input AR functions and use them in a constructional proof for proving the existence of a general AR function. This proof is preferred because it also provides a scheme for generating relatively simple AR functions.

Existence of a 2-input AR function

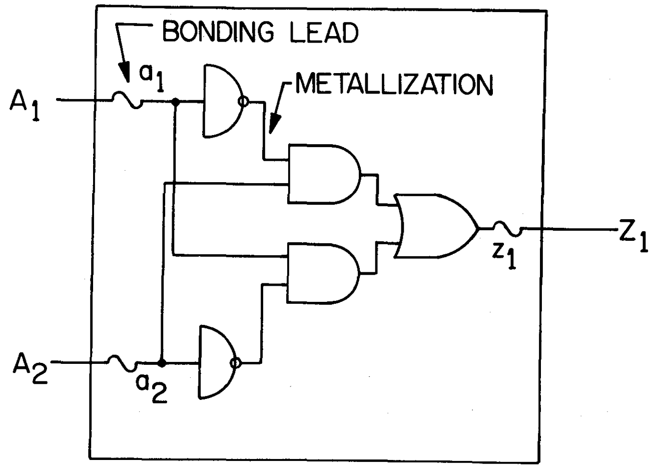
Figure 4 shows a two input exclusive OR function. Also shown are the resulting functions for various faults. Note the uniqueness of the resulting function for each fault. As the resulting function for each fault is unique and non-normal the exclusive OR function is an AR function. Table II shows a test pattern for the AR function. That this is a test pattern can be shown by generating the resulting output vectors for various conditions and showing their uniqueness.

Existence of a 3-input AR function

Figure 5 shows a three input function. Also shown are the resulting functions for various faults. As the result-

* An input fault of F only affects one of the F_i's.

* A single output network using exclusive OR gates.



$$Z_1\ (\text{NORMAL}) = a_1\,\bar{a}_2 + \bar{a}_1\,a_2$$

$$\begin{array}{llll} Z_1(z_1{}^0) & = 0 & Z_1(a_1{}^1) & = \bar{a}_2 \\ Z_1(z_1{}^1) & = 1 & Z_1(a_2{}^0) & = a_1 \\ Z_1(a_1{}^0) & = a_2 & Z_1(a_2{}^1) & = \bar{a}_1 \end{array}$$

Figure 4—A 2-Input AR function

ing function for each fault is unique and non-normal the function has the AR property. Note that the function of Figure 5 is simple compared to a three input parity network. Table III shows a test pattern for the AR function of Figure 5. That this is a test pattern can be shown by generating the resulting output vectors for various conditions.

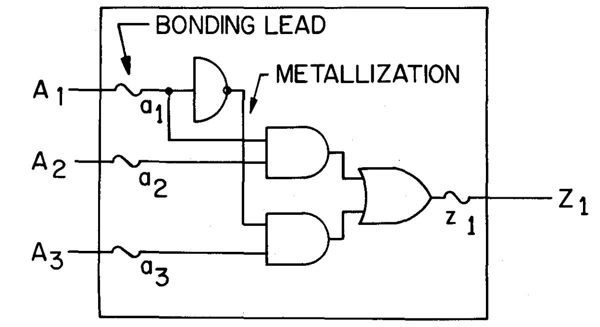
Having shown the existence of 2- and 3-input AR functions we now show the existence of a general n-input AR function for $n \geq 2$.

Theorem 5:

There exists an n-input AR function for any finite $n \geq 2$.

TABLE II—A Test Pattern for the 2-Input AR Function of Figure 4

Test No.	Inputs		Normal Output
	A_1	A_2	
1	0	0	0
2	0	1	1
3	1	0	1



$$Z_1\ (\text{NORMAL}) = a_1 a_2 + \bar{a}_1 a_3$$

$$\begin{array}{llll} Z_1(z_1{}^0) & = 0 & Z_1(a_2{}^0) & = \bar{a}_1 a_3 \\ Z_1(z_1{}^1) & = 1 & Z_1(a_2{}^1) & = a_1 + \bar{a}_1 a_3 = a_1 + a_3 \\ Z_1(a_1{}^0) & = a_3 & Z_1(a_3{}^0) & = a_1 a_2 \\ Z_1(a_1{}^1) & = a_2 & Z_1(a_3{}^1) & = a_1 a_2 + \bar{a}_1 = a_2 + \bar{a}_1 \end{array}$$

Figure 5—A 3-Input AR function

Proof:

We have already shown the existence of 2-input and 3-input AR functions. Consider any integer $n>3$, then it is always possible to find integers q and r ($2 \leq q \leq n/2$ and $0 \leq r \leq 1$) such that $n = 2q + 3r$. In other words, for all even integers, we have $r=0$, and $q=(n/2)$ while for odd integers $r=1$ and $q=[(n-3)/2]$.

Since the OR function of AR functions is an AR function by Theorem 4 (Corollary 3), we can generate an n-input AR function for $n>3$ by generating an OR function of q 2-input AR functions and r 3-input AR functions with conformal structure. Therefore, n-input AR function exists for any finite $n \geq 2$. (Q.E.D.)

THE CONVERGENCE PROPERTY

In the previous sections, we examined few techniques to generate new AR functions. The functions, thus

generated, had the property of failure localization to a single bus for the input/output faults of the resulting function. To that extent, these new functions can be used internal to the LRU to provide the failure localization capability. If we provide an AR function in each LRU, the special output (the output of the AR function) of each LRU must be made observable. Does the possibility of reducing the total number of observable points exist? To answer this, we consider if convergence of AR functions by an AR function preserves the failure localization property.

First, let us illustrate what we mean by a converging connection. Let $F_1, F_2, \cdots, F_n$ be n AR functions. Further, let each F_i have m_i inputs and one output. Also let F_c be an AR function with n inputs. Now consider a configuration, shown in Figure 6, where the output Z_i of each F_i is connected to the ith input of F_c. Let Z be the output of F_c. The resulting structure will be termed a converging connection.

It can be shown[7] that when the inputs to a converging connection are independent and failure exclusive, the input/output faults of each component AR function (F_i's or F_c) are locatable by observing Z alone. Thus a test procedure exists which produces unique output vectors at the final output Z for each of the faults at the inputs (a_{ij}; $1 \leq i \leq n$, $1 \leq j \leq m_i$) or at the outputs (Z_i's or Z_c). Further, it can be shown that the length of such a test procedure does not exceed the sum of the tests in the test patterns of the component AR functions. The detailed proof of this result, which follows a similar line of reasoning as that of Theorem 4, is rather lengthy and is, therefore, not included.

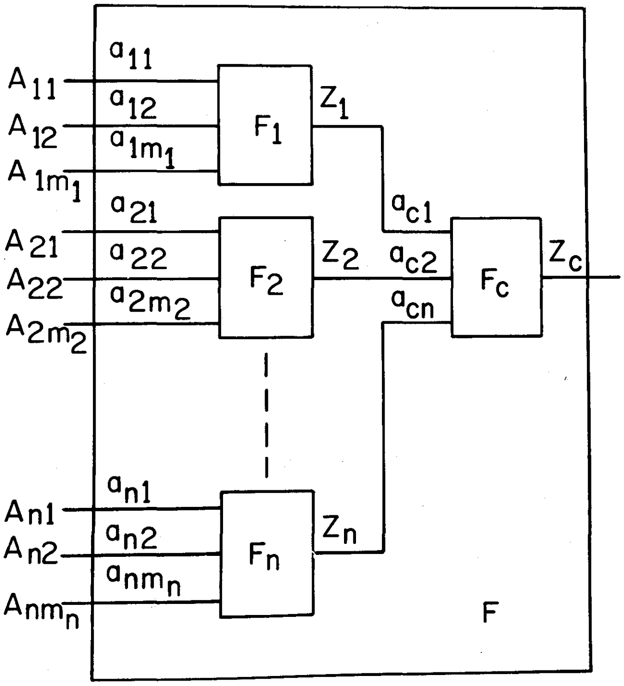

Figure 6—A convergent structure

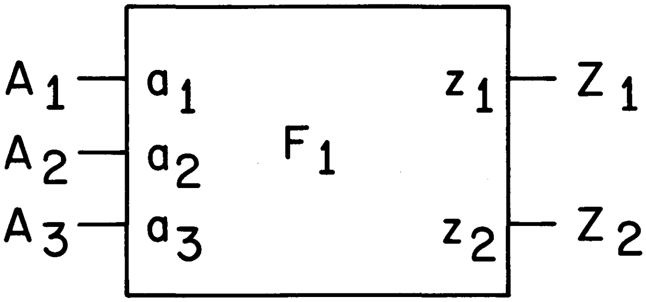


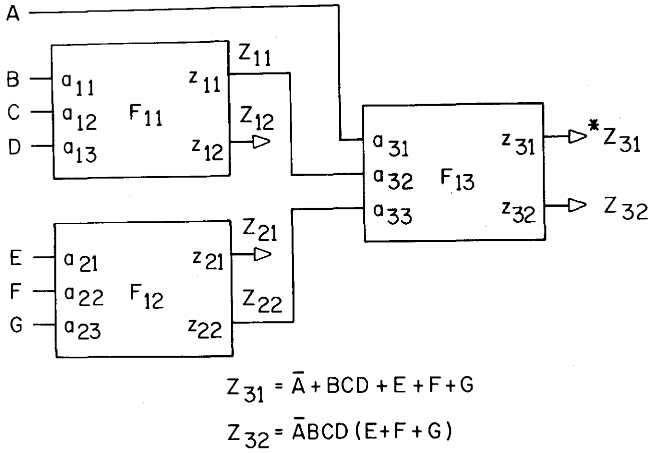
$$Z_1 = \overline{A_1 A_2 A_3}$$
$$Z_2 = \overline{A_1 + A_2 + A_3}$$

Figure 7—A simple LRU for example subsystem

Next we demonstrate the application of converging connections in reducing the number of points which must be observable. Note that in Figure 6 if all AR functions F_i were used in different LRU, all of the n outputs Z_i's must be made observable. In that case, the test pattern T_i however, can be applied simultaneously to each AR function F_i. Thus the number of tests would be equal to the maximum of the number of tests in the test patterns T_i's. On the other hand, by the use of a converging connection we are able to reduce the number of points which must be made observable to one (from n). But the length of the test procedure to obtain the same degree of diagnostic resolution is now equal to (or less than) the sum of the number of tests in all the test patterns T_i $(1 \leq i \leq n)$ and the number of tests in the test pattern T_c for the AR function F_c.

AN ILLUSTRATIVE EXAMPLE

To illustrate the application of AR functions, a very elemental LRU (Figure 7) is selected as a building block of a simple subsystem (Figure 8). Realistic systems, of course, would be considerably more complex. A comparison is made of the AR approach with present day techniques in terms of the required number of



$$Z_{31} = \bar{A} + BCD + E + F + G$$

$$Z_{32} = \bar{A}BCD(E+F+G)$$

Figure 8—An illustrative subsystem
* The points which are to be observable are identified by the arrowhead

observable points and the length of the required test procedure.

A conventional approach

As can be easily inferred from the functions for Z_{31} and Z_{32}, if the observable points are restricted to the final outputs (Z_{31} and Z_{32}), all faults cannot be localized. For instance, the s-a-0 faults at a_{11}, a_{12} and a_{13} and s-a-1 fault at z_{11} are indistinguishable. Similarly, the s-a-1 faults at a_{21}, a_{22}, and a_{23} and s-a-0 fault at z_{22} are indistinguishable. The distinguishability of these faults can be obtained if the outputs Z_{12} and Z_{21} are made observable. Thus to obtain a complete localization we need four observable points.

Table IV shows a conventional test procedure for the subsystem generated by the use of well-known techniques.[4,5,6] The first four tests provide the testing of the faults at the inputs of F_{11}. The conditions at the other inputs are maintained as prescribed to provide a sensitized path to the output Z_{31}. One of these tests also provides an all zero test for F_{12}. The next three tests similarly provide the testing of the faults at the inputs of F_{12}. Note that the input combinations for F_{11}, to provide a sensitized path for the output Z_{22} during these tests, are carefully chosen to simultaneously provide the tests for F_{11} when the output Z_{12} is observable. The eighth test provides partly for the testing of the input a_{31}. Observe that so far only a subset of the total tests required is applied (indirectly) to F_{13}. The conditions corresponding to the remaining tests are applied by the tests 9 through 12. Note the use of carefully chosen input combination at the inputs of F_{12} to simultaneously provide the required test combinations if the output Z_{21} was observable. Finally test 13 is necessary to provide the remaining test combination for F_{12} when output Z_{21} is made observable. Thus we see that a total of thirteen tests and four observable points are required for localization of all faults.

The proposed approach

Next, consider the use of a three-input AR function (F_{AR}) as shown in Figure 9, which is the function discussed in Section 6. One output is to be added to the LRU to make the output of the AR function observable.

Consider the implementation of the subsystem using LRU's with AR functions as shown in Figure 10. Table V shows the required test procedure to locate all faults, except the ones at the outputs Z_{31} and Z_{32}, by observing only the outputs of the three AR functions (Z_{13}, Z_{23}, Z_{33}). Outputs Z_{31} and Z_{32} will be inputs to some other LRU's and therefore their faults will be localized by the AR function of those LRU's. Recall that for each AR function four tests are required (Table III). If the

TABLE IV—A Test Procedure for the Subsystem of Figure 8 (Without AR Functions)

$$Z_1 = \overline{A_1 A_2 A_3}$$

$$Z_2 = \overline{A_1 + A_2 + A_3}$$

$$Z_3 = A_1 A_2 + \bar{A}_1 A_3$$

Figure 9—The LRU with AR function

conditions corresponding to this test pattern are applied to each of the AR functions, then the fault localization will be achieved. The first four tests provide the conditions for the test pattern of the AR functions in F_{21} and F_{22}. In so doing, by applying appropriate conditions at the input A we also manage to provide the conditions corresponding to two of the four tests for F_{23}. The last two tests provide the remaining tests for F_{23}. Note that we use the results at the output Z_{33} only if we have determined that no input fault exists at F_{21} and F_{22} i.e., when Z_{13} and Z_{23} do not show a failure. Thus the output Z_{33} is used only to detect and locate the input faults of F_{23}.

TABLE V—A Test Procedure for the Subsystem of Figure 10 with AR Functions

Test No.	Test Procedure							Inputs to F_{23}		
	A	B	C	D	E	F	G	A	Z_{11}	Z_{22}
1	0	0	1	0	0	1	0	0	1	0
2	0	0	0	1	0	0	1	0	1	0
3	1	1	0	1	1	0	1	1	1	0
4	1	1	1	0	1	1	0	1	1	0
5	0	1	1	1	0	0	0	0	0	1
6	1	1	1	1	0	0	0	1	0	1

Thus a test procedure with six tests and three observable points is sufficient to localize the failures. If we would like to reduce the number of observable points further, we can use a converging (Section 7) AR function F_3 such as the 2-input AR function of an earlier section (Figure 11).[3] The points which must be observed are the outputs Z_{33} and Z_{41}. But when we reduce the number of observable points by converging we pay a penalty in the length of test sequence. Recall that, as per upper bound it would take 11 tests to test the convergent structure (as a two input AR function requires three tests). Two additional tests will be required to provide the remaining tests for the AR function F_{23} as before. And thus a total of 13 tests may be necessary. However, as shown in the test procedure of Table VI, the actual number of tests required for the converging connection is only eight, and therefore, a total of nine tests are required (Tests 1 and 5 are identical). Note that the required test pattern for the

converging AR function F_3 is applied in the process of applying test patterns for the AR functions of F_{21} and F_{22}. Table VII summarizes these results for the subsystem considered in the illustration.

It is important to note that the AR function design is unrelated to the function actually performed on an LRU, but is only dependent on the number of inputs. Thus in practical LSI applications, as the level of integration goes up and as the gate/pin ratio increases, the percentage redundant logic required for AR function will decrease.

CONCLUSIONS

In this paper we have introduced the notion of adding special Ambiguity Resolver functions to Least Replaceable Units in order to provide localization of input/output failures. We have demonstrated the existence of these functions for any number of inputs and shown how they can be synthesized by means of a conformal approach. For those cases in which it is important to further reduce the number of points that must be made observable, a convergent structure is discussed, along with an upper bound on the length of the required test sequence.

The Ambiguity Resolver approach is certainly not the complete answer to the fault localization problem in Large Scale Integrated circuitry, but it is a step in the direction of tailoring the diagnostic technique to the characteristics of the environment.

INTRODUCTION

Major efforts have been devoted to the application of computational techniques to medical diagnosis, a difficult computational task. The amount of information necessary to perform an exhaustive diagnostic search is formidably large. The "costs" associated with making certain diagnoses or eliminating others often affect a tentative diagnosis as much as the probabilities of the conditions being considered. These "costs" are usually intuitively considered by the physician and usually are not available as numerical quantities to use in a linear programming algorithm. Lastly, diagnosis is done both rapidly and well by most physicians.

In contrast stands therapeutics, specifically the administration of medicines. After deciding what and how much effect is desired (choosing the drug and the therapeutic objective) the problem is how much to give and in what temporal pattern. Drug-dosing is inherently quantitative and is presently done sub-optimally. Accordingly, we have approached the construction of algorithmic techniques for determination of drug dosage.

Since drug effects correlate far better with drug levels in the body than with doses administered, a **T**arget **B**lood **L**evel (TBL) approach to drug administration seems reasonable. In order to implement such an approach, estimates of appropriate pharmacokinetic parameters for individual patients must be obtained so that pharmacokinetic models, providing the mathematical framework for drug level predictions, can be used to determine optimal dosage regimens. We have described a conceptual scheme and associated statistical methodology to accomplish this objective.[1] In this paper, we summarize the scheme and methods, provide justification for our approach, report early results, and describe some future plans.

BACKGROUND

Eighteen to thirty percent of all hospitalized patients sustain one or more adverse drug reactions[2,3] and the duration of their hospital stay is nearly doubled as a result. In addition, 3 to 5 percent of all admissions to hospitals are primarily for a drug reaction[2,4] and 30 percent of these patients have another drug reaction during their hospital stay. The economic consequences of these reactions are staggering: one-seventh of all hospital days is devoted to the care of drug toxicity, at an estimated annual cost of 3 billion dollars.[5] The same amount would cover the cost of all prescription drugs used in this country per year.

An encouraging aspect of the large adverse reaction rate is that 70-80 percent of them are direct extensions of the pharmacologic actions of the drugs involved,[6] and therefore should be predictable and preventable. The majority of the pharmacologic adverse reactions are probably not the result of extraordinary individual sensitivity to the actions of the agent, but rather of dosage regimens leading to inordinately high blood levels.

The evidence which associates drug levels in blood or tissues with their effects is striking. It is particularly clear-cut for those drugs responsible for more

* Supported in part by United States Public Health Service Grants GM 16496 and GM 10791.

than 50 percent of dose-related adverse reactions:[6] digitalis preparations,[7] anti-arrhythmic drugs,[8,9] and antimicrobials.[10] As an example, consider digoxin, a drug which, in clinical practice, is both highly useful and formidably toxic. About 20 percent of all patients receiving the drug demonstrate pharmacologic toxicity and as many as 30 percent of those demonstrating such toxicity may die of it.[11] A three-or-more-fold variation in the blood levels of digoxin is seen in different individuals given the same doses of the agent, but toxicity is highly correlated with blood levels: in one study, 90 percent of individuals with levels less than 2 nanograms/ml of plasma were nontoxic and 87 percent of those with levels greater than this amount were toxic.[12] For digoxin, then, individual sensitivity differences may account for as little as 10 percent of clinical toxicity.

That levels of drugs in body fluids should bear a more constant relationship to effects than doses administered is readily understandable. Drugs act on receptors and elicit effects which are proportional to the fraction of occupied receptors. The concentration of a drug at its receptor is a major determinant of drug effect. The utility of blood levels stems from the observation that although few drugs act on receptors in the blood itself, after drug distribution, tissue concentrations of drugs (presumably at their sites of action) bear a reasonably linear and constant relationship to blood levels. Individual variation in absorption, distribution, metabolism and elimination of drugs, however, causes widely varying blood levels to be found in different individuals, despite standard doses.

It seems clear, then, that a TBL approach to drug dosage design is theoretically sound and likely to be beneficial. Pharmacokinetic models can represent and quantify variations in absorption, distribution, metabolism and elimination of drugs. In order to utilize a pharmacokinetic model for the purpose of drug dosage design, some way of predicting individual variation in the parameters of the model must be available. An obvious approach is to measure blood levels of agents at varying time intervals after administration of a standard regimen and to adjust the parameters of the model to yield a best fit to the observed levels. This is analogous to the way in which most physicians administer drugs today: a standard regimen is begun, effects are observed (presumably proportional to levels) and dosage adjustments are made based upon these observations. The quantitative adjustments are more intuitive than optimal. We can do better than merely improve the quantitative aspects of the feedback process described above, although doing only this can lead to excellent results.[13]

The factors responsible for pharmacokinetic variation can be related to the physiological determinants of pharmacokinetic processes. For example, digoxin is primarily eliminated by renal excretion. The elimination rate of the drug should be, and is, proportional to renal function.[14] Tests designed to assess renal function [such as measuring the serum creatinine or **B**lood **U**rea **N**itrogen (BUN)] are routine. These measurements can be used to modify the dosage regimen of digoxin in accord with the excretory ability of the individual patient.

The combination of prior clinical information with quantitative feedback adjustment should produce a system for optimal drug dosage design. In order to do this we require a black box with the following characteristics: the inputs are clinical data, commonly and easily available (such as height, weight, age, sex, and the results of standard laboratory tests, e.g., tests of renal function); the outputs are a set of predicted values for the parameters of a pharmacokinetic model. On the basis of these predicted parameter values, the initial dosage of a drug can be set to produce the TBL. As additional data in the form of blood level measurements or changes in the laboratory tests become available, estimates of the parameters can be optimally modified (by the black box) to improve dosage suggestions.

THE DOSE—BLOOD LEVEL RESPONSE MODEL

The first task in the design of the black box is to formulate a model for the relationship between the

TABLE I—The Conceptual Scheme

IV. K → Blood Level Predictions
type: non-linear pharmacokinetic model
data source: theoretical
example: one compartment model with first order absorption

clinical data and the pharmacokinetic parameters. Our model is outlined in Table I. Clinical observations (O) are used to predict physiological variables (P). These predictions can be defined through study of the general population and need not be restricted to those individuals who have received the drug of interest. The relationships are not restricted as to type; they may be linear, non-linear, discontinuous, etc. The example given in Table I, **B**ody **S**urface **A**rea (BSA), is a quantity estimated from a non-linear function of height and weight and is expected to be more linearly related to metabolic capacity and body "compartment" sizes than either height or weight. In Table I, the pharmacokinetic model itself is a simple one: the one-compartment open model with first order absorption. Its parameters (K) are: Kel, the first-order rate constant of elimination of the drug; Vd, the volume of distribution of the drug; and a series of Ka's and f's, each pair representing the rate constant of absorption and the fraction of dose absorbed for a specified route of administration. The K may be linearly related to the P. For example, the Vd of a drug might be predictable from a patient's body surface area, as shown in Table I. A non-linear function of a K might bear a linear relationship to one or more of the P. An example is the clearance of a drug (the product of Kel and Vd) which would be linearly related to a P describing renal function (the **G**lomerular **F**iltration **R**ate, GFR) if the drug were eliminated by the kidneys. To keep the scheme general, a set of pharmacokinetic variables, Q (distinct from the K) are defined as functions, again of any variety, of the K. The Q are defined wholly from theoretical considerations. Finally, having defined the P and Q so that we expect linear relationships to hold between them, we assert that they are related linearly. The first data-fitting task is that of estimating the coefficients of the linear P to Q transformation. This can be done utilizing data from individuals whose clinical observations are known and whose blood levels of drug have been measured.

The full model allows utilization of general population data and prior information in the form of both theoretical relationships and constraints on the coefficients to be estimated for the P to Q transformations. The use of an extremely simple pharmacokinetic model is justified on two grounds. First, for clinical medicine, our scheme must be responsive to shifts in patient characteristics and inexpensive to operate. More parameters imply more data-fitting, degrading responsiveness, and increasing cost. Second, most drugs with clinical utility do not cause significant toxicity until their blood levels are at least twice those at which significant efficacy is achieved. Therefore, there is no need for great precision; prediction errors of 50 percent should have little clinical import.

Before discussion of the problem of merging feedback (blood-level) information with initial estimates, some preliminary tests of the appropriateness of the conceptual scheme and of the ability to estimate coefficients for the P to Q relationship will be presented.

TEST OF THE MODEL

Dr. Thomas Smith of the Massachusetts General Hospital kindly supplied us with clinical data, dosage history, measured blood levels (one per patient) and determinations of the presence or absence of toxicity in a group of 99 patients who received digoxin. The clinical data for each patient consisted of age, weight and BUN. Fifteen patients were questionably toxic and 18 definitely toxic by published criteria.[11,12] The model was adapted to digoxin from the available clinical data, by using weight as a predictor of BSA, and age, weight and BUN as predictors of renal function. Vd was assumed proportional to BSA. Digoxin clearance was assumed proportional to GFR and BSA since the non-renal losses of digoxin are presumably metabolic and should therefore be related to BSA. All digoxin had been administered orally so that Ka and f values for the oral route only were needed. Digoxin has an absorption value (f) of .85.[15] While the precise rate of oral absorption is not known, it is sufficiently rapid relative to rates of elimination[14] that an arbitrary large value could be assigned to the oral-rate constant of absorption without expected loss in accuracy. Data was adequate to establish an expected value for Kel for normal individuals, and to support the assumption that digoxin clearance should be linearly related to GFR.[16] Data on the rate of non-renal loss of the drug is scanty, and no clear data exist for estimating the relationship between BSA and Vd. Accordingly, the patient data were first used to estimate these values using standard non-linear data fitting techniques. The blood levels were weighted by the inverse of the observed values plus the measurement error in their determination because, on the one hand, with unweighted measurements, fitting to absolute errors inappropriately magnifies the importance of those patients with large measured blood level values, and, on the other hand, data fitting by pure relative error (corresponding to weighting by the inverse of the square of the measured value plus the measurement error variance) remove all bias toward greater predictive accuracy for higher values, which are the more clinically important ones, being indicative of toxicity.

TABLE II—Relation Between Program-Predicted and Actual Blood Levels of Digoxin in a Sample of 99 Patients

Information Used	Correlation Coefficient (r)	r^2	σr^2
1. Daily dose	.29	.08	—
2. 1 + model	.31	.10	+.02
3. 2 + weight	.42	.18	+.08
4. 3 + age	.47	.23	+.05
5. 4 + BUN	.73	.54	+.31

We arrived at a value of 9 percent per day non-renal loss (as opposed to an estimate of 14.4 percent per day[16]) and a Vd value of 351 liters/square meter of BSA. It is noteworthy that these estimates could be easily obtained from the crude clinical data at our disposal. The use of our scheme permits estimation of population values for pharmacokinetic quantities from usual clinical data and does not demand separate and elaborate experiments. This point is crucial, since an individual blood level determination obtained from clinical usage of the feedback portion of the system will not only serve to improve the estimates of that individual's responses, but also add to the data base, making improved population estimates possible.

With the scheme set for digoxin and necessary values obtained from the literature, or as noted above, from the data itself, the ability of the scheme to predict blood levels of the patients, using various amounts of prior clinical information, was examined. Table II shows the resultant correlations. The only upward bias in utilizing the correlation coefficients to describe the predictive capacity of the system stems from the use of one degree of freedom for the estimation of the non-renal losses, since Vd operates in the pharmacokinetic model as a scale factor only. The fraction of total variance in the actual levels which is explained by the computed levels is expressed by r^2; in the absence of any clinical data save the dose administered, only 8 percent of the level variance is explained, while use of all the clinical data allows explanation of 54 percent of the variance. Knowledge of renal function makes the major contribution to accurate predictions, but the patient's weight, the sole predictor of size used, explains as much of the variation in levels as does the dose. In order to exclude the possibility that the few very high values present in the data were responsible for the high correlation we obtained, despite our weighting scheme, predictions were examined when weighted by the inverse of the square of the measured value plus the measurement error variance. Under these conditions, the correlation coefficient for predictions made with full information fell only to .71.

More important, however, than the ability to predict the measured values with a modest degree of accuracy, is the potential clinical implication of the predictions. As has been mentioned, digoxin levels greater than 2 ng/ml are associated with a significant incidence of toxicity. Table III compares the toxicity predictions of the actual measured levels, using this cut-off point, with those of the predicted levels. Although the predicted values are not quite as good at predicting toxicity as are the measured values (there are, however, no significant differences in the columns of Table III by χ^2 analysis), use of the scheme might have prevented 10 of the 18 toxicities in this group of patients. Clearly the potentially prospective availability of the predictions and the non-toxic dosage schemes they would engender outweigh the slight (retrospective) diagnostic advantage of the actually measured levels.

THE FEEDBACK PROCESS

The requirement for feedback adjustment of the model parameters is that it make an orderly transition from estimates of an individual's pharmacokinetic parameters based solely upon population data to ones based to a greater extent upon measured blood levels of the drug. Our approach is based upon an estimation scheme valid in circumstances where an individual parameter vector characterizing responses (in our case, the Q vector "characterizes" the blood level "response") is dispersed about a population mean (that is, individual vectors are similar, but not identical).[17] This regression method allows efficient estimation of the mean value of the parameter vectors in the population, of the extent of dispersion of ind.v.dual parameters about the population mean, and of the

TABLE III—Comparison of Predictions of Digoxin Toxicity by Actual and Program-Predicted Blood Levels

Levels Used	Predictions of Toxicity False +	 False −	Total Correct
Actual	10/66	3/18	71/84
Program-predicted	11/66	8/18	65/84

values of the parameter vectors characterizing each individual. In our case, population data is used to estimate a mean population Q vector, the appropriate adjustments to be made in this vector for the values of clinical observations, a population variance matrix of parameter prediction error, Λ, and the variance of prediction error associated with individual blood levels, σ^2. An individual's Q vector is assumed to be the sum of the population mean vector adjusted for his set of clinical observations, plus an individual shift vector, originally unknown, with mean value, zero. For initial dosage suggestions, the shift vector is assumed to be zero. For the feedback portion of the system, given Λ and σ^2 and the actual versus predicted blood level for the individual, a non-zero value is assigned to the individual shift vector so as to maximize the prediction likelihood function (an empirical Bayes estimator). A more complete description of the statistical methods underlying this approach can be found in References 1 and 18. What occurs, in effect, is that the information content of a blood level measurement is used to decrease the uncertainty of our knowledge of the components of an individual's Q vector (and hence his K vector) so as to minimize the mean square error in the resulting blood level predictions.

TEST OF THE ESTIMATION SCHEME

Examination of the problems attendant upon estimation of a population dispersion matrix has begun. The simpler case of an underlying response model linear in the explanatory variables (the P) was studied first.

Despite the linearity of the underlying model, an analytic solution is not apparent for the dispersion matrix; thus, even in the linear case, one is forced to use non-linear techniques to maximize the likelihood function. For this reason the linear and non-linear cases share many characteristics. If efficient estimation of a dispersion matrix could not be accomplished in the linear case, we would be pessimistic about the ability to do so in the non-linear case. The problem can be reduced to a search over the space of triangular matrices, T, such that $TT' = \Lambda$. The number of parameters to be estimated by non-linear methods is therefore $p = k(k+1)/2$, where k is the dimension of Λ. The Fletcher-Powell algorithm has been used to seek a maximum of the likelihood function over this space. The results of similations to date have been uniformly encouraging. The likelihood function is smooth and well behaved, and is well described by analytical derivatives. Regardless of the initial estimate chosen for T, the search algorithm converges to the same maximum and the same estimate for Ω, indicating that the likelihood function has a unique extremum. Convergence appears to require fewer than 3p iterations in all but a few cases, and 4p iterations has been the maximum. Thus the non-linearity of the problem appears to pose no difficulties.

More important, a relatively small amount of data appears sufficient to generate a satisfactory estimate of Λ. With four simulated observations on each of forty individuals, the estimates have consistently approximated the relative magnitudes of the diagonal elements of Λ, and the signs and magnitudes of the off-diagonal elements.

CURRENT WORK

The preliminary results obtained in the development of both the conceptual and estimation schemes has been encouraging. For the initial prediction portion, it was a simple matter to write an interactive program to run in a time-shared mode (for use via a remote access terminal) which would accept clinical observations on a patient as well as the (physician determined) TBL and deliver a dosage scheme (at present, for digoxin only) adjusted for the individual, and designed to produce the TBL. We note that although it is possible to provide information on the usual range of therapeutic blood levels for a drug through the program, the actual TBL for an individual patient should not be pre-programmed. It is precisely in the choice of this value that the physician is called upon to exercise his judgment as to the severity of the condition being treated, the therapeutic objectives sought and the projected sensitivity of his patient.

The interactive program and the initial dosage suggestions are being tested in a prospective fashion. Out-patients in need of digitalis or in need of adjustment of digitalis therapy are being studied. Both the primary physician and the program are suggesting regimens and predicting blood levels for these patients. The program output is made available to the physician for a randomly selected portion of the patients, and the physicians administer the drug as they see fit. Comparisons will be made in the accuracy of blood level predictions by the physicians and the program, and in the results of treatment (both for efficacy and toxicity) obtained by administration of program-suggested regimens.

The estimation scheme is being further tested by Monte Carlo studies. Multiple blood level data is being obtained on patients receiving digoxin so that the procedures for estimation of Λ can be tested. The questions of major interest are: (1) How much data is necessary to estimate Λ and how valuable is knowledge of the population dispersion in predicting individual blood levels? (2) What is the "trade-off" between clinical observations and subsequent blood level determinations; e.g., how many blood level determinations does it take to make up for lack of knowledge of renal function? (3) Do blood levels drawn early in the course of therapy, when maximum blood levels are not yet attained and toxicity is highly improbable, contribute substantially to the ability to predict future (maximum) blood levels? (4) At what point is the further determination of blood levels unnecessary; that is, when do they cease to contribute new information? We expect to have partial answers to these questions for digoxin at the time of the Spring Joint Computer Conference, and will devote the major portion of our presentation to discussing them.

SUMMARY AND CONCLUSION

We have devised a conceptual scheme which successively relates routinely available clinical observations to measures of underlying physiologic and pharmacokinetic factors and, ultimately, to pharmacokinetic parameters. These parameters can be used in a pharmacokinetic model to produce optimal initial dosage suggestions tailored to individual needs. We have also proposed a statistical methodology for adjustment and improvement of individual estimates in the light of subsequent response data. Preliminary tests of the various portions of the system have been uniformly encouraging. The scheme is highly general; most of the definable influences on drug absorption, distribution, metabolism and elimination can be represented, quantified, merged with others and tested in relation to blood level data. As a consequence of the statistical techniques used and the degree to which extensive exploitation of prior information is possible, determination of even a single blood level for an individual should markedly improve the system's predictive accuracy for him. Drug levels determined in order to improve treatment for an individual also contribute to the underlying data base used to update the various estimated population coefficients. Thus, the system can learn. A broad definition of what constitutes clinical observation will allow us to use the pharmacokinetic variables determined for one drug, for one patient, in the estimation of the pharmacokinetic parameters for another drug for him, if a meaningful relationship holds between them. Hence, the system is a research tool.

Automated therapy for nonspeaking autistic children*

by DAVID CANFIELD SMITH, MALCOLM C. NEWEY and KENNETH MARK COLBY

Stanford University
Stanford, California

CHARACTERISTICS OF AUTISTIC CHILDREN

Earlier publications described our computer method for stimulating language development in nonspeaking children, sketched several case histories (Colby 1968[4]), and gave statistical evidence that our high rate of success (71 percent) was due to our treatment method (Colby and Smith 1970[6]). This paper presents some proposals for making the method more widely available.

The term "Childhood autism" refers to a psychiatric category of mental disorders occurring in children. Though the category is somewhat unreliable, there is a set of characteristics generally associated with autism. Some of the characteristics of autistic children that influenced our approach and our choice of them as subjects are described briefly. More complete descriptions are provided by (Rimland 1964[4]), (Wing 1966[14]), (Ornitz and Ritvo 1968[10]), (Colby 1968[4], Colby and Smith 1970[6]).

An autistic infant's early disinterest in play or being picked up develops into a clear unresponsiveness to people during his second and third years. He avoids contact with other people, sometimes running and hiding from strangers. He does not respond when spoken to, and may be diagnosed as deaf. He may be fascinated by spinning objects and machines, such as phonographs, washing machines, light switches, etc. Far from being mentally retarded, an autistic child may be more adept than normal children at music and mathematics, and may have a better memory.

But the most characteristic attribute is his inability to acquire language. An autistic child has great difficulty understanding the relation between human vocal sounds and meaning. Those that do develop some speech have trouble advancing beyond nouns designating concrete objects to pronouns and verbs with their inherent abstractions. All studies agree that the prognosis for an autistic child is closely correlated with speech development; an autistic child who has not developed speech by the age of five has in the past almost invariably been institutionalized for the rest of his life. If a child has speech, therapy for his other disorders has a far greater chance of success; indeed, absence of language may in itself account for many of his other shortcomings. Having speech, he may begin to play with other children, to go to school, and to build a model of the world that is no longer devoid of concepts transmitted through language.

Though autism is admittedly an imprecise category, the best estimates currently available indicate the incidence of autism to be 4-5 per 10,000 children, about the same incidence as deafness and blindness in children.

The main thrust of our effort, then, is to stimulate language development using a method which is acceptable to an autistic child on his own terms. We give him a chance to play with a machine which happens to be a linguistic entity.

A COMPUTER METHOD FOR TREATING AUTISTIC CHILDREN

While our eventual goal is to implement our method on a system with modest or no computer support, our initial approach was dictated by the resources available to us and by our need for flexibility and modifiability. For these reasons we used the large computer system at the Stanford Artificial Intelligence Project, Stanford University. That system is a time-shared

DEC PDP-6/PDP-10 combination (DEC 1968[8]). The PDP-6 is primarily used as an I/O driver at Stanford; it controls digital-analogue and analogue-digital converters, among other input/output devices. The faster PDP-10 serves as the central processor. Actually a time-sharing system is not particularly suited to our method, because the need for rapid responses of long duration imposes real-time constraints which are incompatible with the philosophy of time-sharing. In fact, our need to output continuous sound of up to three seconds duration has not yet been implemented to our complete satisfaction.

Our goals of a flexible, easily-modifiable system with a minimum of programming effort initially led us to choose a high-level programming language MLISP (Smith 1970[12]), a dialect of LISP. Admittedly this was like using a sledge hammer to kill a fly, but MLISP enabled us to concentrate most of our early effort on the program itself and not on developing a programming system. Subsequently, our entire system was rewritten (by Malcolm C. Newey) in machine language. It was decided to invest the additional programming effort to gain the greater efficiency of machine language because the developmental phase of many of the games had been completed, and they are no longer being modified. In addition to the basic program itself, we and others at Stanford have developed a set of programs and program modules that facilitate the construction and modification of games. Among these utility programs are a drawing program, with which figures and animation can be easily drawn on a display using a light pen, and a sound recording program with which sound of up to three seconds duration may be recorded, digitized, and stored on the disk.

For hardware we use a computer-controlled Information International Inc. (III) graphics display with a screen about 2′×2′ in size that is refreshed 30 times per second. The need for rapid response, including animation, argued against the economy of a storage-tube display. At present, input is by an alphanumeric keyboard resembling a typewriter keyboard; the child presses a key, and a response is generated. We are currently investigating the possibility of light-pen interaction, so that the child can draw his own figures, and of microphone interaction, so that the computer would be activated by a voice signal rather than a keyboard signal. An associated, rapid-response auditory display is generated by randomly accessed, digitized records of voice, animal and mechanical sounds. The sounds are recorded using one of the utility programs, digitized at 20KC, and stored on secondary storage (IBM 2314 disk). About 1000 audio-visual experiences are available in the currently used set of games, requiring nearly 5 million words of disk storage. When a sound is to be played, it is retrieved from the disk, passed through a digital-to-analogue converter, and output through a speaker system. The high recording rate (20KC) was arbitrary; we wanted good clear fidelity, but a lower frequency (10KC or 5KC) could be used since we tend to favor low, vibrant sounds.

Thus we utilize at Stanford a PDP-10, a III display with keyboard, an IBM 2314 disk drive with 5 million words of secondary storage, and a D/A converter with a speaker system. Clearly these heavy requirements make the widespread replication of our total system impossible. However, we have anticipated eventual implementations of the method on small machines, and even on non-computer-controlled devices (as discussed below), by a modular construction of our programs. The sound and display files are organized into separate and distinct "games". Each game emphasizes a particular aspect of linguistic development. In most cases they do not share files; each game may be separately loaded into the computer much the same (conceptually) as tape cassettes may be loaded into a tape recorder. (In fact, that is one possible implementation of a non-computer device.)

The different game modules may be summoned by the sitter, a non-professional adult who is present at all therapy sessions. The following descriptions of the games are from an earlier paper (Colby and Smith 1970[6]). The descriptions are still valid because, as was mentioned earlier, these games are in their final form. Many games continue to be developed, but their philosophy is similar to that of the games presented here. These games are better described by the slides and recordings which will accompany presentation of this paper.

Game 4 is especially worth noting in view of the autistic child's impaired affective relationships with other people. Elements of compassion are introduced obliquely in several of the frames. For example, in one series a cartoon of a large ice cream cone is accompanied by sounds of loud, happy slurping, and the word SLURP! Then the top scoop falls off (PLOP!), and there is a groan of dismay. The sad faces of many children viewing this reveal clear communication of a shared emotional experience.

Game 1: Letters and numbers. The letter, number or symbol of the pressed key is displayed accompanied by a male or female voice pronouncing the appropriate sound. Many of the letters are shown in different sizes and shapes, and a few are drawn in motion automatically on the video screen.

Game 2: Words. Single words appear on the screen in response to pressing a key. The words consist of verbs and adjectives involving affect and motion, e.g., 'laugh', 'jump', and 'angry.' The affect terms are not only stated but enacted, i.e., the voice laughs while saying 'laugh.' All the major positive and negative affects are referred to in an attempt to exercise the child's affective repertoire. For example, the word 'kill' is spoken very belligerently, and the combination 'XYZ' is accompanied by a contemptuous Bronx cheer.

Game 3: Phrases. A letter or number is displayed in response to the corresponding key being pushed. Following the symbol appears a word or a phrase containing it one or more times, with arrows pointing to these occurrences. A male or female voice states the word or phrase. The words and phrases are selected on the basis of common occurrences in the child's life (e.g., 'funny', 'upstairs') and because of their absurdity (e.g., 'fried filet from Farnsworth', 'lambs go baaaaaa!').

Game 4: Cartoon pictures. This game consists of displayed phrases and pictures along with human, animal, machine and other sounds such as music. The figures consist mainly of animals and machines, with very few humans. Crude motion is achieved by moving the animals' legs or moving a vehicle across the screen. The pictures and sounds are intended to be ludicrous, absurd and amusing to children.

Game 5: Phrase completion. A phrase or sentence consisting of several words appears on the screen in response to a key; e.g., pressing 'J' produces 'the cow jumps over the moon.' A male voice expresses the sentence over and over until the child stops it by pressing any other key. When 'J' is pressed again the same thing happens, but on the third occurrence, while the full sentence appears, the voice omits part of it, saying e.g., 'the cow jumps over the ———.' The intent is for the child to fill in the omitted word or phrase, which is omitted one of three times.

Game 6: Word construction. Here the letters of the alphabet appear in a square around the edge of the video display. On pressing a key, a trumpet sounds with the Los Angeles Rams 'Charge!' call, a female voice says, 'Here comes the word,' a male voice states the word, e.g., 'cat,' and another male voice pronounces the letters, which one by one light up and move to the center of the screen to form the word. The word is again stated when the spelling is completed. The game demonstrates how words are put together letter by letter.

Game 7: Phrase construction. The alphabet is displayed at the bottom of the screen. In response to pressing a key, letters move to the top of the screen, following individual paths, to form a phrase, one word at a time. The effect is of chaotic motion resolving itself at the end into a coherent word.

Game 8: Typewriter. The video portion of this game consists of the symbols of the keys pressed appearing in lines from left to right until the screen fills up, whence they are all erased and a new sequence begun. The audio portion involves a male voice offering comments, requests and questions regarding the displayed symbols—e.g., 'Is this really eight?', 'where is O?', 'see the four?', 'now find I.'

Game 9: Spelling. The child types freely. If, by chance or design, he spells any of the words which occur in any of the games, the rest of the screen is erased temporarily leaving the word he has spelled centered in the screen. The appropriate sound is then played.

We are continuing to experiment with new games in an effort to build a library of the most successful approaches to stimulating language.

THE RATIONALE FOR AUTOMATED THERAPY

Colby has already expressed our initial motivation for using a computer in automated therapy (Colby 1968, p. 642[4]):

> My group's interest in a computer-based method for developing language in nonspeaking disturbed children derived from several sources. First, we were interested in the general problem of using computers in the problems of psychiatry, as for example through computer simulation of belief systems (Colby 1967a[2]) (additional references: (Colby and Smith 1969[5]), (Colby et al. 1971[7])) and man-machine dialogues (Colby and Enea 1967b[3]). Second, the work of Suppes (Suppes 1966[13]) and Moore (Moore 1963[9]) indicates that normal children learn reading, writing, set theory, and arithmetic rapidly and enjoyably by means of computer-controlled keyboards and displays. Third, the observation of many workers regarding the great preoccupation of some disturbed children with mechanical objects which they can manipulate and control is impressive. Since language acquisition in a normal child results from interactions with people (relations which disturbed children find difficult), perhaps nonspeaking disturbed children would find a machine such as a computer-controlled keyboard and display a more acceptable source for linguistic interaction. Hence, an effort was made to take advantage of a child's fascination with machines by providing him

> with a speaking and writing machine to play with. Instead of a person controlling a child, the child can control the machine, making it talk and display symbols at his will.
>
> Language is often described as used for expression and as an instrument for social influence. But during normal language acquisition, it is also used by children as a toy. The method used in the present studies offered each child a means of playing with language. The hunch that children might enjoy this activity was further supported by some preliminary experience with normal children who delighted in the play and whose speech was greatly excited by it during and after the sessions. If a nonspeaking disturbed child could become interested in this sort of play and begin to enjoy developing language as play rather than work, the hope was that he would transfer his use of language from a computer context to other social contexts. If a disturbed child talks, a greater chance exists for understanding what troubles him and for helping him.

In addition to eliminating the fear of interpersonal relationships possessed by many autistic children, the computer has other intrinsic advantages over a human therapist. Some children's linguistic difficulties stem from an inability to abstract from complex and changing situations. They are baffled by vocal sounds coming from people. Even the most well-intentioned human therapist will inject variety into the learning situation, thereby including one more variable with which the child must deal. The response of the machine is an absolute constant which forms a firm base for the child to build upon. We frequently observe children striking the same key over and over, and listening intently to the sound. "Adults do not tolerate repetition well, and when a child strikes the same key for twenty minutes, it takes great control not to interfere. We know from experience that if a sitter tries to stop repetitions, the child will resist the interference and refuse to play further. And he is right." (Colby and Smith 1970[6])

> Has a nonspeaking autistic child lost hope of understanding and using language? Has he given up so that nothing seems worth the effort or risk? If so, we get him to try again, to rekindle the hope by providing him a linguistic experience requiring little effort and at which he cannot fail. For a small amount of effort in pressing a key, he produces a large effect; and there is no risk of failure because something always happens, and he is never corrected for being wrong about what happens. He is free to select those symbols he wishes to manipulate. He is free to exercise his curiosity, to explore, to try to make sense out of the games. The experience is designed to be fun, non-serious, not like school (BLEAGGH!). The program is full of foolishness, nonsense and absurdities intended to delight a child and to elicit glee and exuberance. Only personal observation of the children playing with the display can convince adults of how pleasurable it can be. (Colby and Smith 1970[6])

The strongest argument, though, for our method is the favorable results we have achieved. Other treatment methods for nonspeaking autistic children report an improvement rate of 3 percent-57 percent (Bettelheim 1967[1]). To date (Nov. 1971) we have treated 21 cases over the past four years. We have estimated 15 (71 percent) to have improved in language development. We classify a child as nonspeaking if he is mute or utters only a word or two per month or year. He will also generally utter other sounds that are unintelligible. (However, all but one of our children have shown some language comprehension.) We rate a child improved if he moves from this state to volunteering appropriate intelligible words and phrases in social communication. The speech must be non-echolalic and be initiated by the child with the intention of communicating information. Though the enunciation need not be perfect, it must be sufficiently good so that the child can make practical use of language in interpersonal relations. Sometimes the children offer quite well-constructed sentences, but more often they utter short, primitive sentences or phrases.

AN ECONOMICAL THERAPY MACHINE (ETM)

Our implementation of an automated therapy laboratory on the PDP-10 is clearly not feasible for most clinics, schools or even hospitals around the country. The computer requirements described above would cost well over a million dollars if duplicated faithfully. But this approach is not even desirable. Our goal was to use whatever resources were available to experiment with automated therapy techniques, bypassing as many developmental problems as possible. Now that we have had several years of experience with this type of treatment, we can begin to specify the characteristics of an economical therapy machine (ETM). By this we mean a machine suitable for use in a large number and variety of institutions dealing with language problems.

First and foremost is effectiveness; the machine must be at least as effective as our system in treating language disorders. Thus it must have many of our system's features which we have found to be important: (1) a video screen and provisions for showing still pictures and (at least crude) motion. (2) An audio device capable of producing continuous sound in synchronization with the pictures. (3) A keyboard or similar device with which the child may select a picture/sound, plus the appropriate logic for selecting his choice from the storage. (4) Storage devices for pictures and sounds; they could use the same device (e.g., movie film with sound track) or separate ones. The storage devices and their accessing logic must have at most a one second delay (⅓ second is optimal) between the time the child requests a picture/sound and the time it is played for him. The child's attention span will not tolerate a longer delay.

Next in importance is low cost. The machine must be economically feasible for a wide range of institutions; individual machines can and should cost no more than \$1000-\$5000. It may be possible to group several terminals together under one system, in which case a small computer (e.g., a PDP-8) could be used for the logic. A system with five terminals should cost around \$15,000. These are only rough estimates; they might be improved upon.

Other essential characteristics are that the machine be reliable, rugged (the keyboard, at least, must be able to withstand rough handling by children), easily and cheaply repairable (hopefully using stock, readily-available parts), portable, self-contained and requiring no special environmental controls (such as air conditioning or humidity control).

This is admittedly a formidable list of requirements, but one which we believe to be well within the capabilities of current technology. Some suggested implementations are presented below.

There are other characteristics that are desirable but not essential in a therapy machine: (1) Color in the pictures. (2) Better motion than the 2-4 frame motion we use; also more professional cartoon characters. (3) Longer sound than our current three-second time limit. (4) Flashing lights and changing geometric patterns, accompanied by music; the children are fascinated by orderly motion. (5) More physical involvement while participating in the games. Many children are hyperactive and squirm and fidgit when required to sit in a chair to play the games. If they could run around the room punching buttons or jumping on pedals to activate the machine, it would not only be more enjoyable to these children but would probably increase their attention span as well. (6) Finally, custom tailoring is important. It should be easy to construct a new game specifically for an individual child. Frequently a child will show interest in a particular sound or word or phrase; it should be possible to construct a new game exploiting this sound for the child's next therapy session.

All of these features are designed to hold the child's interest and to stimulate his involvement with the machine. Variety and novelty are the key characteristics. Any suggestions the machine designer would have would, of course, be welcome.

POSSIBLE IMPLEMENTATIONS OF AN ETM

The following are some rough ideas we have had on the form an economical therapy machine might take.

The video screen could be most simply realized as a standard slide-projector screen. This would exclude some versatility, such as permitting the child to draw on a display screen with a light pen, but the cost would be very low.

The pictures could be generated using a standard film strip driven by a high-speed stepping motor. The motor would have to be fast enough to advance over several frames of the film to get to the desired frame within the ⅓-1 second time constraints. It should also be able to stop, so that a single frame remains shown, and to proceed at a slow rate suitable for showing motion. Alternatively, a plate of fiche with the pictures imprinted on it would be used together with a scanning head. Both of these approaches require the design of logic circuitry to control and count the stepping of the motor or the positioning of the scanning head. This circuitry constitutes the main non-standard aspect of the ETM. It has to be designed from scratch; but presumably, once the design costs have been met, it could be constructed inexpensively using low-cost integrated circuit chips.

The sound could perhaps most easily be recorded on a sound track on the film strip. This requires that the film strip be constantly moving, even for still pictures. The advantage is that each game could be packaged in a self-contained and easily-changeable cassette. The problem of constructing new games tailored to individual children reduces to the problem of making new cassettes; there is much inexpensive movie-with-sound recording equipment available today. Alternatively, a separate sound tape could be used in conjunction with the picture producing device. This would complicate the controlling circuitry, since two tapes would have to be coordinated (one for the pictures, one for the sound). A small computer might become feasible with this approach, particularly if several terminals were to be used. Another approach is to have a rapidly rotating drum on which the sound, and possibly the pictures, is recorded. Movable or fixed read/write heads would be used to access the sound; a high RPM would insure that latency is sufficiently small. This arrangement is particularly suited to time-sharing several terminals using a small computer; one copy of the sounds could be used by all the terminals connected to the drum.

We envision a very wide market for a machine designed along these lines. Many hospitals, clinics and schools are becoming increasingly concerned with correcting language disorders. Furthermore, normal children thoroughly enjoy our system. If used in the schools, it could provide a powerful stimulus for their early interest in language, leading perhaps to increased reading efficiency at an early age.

An inferential processor for interacting with biomedical data using restricted natural language*

by DALE W. ISNER

University of Pittsburgh
Pittsburgh, Pennsylvania

INTRODUCTION

This paper describes the design and implementation of a natural language system (hereafter referred to as ENGOLISH) which was developed to support and enrich the utilization of computer models of physiological systems. In addition to providing capabilities for interrogating data bases using a subset of English, ENGOLISH also provides capabilities for defining and structuring data bases using this subset of English. In particular, this facility has been used to encode relevant information from documents concerning these models to enrich their utility. ENGOLISH is structured around GOL (**G**oal **O**riented **L**anguage) which is a programming language developed by H. Pople to provide a means in which to express algorithms involving heuristic search and problem solving. GOL provides not only the basis for organizing and searching ENGOLISH data structures but also provides the basis for ENGOLISH's heuristic parsing algorithms. For a description of GOL, see Pople.[13]

The development of retrieval systems, using subsets of English to interrogate structured files of data, has received considerable attention. Simmons[23] summarizes much of this work. In general those retrieval systems referred to as "fact-retrieval systems" or "question-answering systems" consist of the following basic components:

(1) A query language (in this context a subset of natural language).
(2) An internal language or data structure in which facts may be represented or encoded.
(3) A translator for translating questions posed in the query language into programs or subroutine calls to search the internal data structures.

In addition to the above basic components, the following are regarded as features which are desirable in such systems:

(1) A general internal representation (ability to add new and perhaps differently structured data to the system without major modifications).
(2) Ability to build and expand the data base using the query language.
(3) Ability to alter or extend the query language.
(4) Inferential capability, including the ability to handle quantifiers.
(5) Capability for dealing with modalities and state spaces.

In regards to such systems, Schwarcz et al.[17] have identified the need for solving the following three major interrelated problems.

1. The development of a formalized data representation language in which the aspects of meaning that are relevant to the system's uses are explicitly and unambiguously represented;
2. The development of algorithms for translating inputs in the English subset into appropriate storage and retrieval commands for operation on the data base, making appropriate use of contextual information to resolve both syntactic and semantic ambiguity, and for translating structures retrieved from the data base into well-formed English answers;
3. The development of algorithmic and/or heuristic methods for determining what subset of the data base is relevant to filling a given retrieval request and, using the logical relationships

* The work incorporated in this report was carried out under NIH Contract 70-4121 and also supported in part by NIH grant PM 00049-02.

represented in the data base, for deducing answers from this subset to meet the request.

SEMANTIC ORGANIZATION AND EXAMPLES

The primary consideration in the development of a question-answering system is the definition of the data structures which are to be used for its semantic basis. Currently most such query systems use one of two approaches. The first (hereafter referred to as a "logic-based system") uses a logic as its basis, usually a first order theory, and employs a theorem prover as its means for searching and inferring facts from the data base. (For examples see References 6 and 16.) The

*
```

Figure 1

second approach utilizes networks for representing the primary relations concerning its data base. Higher level relations as well as searching and inferential capabilities are normally encoded as special purpose programs. For future reference, we shall refer to these as "program-based systems." (For examples see References 7, 14, 17, 21, 24 or 25.) In general, logic-based systems offer more powerful inferential capabilities and permit input data using variables and containing quantifiers. Normally the addition of such deduction rules in a program-based system entails modifying existing programs or adding new routines to the system. However, logic-based systems currently lack capabilities for handling higher order logics (thus making it difficult to handle many features such as a "How many" type question), and in general their inability to deal with relevance makes them impractical for other than very small data bases consisting of a limited number of deduction rules. On the other hand, program based systems, by their nature, allow some degree of relevance to be incorporated into the data structures as well as the routines for searching these structures, at the expense of some degree of generality, and hence can be made to operate more efficiently on larger data bases. Furthermore it is difficult in either of these approaches to incorporate linguistic data into their data structures to provide a natural language capability with the system. As a result a natural language capability is usually provided by a separate component in the system which makes it difficult to allow the development and expansion of the subset of natural language in conjunction with the data base.

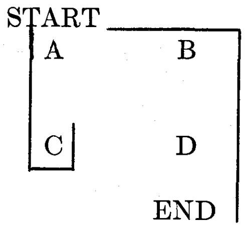
We feel that use of a heuristic problem solving language such as GOL as a basis for the semantic organization will permit the incorporation of the advantages of each of the above systems. The semantic representation used in ENGOLISH is a data structure (hereafter referred to as the DELTA notation) which is an extension of the GOL extensional and intensional data structures. The extensional data structures in GOL enable the definition of n-ary relations by an explicit encoding of the appropriate n-tuples. Alternatively, patterns containing free variables may be used to describe classes of n-tuples in compact form. The intensional data structures are λ-expressions which provide for the definition of one relation in terms of others; such definitions may be recursive. (For further details see Reference 13.) The DELTA notation combines these two into a single data structure also allowing provisions for representing negative data. In addition, it provides the capability for having string variables, as well as free variables; this makes the DELTA notation ideal for expressing grammars as well. The syntax for the DELTA notation is given in Figure 1 below.

As an example, in GOL one might code a maze solving routine by defining a GOL intensional data structure such as SOLVE-MAZE given below.

```
SOLVE-MAZE

 (S0000 (LAMBDA (X Y)
        (OR (CONNECTED X Y)
             (EXISTS (Z) (AND
                    (CONNECTED X Z)
                    (SOLVE-MAZE Z Y))))))
```

Then a maze such as the trivial example below



may be encoded with a GOL extensional data structure CONNECTED such as follows.

```
CONNECTED

 (SOOOO (EXT  (NIL)
              (START A)
              (A  B)
              (A  C)
              (B  D)
              (D  END)))
```

Alternatively, one could combine the two and use the single DELTA definition MAZE given below.

```
MAZE

 (SOOOO (DELTA  ((X Y))
                (T  (START A) T)
                (T  (A B        T)
                (T  (A C)       T)
                (T  (B D)  T)
                (T  (D END)  T)
                (T  (X Y)  (EXISTS (Z)
                  (AND (MAZE X Z)
                          (MAZE Z Y))))))
```

Here X and Y are defined as free variables and the first five "delta entries" encode the extension of MAZE (equivalent to CONNECTED defined above) and the last delta entry its intension (equivalent to SOLVE-

MAZE given above). The first delta entry

```
                (T   (START A)   T)
```

encodes the fact that MAZE is true of the 2-tuple (START A) under all conditions, and the last delta entry

```
(T  (X Y)  (EXISTS  (Z)
                    (AND (MAZE X Z)
                         (MAZE Z Y))))
```

encodes the fact that MAZE is true of any 2-tuple under the condition that there is a path connecting them.

Thus with respect to defining the "meaning" of natural language concepts, DELTA allows one to have an extensional as well as an intensional part as proposed by Carnap [3] in his method of extension and intension.

Thus

```
UNCLE
(SOOOO (DELTA ((X Y))
              (T     (HARRY   BILL) T)
              (F     (JOHN   SALLY) T)
              (T     (X Y) (EXISTS (Z)
         (AND (PARENT Z Y)
           (OR (BROTHER X Z)
              (BROTHER-IN-LAW X Z)))))
              (T     (X)     (EXISTS (Z)
           (UNCLE X Z)))))
```

would encode

(1) Harry is an uncle of Bill.
(2) John is not an uncle of Sally.
(3) X is an uncle of Y if X is a brother or brother-in-law of a parent of Y.
(4) X is an uncle if X is an uncle of someone.

with (1) and (2) being extensional and (3) and (4) expressing the intension of the binary relation "uncle" and unary relation "uncle" respectively.

GOL data structures such as above may subsequently be used to evaluate GOL-expressions which contain them. This evaluation may consist of testing the truth value for atomic arguments or generating values for arguments consisting of unbound variables. Thus

```
(LAMBDA ( ) (UNCLE (QUOTE HARRY)))
```

could represent the question

"Is Harry an uncle?"

and if applied to the above data structure UNCLE would result in a value of T. Similarly the GOL expression

```
(LAMBDA (A) (UNCLE A (QUOTE BILL)))
```

could represent the question

"Who is an uncle of BILL?"

and if applied to the data structure UNCLE would generate instances for the lambda-variable A.

To briefly illustrate the representation of a grammar, consider the following trivial example which defines the positive binary integers and which is equivalent to the context free grammar given in BNF below.

```
⟨positive-binary-integer⟩ : : =
                    0 | 1 | ⟨positive-binary-integer⟩ 0 |
                          | ⟨positive-binary-integer⟩ 1
```

```
POSITIVE-BINARY-INTEGER

(SOOOO (DELTA(  ( )  $X)
              (T         (0)      T)
              (T         (1)      T)
              (T         ($X 0)
 (POSITIVE-BINARY-INTEGER (QUOTE ($X))
              (T         ($X 1)
 (POSITIVE-BINARY-INTEGER (QUOTE ($X))
              (T         ($X)     T)
```

$X is defined as a string variable and the last entry above may be thought of as a completeness statement i.e., no other strings are positive binary integers.

DISCUSSION AND EXAMPLES

Although ENGOLISH is applicable to defining and interrogating various types of data bases, its development was guided by the desirability of building an interrogation system around physiological models, in particular a neural model which is under development as a means of representing facts concerning pharmacological data.

The first problem in this development was the choosing of some subset of English which was felt to be adequate for expressing questions concerning the information represented in such models. Because of the structural similarities between these models and pictures of simple objects, we began with a subset of English similar to that given in Kochen[9] and pioneered by the work of Kirsch,[7] concerning grammars for talking about pictures. Since any grammar for a collection of ques-

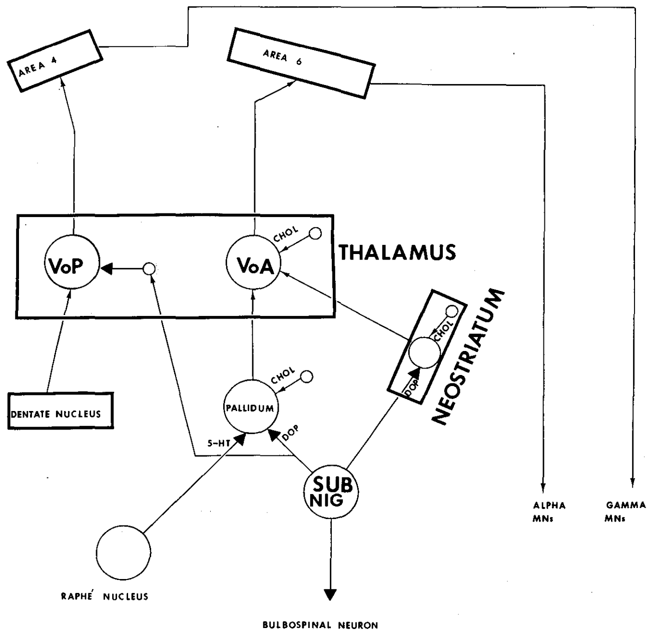


Figure 2

tions also entails as a subset a grammar for statements, it was decided that the defining of relations using such statements would also be a useful feature, thus allowing the construction of the data base itself using natural language. Since the language into which we translate such questions, i.e., GOL expressions is the same language in which the data base is structured, this was possible.

Illustrative example

As an illustrative example assume we wish to define and interrogate the prototype of a simple neural model given in Figure 2. The statements given in Figure 3 were used to define this data base in ENGOLISH.

Schema of Neural Structures and Their Transmitter Mechanisms for Figure 2.

VOP: Nucleus Ventralis Oralis Posterior
VOA: Nucleus Ventralis Oralis Anterior
ALPHA MNs and GAMMA MNs represent their respective motorneurons
AREA 4 and AREA 6 are the cytoarchitectural divisions of Motor Cortex
CHOL: cholinergic transmitter mechanism
DOP: dopaminergic transmitter mechanism
5-HT: serotonergic transmitter mechanism

Since ENGOLISH requires no prior knowledge concerning the given data base, i.e., the basic vocabulary of objects and names of relations, the model builder should enrich the vocabulary of the system for relations requiring more than one English word by using the SUBSTITUTE statement as illustrated in lines 00001 and 00003 above or by using a hyphen in the first appearance of the phrase as with "connected-inhibitory" in line 00005.

Using the small data base created by Figure 3, Figure 4 below illustrates types of questions which could be asked of it using ENGOLISH. (Lines preceded by * illustrate questions asked and the line (s) following the response from ENGOLISH.)

Note in the preceding that following "what-questions" the command "ANOTHER" may be used to elicit further instances for the "what-question" from ENGOLISH. Similarly, "REST" may be used for all remaining answers.

Encoding of literature

In addition to the information encoded within models, another important source of information is from literature which is relevant to such models. These could be used not only to cite justification for the structure of a given model by the model builder but also to contain published laboratory data which may corroborate or contradict results obtained when using such models.

To accommodate this type of data we decided that it should be encoded within the same data structures so that the same processors which search for answers to questions within a model, could also be used to answer such questions from the literature. Furthermore, the user should have the option of deciding to which source he wishes his interrogations directed—to a model, the literature or both.

As a result, we currently envision the top level structure of this data base as a hierarchic state space. This is feasible because of GOL's existing capability for dealing with state-spaces in heuristic problem solving. The user then focuses attention on some node of this state space by the statement (LETS DISCUSS —) or by including the phrase (. . . ACCORDING TO X . . .) within a statement. Having done so, he then restricts the context to that state and any states accessible from it.

The indexing of data by states also provides the user a means of indexing his data base so that questions may be directed to specific parts of the data base, thus saving substantial searching time.

Figure 4 (Cont'd)

A complete example

Within the framework of the previous section one may include facts from the literature into such a data base by expressing them as ENGOLISH statements as represented by the example in Figure 5.

In a similar manner, the model builder may encode comments about his model. Such data is useful not only for future reference by the model builder but also by future users of such models to explain and justify aspects of them.

Having encoded such data for a neural model and several documents relevant to it, one may then interrogate this data base with queries such as illustrated in Figure 6.

ENGOLISH IMPLEMENTATION

The current version of ENGOLISH is implemented in GOL enriched LISP. The translator consists of a top-to-bottom parser utilizing heuristics on syntactical patterns as well as the data base itself to aid in the recognition of sentences, questions, names, etc. These patterns are defined by GOL DELTA data structures and the parser and heuristics by GOL intensional data structures and LISP subroutines. As a result it resembles the conceptual parser described by Shank[19,20] as opposed to totally grammar based systems. The parsing algorithm places stress on "function words" such as articles, prepositions, quantifiers etc., and as a consequence is capable of parsing sentences containing nouns, verbs, and adjectives which were not previously defined within the data base and for which no syntactic information is available. Such words which are defined in the data base are used to aid in the parsing and disambiguating of sentences.

Having parsed an English statement or query, the phrase marker generated is used to generate the equivalent GOL expression. This expression is then evaluated, and if a statement, it will result in the appropriate data structure being defined or modified, and if a question, in the appropriate value being generated or retrieved, to provide an answer to the question.

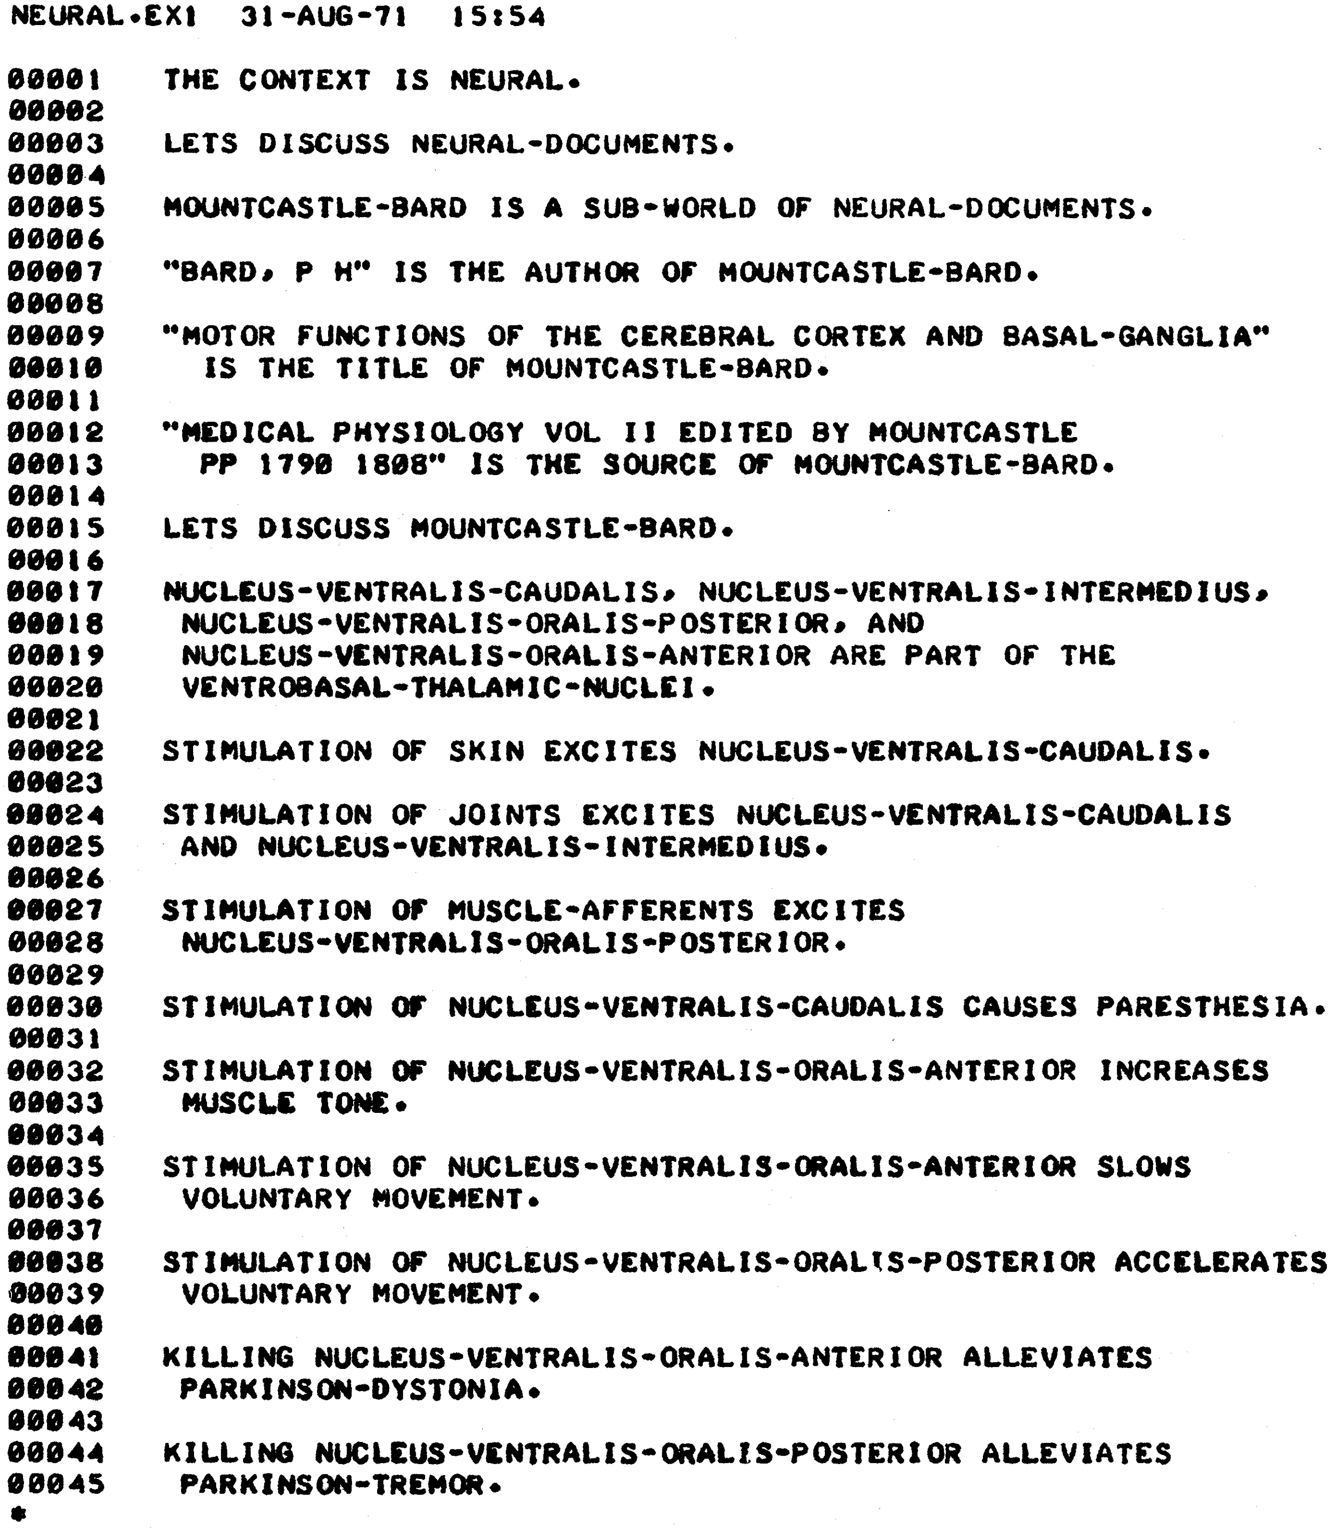
DISCUSSION AND FUTURE DEVELOPMENTS

The preceding sections described the current status of ENGOLISH. Even though it has convinced us of the feasibility of translating from a subset of English to GOL and of its desirability as a basis for a query system, there still remains much to be done.

Currently, steps are being taken to expand the conversational capabilities of ENGOLISH. In addition to expanding the syntax, there is need for more interaction between man and machine. In addition to utilizing its own data base to answer questions, ENGOLISH's utility would be increased by adding capabilities for it to generate sub-questions to the user, i.e., to also make use of the users knowledge in answering his questions. For example, consider a true-false question such as IS SUBSTANTIA-NIGRA BLOCKED BY ATROPINE? This question would currently result in a "YES," "NO," or "NOT TO MY KNOWLEDGE" response from ENGOLISH, depending on the success of searching out pathways to Substantia-Nigra for a neural structure which is cholinergic (see Figure 3). If none were found, but neural structures were tested for which no transmitter was known, it would be desirable to have the system query the user with

IS _____ CHOLINERGIC?
or
WHAT DOES _____ LIBERATE?

as opposed to merely responding "NOT TO MY KNOWLEDGE."



```

Figure 6 (Cont'd)

Effectively, ENGOLISH could then answer questions or sub-questions by searching its data base, running dynamic models, or querying the user. Furthermore this capability could also be used to allow the system to ask questions concerning new data presented to it and perhaps eventually the grammar itself which is being used. Thus, given a user who did not know the organization of the data base, but who wished to encode a fact such as

NEURON-A IS CONNECTED TO NEURON-B

would result in the structure "CONNECTED" being defined or updated. Of more use would be the capability for the system to respond with

IS NEURON-A CONNECTED-EXCITATORY to NEURON-B

or

IS NEURON-A CONNECTED-INHIBITORY to NEURON-B

so that the new information could be represented more consistently with existing information.

Another addition consists of making the state transformation facilities of GOL available to the user of ENGOLISH. In addition to defining states the user could then define actions or transformations (such as drug administrations would entail), capable of creating new states from old ones. This should increase the utility of ENGOLISH for problem solving in general, since problem solving often involves changing some model, by using specified transformations or actions, in search of a desired goal state for the model.

Furthermore, we are also exploring the potential within the current system for the generation of meaningful discourse by machine. This would enable the generation of answers to some "how" and "why" questions, by generating text describing the path of the GOL heuristic search process. Thus, it would describe the sequence of transformations and their effects in a search for the goal state in a problem solving situation.

An information processing approach to theory formation in biomedical research*

by H. POPLE and G. WERNER

University of Pittsburgh
Pittsburgh, Pennsylvania

INTRODUCTION

The extensive literature on modeling of biological systems published in the past decade reflects the growing expectation that theories of biological functions can be subject to more exacting tests of consistency with the natural system, and yield more powerful predictions if embodied in the formal structure of computer programs.

One principal aspect of the usefulness of such models of biological systems is attributable to their capability to generate predictions under conditions which transcend the human mind's limited capacity to trace implications through long chains of causal connections, notably when there exist possibilities for multiple interactions between components of a system designed for insuring some degree of homeostasis. Moreover, once sufficiently elaborate, refined and acceptable to a community of investigators, a model could be expected to generate upon request observable facts at various levels of resolution and generality, without having all of these facts explicitly encoded and stored. In this form, the model could be regarded as an information storage and retrieval device from which data can be generated by suitable programs and algorithms.

Irrespective of the particular purpose a model may subserve, it can be considered as an aggregate of components whose initial properties are given in the form of a set of definitions, and whose interactions are determined by suitable transfer functions. The modeler's task is, therefore, twofold: in the first place, suitable algorithms need to be selected to represent the input-output transfer functions of the individual model components. Second, the task consists in designing an explicit structural arrangement of the components, and a pattern of information flow between them, which is suggested or implied by the information in the data base, and which enables the model to mimic the performance of the natural system.

In some sense, one may anticipate that the potential usefulness of computer based models grows with the complexity of the natural domain they represent. However, as the latter increases, model building itself turns into an increasingly more formidable task, frequently complicated by either incompleteness or ambiguity of some of the available observational data. The implication of this is that the relation between a theory and its data base on the one hand, and a corresponding model on the other hand, need not be unique; instead, each given set of observational data of a certain complexity can generate a class of models. Consequently, in order to work toward a parsimonious model compatible with the available evidence, the modeler must engage in the iterative process of identifying alternative interpretations of the data, selecting between them, and evaluating their consequences. In those natural domains whose complexity makes modeling most desirable, this information processing task tends to assume a degree of complexity that impedes model development. To explore ways of assisting the modeler in this task, we have inquired into the nature of the information transactions underlying the modeling of complex biological systems. In the following sections, we discuss the nature of this information processing task. We, then, focus on the problem of *structure optimization* of neural networks, that is: the adaptive process of fitting together a neural network which, when simulated, gives rise to behavior analogous to that observed in the natural domain. Finally, we discuss computational procedures designed to aid in this process.

SOME ASPECTS OF THE MODELING TASK

In our work with models of complex neural control systems, we have come to recognize the need for drawing

* This work was supported by NIH Contract 70-4121.

a sharp distinction between the concept of "hypothesis model" and that of "simulation model." The hypothesis model is what the investigator carries in his head; it consists of a collection of facts and a set of interpretive rules that allows the researcher to perceive relationships in the data, make predictions concerning consequences of untried experiments, etc. A simulation model, on the other hand, is a computer program in which the researcher can express the essential features of his internal hypothesis model, enabling rigorous tests of validity. As such, it requires a degree of explicitness which goes beyond that commonly available in the hypothesis model. We emphasize this dual aspect of the modeling process in order to bring into focus the interplay that takes place between data, hypothesis, and simulation.

In many cases, the implications of biological data, in terms of the scientist's hypothesis models, may give rise to a multitude of possible interpretations. For example, the finding that "electrical stimulation of Deiters Nucleus elicits IPSPS (inhibitory postsynaptic potentials) in gamma-motorneurons" could suggest a variety of structural connectivities; some of those are:

(a) an inhibitory pathway between the cells of Deiter's nucleus and the flexor gamma-1-motorneurons;

(b) an excitatory pathway between the cells of Deiter's nucleus and some spinal-interneurons which, in turn, inhibit gamma-motorneurons on the extensor side;

(c) orthodromic and antidromic conduction along collaterals of axons which originate in some cell group with inhibitory connections to, both, Deiter's nucleus and certain gamma-motorneurons.

While it may be possible to rule out certain of these alternatives on the basis of other data, the researcher is invariably forced—in the course of constructing a simulation model—to make essentially arbitrary choices for which there is no conclusive evidence, either in the theory or in the data.

If a hypothesis model is subjected to a simulation test that is successful in the sense that the latter exhibits behavior which is consistent with the predictions by the former, then the researcher is reinforced in the choices that were made. On the other hand, if this correspondence is not attained, a reexamination of data, of hypothesis model, and of simulation model performance may direct the investigator to more rational choices. This is one of the principal benefits of using simulation: it can reduce the degrees of freedom available to the model builder, and can force a restructuring of his hypothesis model which, in the absence of a simulation experiment, might not take place.

However, in order to exploit the full value of negative simulation results, the researcher needs to know much more than simply that the results were unsatisfactory. Of course if that is all he knows, he can still proceed with revision of the model and additional experimentation. He might, for example, go to some point in his hypothesis model where an arbitrary choice from among alternative interpretations of the data had been made, and simply try another choice. In following such an exhaustive search procedure, he may be forced to go through a large number of variations of the simulation model until one is found that supports his theoretical model. Provided he has the patience to persevere in this endeavor, it could lead ultimately to an enhancement of his theory.

As is the case in most such search processes, it is reasonable to expect that some heuristic procedure which makes use of the detailed information developed in the course of a simulation, would provide substantial improvement in terms of the time and effort required to obtain a fit with the data. The important questions are:

(a) what kind of information does the researcher need; and

(b) in what form will this information be of most use to him.

In a later part of this paper, we will describe the kinds of information support systems that we currently have under development to provide relevant inputs for the restructuring of hypothesis models. Their development was engendered by the experience gained in the design of a simulation model of the central neural control of skeletal muscle tone and reflexes. As a prelude to the discussion that follows, it will be useful to describe at this point the way in which one observes the macro- and micro-behavior in this motor control simulator, further details of which are described in the appendix.

OBSERVATION OF MODEL BEHAVIOR

The main tool for observing macro-behavior in the motor-control system models is the ANALYZE program (see appendix), which is used to develop behavioral comparisons of two states of a model (one of which typically represents the normal condition, the other some pathology). This program provides a verbal output that describes deviations in behavior in one state of the model, relative to another, along certain key dimensions. Changes in such attributes as amplitude and rate of muscle contraction, force required for smooth passive stretch, frequency of oscillatory behavior, and others are perceived and reported to the user by this processor.

While in the model-building/data-fitting phase of his work, the researcher can use ANALYZE to test his developing hypotheses concerning representation of pathology in the model. For example, he might know from a review of the data that a lesion affecting the motor-cortex (area 4) would be expected to yield predominance of extensor muscle tone in the organism. Moreover, he might already have established in his model a number of connections emanating from the motor-cortex that could explain such a change in behavior. There might, for instance, be an excitatory pathway from this cortex to alpha motoneurons supplying flexor muscles. In approaching a simulation of this pathology, the researcher would therefore start with a number of pre-conceptions and expectations. In particular, since he intends that the structures which appear in the model should have a functional correspondence with their counterparts in the real system, he would expect (and indeed would insist for the model to be considered acceptable) that destruction of the motor-cortex of his model would be comparable, in its behavior manifestations, to ablation of the real structure in the living organism.

Unfortunately, it often happens in the process of model building that such pre-conceptions are not supported by the simulation results, and it becomes then necessary for the researcher to engage in a kind of post-mortem where he reviews his assumptions and the simulation results in an attempt to assess what went wrong. Any number of things could have happened. For example, the researcher might have expected some pathway to be 'turned off' in the pathology because its source of excitation would be all or partially removed. He may find on closer examination that this particular pathway is not sufficiently active in the normal model; this would of course explain the failure to induce the anticipated pathology. There may also be other, more complicated reasons for the model to deviate from the anticipated behavior: for instance the simulated lesion may give rise to widely dispersed changes in the activity pattern that are difficult to trace in the hypothesis model, and which are therefore less likely to have been anticipated during the theoretical analysis.

The ANALYZE program is of limited value in identifying such failures in the reasoning process. While it provides an answer to the question: "How did the model fail?" it does not address the equally important question "Why?" In order to gain insight into *why* a model fails, we must examine the micro-structure of model behavior and the information flow at key structures along various pathways. The analysis of this information flow in the model typically requires an extensive series of simulation tests, involving various diagnostic procedures in both the normal state of the model and in the intended pathology. Once this analysis has been completed, the researcher must then determine what these new insights concerning information flow imply with regard to his hypothesis models, make the appropriate adjustments, and try again.

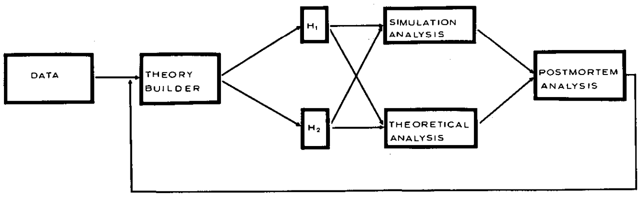

Figure 1

The basic tasks involved in this modeling process are illustrated by the flowchart of Figure 1. Here, the nodes H1 and H2 represent hypothesis models corresponding to the two experimental conditions being compared. The arcs connecting these nodes to the box labeled 'Simulation Analysis' correspond to sequences of commands of the form: 'Cut,' 'Tie,' 'Block,' 'Facilitate'—operators which have been provided as part of the motor-control simulator package for use in constructing various versions of the simulation model (see appendix).

Other aspects of the flow chart are less well defined, being part of the informal analysis engaged in by the investigator. The box labeled 'Theoretical Analysis,' for example, represents the researcher's attempts to rationalize the expected change in macro-behavior on the basis of probable changes in micro-behavior; that is, it reflects his attempts at predicting the cause and effect relationships that are operative in the pathology under consideration.

These predictions feed into a comparator labeled 'Post-Mortem Analysis,' which also receives the actual observations that result from running the simulation model. In the event that prediction and observation fail to match, an 'error signal' is generated and is fed back to the box labeled 'Theory Builder' causing a restructuring of the hypothesis models and a reiteration of the verification cycle.

Whenever this procedure requires an alteration of the hypothesis model, the experimenter must examine whether all experimental conditions accounted for in the previous version of the hypothesis model, are still satisfied. Thus, the flowchart of Figure 1 describes just one phase of the total information processing task associated with the development of a general hypothesis model that accounts for a number of different experimental results.

INFORMATION SUPPORT SYSTEMS

The modeling task described in the preceding sections comprises an extremely complex problem in information processing. Although much of the work seems to be of a routine and mechanical nature—tedious is perhaps the right word—there has been no methodology available to relieve the inordinate burden this procedure places on the researcher. To provide an effective research tool, capable of supporting a wider spectrum of the investigator's activity rather than merely the mechanics of simulation, there is need for computational procedures that will aid in the theory building phases of the total information process, and also facilitate theoretical and post-mortem analysis.

In order to state these objectives more precisely, let us consider again the dilemma of a researcher who is attempting to develop theoretical models to explain data pertaining to the motor-control system. He has access to a number of different kinds of experimental results that can be grouped according to the following classifications:

(a) anatomical
(b) physiological
(c) pathological
(d) pharmacological

Assuming fixed algorithms for the neural elements and the peripheral motor and sensory components of the system, the researcher's task is that of developing a theoretical model—in the form of a neural connectivity network—which is consistent with the observational data of each of these four domains, and the implications thereof.

What we have set out to do is reduce this task to a computational procedure. Toward this end, we have designed and implemented an inferential processor that can be used to analyze data and propose hypothesis models. Because of its central role in the total information system concept, we discuss next, in some detail, the conceptual basis of this theory building program.

THE THEORY BUILDER

The first step in developing computational procedures for dealing with theory is a formalization of that theory. There are, of course, a number of computational procedures extant—e.g., resolution, model elimination—for dealing with the deductive aspects of theory.[1,2] However, our problem is concerned not so much with what the theory implies as with what theory is implied. This converse problem, referred to variously in the literature as 'apagoge' or 'abduction,'[3] is put succinctly by McCulloch:[4]

> ". . . *abduction* starts from the rule and guesses that the fact is a case under that rule: All people with tuberculosis have bumps; Mr. Jones has bumps; perhaps Mr. Jones has tuberculosis. This, sometimes mistakenly called an 'inverse probability,' is never certain but is, in medicine, called a diagnosis or, when many rules are considered a differential diagnosis, but it is usually fixed, not by a statistic, but by finding some other observable sign to clinch the answer."

If we express the syllogism contained in this argument symbolically:

$$\begin{array}{r} Tx\supset Bx \\ Ba \\ \hline \text{Perhaps}\quad Ta \end{array}$$

it is clear that a stronger conclusion 'Ta' would be fallacious, and the qualifier 'perhaps' is a necessary part of the abduction. The uncertainty that attaches to such a result can be lessened, however—as McCulloch points out—by finding additional evidence to clinch the case. Even another abduction argument can lend support; for instance, if we also have:

$$\begin{array}{r} Tx\supset Cx \\ Ca \\ \hline \text{Perhaps}\quad Ta \end{array} \qquad \text{and} \qquad \begin{array}{r} Px\supset Cx \\ Ca \\ \hline \text{Perhaps}\quad Pa \end{array}$$

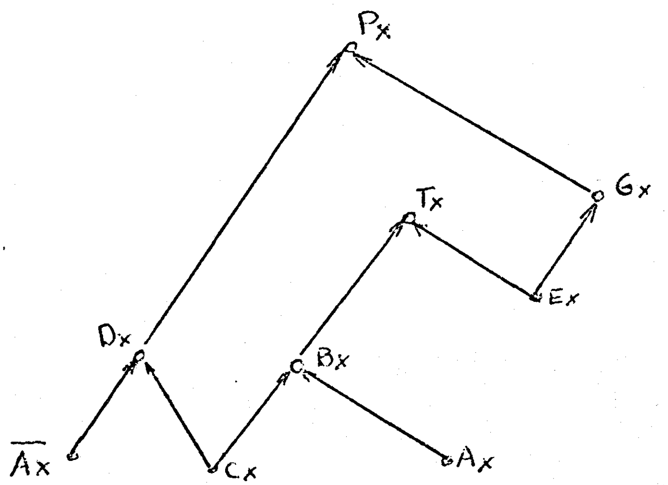
the occurrence of two distinct data supporting 'Ta,' while only one supports 'Pa,' would cause most of us to hypothesize 'Ta.'

Such support can also come indirectly through a somewhat lengthier chain of reasoning. Consider for example the set of rules:

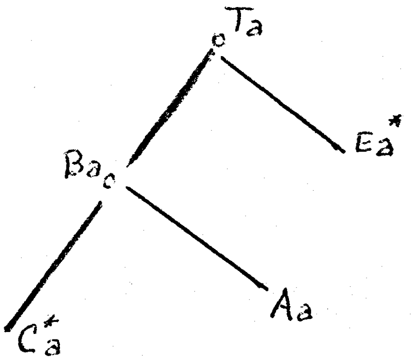
$Tx \supset Ex \quad Tx \supset Bx \quad Bx \supset Cx \quad Px \supset Gx \quad Bx \supset Ax$

$Dx \supset Cx \quad Gx \supset Ex \quad Px \supset Dx \quad Dx \supset \overline{Ax}$

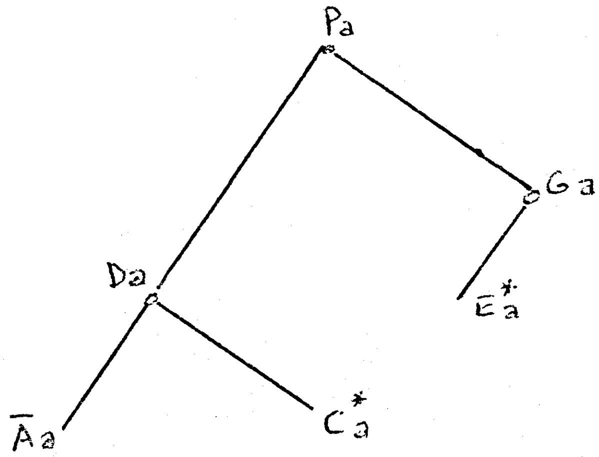
We can illustrate the network of implications contained in these premises graphically as follows, where the upward branches at any node denote 'reverse implication':



If we observe the data: {Ca, Ea}—then we might reasonably hypothesize: {Ta, Ba, Aa}—since this collection of nodes defines a sub-graph of the net that is mutually supportive:



Since only 2 of these 5 nodes have actually been observed, however, any assumption concerning the others is merely theory. An alternative theory that might be put forth to account for these same data would be:



where again, only 'Ca' and 'Ea' correspond to the actual observations.

If we have the opportunity to ask questions, we often are able to discriminate between alternative theories. For example, in this case if we ask "Aa?" then one or the other of the proposed theories will necessarily be set aside. Note that although the pair $\{A \supset B, B\}$ does not yield a definite conclusion, the pair $\{A \supset B, \bar{B}\}$ does.

Provided we have data that can be structured in the form of an implicative or causal net—as above—we can clearly write heuristic computer programs that engage in the abductive process of theory building. The objective of such a program would be to find a single connected subgraph that 'covers' all of the observations; or, failing that, a pair of such subgraphs; or a triple, etc. Since each additional subgraph included in a theory contains an additional basic assumption (top node), the goal of parsimony in theory development would provide a rule for selection from among alternative hypotheses even in the absence of other criteria. If, in addition, we have the ability to ask questions of the user, of a simulation model, and of the structured and unstructured data files, the power of our program to develop sound theory is clearly enhanced.

We have encoded and successfully demonstrated a heuristic processor, using a combination of LISP[10,11] and GOL[5] routines, that constructs hypothesis models on the basis of the heuristic procedure outlined above. We are in the process of interfacing this Theory Building program with a natural language query system that also possesses some inferential capability, subsequently referred to as ENGOLISH.[6] This makes it possible that:

(a) an uninterpreted literature data base, in the form of ENGOLISH data structures, can be accessed by the theory builder program, and

(b) the theory builder program can be invoked to develop hypothesis models while engaged in an ENGOLISH dialog with the user; thus avoiding inconsistencies, ambiguities, and incompleteness in the data base recorded.

The set of rules that generates the abduction net of the theory builder is encoded in a table of associations called SUGGESTS, the present form of which is as follows:

```
(GOLDEF  SUGGESTS
 (S0000

         ((PATHWAY MONOSYNAPTIC Y S Q)  (PATHWAY X W S R)))
        ((INTERRUPTED (PATHWAY ANTIDROMIC P Q R) U)
         ((ORTHODROMIC X)  (MATCHA P X Y W)
                           (DISTINCT Q S)
                           (DISTINCT R S))
         ((PATHWAY MONOSYNAPTIC Y S Q)
          (INTERRUPTED (PATHWAY X W S R) U)))))
```

This table is encoded as a GOL extensional data structure[5] in which the symbols: (P, Q, R, S, U, V, W, X, Y, Z) stand for universally quantified variables. Each entry of the table consists of three parts, (A B C), which can be read:

"C implies A under conditions B"

For example, the first entry would be interpreted:

> A(P, Q, X, Y, Z) pathway (monosynaptic, X, Y, Z) $\supset$ projects (P, Q); *where* (polarity (X) $\wedge$ cell-type (P, Y) $\wedge$ cell-type (Q, Z).

In this expression,

- 'pathway' predicates a monosynaptic connection, of polarity X between cells of type Y and type Z
- 'projects' predicates a fiber projection between neural structures P and Q.
- 'polarity' is the property: {excitatory, inhibitory}; and
- 'cell-type' is a relation that associates the names of neural structures with the various neural populations subsumed thereunder.

The operation of abduction, using the SUGGESTS data structure entails an associative access whereby some observational datum (e.g., 'projects motor-cortex-4 flexor-alphas') is matched against the first position (A) of appropriate entries of the table, with the result a hypothesis (C) qualified by the expression (B). The reason for employing quantifiers and qualifiers in the SUGGEST-Table is that this permits large numbers of nodes to be represented compactly by a single entry; furthermore, it enables the use of much more powerful search techniques than would otherwise be possible. This refined principle of operation would appear to have the same relation to simple abduction that resolution holds to Herbrand expansion.[2]

While these concepts and their relationship to other paradigms of artificial intelligence will be the subject of subsequent publications,[7] we present at this juncture an illustration of their operational aspects. For this purpose, we consider an application of the theory builder in the context of a collection of typical neurophysiological data giving rise to alternative hypothesis models.

In a discussion of the diversity of the effects of cerebellar stimulation, Eccles et al.[8] describe the various pathways which mediate the inhibitory influence of the cerebellar cortex on a cell group in the vestibular nuclei. Some aspects of this discussion can be stated in terms of the following propositions:

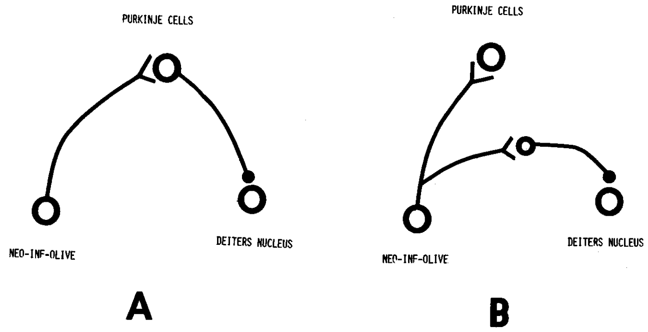

Figure 2—Schematic diagrams of the neuronal connectivity proposed by the theory building program. The empty circles are neural structures whose names correspond to those appearing in the program dialogue. The connecting pathways ending with an open branch signify excitatory, those ending with a solid circle inhibitory connections

(1) the inferior olive projects monosynaptically *via* the climbing fibers to the cerebellar cortex;
(2) activity engendered by electrical stimulation in the main inferior olivary nucleus (neo-olive) elicits EPSP's in Purkinje cells;
(3) activity engendered by electrical stimulation in the main inferior olivary nucleus elicits IPSP's in Deiters Nucleus.
(4) electrical stimulation of Purkinje cells elicits IPSP's in Deiters Nucleus.

To deal with these propositions meaningfully, some general background knowledge is required which finds its representation in the data encoded in the SUGGEST-table, given previously:

(a) fiber projections identified by neuro-anatomical procedures *are* monosynaptic pathways;
(b) electrical stimulation in the typical experimental procedure elicits activity not only in the target cells, but also in fibers and their termination in the vicinity of these cells.
(c) impulse traffic in fiber tracts under condition of artificial electrical stimulation can be either ortho- or antidromic, or both.
(d) chronic lesion of a structure interrupts impulse transmission (both, ortho- and antidromic) in all pathways of which this structure is a part.

As illustrated by the following dialogue and in Figure 2a, when supplied with just these propositions and facts, the theory builder proposes a partial model, consisting of one excitatory and one inhibitory monosynaptic pathway:

```
*(STRUCTURE  INFERIOR-OLIVE  NEO-INF-OLIVE  PALEO-INF-OLIVE)
NIL
*(STRUCTURE             CEREBELLAR-CORTEX           PURKINJE-CELLS
                       GOLGI-CELLS          BASKET-CELLS)
NIL
*(STRUCTURE             VESTIBULAR-NUCLEI           DEITERS-NUCLEUS
                        MEDIAL-VN           SUPERIOR-VN      DESCENDING-VN)
NIL
*(OBSERVATION           (PROJECTS           INFERIOR-OLIVE
                        CEREBELLAR-CORTEX))
NIL
*(OBSERVATION           (ELICITS            (STIM     NEO-INF-OLIVE)
                                            (EPSP     PURKINJE-CELLS)))
*NIL
*(OBSERVATION           (ELICITS            (STIM     NEO-INF-OLIVE)
                                            (IPSP     DEITERS-NUCLEUS)))
NIL
*(OBSERVATION           (ELICITS            (E-STIM   PURKINJE-CELLS)
                                            (IPSP     DEITERS-NUCLEUS)))
NIL
*(PONDER)
(PROPOSE MODEL:
     ((PATHWAY          MONOSYNAPTIC        EXCITATORY
                        NEO-INF-OLIVE       PURKINJE-CELLS)
      (PATHWAY          MONOSYNAPTIC        INHIBITORY
                        PURKINJE-CELLS      DEITERS-NUCLEUS)))
```

If now provided with the additional observational datum that a chronic lesion of the inferior olive abolishes the inhibitory response in Deiters nucleus that follows electrical stimulation of Purkinje cells, the program recognizes the inconsistency between the implications of this finding and its internal model. This gives rise to a restructured hypothesis model, as follows (see Figure 2 B):

```
*(EXPLAIN          (ABOLISHES          (CHRONIC-LESION          INFERIOR-OLIVE)
                                       (ELICITS  (E-STIM  PURKINJE-CELLS)
                                                 (IPSP  DEITERS-NUCLEUS)
                                                                   )))
(THIS FINDING INCONSISTENT WITH PREVIOUS MODEL)

(PROPOSE PARTIAL MODEL):

          ((PATHWAY     MONOSYNAPTIC       EXCITATORY
                        NEO-INF-OLIVE      PURKINJE-CELLS)
           (PATHWAY     POLYSYNAPTIC       INHIBITORY
                        NEO-INF-OLIVE      DEITERS-NUCLEUS)))
```

The operation of the theory building program starts with the definition of the domain of discourse: this is accomplished by use of the STRUCTURE—command. The first argument of this command designates the name of a neural structure; subsequent arguments identify its components. The command OBSERVATION is used to perform a preliminary encoding of an observational datum which may be either a statement concerning automical connections, or a description of functional relations. Supplied with these facts, PONDER is called to invoke the abduction process which generates a parsimonious hypothesis model that accounts for the data supplied thus far.

The continuation of the model building process consists of the addition of new data and their evaluation relative to the existing model. The macro command EXPLAIN is available for this purpose: in the first place, it enables the user to supply a new observational datum; the program, then, ascertains whether this new fact is consistent with the existing hypothesis model: if this is the case, it renders an account of that part of the existing model which has been enriched, either by way of confirmation of an existing aspect of the model, or by expanding its domain. Alternatively, the program may discover an inconsistency between the model it contains and the new datum, in which case it reverts to PONDER to attempt the generation of a new model which accommodates all of the facts it has been given up to that time.

ON MECHANIZED MODEL BUILDING—AN OUTLOOK

Having presented and illustrated the mode of operation and capability of the theory building program, we are now in a position to assess its role within the total information support system for model building. With reference to the flow chart of Figure 1 which dissected the process of model building into identifiable steps and the interrelations between them, we have demonstrated that the theory building program can generate hypotheses on the connectivity of model components which correspond to the boxes labeled H_1 and H_2 in that Figure: that is, a connectivity that may obtain under normal, and also satisfies some abnormal, conditions; the latter consists in the example given of an artificial, experimental lesion. The hypotheses concerning connectivity are of a form which permits them directly to be represented in the simulation model by means of the CUT and TIE commands (see appendix).

The example illustrates that the formation of hypothesis models can be mechanized, which was the principal objective we have set out to accomplish. Beyond this, the theory building program contains features which enable it to contribute also in other ways to the development of theoretical models; namely, by posing questions, and by proposing experiments to be conducted in the "simulation laboratory." To this end, the EXPLAIN command can be used to generate predictions and expectations for meaningful post-mortem analysis (see Figure 1): it directs the investigator's attention to those components and pathways of the simulation model which are expected to be most prominently involved in the anticipated behavioral differences. The outcomes of the theoretical and the simulation analysis can now be compared; if significant differences obtain—which would signify the negation of some implication of the hypothesis model—this new datum can be fed back and employed in the restructuring of the hypothesis.

Operating in this manner, the theory-building program can now be envisaged to perform the structure optimization of the neural network, relieving the investigator from the tedium of the iterative process of fitting observational data into a useful simulation model. Instead, once he has defined the first principles which will serve as the basis of theory formation—in the form of rules in the SUGGESTS data structure—he is able to assess continuously the sufficiency and necessity of his concept of the natural domain under study, and the consistency of this concept with newly acquired data.

APPENDIX

Modeling tools of the motor control system simulator

The motor control system simulator is a processor that can be used to construct and evaluate simulation models of neural control mechanisms which play a role in the regulation of certain skeletal muscle reflexes and of muscle tone. This requires, in the first place, that the investigator have available a versatile set of commands to define neural structures and to interconnect them by pathways of suitably chosen length (i.e., conduction time). These commands are intended to enable the investigator to formalize his conception of the system under study in the form of a model that can be altered conveniently in accord with new evidence; that can reflect some experimentally induced condition; and that can mimic disease states as well as effects due to administration of pharmacological agents. The second requirement was to provide programming tools which would exercise the model in a manner analogous to the tests used by the experimentor to ascertain the functional capabilities of the natural system. Thirdly, it seemed to us necessary to provide the ability for examining the performance of components in the model, and of the model as a whole, at different levels of resolution, comparable to the procedures used by the experimenter: at one time he may be interested in the fine temporal pattern of activity in one single node of the model; and another time, in a time average of the activity, or in the trend; and at some other occasion, in the gross overt performance of an effector organ (in the case of the prototype model: muscle length and tone), or merely in the deviation of this performance from a normal baseline; finally, the investigator may wish to recognize the relation between performance of an effector organ and the pattern or activity flow between the interacting components of the (neural) control system. Accordingly, programs to extract and perceive any one of these aspects of the model's behavior are available for selection by the user.

Algorithms of system components

The basic element of the simulated neural system is a stylized neuron whose activity state is described by a quadruple of numbers, each ranging over the numerical values from zero to four. These numbers designate, in this sequence, output, threshold, input, and a term representing a "driving force." The latter is a constant which sums algebraically with the value of the threshold and enables the user to set a positive or negative bias value on the neuron computation.

These formal neurons can be connected by excitatory or inhibitory links to form a finite state machine in which each neuron can receive an arbitrary number of inputs. These are summed algebraically to determine the net input. Computation within the neural network is deterministic and proceeds in discrete time steps, each corresponding to the synaptic delay of approximately 1 millisecond duration in real time. At each time slice, the input and output values of each neuron, representing a neurophysiologically characterized neuron population, are updated on the basis of the following algorithms:

```
if $((\text{input}(t-1) > \text{thresh})$ and
  $(\text{output}(t-1) < \text{input}(t-1))$ and $(\text{thresh} \neq 4))$:
    $\text{output}(t) = \text{output}(t-1) + 1$
if $((\text{thresh} = 4)$ or $(\text{input}(t-1) < \text{thresh})$ or
  $(\text{output}(t-1) > \text{input}(t-1))$:
    $\text{output}(t) = \text{output}(t-1) - 1$
else: $\text{output}(t) = \text{output}(t-1)$
$\text{input}_j(t) = \sum_{k \epsilon A} (\text{output}_k(t - d_{kj}))$
```

(where A is the set of structures K that are connected, *via* delays of lengths d_{kj}, to the j_{th} neuron.

The neural network controls the length of reciprocally connected flexor and extensor muscles through the algorithm of *table* 1 which also computes for each value of muscle length and gamma motorneuron output the feedback signals generated by muscle spindles (nuclear bag and chain organs) and Golgi tendon stretch receptors as schematically illustrated in Figure 3 (for review, see Reference 9). The connecting links between the neural control network and the muscle effector system are provided by three motor neurons, each, on flexor and extensor side; and by afferent pathways originating from the length and tension transducers of muscles and tendons. Items 1 through 6 of Table 1 designate the relationship between the respective motor neurons and the variables appearing in the periphery algorithms; items 21 through 26 designate the sources of feed back signals. The parameters appearing in these algorithms have the following meanings:

flex-mult [ext-mult]: scale factor used to translate the tension changes of flexor [extensor] extrafusal muscle fibers into length changes;

cmult [ecmult]: a scale factor to accomplish the same for intrafusal muscle fibers of the nuclear chain receptors;

bmult [ebmult]: a scale factor for intrafusal muscle fibers of the nuclear bag receptors;

scale: a scaling function that uses the tabular functions KBAG and KCHN (see later) to translate length differences between extra- and intrafusal muscle fibers of nuclear bag and nuclear chain receptors, respectively, into the static component of the transducer outputs.

It might be useful at this point to comment on issues of implementation. We have had access for this development to a medium scale PDP-10 system, on which a superb LISP interpreter[10,11] is available. To provide the user a convenient means for interacting with his simulation models, we have encoded a set of supervisor and exercisor routines—to be described presently—that operate in the context of this LISP interpreter. Since LISP is singularly inefficient in its provision for numerical computation, those algorithms described above which define computations at the neural nodes as well as in the peripheral effector and sensor organs have been encoded in FORTRAN, and the resulting compiled modules have been incorporated in the LISP system as callable subroutines. Thus in the discussion that follows, although the notation used to illustrate features of the simulation system if that of LISP, the reader should be aware that the actual simulation results are produced by execution of the appropriate FORTRAN subroutines, upon direction by the LISP supervisor programs.

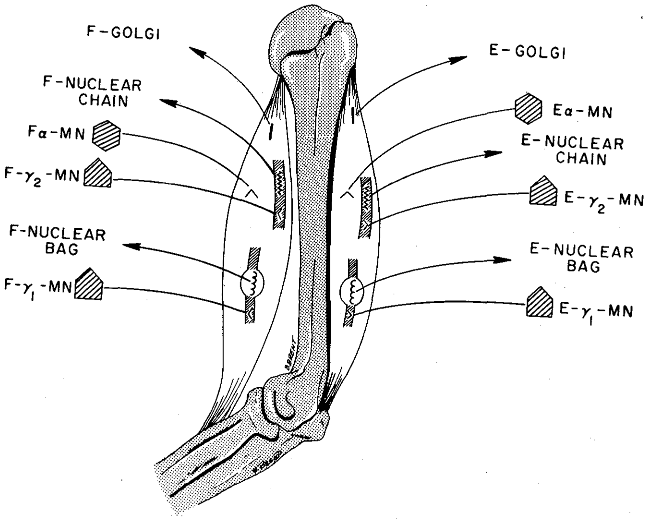

Figure 3—Schematic display of an antagonistic muscle pair (F = flexor, E = extensor muscle), and their efferent and afferent innervation. α — MN = motorneurons supplying the extrafusal muscle fibers; γ_1- and γ_2-MN's: gamma-motorneurons supplying the muscle fibers of nuclear bag and nuclear chain transducers, respectively, from which the afferent nerve impulses signaling muscle length originate. Golgi = receptors situated in muscle tendons and signaling muscle tension

Command structure for model building

The devices needed to build a model and to alter connections, add or delete structures, specify delays (i.e., conduction times between neural structures, in milliseconds real time) and to pass numerical parameters to the computational algorithm are available in the form of a set of LISP functions. Examples of some steps in the building of a model are illustrated in the following interactive dialogue with the model building supervisor:

```
*(ADD NEURON @N-RUBER 1$

NIL
*(SAVE RUBER$
JOB-SAVED
```

In this example, the user wished to add a new structure to the model, namely nucleus ruber (N-ruber), and to connect it *via* appropriate delays so that it would get excitatory input from the deep-cerebellar-Nucleus (already in the model), and deliver excitatory output to the alpha- and gamma-1 motorneurons on the flexor side. The instruction (ADD N-RUBER) requires specification of the new structure's threshold which was chosen to be 1.

Upon requesting the addition of delays (ADD DELAY with the statement of point of origin and duration), the program returns the call by assigning a number to the new delay (the numbers 40 and 36 were assigned, respectively).

The counterpart to ADD is the instruction DELETE (not shown here).

Once all new structures are added and their thresholds and delay length specified, the user applies (TIE) which calls for three arguments: excitatory (or inhibitory)

name of the structure of origin

name of the structure of endpoint of new link.

The input to the newly added delays is already furnished by the instruction ADD. After the new connection is established, the program lists all excitatory and inhibitory inputs to the recipient structure of the new connection in the form if (IMPINGE+ . . .) and (IMPINGE− . . .), respectively.

The counterpart to TIE is CUT which severs existing connections and requires the same format of arguments as does TIE.

The user then decides to save the new model under the name of RUBER.

Two more changes are then made: a driving force of +2 is added to the Deiters-Nucleus by means of the instruction (TRY DRIVER . . . value). This means that deiters nucleus will now have an output of two in the absence of any excitatory input, and this value of two will be added to any output level computed (with the ceiling value, of course, remaining 4). Furthermore, the sensitivity of the nuclear bag end organs is changed: first, the user examines their old value with KBAG; there are 4 criterion levels set (1 through 4); any length difference between extra- and intrafusal muscle fibers up to 25 generates an output of 1; similarly, the values 2, 3 and 4 are generated by the specified length differences. These criterion values are changed by STORE (KBAG etc.).

Neurological lesions can be simulated by the command (KILL—name of structure—) which sets the threshold of this structure to the value of 4 and, thus, effectively eliminates the structure from the flow of activity in the network.

The command BLOCK, decreases the activity level of a set of one or more structures by a specified value: for example, (BLOCK T 1 @(RAS RAS-INTERNEURON)). The neural structures within the parentheses are affected. The converse effect is generated by the command (FACILITATE T +1 @(RAS)) which mimics an excitatory drug effect.

OBSERVATION OF MODEL PERFORMANCE

To enable testing the performance of the model with the types of maneuvers applied by neurophysiologists or neurologists to evaluate the functional state of the motor system, two functions are defined:

> *PULSE,* designed to mimic a brief muscle pull, and consisting in the application of input pulses to the muscle spindle afferents of a specified muscle for a brief, specified period of time. This function is intended to test the motor system for its ability to support a phasic stretch reflex of the kind commonly employed in the form of the "knee jerk."
>
> *STRETCH,* on the other hand, is designed to test for active resistance to muscle stretch, developed in the course of slow extension of the muscle under study, with rate and duration of passive muscle stretch to be specified by the user. The muscle tension developed during passive stretch is computed as the incremental activity required at the Golgi stretch receptors to sustain the specified rate of muscle elongation during the stretch interval.

For the assessment of the model's response to these kinds of stimuli, the important variable to be observed is that of muscle length. In addition, the user may wish to observe activity levels of selected neural structures. He can accomplish this defining a "WINDOW" that lists these structures by name.

Even if only a few structures of the model are being monitored, the output generated as a result of several hundred state transitions in discrete time becomes bulky and cumbersome to interpret; details that should stand out to attract the user's immediate attention, tend to become obscured. Thus, some compression of output is needed to enable quick and reliable "perception" of the performance.

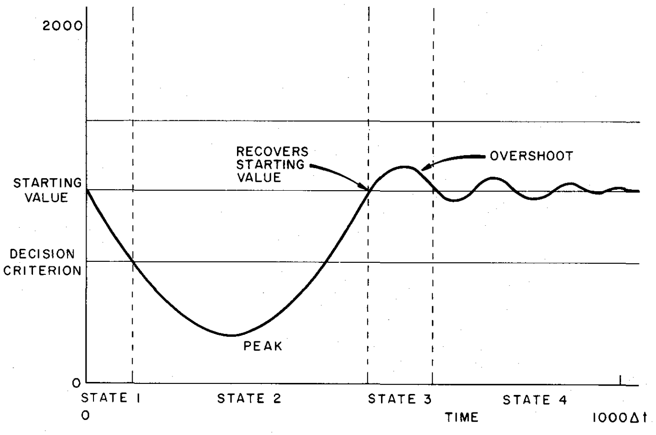

Figure 4

For the purpose of perceiving the characteristic features in muscle behavior following PULSE or STRETCH perturbations, we view the resulting transient departure from resting muscle length as comprising four states (Figure 4):

State 1: commencing with the application of the stimulus and extending until deviation of muscle length exceeds criterion level;

State 2: follows state 1 and extends until resting muscle length is recovered; value and time of occurrence of the extremum, and time till recovery are recorded.

State 3: follows state 2 and encompasses the period during which the primary overshoot occurs; its magnitude is recorded.

State 4: encompasses the remainder of the observation period during which mean muscle length, maximal excursions and frequency of oscillation are recorded.

In the case of what would be considered a normal reflex, the observation terminates in state 4. Abnormal or abortive reflex behavior can cause the perception algorithm to terminate in any of the earlier states, in which case appropriate messages are generated.

For the neural structures named in a WINDOW, the compressed output consists of a mean activity level over the observation period and the number of oscillations that may have occurred. Moreover, as shown below, the algorithm records duration and time of occurrence of the longest sustained periods of high and low levels of activity. Although not illustrated, the program also computes time of occurrence and intensity of the first burst of activity triggered by the test procedure; this reflects the temporal dispersion of transient activity in the neural network.

While these perception algorithms describe model behavior in absolute and numerical terms, observational records in the natural domain are typically stated in terms of qualitative descriptors, most commonly of a comparative nature; that is: in terms of deviations from a reference state. To enable the modeler to perceive his simulation results in these same terms, we devised the program ANALYZE. This program performs a sequence of tests on two specified states of a model, compares the results and generates a verbal output that describes differences in behavior along certain key dimensions. An application of this program is illustrated below: at first, a lesion of substantia-nigra is produced by applying the KILL-instruction; this causes the behavior of the model to depart from the normal condition in a manner resembling that of Parkinson's disease in that the response to a PULSE stimulus of the flexor muscle is augmented and abnormally prolonged while the STRETCH of the flexor muscle induces an oscillatory response (i.e., tremor).

```
*(KILL SUBSTANTIA-NIGRA)

  RECOVERS))
*
```

The tremor component of this pathology is in the next simulation run alleviated by combining the lesion of substantia nigra with a second lesion, intended to mimic one form of neuro surgical management of Parkinson's disease, namely a lesion of the nucleus ventralis anterior of the thalamus:

The clinical significance of simulation and modeling in leukemia chemotherapy*

by T. L. LINCOLN

The Rand Corporation
Santa Monica, California

INTRODUCTION

It seems certain that in the next thirty years—by the year 2001—the computer will become a major instrument in support of clinical practice. Part of our task today is to look beyond the frustrations, expense, and apparent waste of our present prototype systems and to distinguish the important themes which will bind medicine and computers together. In computer medicine we are clearly in the exploratory phase of a new technology—a position analogous to the early designers and users of automobiles. With the introduction of the automobile came a great variety of expensive, made-to-order cars which could only be run on poorly maintained muddy roads. To drive required a large measure of patience, enthusiasm, and self-reliance, coupled with a fine sense of the ridiculous. Moreover, the automobile scared the horses, and otherwise challenged the established order of things. And still it came, demanding new conventions to make its use effective: freeways, parking tickets, campers, bedroom communitites, air pollution—the good with the bad.

This is a talk about mathematical modeling, simulation, and leukemia chemotherapy; but I have opened in this way because it is not the details of leukemia chemotherapy which I want to emphasize, but rather the far-reaching changes which information processing is destined to bring to this field. The primary changes will be found in the conventions of clinical decision-making. The use of mathematical modeling and the computer in leukemia chemotherapy is particularly illustrative of a new form of medical practice because (1) the untreated disease is usually rapidly fatal and deserves the investment; there are 14,000 new cases a year, many in children and young people; (2) it is quantifiable; the leukemia cells can be sampled in the blood and the bone marrow; (3) it responds to rational, well-organized therapeutic regimens; effective drug doses and schedules can be set up which depend upon cell kinetics (models of cell behavior) and pharmacokinetics (models of drug distribution); (4) the impact of drug therapy is quantifiable, thus the regimens can be evaluated and the models verified; and (5) good results depend upon a persistent, well-organized approach.

We might put the argument another way: We have strong drugs with which to treat leukemia, but our therapeutic advantage is sufficiently small, and our knowledge sufficiently limited that the penality for sloppy thinking and sloppy patient management is particularly high. This disease is a test of our ability to manage medical information, to understand its implications, and to apply our knowledge wisely. Because quantitative data is the key aspect of decision-making in this disease, skill in the use of quantitative information is essential to success. At the same time, because of the importance of teamwork between the specialties of hematology, clinical oncology, infectious disease, and laboratory medicine, leukemia therapy is an excellent test of the ability of computer technology to coordinate the relevant information. Moreover, success, short of a cure, requires long term sophisticated maintenance therapy, and thus effective long term records. To pursue the automobile analogy, we might consider the skill, the teamwork, and the endurance required for this information processing system to be in some sense parallel to that required to run in the Indianapolis 500.

DISCUSSION

The chemotherapy of acute myelogenous leukemia was chosen for my research as the principal area for modeling. This disease lends itself to a quantitative

* This work is supported under NIH Grant CA-12369.

analysis because there are good measures of success, failure and complications. Treatment is quantitative and offers a spectrum of options in detailed implementation. The purpose of simulation is to make the choice of treatment options more rational. Leukemia can be compared to the growth of crab grass in a lawn. If left by itself, this agressive grass will overtake the lawn and destroy it. In a like manner, leukemic cells grow in the bone marrow and come to replace the cells which are usually present there. As the bone marrow is encroached upon, its normal function—to supply red cells, granulocytes, and platelets to the blood— is compromised. The lack of red cells leads to anemia; the lack of granulocytes leads to an increased susceptibility to bacterial infection; and the lack of platelets—a cell needed for blood clotting—leads to hemorrhaging. If nothing is done, the patient will die quickly from one of those complications. Treatment must stop the process and turn it back. The ideal objective of chemotherapy is to kill the encroaching leukemic cells without injurying the normal cell lines. However, the best that can be done is to establish a differential kill rate based on differences in growth characteristics, so that on balance more leukemic cells die than normal cells. In the crab grass analogy, the use of a growth poison, such as chlordane, achieves a differential kill rate because the crab grass grows more rapidly than the lawn grass. It is generally not possible to irradicate crab grass completely. If treatment is stopped, the crab grass will recur. But it is possible to reduce it to a nearly imperceptible level, and to maintain the lawn with continued intermittent treatment. The best results depend upon adjusting the dose of chemical and the interval between doses to keep the lawn and to kill the weed. Two different strategies are needed: one to get rid of the visible crab grass; the other, to maintain a healthy looking lawn. This healthy looking state is medically equivalent to remission.

In leukemia chemotherapy the first strategy is to achieve remission induction, the second remission maintenance. Modern experience indicates that large doses of drugs given at intervals of about 14 days, which first produce marrow depression and then allow for marrow recovery, give the best induction results and lower doses at longer intervals provide good maintenance. The toxic effects of the drug, by reducing the function of the marrow, lead to the same complications: anemia, infection due to lack of granulocytes, and bleeding due to lack of platelets.

This is the briefest overview of the clinical situation and the short term clinical objectives. Clearly, one would like to develop methodologies which will cure the disease, but in the meantime, the clinician must move between the two sources of marrow disfunction: overtreatment and undertreatment. He has at his disposal few objective measures which might be considered as "control variables."

For example, the concentration of the cellular components in the blood reflect bone marrow function. Daily blood samples can chart not only the impact of the chemotherapeutic drugs, but also the likelihood of complications. Bone marrow biopsy allows the developing blood cell components to be counted and provides an assay for the encroachment on the marrow of leukemic cells and the depletion of the marrow by drug.

Classically, decision procedures based on these data have been organized into clinical rules of thumb—a heuristic syntheisis of experience. For example: "When the platelet count drops to 20,000, there is danger of bleeding, and we give platelet transfusions." These rules of thumb are modified by clinical asides: "The threshold is set a little high on purpose—the patient probably won't get in trouble until his count reaches 10,000."

Computer programs have been written which incorporate such rules of thumb. The best known are those on electrolyte balance. One might say that these programs automate the professor in a dogmatic way and can only be as successful as his dogma. The same can be said for programs which set up trees for sequential decision-making. The output of the program is no greater than the input.

The advantage of a simulation is that one can explore new territory. If the problem has been formulated in a mathematically explicit way so that the interaction among the variables is accounted for, new states of the system can be explored. If the simulation were perfect, then the simulation would be equivalent to the essence of the problem and could serve as a near perfect advisor. However, in a situation as complicated and as incompletely understood as the biology of cancer chemotherapy, we can hardly expect to fulfill this ideal. What then is the purpose of mathematical modeling, of simulation, and of the most expensive luxury of all—on-line interactive graphic simulation?

As a physician working in this field, I can only present my experience with the hope that it offers some generality. To build my models, I have been using BIOMOD, a Rand-developed software package designed specifically for on-line interactive model building and simulation. It provides a data tablet, keyboard, and full graphics capability with a resolution of 1024 by 1024. The system has the capacity of enter models in mathematical formats so that the computer does the machine-language programming and can produce, compile, and run a new program in a matter of minutes. The system can keep track of 20 output curves and display five of these on command. As a simulation progresses, the evolving curves are presented on the screen. The scale of the graphic output can be changed interactively and the displayed variables combined and redefined. The simulations can contain up to 20 modifiable parameters so that the simulation can be stopped, parameter values changed, and then allowed to proceed. In BIOMOD II, the new FORTRAN-based revision of BIOMOD, we now have the capacity to compare the output with data curves which can be entered directly through the tablet.

These capabilities cannot be provided in batch processing. In short, for a physician this is a very fancy system. What are the returns? To present these, I identify four different levels of model building.

1. *Parameter Identification.* The process of trying to build a simulation of a medical problem is in and of itself elucidating. The necessary first step in this exercise, however primitive the quantitative results may be, is the identification of those parameters which ought to be considered in the model. In leukemia chemotherapy we presume that the clinical phenomena can be understood by constructing models which simulate the growth of cells and developmental characteristics of the blood cell precursors in the bone marrow. Ultimately our models must incorporate the following biological processes:

1. The mechanisms by which blood-forming tissues sustain themselves.
2. The control mechanisms that regulate the growth and differentiation of particular blood-cell types.
3. The relationships between the blood as a circulating pool of cells and the other tissue spaces where blood cells are sequestered.
4. The processes of attrition that lead to the natural loss of cells from the blood.
5. The ways in which cytotoxic drugs act on blood-forming tissues (e.g., the sensitivity of cells in different phases of the cell cycle to particular drugs).
6. The rates of transport and the detoxification of particular drugs.
7. Growth characteristics which distinguish leukemic cells from normal cells.

This biological analysis gives focus to the data items which can be collected in a clinical setting. Some items are collected to evaluate parameter values. For example, tritium thymidine studies can evaluate cell kinetic characteristics. Some are collected to follow the evaluation of certain control parameters, for example, the platelet count. Given even a simple model of platelet destruction, it is possible to observe when the count is falling as a function of the platelet pool only, i.e., when no platelets are being made. Now the clinical decision rule can become an anticipatory one: "If the halving time of platelets is under 36 hours, then prepare to give a platelet transfusion before the count falls to 10,000." The result, at the very least, is a data flow chart with explicit organization and meaning, very much in the spirit of Larry Weed's automated record. Manual and now automated flow charts have come into use at the M. D. Anderson Hospital to monitor the changes in important variables. These allow a chief of service to review thirty patients in less than two hours rather than by an exhausting set of card rounds. Such flow charts can condense the information both numerically and graphically. The prototype of the graphic representation is the temperature chart, long clearly useful. The updatable graphic record of lab value changes over time, coupled with important therapeutic decisions, provides a scanable situation report which should come to replace the chaos of the classical record.

2. *Functional Organization.* A step beyond the assertion that a certain group of parameters are important and somehow related is an explicit graph of this relatedness. In the case of the blood and the marrow, this is illustrated by Diagram I. Such a block diagram does not describe the exact relation among the variables. Rather it sets the stage for their discovery through the organized analysis of experimental and clinical data. Mathematical models of bone marrow cell kinetics and leukemic cell kinetics have been formulated to conform to the available clinical and experimental data. The models that we have been building depend for their

clinical input on the treatment protocols and the resultant data from the adult leukemia service of the Department of Developmental Therapeutics, M. D. Anderson Hospital, University of Texas, Houston, Texas. Here the greatest pay-off is ins'ght, however incomplete. For example, we observe clinically that the platelet count rises two to three days before the granulocyte count, when a heavily treated marrow is undergoing recovery. If the granulocytes are dangerously low, the platelet count is a good predictor of how long the count rises two to three days before the granulocyte count, when a heavily treated marrow is undergoing recovery. If the granulocytes are dangerously low, the platelet count is a good predictor of how long the white cells will be depressed. The relationships which outline the flux of cell types through the bone marrow provide us with this qualitative observation. In biological simulations it is important that the system can handle time delays and other processes which exhibit historical dependence. For example, the attrition rate of red cells is proportional to the age of the cells, with an expected life-span of 120 days. Thus, a marked variation in cell production influences the number of cells present at a much later date. BIOMOD incorporates efficient means of handling delays and some kinds of historical dependence.

3. *Teaching Model.* These simulations exhibit properties which are thermatically correct. In our case, it is the typical response of a typical leukemia patient to a typical course of drug therapy, either for remission induction or remission maintenance. At this stage interactive intervention in the evaluation of a simulation becomes useful and of insight. There is a natural inclination for physicians to extrapolate a little bit ahead of the available results. Thus the ability to watch a simulation unfold allows learning, model correction, and experimentation. At present, we can only project the clinical impact of such a system. We observe that it allows an exploration of therapeutic alternatives in a very real and believable Socratic Dialogue. It is also well to observe that it presents a danger, which might be called the "Las Vegas effect": There is a fascination with on-line simulations which can eat up computing time and money, the implication being that some form of success is just around the corner.

Our present modeling efforts are aimed primarily at the teaching model level of sophistication. On the biological level, teaching models test the consistency of our hypotheses. For example, present models point to a major discrepancy between our theoretical understanding and our practical results. The models suggested by the work on the L-1210 leukemia in mice and first outlined by Skipper have led to considerable clinical success. In mice the differential kill rate of leukemic cells over normal cells depend on constant differences in the cycle time, the growth fraction and the length of the DNA synthesis phase between the L-1210 cells and the mouse marrow. The experimental tumor grows faster, all cells are actively dividing, and are thus more susceptible to cycle sensitive drugs like cytosine arabinos'de. Very successful schedules have been set up assuming similar cell kinetics for human leukemics. However, in the latter case, Clarkson has demonstrated that in relapse, with a bone marrow full of leukemic cells, the leukemic cycle time is longer than that of normal cells, and the growth fraction smaller. This points to a new modeling requirement, a new iteration: the analysis of transient growth states leading to a new hypothesis for the same output phenomenon.

We see that the clinical pay-off from a teaching model is *clinical courage*, the willingness to carry through a plan because, in spite of limitations in the underlying rationale, the phenomena have become more or less predictable. Modification must be made for the individual patient using classical clinical judgment.

4. *Patient-Specific Model.* Whereas the teaching model provides a skeleton for action, the patient-specific model demands that parameters be modified to take into account individual differences. If this can be done successfully, i.e., with clinical verifiability, then the modeling process becomes a component in the therapy itself, a medical tool like any other. In cancer chemotherapy we have not taken this step, and except for very simple model components, this form of modeling remains largely a vision of the future. However, we can see it as a vision of the immediate future, because at least one strategy for implementation already exists: at a given point in time, the measure of a biological response of the patient can be derived from the data accumulated over the past course of therapy. Thus, an initial protocol course of drug has the dual objective of therapy and a calibration of future therapy. We envision combining protocol data curves with our simulations, using subroutines to automate the evaluation of parameter values.

This approach should open up new potentials in protocol studies of cancer chemotherapeutic drugs. Present protocols treat patients by a formula which supposes that each is the average case of the teaching model. Drug courses are set up so that cons'stency is achieved by using standard doses. This imposes certain obvious rigidities which limit success. By using a model approach, it will be possible to keep the relationship between drugs and patient parameters constant. Thus we can seek to test the input of drugs on the biology of the patient and his disease, rather than treating him as a block box, susceptible only to statistical analysis.

CONCLUSION

The impact of model building and simulation on clinical medicine is just beginning to be assayable. Many of the themes which will ultimately be important can be observed in prototype. Long-term effects will be felt (1) on the operational organization of medical data, in the medical record; (2) on the formulation of the biology of disease; (3) on the methodology of medical teaching; and (4) on the precision and focus of clinical research.

Graphics software for remote terminals and their use in radiation treatment planning*

by KARL H. RYDEN and CAROL M. NEWTON

University of California at Los Angeles
Los Angeles, California

INTRODUCTION

Interactive graphics' ability to provide a meaningful interface to investigators in a variety of applied fields has been recognized for many years. Nowhere is this promise greater than in medicine and the life sciences. Levinthal's[1] interactive program for constructing and displaying complex molecular structures is well-known. Neurath[2] and Frey[3] have analyzed chromosome spreads by delegating to human perception the light-pen dissection of individual chromosomes from overlapping clusters while leaving subsequent measurements and final classification to the computer. Cox and Clark's Programmed Console[4] has introduced many radiotherapists to the use of computers in treatment planning. Other applications at this facility[5] and elsewhere[6] illustrate the great value of interactive graphics support in deriving insight from large clinical data bases, exploring complex biological models in the hope of improving treatment strategies, and developing cost-effective algorithms or special hardware for patient monitoring.

That the use of computer graphics in biomedical and other fields has not developed more rapidly has been in large part attributable to two factors, the high costs associated with hardware and development of applications programs, and the general unavailability of graphics terminals that can operate remotely using common carrier communications facilities. The latter capability is not needed when modest computational requirements enable support by a dedicated small computer, as in the case of the widely used Programmed Console. But, as illustrated by other of the projects mentioned above, many biomedical applications require access to a level of computer support which is most economically provided on a shared basis. The recent commercial availability for less than $20,000 of a terminal (IMLAC) which has many characteristics of the higher quality graphics systems and which uses common carrier telephone facilities to communicate with its host processor, has motivated a substantial investment in systems support at UCLA's Health Sciences Computing Facility (HSCF).

The setting for this work will be described, previous efforts in graphics and the development of an operating systems environment appropriate for supporting a multi-terminal remote graphics system. Subsequent discussion of a set of interactive graphics programs that are being developed for radiation treatment planning will illustrate some of the problems that must be faced when a graphics terminal is to be supported by low-bandwidth communications. After describing the related hardware, current and projected software developments will be discussed with reference to the foregoing applications.

PREVIOUS DEVELOPMENT OF GRAPHICS AND OPERATING SYSTEMS AT HSCF

HSCF is maintained by the National Institutes of Health to explore and develop computer-implemented analytical support to research in biology and medicine. The BMD statistical package programs, TORTOS operating system, and other developments at this facility have originated in response to explicit needs of biomedical researchers.

TORTOS (**T**erminal **O**riented **R**eal **T**ime **O**perating **S**ystem)[7] was developed in response to the variety of needs that prompt biomedical researchers to share access to a large computer. It has been designed to take

* This work is being undertaken at the Health Sciences Computing Facility, UCLA, sponsored by NIH Special Research Resources Grant RR-3.

advantage of the large high-speed core (2000K bytes) and computational speed of the 360/91 processor, making these resources available to the facility's users with as few constraints as possible on the types of programs accommodated. The terminal user has at his disposal the full facilities of a standard OS/MVT system as well as the specialized interactive functions developed here to aid conversational access to the system (monitor programs, a convenient file service, input/output interfaces, text editor, a FORTRAN compiler, and a library of statistical and biomedical applications programs). The system concurrently supports local and remote batch operations. Its versatility is exemplified by the wide range of uses to which it is being put. These include multivariate statistics, computer-aided instruction, management information systems in the Biomedical Library, biological modeling, and several clinical applications. Although not presently in use, the system has supported a high speed, real time link to an SDS 9300 located in UCLA's Brain Research Institute.[5] Since the remote graphics terminals are time-shared as an extension of the conversational terminal system, they have access to all facilities developed for the latter.

For the past five years, we have developed and use-tested systems to make the IBM 2250 graphics terminal accessible to biomedical programmers. Interactive graphics interfaces are intended to be meaningful to the scientists who use them. A growing number of biologists and physicians are capable FORTRAN programmers. Many of this facility's medically or biologically oriented graphics programs have been developed by such people, using our FORTRAN callable subroutines, GRAF (**G**raphic **A**dditions to **F**ORTRAN)[8,9] or a similar interface, PL/OT,[10] developed for use with PL/1. These include[5] programs for data analysis and statistics, teaching, image processing, modeling of cellular and physiological systems, interactive retrieval, simulation of disease propagation in adjacent urban environments, design of coronary-care and obstetrical monitoring systems, and radiation treatment planning.

The GRAF programmer has at his disposal routines for generating the primitive elements of an image (blanked and unblanked points, lines, and alphanumeric characters) which are combined into a structured display file whose basic element is called a display variable (DV). Additional routines are provided for combining the DV's into display frames for presentation on the terminal's screen. There are also facilities for servicing the input devices associated with the graphics terminal (alphanumeric and function keyboards and light-pen) and for character-string manipulation.

REMOTE GRAPHICS SUPPORT TO RADIATION TREATMENT PLANNING

Distributed-processing capabilities being developed for the GRAF subroutines designed for terminals operating over low-bandwidth communications systems are discussed in later sections. One of the biomedical projects whose needs influence this work, a set of programs for radiation treatment planning, is described here. Preliminary program development on the IBM 2250 has been reported.[11]

Previous work in radiation treatment planning

Radiation treatment planning is among the earliest established areas of computer support to medical practice. Stovall's[12] recent bibliography provides access to most of the formal publications in this field and is recommended as a basic reference for this section.

The radiotherapist's primary concerns in treatment planning may be briefly summarized as follows: He has at his disposal radioactive sources that can be placed within the body and beams of radiation that can be directed to it from various angles outside. He seeks a combination of either, or sometimes both, so that the resulting spatial distribution of dose delivered throughout the tumor volume is large compared to that delivered to normal tissues he wishes to spare. He also desires a relatively homogeneous distribution throughout the tumor volume itself. Fear of tumor regrowth in undertreated areas, "cold spots," dominates the latter concern, but excessive tissue breakdown in hot spots also is to be avoided. Either formulas inherited from research on the interaction of radiation and high-energy particles with matter, or tabulated empirical measurements of fields surrounding sources or beams in water or other materials of known composition, enable him to compute the desired dose distributions. Palpation, scanning or other techniques are used to estimate the location and extent of the tumor. Special radiographic techniques such as tomography help to locate the boundaries of internal organs to be spared or whose tissue densities are to be taken into account when the dose distributions are calculated.

When done by hand, even the simplest calculations, such as the dose distribution for two or three superimposed beams in a homogeneous unit-density medium, are extremely tedious and tend to be undertaken infrequently and reluctantly where computer support is not available. Thus in many places radiation therapy adheres to longstanding conventional prescriptions that have proven relatively effective for the "average patient" given the constraint that the risk of notable side effects in all is to be vanishingly small. Computer-assisted treatment planning seeks to individualize therapy, to help the therapist take every possible advantage of a particular patient's tumor location and body geometry. It also encourages him to explore new general treatment strategies which might, even in places that do not use computers, become part of the conventional armamentarium of treatment plans.

Two types of computer support for treatment planning are regularly used in a small but noteworthy number of treatment centers.[12] Some excellent *batch programs* for external-beam therapy have been tested by many years of use. Representative of these are Theodor Sterling's programs (University of Cincinnati and Washington University, St. Louis), Jack Cunningham's (University of Toronto), and those developed under the direction of John Laughlin (Memorial Hospital, New York). The latter are widely available via remote typewriter terminals. The earliest program extensively used for implant therapy (placement of sources within the body) was developed by Robert Shalek and Marilyn Stovall (M. D. Anderson Cancer Research Hospital, Houston). Both the three-dimensional complexities of implant therapy and the corrections for tissue inhomogeneities found in the batch programs for external beams require major processors.

The Programmed Console developed by Jerome Cox, Wesley Clark, and their associates (Washington University, St. Louis) provides clinicians an economical *interactive graphics* system for treatment planning. It permits simple beam superimposition in a homogeneous body whose outer contour is specified to the computer by a rho-theta digitizing scribe. Program modifications are relatively difficult to introduce because of full utilization of the small processor dedicated to the system, and a number of the capabilities available in batch programs understandably are not present. However, the Programmed Console has demonstrated by wide acceptance the radiotherapist's strong preference for a hands-on graphics system which provides him rapid graphical dose distribution feedbacks for a sequence of conveniently repositioned superimposed beams. Other small-processor graphics systems have been developed in the United Kingdom and elsewhere.

*Remote graphics radiation treatment planning***

Clearly, one wishes to combine as economically as possible the advantages of interactive graphics and major processor support, developing programs having the greatest possible degree of exportability. IBM 2250 programs utilizing GRAF have run on a variety of IBM 360 computers operating under OS, and the new version of GRAF designed for the IMLAC terminal has been organized and will be documented in a manner that should facilitate its rewriting for other processors. Immediate exportability is enabled by the IMLAC terminal's low price and its ability to operate over conventional telephone lines.

Information has been entered for the first beam, a Co-60 beam whose center and range of oscillation is indicated by the angular structure to the left of center

The first two members of our package of graphics programs to support radiation treatment planning have been selected as follows: First, one wishes to take fullest possible advantage of excellent batch programs that have been tested by years of use. The initial program in this category is a graphics adaptation of Memorial Hospital's external-beam program. RADCOMP III, the most recent version of M. D. Anderson's program, and Sterling's program will be next. Although there is some overlap among these, it is desirable to offer the different programs that have won various radiotherapists' confidence. Second, we want to explore the special advantages of our system. For this we have chosen a three-dimensional implant application, the widely used Fletcher-Suit intracavitary method for treating cancer of the uterus.

Several capabilities are common to all programs: input of a brief information record for each patient, routines for providing a proper scale and assessing its

If this visual check is satisfactory, the user may select from several levels of redundancy in specifying information from a lateral view

uniformity throughout the CRT display whenever graphical information is to be specified by light-pen, and contour plotting routines for displaying dose distributions.

1. *The external-beam program.* When users wish to take advantage of the Memorial Hospital program's capability to correct for tissue inhomogeneities, they must specify contours and densities for the various organs. They may do so by taping a transparent drawing over the CRT face, using the light-pen for a point-

to-point specification of each contour. (A continuous light-pen tracking capability is available on the IMLAC and on some other IBM 2250 models.) It is easy to revise or restart contours. The expense of additional input scribing equipment is avoided. This is much simpler to execute and easier to verify visually than providing the numerical contour specifications required for the batch program. Further burdens of coding input information are relieved as the user next responds to a conversational program that requests information concerning the beams to be used and how they are to be directed (i.e., from a given angle, rotating about a given point, or oscillating within specified angular limits). Brief notations for each beam are added to the body-contour diagram (see Figure 1). Dose-distribution in the plane containing the beams then is displayed. This may be filed for later comparison with other treatment plans.

2. *The intracavitary program for uterine cancer.* In afterloading approaches, hollow instruments (the afterloaders) are placed securely at various locations in the tumor area. Subsequent introduction or removal of radioactive sources within the lumens of the afterloaders may therefore be accomplished without further discomfort to the patient or disturbance of the tumor-source geometry. The Fletcher-Suit afterloading system for uterine cancer comprises a long curved tube which is introduced into the uterine cavity (the tandem) flanked laterally by two source holders (the colpostats) externally adjacent to the uterus. Each of the latter can hold a single radioactive source, and a sequence of sources can be spaced along the central axis of the tandem. Frontal (A-P) and lateral radiographs are used to locate the afterloaders.

A conversational program facilitates light-pen specifications of afterloader locations, taking full advantage of their known geometries. The user may elect tradeoffs between rapidity of input and the security of checks enabled by obtaining redundant geometrical information (see Figure 2). He also may control economy vs. quality of computation by such means as specifying the length of segments to be used to approximate linear radiation sources of uniform density. For instance, an economical initial exploration which approximates each linear source by three segments can be followed by a computation of higher quality which assumes a segmentation of nine or ten. Dose-distribution displays may be requested for any A-P, lateral, or transverse plane (see Figure 3). Inventories are maintained for the afterloaders and sources.

Arrangements are being made for live demonstration of these programs on the IMLAC terminal, in addition to motion-picture illustrations of their use.

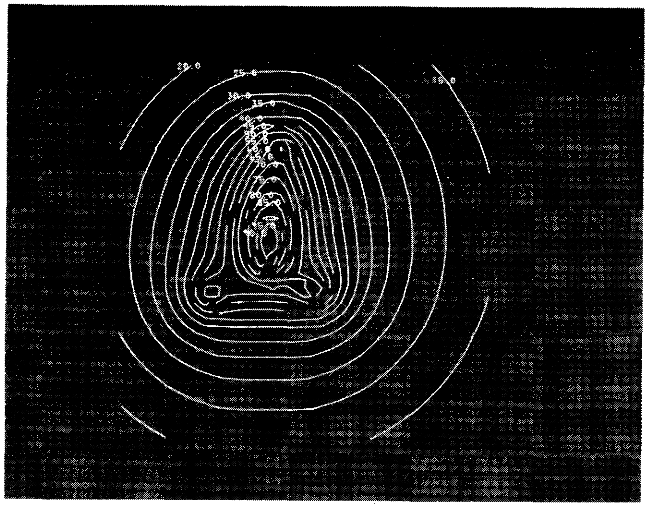

Figure 3—Isodose plot for uterine treatment: Dose distributions may be requested in any A-P, lateral, or transverse plane. This display may be transmitted line-by-line as it is being computed. An occasional segment may be missed by the economical algorithms used here

Possible implications of graphics in the acceptance of treatment-optimization programs

Linear programming[13] and other approaches[14,15] have been suggested for optimizing spatial dose-distributions, and one[14] is being used regularly in a small number of radiotherapy centers in Great Britain. Graphical demonstrations tend to be more convincing than mathematical proofs to the average clinician, and they help him to bring his experience to bear on criticizing the outcomes of using various criteria for optimality. One therefore anticipates that the present conjunction of an interactive graphics terminal with a processor capable of performing optimization calculations will encourage serious investigation, improvement, and perhaps eventual acceptance of more optimization procedures in radiotherapy.

Implementation over low-bandwidth communications systems

Transmission over conventional telephone lines poses serious response-time problems for the more complex graphical displays of organ contours and dose-distribution. Subsequent recall for display purposes rather than initial point-to-point specification is of main concern in the organ-contour display. However, methods currently

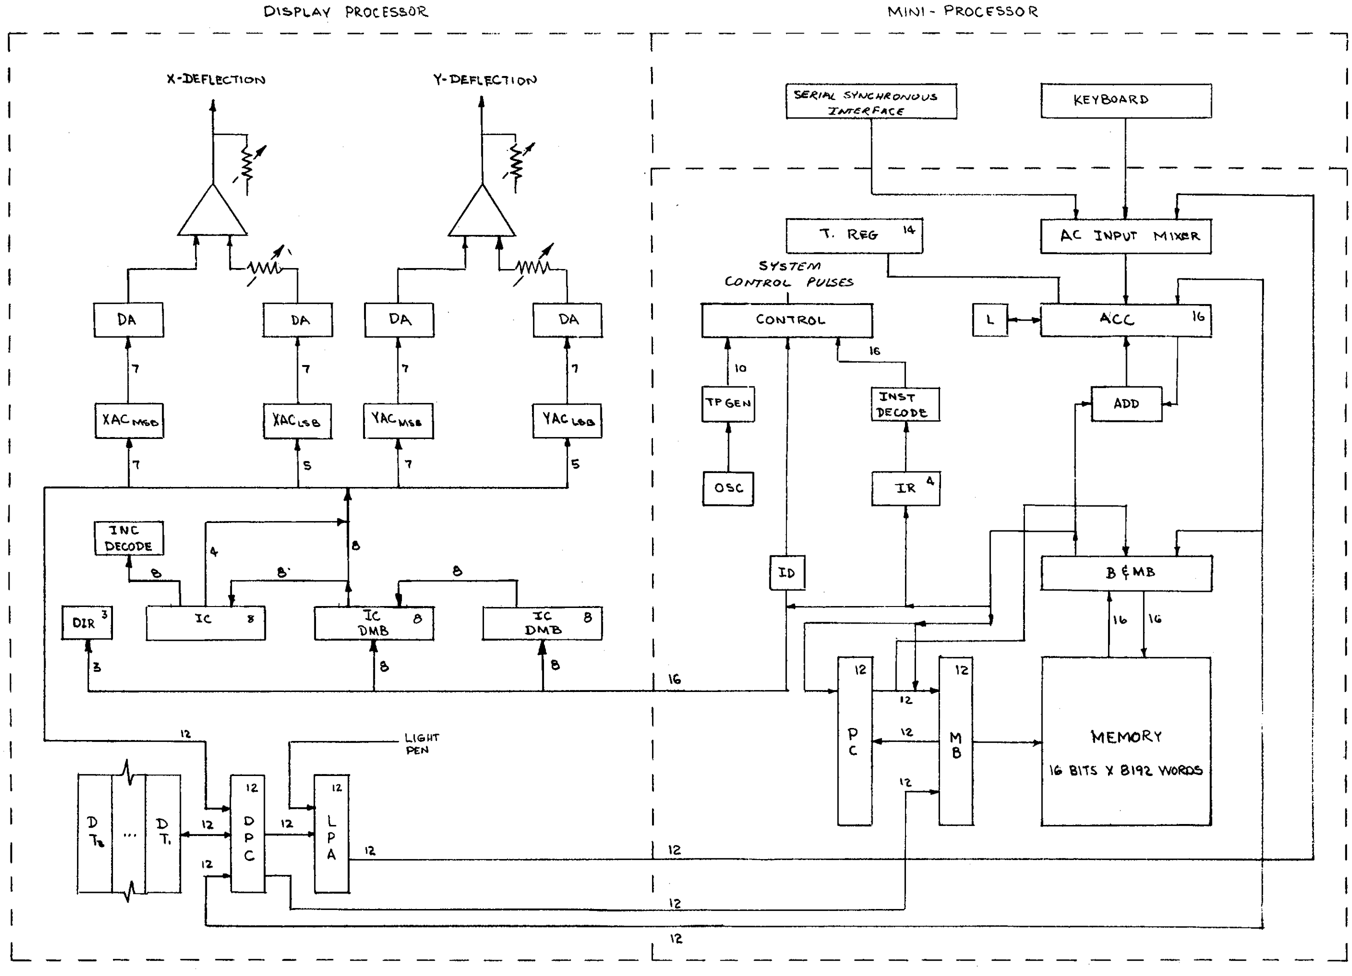

Figure 4—IMLAC PDS-1 system block diagram (redrawn with permission of the IMLAC Corporation) indicating the dual processor nature of the systems design

being explored to expedite transmission of a retrieved display may simplify the initial input as well. Advantages of the interactive approaches that are possible for anatomical specifications or the input of graphical field-distribution data for sources and beams cannot be realized for the computed dose-distributions, since the latter are initiated at the host processor. Research on these problems in graphical representation is being pursued initially on the IBM 2250 while the remote terminal version of GRAF is being developed and tested on the IMLAC. However, both efforts assume a distribution of processing between the terminal and host computer which has not been feasible on the IBM 2250. This work is described in a later section, and additional presentations will be made at the time of the conference.

REMOTE GRAPHICS HARDWARE

The remote graphics system consists of three major hardware components: the host processor, a 360/91 computer with 2 million bytes of high-speed core and 672 million bytes of secondary direct-access storage; the graphics terminal, a mini-computer (PDS-1) manufactured by the IMLAC Corporation; and the data link between the two processors. While the typical graphics program does not normally require the resources of a computer like the 360/91, it does permit the computer to simultaneously service far more graphics terminals than could be handled by a less powerful machine. In addition, the occasional heavy demands for arithmetic processing can be absorbed without severely impacting other concurrent activities, for as at most computer centers, graphics is only one aspect of the computer's total load at HSCF.

The development of a remote graphics terminal is not a new idea, nor is using a small computer to overcome the restrictions of low-bandwidth data links, as has been done elsewhere.[16–18] There are also available today at least five different storage-tube terminals which have a serial-communications interface that permits them to operate from a remote location without a mini-computer. Storage tubes do not need local refresh memories and their display capacity is limited only by the resolution of the screen. By contrast, the display capacity of refreshable tubes is limited by the size of the local refresh memory and the drawing speed (refresh cycle) of the deflection system. However, the storage-tube terminal's limited capacity to selectively erase one component of a display from the screen requires compromises between response time and the ideal presentation of information to be displayed. In order to modify one component, the screen must be erased and the entire modified display retransmitted to the terminal. In one storage-tube system it is possible to erase information from the screen by retransmitting the orders which created the display, but this also erases other components of the display frame which may have intersected the portion which was erased. Lack of a selective erase can be overcome to some extent by the use of a local computer which can regenerate the image; this, however, nullifies much of the cost advantage which the storage-tube terminal otherwise enjoys. The GRAPHIC-II system[16] developed by Bell Telephone Laboratories is similar in many ways to ours. There are, however, some major differences in approaches to optimizing the use of the data link and to distributing tasks between the remote and host processors. The PDS-1 is one fourth the cost of the PDP-9 system used in GRAPHIC-II. In part, this reduction in cost is a result of technological advancement; however, much of it is due to the fact that the PDS-1 was designed specifically as a low-cost display computer.

The IMLAC PDS-1 (see Figure 4) computer is a dual processor machine with each processor sharing the same memory. The main processor executes an instruction set which is typical of most small computers (ADD, SUBTRACT, BRANCHING, LOGICAL and INPUT/OUTPUT operations) while the display processor, which is controlled by the main processor, executes a set of display instructions that generate the image on the CRT (see Figure 5). The display image is drawn using incremental vectors; each incremental order (8 bits) can move the CRT beam in one of 32 directions for a distance of 0-9 raster units (a raster unit is 0.011 inches). Line segments, characters and other graphics figures are generated by display subroutines composed of incremental orders. An eight-level hardware push-down is provided for nesting display subroutines.

The principal disadvantage of the incremental drawing technique used by the IMLAC is the slightly jagged appearance of lines or curves that results from the 32-direction restriction on elements composing them. This can be a serious problem if high-quality images are required. For instance, depth cues of the perspective transformation might be blunted when three-dimensional images are being generated. However, in the majority of medical applications, this is not a serious problem and the economies that result from the use of incremental drawing seem to outweigh the disadvantages.

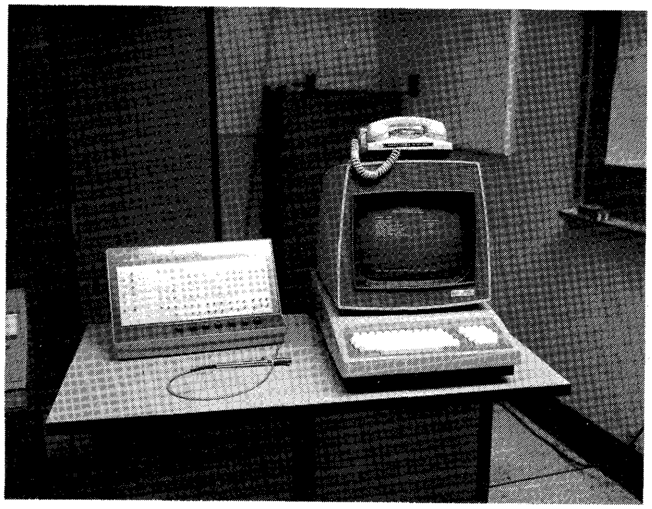

Figure 5—IMLAC graphics display terminal: Light pen and optional programmers console are shown to the left of the keyboard and display

The choice of a data link between the graphics terminal and the host processor was dictated by universal availability, low cost of modems and interfaces, and speed, in that order of importance. We chose to use a serial-synchronous communications format employing switch network telephone facilities at 2000 bps (WE-201A type modems). However, while meeting our requirements of availability and low cost, the transmission speed represents what can only be considered a minimal level. A major component of the programming support is devoted to overcoming deficiencies of the data link.

REMOTE GRAPHICS SOFTWARE

Programming systems support for the remote graphics terminals consists of a control program for the terminal computer, the host processor control program, and the applications programming "language." The latter two components are 360/91 programs while the first executes in the PDS-1 computer. Application programs are written in FORTRAN using a collection of subroutines called GRAF[9,10] which were originally designed for use with the IBM 2250 and whose external format has been preserved in the remote graphics implementation. Thus, use can be made of the large number of programs written using GRAF at UCLA and elsewhere over the past four years. Although an emulation of the 2250 would have provided access to more existing programs, it would have compromised effective use of the data communications facilities.

Strategies for overcoming the limitations of low-bandwidth communications systems

Transmission over conventional telephone lines poses serious response problems for the more complex displays (see Figures 1 and 3). In Figure 1, the organ contour display, the main concern is with the subsequent recall of the image rather than its initial point-to-point specification whereas in displays like Figure 2, response is poor because the terminal fails to react quickly to simple interactions. The logical and arithmetic capabilities of the remote processor offer several means of improving response. Data compression can increase the information density by removing extraneous bits from the graphic data structure or bits whose meaning is implicit from the context in which they are used. Another method is to organize the graphics data so that inactive static segments of the display are saved and recalled into the active display by the transmission of a single command. Labels, grid lines, indexes, and explanatory text are examples of data which are fixed throughout the course of the typical graphics program and need only be transmitted once when sufficient remote processor storage is available. Response time is determined by the variable display data.

Approaches that decrease the number of bits transmitted to specify graphical or other data will be discussed in the next section. The portions of GRAF initially developed for remote IMLAC terminals have emphasized storage-management and look-ahead capabilities that facilitate terminal response by avoiding retransmission of graphical information that may be displayed repeatedly and by anticipating transmission of that information which is most likely to be used next.

Unless the remote computer is augmented by a peripheral storage device, the static display data which can be retained generally will not exceed two or three display frames. The added cost of direct-access storage caused us to prefer extending the storage capacity of the standard terminal by formulating a procedure which retains those inactive segments of the terminal's display buffer which are most likely to be reused when it becomes necessary to overlay some segment in order to accommodate a new segment. This procedure is primarily a storage management technique and has been augmented by look-ahead facilities which are designed to anticipate the requirements for new display segments and transfer them during intervals when the data link would otherwise be idle.

New GRAF storage-management facilities

Implementation of the storage management and look-ahead facilities is largely unknown to the GRAF programmer although he has some control over the transmission of graphics data to the remote processor.

As in the IBM 2250 version of GRAF, the basic element of the graphics data structure is the display variable (DV), which is composed of the primitive elements that generate the display. The DV is formulated in the host processor by graphics subroutine calls, for subsequent transfer to the display buffer, that portion of the terminal's memory which services plotting.

The display buffer of the remote processor is divided into primary and secondary display lists. The secondary display list entries correspond to a subset of the DV's in the host processor. The primary list consists of pointers (display subroutine jump instructions) to each entry in the secondary list which is currently being displayed on the CRT screen. DV's are added or removed from the screen by adding or removing appropriate pointers in the primary list. A display frame is composed of one or more DV's which may contain their own screen coordinates, or the position which the DV occupies may be determined by positioning orders in a DV which "calls" it. The DV can be considered a display subroutine, and in the instance of a relative DV (one which does not contain absolute positioning orders), only one copy of the DV is stored within the remote graphics processor.

The best response characteristics will be obtained when each frame is segmented into DV's such that the static information is separated from the variable data, and when display components which are used repeatedly are each declared to be unique DV's rather than combined into a few DV's. Thus, the user can improve response characteristics not only by partitioning each display frame into fixed-format and variable DV's but also by further subdividing the fixed-format portions to take advantage of relative DV's that are to be used repeatedly. For example, in a single session with the computer, the radiotherapist probably will explore up to three or four treatment approaches for each of several patients. There will be delays when DV's guiding conversational input are initially called, but use of the program thereafter would, for the most part, flow as freely as on the IBM 2250. The saving is especially notable for the grids supplied to effect input of graphical data. One coarse grid covers the entire screen, but for more precise description of curves a finer grid patch is moved to desired locations on the large grid. Treating the patch as a relative DV, only the transmission of two coordinates is required to reposition it. Because of frequent use, DV's representing both types of grid would have a high probability of remaining on the secondary list of the terminal's display buffer.

All of the decision making and tables for managing the remote processor's display buffer are provided by the host processor. The graphics processor's storage management functions are limited to unpacking the transmission records, relocating addresses, and moving entries within the primary and secondary lists. When a new DV is to be transmitted to the remote terminal, its storage requirements are determined by the host processor and it is assigned a relative location within the display buffer. If sufficient free space is available either in one contiguous block or in multiple free blocks, the DV is placed in this region. When a single region is not available, commands to compact the display buffer are transferred ahead of the graphics data. Normally, all free space will be in one continguous block, since the host processor's storage management routines use idle time on the data link to transfer the commands necessary to compact the secondary display list. Upon receiving the DV, the remote processor unpacks the data and relocates all relative addressing information into absolute display buffer addresses. When members of secondary display lists are moved from one location to another to compact the list, all absolute addressing information in both lists is again relocated.

When insufficient free space exists for a new DV that is to be transferred to the terminal, the required space must be created by some combination of using free space and removing secondary display list entries. The criteria used for choosing which blocks(s) in the secondary list should be deleted attempt to reduce the chance of deleting DV's which could be used in a subsequent display while also minimizing response time, since further action by the terminal user is suspended until a successful transfer enables the DV to become part of the active display. Three decision levels are used: (1) The system first tries to find a contiguous set of free or inactive blocks within the secondary display list. The inactive DV's which are chosen are those with the lowest probability that they will be reused. The assignment of these probabilities is described later. Contiguous sets are sought in order to avoid an additional pause to transmit commands required to compact the secondary display list. (2) When a contiguous set has not been found, the free blocks and the inactive DV's with lowest reuse probabilities are collected into a list, weights assigned, and a good set chosen to be deleted. The secondary display list subsequently must be compacted. The weight assigned to each DV is a function of its size, its position in the secondary display list (which determines the delay necessary to compact the list if this DV is deleted), and the reuse probability. The optimum set, that which provides enough space while minimizing the summed weights of DV's to be removed, can only be chosen while examining all possible combinations. Since this would burden the host processor, an alternative, approximate stepwise procedure is used. First, the list is sorted by weights and partitioned into two groups. Initially, the first group will contain the first *n* elements of the list whose total size is sufficient. The procedure then compares the sum of the weights of each pair of elements in the first group with the weight of an element of the second group. An element in the second group replaces the pair in the first when its weight is less and its size is greater than or equal to the corresponding pair in the first group. Similarly, the process is repeated by comparing combinations of three elements in the first group with pairs and single elements of the second group. We have found that continuing the search beyond three combinations does not yield a significant improvement. (3) If a check made prior to pursuing (1) and (2) reveals that the total free space and that occupied by inactive DV's is less than the space required, the operator is permitted to delete DV's from the active display by using the light-pen. This final means of obtaining the required space in the display buffer is provided primarily for program debugging, permitting the program to continue when it otherwise would have been abortcd.

Look-ahead facilities

The communications link between the graphics terminal and the host processor is normally idle for several seconds between each interaction. During this interval, the user is determining his next step. This suggests that if the host processor has a reasonable probability of predicting the user's choice, the effective transmission speed of the data link could be increased by using the idle time to transmit the graphics data most likely required for the next display frame. The display program can be represented as a discrete Markov chain whose states are all the possible display frames which the program may generate. In GRAF, the states are defined by the DV's which generate the display frame. The transition from one state to the next occurs at each interaction (light-pen detection, keyboard entry, or terminal processor interrupt).

To predict which state is most likely to occur next, we form a transition probability matrix

$$P_{ij}^{n,n+1} = P_r\{X_{n+1} = j \mid X_n = i\}$$

$P_{ij}^{n,n+1}$ is the probability that j will be the display program's next state given that i is the current state.

Each time the program enters a waiting state for some form of remote processor interrupt, the transition probabilities of the current state are examined and the DV's corresponding to the most probably next state of the program are transferred to the remote processor to the extent permitted by time and by space in the display buffer. Not all of the DV's corresponding to the next state can be transferred in advance since some may not be defined until after the operator interaction is completed and others, although fully specified, may not have been generated in advance.

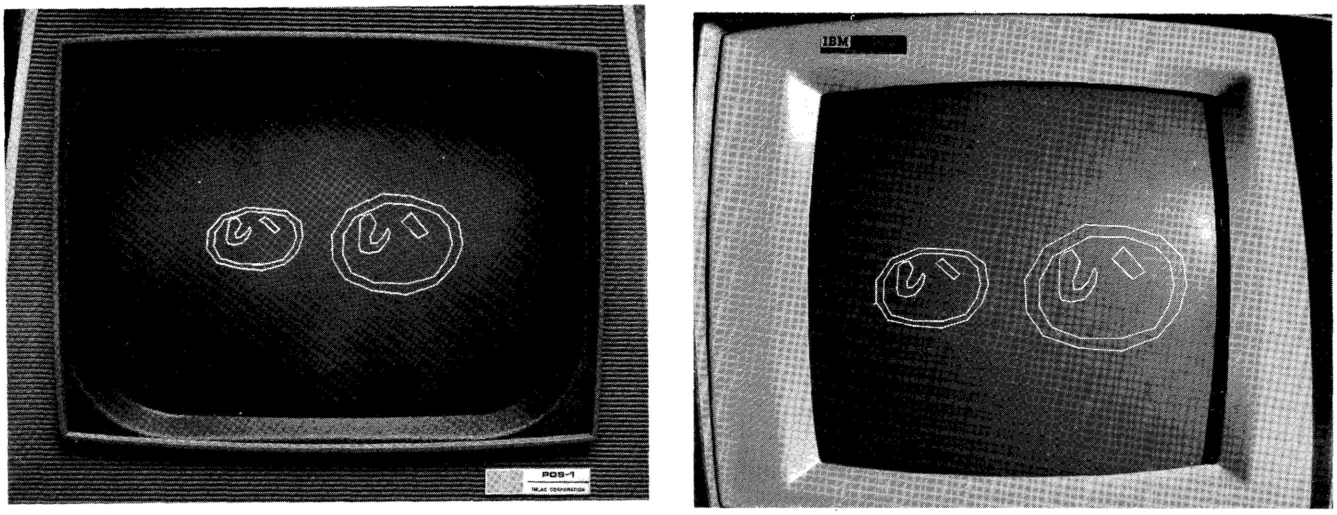
The state matrices are of two types: When the program is being executed for the first time, no information about the transition probabilities exists. All probabilities are assumed equal unless the programmer specifies otherwise. The second type of state matrix represents a typical use profile for the program which has been accumulated through many executions of the program. Even when an extensive use profiles exists, considerable improvements in the predictions can be made by dynamically updating the transition matrix so that it will more accurately predict the current use of the program. Provisions are made for each user to save and update his own transition matrix to tailor the program's response to his own needs. For example, new users of the intracavitary radiotherapy program will tend to seek more explanatory material and to elect more conservative approaches for locating the afterloaders. They will tend initially to use the transition matrix provided by the system, changing to their own when familiarity with the program motivates expedition of shortcuts and other preferred routings through the program. Thus, the system's matrix for each program will tend to remain oriented toward its most likely client, the new user.

Data-compression techniques

Processing capabilities of the graphics terminal enable unpacking of information transmitted from the host processor in a variety of condensed formats. While computations required for condensation can be complex without taxing a fast host machine, unpacking must be efficient enough to provide the desired advantage over unpacked transmission formats. The radiotherapy programs have directed attention to the problem of compacting information required for specifying graphical displays. Investigations proceeding on the 360/91 and 2250 while basic GRAF software is being tested are mindful of the two types of local graphics interfaces provided by the remote terminal: (1) specialized function generators such as those supporting curvilinear display generators, the light-pen tracking routine, routines which can translate, scale, and window display variables; and (2) routines which are written in the IMLAC PDS-1 machine code by applications programmers. The routines for both types of interface are assembled by the host processor and stored in a library to be dynamically loaded into the remote processor as they are required by the graphics programs. For purposes of memory management, the relocatable PDS-1 programs are considered to be display variables. Remote processor programs can extend the capability of the entire remote graphics terminal system, particularly where display dynamics are involved.

More general, conventional approaches to parameterized representation of graphical data are being explored initially, e.g., conic sections[19] and families of exponential curves,[20] as alternatives to piecewise representation by straight-line segments. The combined processing capabilities of this system permit additional approaches to be explored without the immediate constraint that they be implementable in hardware. For instance, for specification of organ contours or the distribution of fields around radioactive sources or X-ray beams, the approximation of large segments by French curves visually fitted at the terminal is being investigated.

Graphical information originating at the host processor, such as the dose distributions calculated for a given patient, cannot benefit initially from interactive approaches such as the latter. However, since considerable computation is required for each point in the dose-distribution field, procedures that transmit graphical



(a) IMLAC: (b) IBM 2250

Figure 6—Polar transform with different expansion moduli: Among approaches being explored to compact patient anatomical information for subsequent rapid transmission is representation of an individual's configuration by transforms mapping it into standard anatomical cross-sections. The outer contour on the left (non-anatomical) figure is being mapped into that shown on the right by expansions around a central point that assume different "expandability" of various domains. In this case, the outer (fat) layer is assumed to vary more than other "tissues."

information as the doses are being calculated alleviate much of the transmission delay. They have the additional advantage of enabling the radiotherapist to economize by terminating computations when the information displayed suffices for decision making. The contours shown in Figure 3 were generated line by line. The line at which computations are to commence may be indicated by the user. Another routine is available which computes and displays contour by contour.

An interest in transforms of related sets of graphical data is aroused by the awareness that a number of radiotherapists estimate internal-organ location by adjusting standard anatomical atlas cross-sections to measurements of the patient's external contour. We are exploring an improved version of this approach which allows different size-preserving factors for various tissues to be observed while transforms are being applied (see Figure 6). The objective is to reconstruct an adequate display of an individual's anatomical cross-section, using processing capabilities of the graphics terminal, locally stored standard cross-sections, and a small number of parameters characterizing a previously determined resultant transform. The latter would be obtained initially at the graphics terminal, as the radiotherapist seeks by a number of transforms on the entire cross-section or on individual organs to achieve an adequate correspondence between a transformed atlas cross-section and that determined for the patient by tomography or other methods.

By storage-management and look-ahead facilities, we have sought to provide users the most economical terminal possible. However, should radiotherapists wish to add a disk at the terminal for more complete anatomical atlas storage or capacity for additional stand-alone applications on the IMLAC, it would be worthwhile to investigate transferring to the terminal processor a stand-alone capability for many conversational portions of anatomical and treatment specification, to reduce subsequent communications charges. These program developments would be expedited by a 360/91 FORTRAN compiler that generates object code for the IMLAC.

Performance measurements

At this writing, we have not had enough experience with user programs to give any quantitative assessment of the remote graphics terminal's performance as compared to the 2250 terminal. There are areas where further development is already indicated. Decreasing response time by facilitating programmer's access to the remote computer through a compiler or by the addition of hardware components are areas to which we are now turning our attention.

In order to evaluate performance of the system and to quantitatively measure the effect of changes in the hardware and software, an extensive data collecting facility has been built into the programming packages. The programs continually log information regarding response time, data link utilization, storage utilization, display variable characteristics and other parameters which are believed to relate to system performance. This information is printed for the programmer at the end of each graphics job and is accumulated in a historical file for later analysis. Being provided with performance information regarding the execution of his graphics program, the user is likely to take an interest in those aspects of the program which affect its performance and to take the necessary steps to improve his program. The data gathering routines of the graphics system can also be instructed by an execution time parameter to collect a complete profile of a graphics job to the extent that its execution can be reproduced by using the profile as an input source instead of the terminal. This is particularly useful in debugging the system by providing a reproducible set of test jobs which can be run over and over until an error is found and corrected or the desired performance improvements have been made.

Automated information-handling in pharmacology research

by WILLIAM F. RAUB

National Institute of Health
Bethesda, Maryland

Pharmacology in its broadest sense involves the multitude of interrelationships between chemical substances and the function of living systems. Since these interrelationships manifest themselves at all levels of physiological organization from the individual enzyme to the intact mammal, research in this area involves concepts and techniques from almost every biomedical discipline. Detailed understanding of the mechanisms of drug action is the best prescription for the discovery of new therapeutic agents and the rational use of old ones.

The breadth and complexity of the domain of pharmacological inquiry interact to produce a class of information-handling problems as formidable and enticing as any that can be found in the medical area. In recognition of this, the National Institutes of Health (NIH), through its Chemical/Biological Information-Handling (CBIH) Program, is attempting to accelerate the acquisition of new pharmacological knowledge by designing and developing computer-based research tools especially for scientists in this discipline. Working through a tightly interconnected set of contracts with universities and colleges, nonprofit research institutes, profit-making organizations, and Government agencies, the CBIH Program seeks to blend the most advanced information science methods into a computer system which can be an almost indispensable logistical and cognitive aid to these investigators. This paper characterizes the current status of these efforts.

THE PHARMACOLOGICAL INFORMATION-HANDLING "PROBLEM"

The ultimate goal of pharmacology is a well-validated theory having the following two properties:

(1) given the identity of a chemical substance and the parameters of its administration to a given living organism (e.g., the dose, route, course, etc.), predict the effect, if any, on the behavior of the biological system; and

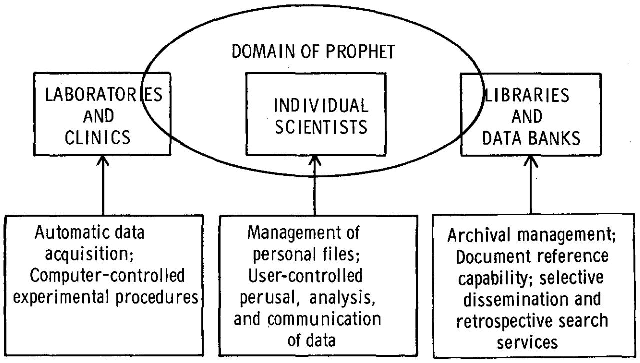
(2) given a desired behavioral end state for a given biological system, predict the specific chemical substance(s) and parameters of administration which can bring about that end state.

Only when such a theory is in hand will it be possible to make an accurate assessment of the therapeutic efficacy of a new substance without extensive testing in animals and human subjects. Only then will one be able to assume with confidence that a given drug will not have adverse side effects in a particular clinical context.

As is painfully obvious to both pharmacologists and laymen alike, an all-encompassing theory of drug action is nowhere in sight. Present understanding of drug action still is based almost exclusively upon empirical observation. Only a figurative handful of investigators have made extensive attempts to formalize their knowledge through mathematical modelling and the like. Natural language still serves as the predominant medium for the expression and communication of concepts. And textbooks and review articles constitute almost the entire body of organized knowledge.

Nor has information science and technology done much to aid in the development of a broad-based theory of drug action. On the contrary, even the most sophisticated document reference and archival management systems are only marginally useful in helping pharmacologists cope with the plethora of literature which is relevant to their interests. Moreover, outside of a few parochial areas, there are essentially no truly effective data retrieval (as opposed to document retrieval) services. And easy-to-use tools for building, exercising, managing, and communicating models of drug action are much more nearly fantasy than they are routine offerings of the typical general-purpose computer center.

Thus, the pharmacological information-handling



DOMAIN OF PROPHET
LABORATORIES AND CLINICS
INDIVIDUAL SCIENTISTS
LIBRARIES AND DATA BANKS
Automatic data acquisition; Computer-controlled experimental procedures
Management of personal files; User-controlled perusal, analysis, and communication of data
Archival management; Document reference capability; selective dissemination and retrospective search services

Figure 1—The PROPHET system in context

"problem" can be stated as a series of interrelated questions:

(1) Can one design computer-based information-handling tools which encourage formalistic rather than empirical approaches to the study of molecular structure/biological activity relationships?
(2) Can one use these tools to facilitate the interchange of data, procedures, and models among geographically and disciplinarily disjoint scientists whose work is relevant to the understanding of drug action?
(3) Can one use mathematical models and other formalisms to enhance traditional methods for the storage and retrieval of pharmacological information?

These questions circumscribe the domain of the CBIH Program. Some very preliminary answers are included in later sections of this discussion.

RELATED WORK

The interests of the CBIH Program in attacking the pharmacological information-handling "problem" intersect in one way or another with a large number of activities in the information science area, for the rubric "computers in pharmacology" covers a wealth of topics. As depicted in Figure 1, the CBIH Program in its work on the PROPHET System and related projects focuses on only a small—albeit crucial—subset of the potentially valuable applications for automated information-handling methods. Most notable is the absence of concern with (a) data acquisition and process control for experimental laboratory and clinical care settings and (b) automated archival management methods and other uses of computers in libraries. Since these topics are only of marginal interest to the CBIH Program (though obviously of utmost importance from other perspectives), they are not treated further in this account.

Turning attention specifically to the topic of personalized pharmacological data-management and analysis (i.e., the middle portion of the spectrum shown in Figure 1), there are two major classes of activity upon which the CBIH Program draws. The first is the collection of efforts concerned with chemical information-handling, especially those involving highly dynamic man/machine interaction about molecular structure data. The second is the collection of efforts concerned with general-purpose data management, especially those systems which offer the user great flexibility in the definition of file structure and which are designed to operate in a time-sharing environment.

Chemical information

The use of computers in handling chemical data (primarily structural information) is widespread and dates back to the mid-1950's. The need to deal most effectively with large numbers of organic molecules (in some cases hundreds of thousands) provides the continuing strong motivation; the fact that structural data is readily codified for machine manipulation makes this aspect of chemical information processing the most nearly tractable—and, hence, the most popular. Among the organizations who have made significant contributions are the Chemical Abstracts Services, the Walter Reed Army Medical Center, the Institute for Science Information, and a number of leading chemical and pharmaceutical manufacturers. The bulk of the efforts in this field are reviewed in two publications of the National Academy of Sciences-National Research Council.[1,2]

The subject of greatest concern in the chemical information field over the years has been the selection of an appropriate notation for encoding molecular topology. Almost every group has struggled with the choice between connectivity tables and linear ciphers. The connectivity tables have the advantage of being direct atom-by-atom/bond-by-bond descriptions of molecules and, hence, they allow one to perform searches for essentially any subgraph without the need for predetermined indices. Connectivity tables invariably make heavy demands upon storage, however, and, in the case of even medium-sized files (e.g., 10,000 structure records) the extensive processing time required for many substructure searches renders them impractical for production use without some fairly rigorous preliminary screening of the queries to the file. By contrast, linear notations are compact in terms of internal representation, are processed with relative ease and economy, and, with some perseverance, can be mastered by the scientist for direct use as a form of nomenclature. But linear notations do not allow readily for the full range of possible substructure queries, and this shortcoming has proved serious in some cases.

Obviously, the strengths and weaknesses of these two basic approaches are highly context-dependent, and there is not likely to be a move toward consensus until additional advances in retrieval methods (e.g., in hash-coding strategies) are made. Moreover, since there are many possible compromises (e.g., the linear notations are useful in substructure searching as screening terms preliminary to full-scale topological tracing), the study of search and retrieval methods for chemical information is almost certain to be an active area for the foreseeable future. And since chemical structure data is of direct concern to pharmacologists, the CBIH Program will attempt to insure that the pertinent results of the many efforts involving new chemical information-handling methods will be available for their use.

Another major problem area in the chemical information field is the man/machine interface, and in this case CBIH Porgram contractors have played a rather substantial role. Especially noteworthy are (a) the efforts of Corey and Wipke[3] on easy input of two-dimensional chemical graphs via computer-controlled stylus and tablet and (b) the efforts of Levinthal and Katz[4] on the computer-driven display and manipulation of three-dimensional molecular models. Both of these groups have amply demonstrated the viability of these man/machine methods in the context of medically relevant research—Corey and Wipke in the area of artificially intelligent systems for the design of organic chemical syntheses and Levinthal and Katz in the area of macromolecule structure and function. Moreover, as described further below, a number of the results of these groups have been integrated by yet a third CBIH Program contractor (Bolt Beranek and Newman Inc.) into a powerful computer graphics front end for a pharmacological information-handling system called PROPHET.

General-purpose data management

In parallel with the work on chemical information-handling via computer, the concept of a general-purpose data management system has received considerable attention. In brief, many groups have recognized the need for a software system which can be used to manage a wide range of files flexibly and efficiently and with little, if any, requirement for programming on the part of the user. Among the most active organizations are System Development Corporation, Computer Corporation of America, and many of the major equipment vendors. A somewhat dated but still useful characterization of work in this area is given in the review article of Minker and Sable.[5]

From the CBIH Program perspective, the most interesting data management systems are those designed to operate in a time-sharing environment. Since personalized information-handling tools for pharmacologists almost inevitably will need be highly interactive if they are to be effective, the successes and shortcomings of the many ongoing efforts involving time-shared data management systems will do much to influence how this technology is applied in support of drug research. For example, the various compromises involving the degree of file inversion (in part, a trade-off between the speed of file update and the speed of retrieval) and the degree of optimization to a particular storage medium (in part, a trade-off between speed and generality) are especially instructive. Moreover, within the CBIH Program's own activities, the use of a powerful interactive text editor as a simple file management tool for the study of structure/activity relationships in morphine-like substances has served to clarify a number of system design questions.[6]

MAJOR CBIH PROGRAM EFFORTS

Turning to the currently ongoing activities receiving direct CBIH Program sponsorship, the remainder of this discussion is devoted to two projects: (a) the design and prototype implementation of the PROPHET System by Castleman, Briscoe, and colleagues at Bolt Beranek and Newman Inc. (BBN) and (b) the studies of automated management of pharmacological knowledge by Werner, Pople, and associates at the University of Pittsburgh. Both of these projects are extensive, multiyear endeavors and can only be described in broad outline here; nor do they constitute the total range of current program efforts. Nevertheless, they best portray the CBIH Program's strategy for dealing with the pharmacological information-handling "problem," and their early results provide invaluable indicators of the promises and difficulties which lie ahead.

The PROPHET system

PROPHET is an experimental information-handling system designed specifically to subserve pharmacology

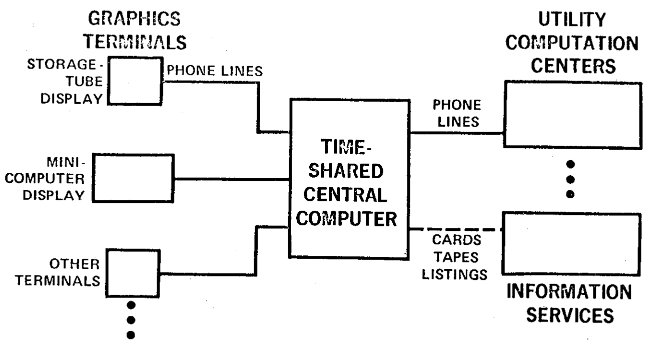


Figure 2—PROPHET system equipment organization

research. It is intended to be a medium through which the latest pharmacologically relevant information-handling methods can be developed, integrated, and made available to practicing scientists throughout the nation. It is viewed as a research tool encouraging more rigorous approaches to the organization and analysis of laboratory and clinical observations. Its ultimate goal is to facilitate the acquisition and dissemination of knowledge about mechanisms of drug action across a span of disciplines ranging from molecular biology to human clinical investigation.

The general nature of PROPHET is given in Figure 2. As shown there, PROPHET is designed to employ a dedicated, medium-sized, time-sharing computer (a Digital Equipment Corporation PDP-10) and to serve a geographically dispersed set of users via remote graphics terminals operating over voice-grade telephone lines. Information-handling procedures and data files reside in the central computer. Provision is made for eventual interfacing with both utility computers and information services. A detailed description of the system is given in the document entitled "The PROPHET System: A Final Report of Phase I of the Design Effort for the Chemical/Biological Information-Handling Program."[7]

The primary features of PROPHET as seen from the perspective of computer technology are five:

(1) a powerful interactive command language enabling even a computer novice to effect sophisticated procedures for handling empirical data on chemical substances and their biological consequences;

(2) a simple procedural language syntactically modelled on PL-1 which is coextensive with the command language and which allows essentially unfettered interleaving of system and user-defined functions;

(3) a special emphasis on making complex computational processes relatively invisible to the pharmacologist user (e.g., presenting sophisticated data management strictly in terms of operations on tables, allowing stylus and tablet input and CRT display of molecular structures, etc.);

(4) a rich substrate of special data types for handling such pharmacologically relevant data structures as tables, molecules, graphs, and nodal networks; and

(5) a design which attempts to circumscribe the full power of a general-purpose digital computer in such a way that communication among users is strongly facilitated without inappropriately constraining options for individual initiative.

In other words, by specifically encouraging user-system and user-user interactions within the somewhat rigid context of standard predetermined data types, PROPHET is designed to allow research pharmacologists to handle their personal data files and communicate with their colleagues more effectively than they can any other way.

Although PROPHET, like most complex computer systems, is better demonstrated than described, a few simple illustrations may prove useful. Figures 3 and 4 show the system commands for operating on tables and molecules, respectively. Arguments for the commands are given in small letters; square brackets enclose optional portions; braces enclose alternative forms. These two lists are only a fraction of the commands available to the user. Note especially the integration of the various data types—e.g., the data type molecule can be an entry in the cell of a table.

```
1. MAKE TABLE unused-name [FROM table-name [FOR relational expression]]

2. ADD {COLUMN[S]} TO table-name [FROM table-name]
       {ROW[S]   }

3. ENTER [ROW[S] {row-name(s)  }              ] OF table-name

9. DISPLAY molecule-name WITH molecule-fragment-name

Figure 4—Summary of molecule-handling commands

The nature of PL/PROPHET, the procedural language is illustrated in Figures 5-8 using data drawn from a study of antileukemic drugs being conducted by the Southern Research Institute in Birmingham, Alabama. Figures 5 and 6 show selected columns from a user-defined table set up to handle survival time data on mice inoculated with various quantities of L-1210 leukemic cells; the numbers in the cells of Figure 6 indicate the number of mice which died on that particular day. Note that columns 19 and 20 of the table (Figure 5) are blank since they are intended to accommodate results derived from earlier columns.

Figure 7 lists a brief user-defined procedure for calculating the number of 11-day survivors and the mean survival time from the observations recorded in columns 4-14 and storing them in columns 19 and 20. Figure 8 then gives the result of calling this new function—i.e., an updated version of the table with the derived values in place. Note that the user need take no special action to have his personal PL/PROPHET procedures operate in conjunction with the standard system functions.

At the present time PROPHET is available on a dedicated PDP-10 computer housed and operated for the CBIH Program by First Data Corporation of Waltham, Massachusetts, and is ready for extensive evaluation by research pharmacologists in the context of their day-to-day activities. It is hoped that the testing period now beginning will help both to refine current concepts and to identify areas for future investigation. It is also hoped that these collaborative projects using PROPHET will result in clear-cut demonstrations of the utility of modern information-handling methods in the search to understand the mechanisms of drug action.

Automated management of pharmacological knowledge

A vital complement to the initial work on the PROPHET System is the basic research being conducted by Werner, Pople, and their associates at the University of Pittsburgh.[8] This group is exploring the problems and promises of using automated inference methods as cognitive aids to the individual pharmacological investigator. They seek to demonstrate where and how the concepts of artificial intelligence might be applied to achieve marked qualitative and quantitative improvements in current capabilities for the storage and retrieval of information.

The Pittsburgh team has concentrated the bulk of its efforts to date on model-handling tools—i.e., system functions which make it relatively easy for even the computer novice to construct and exercise models of pharmacological processes, assuming, of course, that he has the basic biomedical knowledge to engage realistically in such an endeavor. The intent is to aid individual investigators not only in expressing their concepts about mechanisms of drug action but also in assessing the validity of those conceptualizations through digital simulation and other algorithmic processes. Put another way, the goal is to produce an easy-to-use software system whose capacity to absorb and operate upon pharmacological knowledge is unprecedented in its scope and power.

Werner, Pople, and their associates have found especially useful the class of models known as finite state automata. In brief, the builder of the model specifies each node in a network in terms of algorithmic processes, direction and nature of connectivity, threshold logic and other control information, and the like. Proceeding a "fact" at a time, so to speak, the user can build arbitrarily large and complex model structures. To effect a simulation, the state of each node in the network is determined at each of a succession of discrete time steps using the algorithms and other information provided at the time of model construction. Moreover, by having the user (or another computer program) monitor the time course of the state transitions at selected nodes, one can perceive the behavior of the model in response to various stresses and compare this behavior with observations made in the laboratory or clinic.

Figure 10—Use of the model exercising command "Analyze"

The neuropharmacology associated with the control of skeletal muscle movement has served as the prime subject for the Pittsburgh group's early efforts. As shown by Figure 8, even a simple model of this pharmacological system is essentially unmanageable without computer assistance. However, using an early version of their model-handling tools, these investigators have achieved some most encouraging results. While the following brief series of examples can hardly given an adequate characterization, they should impart the general flavor of the work.

Figure 9 shows how the model building commands (i.e., ADD, DELETE, CUT and TIE) are used; in this case the user is adding the Nucleus Ruber to the model, assigning it a threshold value of 1 and connecting it via appropriate delays so that it gets excitatory input from the Deep Cerebellar Nucleus (already in the model) and delivers excitatory output to the alpha- and gamma-1 motorneurons on the flexor side. Figure 10 illustrates the model exercising and perception functions; in this case the command ANALYZE is entered, causing the model to be stressed by a standard set of stimuli analogous to the tendon taps and passive muscle stretch used routinely in clinical neurology examinations. The user has the option of setting a window

Figure 11—Use of the model exercising command "Bringabout"

such that he may observe the time course of activity at only selected nodes. The command ANALYZE also invokes a perception program which monitors the time course of the simulated muscle length and, by applying a succession of linguistic abstractions to the output, produces a description of the model's behavior in clinical terminology.

Drug effects, of course, may also be studied with this system. In brief, the computer is provided with a list of drug names and the associated changes the drugs are thought to induce in the model's structure and/or control parameters. When the command to administer a given drug is entered, the software system automatically makes the indicated alterations. Note that surgical procedures (e.g., decerebration) can be handled via the same mechanism.

Emphasis also has been directed toward having other computer programs exercise the neural model. Pople has experimented with a problem solving system whereby a high level executive processor accepts user queries and answers them by an appropriate combination of structural modifications and simulation runs. This allows the user to investigate hypotheses about drug action on-line by observing how the system can BRINGABOUT specified end states in terms of structural and functional changes in the model such as drugs are known to cause. Figure 11 gives a brief example of some preliminary results. In this case the system is asked to find an alteration which eliminates the prolonged oscillations following muscle stretch on a model mimicking Parkinson's disease. After two unsatisfactory maneuvers (i.e., adding driving forces to the Intralaminar Nucleus and the External Nucleus Ventralis Lateralis, respectively), the BRINGABOUT command discovers that applying a driving force of -2 to the Nucleus Ventralis Lateralis leads to the goal state.

For the immediate future, the Pittsburgh group plans to continue its investigations into techniques whereby artificially intelligent computer programs can exercise or otherwise manipulate pharmacological models. For example, studies are now under way on such topics as (a) automatic selection of the appropriate level of resolution of a model when it is used in a specific question-answering context, (b) definition of a quasi-English language whose utterances are equivalent to data structures in the model, and (c) development of techniques for using a model to organize and retrieve references to the experimental literature which is associated with that model. These investigators have only scratched the surface on a fascinating and formidable collection of information-handling problems.

FUTURE PROSPECTS

The CBIH Program's progress to date represents a collection of small (but nevertheless real) inroads into an enormously difficult task. In the years ahead the Program must deal with three basic questions:

(a) How can the evolving PROPHET System best be integrated into the mainstream of pharmacological research?
(b) When and how can PROPHET be enriched with capabilities for model management?
(c) What additional research topics in the information science field should be addressed if the information storage and retrieval aspects of PROPHET are to be made most effective?

The first two of these questions will be met initially at least by continuing the work at BBN and the University of Pittsburgh, taking steps specifically to coordinate these efforts even more closely with one another and with leading pharmacology laboratories throughout the nation. The third question, to the extent that funds permit, will be approached by experimenting with new pharmacological data types and representation conventions and by exploring such notions as the utility of data description schema.

To recapitulate the opening theme, pharmacology offers an enormously rich problem space for those interested in applying computers in the biomedical world. Pharmacology impinges on almost every area of medical science and its progress is heavily dependent on the continuing erosion of disciplinary boundaries. Moreover, its information-handling requirements strain at the frontiers of computer science in almost every direction. And the overwhelmingly important implications for society that accompany even small advances in our understanding of drug action make it urgent that the challenge for further inquiry be accepted.

Where do we stand in implementing information systems?

by JAMES C. EMERY

University of Pennsylvania
Philadelphia, Pennsylvania

ACHIEVEMENTS OF THE COMPUTER INDUSTRY

By any reasonable yardstick the computer has been a fantastic success. It has grown in one generation from a laboratory curiosity to one of our major industries—perhaps the most vital one in our information-oriented post-industrial society. Raw computational speed has increased during this period by an order of magnitude every four or five years. The cost of computation has dropped to the point that we can employ it lavishly on everyday tasks.

The computer has already brought significant changes in science, engineering, and commerce. Some branches of technology, such as space exploration, would scarcely be possible without the computer. Virtually all scientific fields have been affected in varying degrees. Without the modern computer it would be very difficult to perform the myriad data processing tasks required to run a large organization. Indeed, many of the companies most heavily involved in data processing, such as those in the banking and insurance industries, could simply not exist in their present form without the computer.

PROBLEM IN APPLYING COMPUTERS

Despite these unprecedented achievements, we computer professionals are not universally hailed as heroes. In fact, we have a difficult time staving off our detractors. It would be comforting to think of them as ungrateful wretches who resent the bounty that we have bestowed upon them. Unfortunately, much of our difficulty stems from our own failures to exploit the technology nearly as well as we might. It is all too easy to identify these failures.

Underestimating complexity

Man seems to have a natural bias toward underestimating the complexity of information systems. It is easy to see how this can come about. When we think about a problem we tend to concentrate on the normal combination of circumstances; we often overlook the exceptions. And yet it is the exception that causes much of the work in designing and implementing an information system. It is not uncommon, for example, for over half of the design effort to go into the handling of exceptions that account for a few percent of the transactions entering the system. One approach, of course, is to handle the rare exception outside of the automatic system. But even this requires considerable design effort to detect the exception and control the eventual entry of the corresponding correction.

Just as man seems to have a proclivity to ignore the exception, he also seems to have a bias toward optimism. Estimates are frequently based on the assumption that everything will work out as planned, ignoring the overwhelming evidence to the contrary. Critical difficulties often appear in the process of linking individual subsystems into the overall system. System integration and testing typically account for over half of the total cost of implementing a complex system, but it is the rare estimate that provides this level of funding.

Reinforcing these psychological biases are certain institutional biases toward optimistic estimates. The cost of implementing a large system is very great, but many organizations have not been willing to face up to this fact. More than once I have heard an MIS director say that he could never get authorization approved if he gave honest estimates.

Underestimation of the complexity of a system leads to a number of unfortunate consequences. An obvious one is the cost and schedule overrun that we so often experience. This, in turn, often leads to hasty shortcuts that result in systems that are error-prone, inflexible, and poorly documented.

Design of overly sophisticated systems

Underestimating complexity can lead into the trap of striving for too much technical sophistication. A technician naturally wants to design systems that move to—or even extend—the frontier of technology. Often overlooked is the cost-effectiveness of marginally useful sophistication.

A common example is an overemphasis on quick response. On-line file updating and retrieval, with response times in the order of a few seconds, can add enormously to the cost, complexity, and technical risk of a system. Alternatives exist that may give nearly the same benefits at much lower cost. For example, skip sequential processing of indexed sequential files permits short batch cycles—perhaps in the order of an hour or less. If this is not short enough, it is possible to provide on-line data *retrieval* without the much greater complexity that on-line *updating* requires. There are certainly cases where the extra cost of on-line updating is more than justified by substantial incremental benefits, but these tend to be quite exceptional.

The bias toward sophistication manifests itself in other ways. Designers and programmers often strive too much to achieve machine efficiency. In doing this, they ignore the broader aspects of efficiency that include programming costs, flexibility, and maintainability. We live every day with past mistakes of this sort—for example, the ludicrous situation in which a third generation computer spends its time emulating a second generation computer because earlier systems were programmed in assembly language to gain efficiency. We tend not to make this mistake now; instead, we make errors at a higher level by rejecting, for example, use of a generalized software package because of its "inefficiencies."

Failure to exploit existing technology

Paradoxically enough, while we strive for sophistication we also ignore well established technology. This is perhaps understandable in a technology that has been expanding so rapidly: it is almost impossible for the practitioner to keep up with his field. Nevertheless, it is painful to see.

A good example of the problem is our failure to include an information retrieval capability within a management information system. The ability to handle *ad hoc* inquiries has been available for well over a decade. Some companies began to apply such systems in the late 1950s, and proprietary retrieval packages came on the market soon afterwards. Although there is now widespread interest in such systems, they are used much less than they ought to be.

Poor human factors design

One of our greatest failings is the incredibly poor job we often do in serving the human user of our systems. Anyone who has tried to correct a billing error knows the problem. Systems are too unreliable, unforgiving, and uncorrectable. They spew out masses of data that are often poorly identified and displayed in a form that is difficult to comprehend. It is no wonder that users shudder a little when the computer moves in.

IS THERE A BETTER WAY?

Clearly we can do better than we have; the relatively few organizations that have done an outstanding job demonstrate what can be done.

There is no simple prescription for success in this business. Nevertheless, there are certain steps to follow that are probably necessary, but not sufficient, for success. I offer them not as a unique set of guidelines—indeed, they are all well-known—but as a reminder of those things we frequently choose to ignore.

Stay within the state of the art

It is a well-known aphorism in our trade that pioneers are distinguishable by the arrows in their backs. With rare exceptions, it does not pay to develop systems that rely on an extension of the frontier of technology. Even military systems, which have a better justification than most for such a strategy, usually are well advised to stick with proven hardware and software.

Exploit available technology

Staying within the state of the art is not a very serious limitation. The art has advanced to the point that technology does not impose many real constraints. It is perfectly feasible, for example, to design systems that have the following characteristics:

1. Considerable use of shared computer resources. Although the issue of centralized versus decentralized computation is not closed, most advanced systems will find it exceedingly attractive to combine computational loads into a few (often one) large computers. Centralization offers the undeniable advantages of economy of scale, the power of a large facility, load levelling, and the availability of a centralized data base. There will no doubt always exist systems that call for the simplicity and economy of specialization that a small decentralized computer can provide, but for the bulk of our needs we should surely look to relatively centralized facilities.
2. Considerable integration of the data base. The consolidation of files has been going on apace for a number of years. This has resulted in a reduc-

tion of redundancy and greater sharing of data across programs. There still remains, however, the need to link non-contiguous records. This only becomes feasible when one employs a fairly sophisticated data base management system for on-line storage. The capability of linking records has existed for a number of years now—beginning with General Electric's IDS—but it has yet to be widely applied. This technology has now matured to the point that it should be considered in the design of any new system.

3. Interactive computation. My earlier comment on the overemphasis given to short response time should not be interpreted as a blanket rejection of quick-response systems. Certainly the technology is available to provide reliable on-line response or file updating when the resulting benefits justify the added cost. Our strategy should not be biased in favor of either short or delayed response; rather it should aim at a *tailored* response that allows each application or user to have the response that best balances costs and benefits. Such a system will very likely provide a whole spectrum of response times—from interactive retrieval and data entry to periodic batch processing.
4. Finally, virtually any well designed system should include some decision making models. The models can vary from analytical optimizing models to man-machine decision systems that rely on elaborate simulation models. It is only when the information system provides direct support of decision making that it really begins to take advantage of the full capabilities of information technology. The most serious issue facing the designers of such systems is the extent to which the models should be embedded within the information system. It is always a difficult task to provide formal, automatic links between transaction processing and decision models. They should therefore be provided only in the case of high-volume and rapidly changing inputs and outputs; in the remaining cases the models can be loosely coupled to the transaction processing through some sort of manual intervention (e.g., smoothing or normalizing transaction data to generate inputs, and reviewing and adjusting decision outputs prior to introducing them into the operational part of the system).

Provide long-term organizational commitment

If there is anything certain about our business it is that the development of successful systems calls for long-term, sustained support. No system is ever really finished; it undergoes continual modification and adaptation over the course of many years. Eventually it may be scrapped and replaced by an entirely new system.

An organization's commitment to a long-term program should take a number of forms. One requirement is for relative stability in the resources devoted to systems development. Insofar as possible, these expenditures should not be viewed as an easy target for cash savings in time of belt tightening.

Management's commitment should also take the form of participating in the design of the system and smoothing the way for its introduction. The call for such participation has become a commonplace in our profession, but it is no less true because of that. A well designed system should become an integral part of the management process of an organization, and it is hard to see how this can come about without continual support by all levels of management. Many important management policy decisions are embedded within the MIS design, and so managers must participate to the extent required for them to resolve these issues.

A long-term commitment implies an explicit program to develop systems personnel. The need is especially critical at the management level within the systems group itself. The philosophy that any good manager can head a systems group has surely been discredited by now. The body of knowledge within the field has grown to the point that this knowledge cannot be quickly or casually acquired; the development of real professionals requires a long-term program. We should be no less reluctant to turn over systems development to the untrained and unseasoned manager than we are to trust the removal of an appendix to a barber.

An organization's commitment is also measured by the calibre of personnel they assign to the MIS function. Little success can be expected if the function is considered a dumping ground for misfits, if it does not get its share of the organization's fair haired boys, or if it does not attract outstanding computer professionals. Without at least a sprinkling of really top-flight designers, analysts, and programmers, the organization would be well advised to scale down its aspiration level to meet only bare requirements.

Emphasize users

Everyone talks about the need to serve users, but we nevertheless continue to make many of the same mistakes. Evidentally we must take much more formal and explicit steps to deal with this problem.

The use of steering committees is one way to get user participation. They can certainly help in making resource allocation decisions and in resolving policy questions. They are equally applicable at all levels in the organization—a high-level committee to deal with broad, long term issues, for example, and lower-level committees to deal with operational subsystems. The form of the committees and their tenure may vary considerably, but certainly some relatively formal means is needed as a forum for dealing with issues that cross existing organizational boundaries.

System groups should include staff members who are specifically assigned responsibility for human factors design. Included within their scope of activity should be such matters as the design of hard copy forms and CRT display formats, procedures connected with the information system (including error handling procedures), specification of the operating characteristics of terminals, and concern for the ability of the system to adapt to changing user needs. These responsibilities tend to be scattered about within most groups, rather than dealt with as a whole.

A formal user sign-off procedure should exist so that users have an explicit opportunity to get their views incorporated into the MIS design. Such sign-off should be required at all major stages of the implementation—the feasibility study, functional design, detailed design, testing procedures, and final operational acceptance.

It might be a good idea for each organization to have an ombudsman to look out for users' interests. As information systems become more and more pervasive throughout the organization, we stand some chance of being swallowed up by them unless someone is around who can pull the plug in an emergency. To be effective, the ombudsman should remain independent of the MIS group, have the authority to investigate all matters connected with the information system, and have the right to voice his opinions at the highest levels of management. One would probably not find enthusiastic support for such a position among systems directors, but it nevertheless may provide a very useful safeguard.

Devote more effort to project management

The implementation of a large MIS has itself become a formidable management task. It may require the efforts of over a hundred persons extending over the span of several years. The various subsystems tend to interact closely with one another, and therefore call for a high degree of coordination among the project teams.

An activity as complex as this requires more attention to its management than normally given. Techniques exist for dealing with the problem—network scheduling and resource allocation models, documentation and configuration management procedures, simulation packages for analyzing alternative designs, and all the rest. Unfortunately, however, most projects do not formalize project management to the extent necessary. The direct cost of good management is quite high, but the indirect cost of poor management is staggering.

Centralization of systems management

It is hazardous to generalize too much about the proper degree of centralization of systems activities. Organizations thoroughly committed to decentralized management find it hard to treat the systems activity as a centralized exception. Centralization can also increase problems of keeping the system responsive to users' needs.

Nevertheless, considerable benefits can come from a certain amount of centralization. The benefits basically stem from the economies of shared use of hardware, software, and data.

For most organizations it does not make much sense to maintain more than one group concerned with the development of standards for programming, documentation, languages, data base design, and project evaluation. Vendor hardware and software evaluation should likewise be centralized in most cases. Design of common application programs might even be centralized. Clearly we are already seeing more and more centralized computer facilities.

Centralization of this sort does not imply isolation from users. Specialized applications can—and probably should—be handled on a decentralized basis. A remote termial hooked to a centralized computer should be viewed logically by decentralized managers as an independent resource with the capabilities of a large machine at a fraction of its full cost. To be sure, any centralization imposes some constraints on the organization's subunits, but when intelligently applied the constraints still can leave ample room to meet users' requirements. After all, we all must live within certain constraints, whether imposed internally or externally by governments or vendors.

Incremental development

A comprehensive system takes many years to develop. No one can foresee how technology and users' requirements will evolve over this length of time. It is therefore absolutely essential that systems be designed in a way that permits continual modification and extension.

A number of steps can be taken to achieve a much higher degree of flexibility than most systems offer. Perhaps the most important requirement is a master plan to guide the development of separate subsystems. Such a plan defines the subsystems that will comprise the eventual overall system, and establishes the major interfaces among these subsystems. It is only when such a plan has been developed that one can have any assurance that all of the subsystems will mesh together.

The master plan need not go into great detail. Its purpose is to establish constraints within which each subsystem can be developed more or less independently. In principle, one should limit the detail to just that level required to define the interfaces among subsystems. Detailed work beyond this level can wait until the actual implementation of the separate subsystems.

Insofar as possible, the subsystems should be implemented in a sequence that provides early interim benefits. Certain technological constraints may partially limit the choice of sequence—for example, some generalized software may be required before application programs can be written, and a forecasting program cannot be implemented until the order entry subsystem from which it gets its inputs has first been developed. Other factors, such as the particular skills available and political considerations, may play a part in choosing the implementation sequence. The basic strategy should be, however, to implement each subsystem in a way that provides interim benefits that justify development costs, while at the same time leading toward the eventual accomplishment of the master plan.

The plan should evolve along with the system: it is not meant to impose inflexible constraints on the design. Changes will inevitably occur as technology advances, the organization's needs change, and the system matures. The changes should, of course, be controlled and consideration given to trade-offs and the need for coordination among subsystems.

In addition to the development of an evolutionary master plan, other well-known techniques exist for increasing the flexibility of a subsystem. These include use of higher-level languages, modularity, data and program independence, avoidance of unnecessary program complexity, and careful documentation. These techniques typically carry a short-term price, but they are vital for long-term success.

CAN SUCCESS BE REPLICATED?

We know that real success can be achieved, but we also know that it is relatively rare. This is so because success requires the rare combination of exceptional management, sustained support, and top-flight technical personnel. Without these ingredients, results are likely to be marginal at best and disastrous at worst.

Unfortunately, there is not enough talent to insure that each organization has an adequate supply. The great challenge we face is to develop a technology that does not require genius to implement. Conversion of a field from an art to a routine science is the chief sign of its maturity. To achieve this in our field we must devote a great deal more effort to gaining a better theoretical understanding of complex systems, planning and control of large organizations, and the behavioral aspects of formal information systems.

MIS technology—A view of the future

by CHARLES H. KRIEBEL*

Carnegie-Mellon Universiy
Pittsburgh, Pennsylvaina

INTRODUCTION

Industry tabulations for 1970 indicated there were some 85,000 computer installations in the world, valued in excess of $40 billion. By 1975 these figures are expected to double; in ten years they may be redoubled. The continuing exponential growth in raw computing power prompted Art Buchwald recently to editoralize on "The Great Data Famine" of the 1970's. According to Buchwald's expert source by January 12, 1976 ". . . every last bit of data in the world will have been fed into a machine and an information famine will follow." To cope with this impending disaster, a crash program is urged in which (1) "no computer can be plugged in more than three hours a day"; (2) the government will spend $50 billion to set up data manufacturing plants and their output will be mixed with soy bean production; and finally (3) a birth control program will be advocated for all computers—provided, "the Vatican's computer gives us its blessing."

On Tuesday evening, September 9, 1965, the largest power failure in history blacked out all of New York City and some 80,000 square miles of neighboring areas in which nearly 25 million people live and work. The blackout lasted for three hours before partial power was restored. It is awesome today to imagine what the consequences would be if a computer blackout were to occur throughout the world. Yet in spite of our increasing dependency over the past twenty years on computer technology, one continues to hear of a "technology gap." Instead of a "data famine" the technological issue today is that computers haven't been able to do all that was expected of them. In stronger language, Isaac Auerbach stated at the closing session of the recent fourth triennial Congress of the International Federation for Information Processing that the performance obtained by users of computers for business data processing shows: 20 percent are successful, 40 percent are marginal, and 40 percent are failures. Reviews by others of computers in management information systems also sharply criticize the notable lack of results in spite of great expectations.[2] If true, this is a dismal return for a $40 billion investment in equipment. What went wrong? Who's at fault?

On the one hand computer manufacturers and the industry have been blamed for overselling, for not developing the right technology, and for not solving the users' problems. On the other hand the user and managers have been criticized for overbuying hardware, for misapplying an inert technology, for "living in the last century" and not exploiting the modern methods of today. There is some truth on both sides of these arguments. But acknowledging the existence of a gap is at best only the beginning of a solution. What are the dimensions of "the gap?" What remedies are proposed to close it? What future developments can we anticipate towards progress in MIS? Before gazing into a crystal ball for the answers, we can gain perspective on the problem by briefly probing the surface of the issues involved. A conceptual framework is particularly important in this case because the broad connotation of MIS and misunderstanding are the source of most of today's difficulties.

INFORMATION STRUCTURES AND MIS

The phrase "management information systems" or "MIS" has gained popularity as a descriptor for information processing activities in support of management. If one explores the environment of management it is soon apparent that decision making is the primary function that distinguishes managerial activity from other behaviors. In fact, management decision occupies a singular role in management literature, since other

* The author wishes to acknowledge many enlightening conversations on MIS with Dr. David B. Hertz and R. George Glaser, Jr. of McKinsey and Company, Inc.

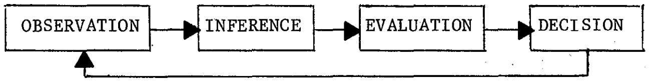

Figure 1—Basic stages of activity in decision processes

behavior—such as planning and control—is often defined in terms of decision activity. Thus, an understanding of the central issues in MIS might logically begin with the concept of management decision.

To economists decision making is the allocation of scarce resources. Other writers emphasize the choice activity in that for them, decision making is selecting the "best" action from among available alternatives—where the criterion of choice might also be viewed as one of the alternatives. Since our immediate interest concerns informational aspects of decision, it is instructive to adopt a broader view of the process by considering the stages which rationally precede the choice of action and a commitment of resources.

Although a variety of elegant models are available in the literature, the essential ideas behind a rational structure for decision making are really quite simple. A parsimonious description of the decision process would include four identifiable stages of activity: observation, inference, evaluation and choice (see Figure 1).* Within the limits of this model, the process begins with observing states of the environment; surrogate images are assigned to natural events, measurements are taken, and data is collected, encoded and stored. The second stage in the process involves analysis of the recorded data as a basis for inference and prediction. Here, in effect, reports are made and reviewed to determine whether or not a situation requires a decision to be made. Stage three is initiated by the need for a decision. At this point inferences and projections are analyzed to identify action alternatives and these in turn are evaluated with respect to goals, constraints and efficiency. Finally, an alternative is selected which is preferred (or "best") under the criterion of choice, the action is communicated, resources are committed, and the decision is implemented. As implied by the diagram the process actually perpetuates itself through cycling and feedback, since upon implementation the decision becomes a source for new observation; and so on.

Now suppose we consider the development of information structures in support of the activities involved in each stage of this process.* That is, the simplistic decision model can serve to characterize four levels of the relative maturity (or sophistication) achieved by an information system. In its most elemental form an information system is simply a repository or data bank, encompassing only the "observation" activities of the model. The raw data has been organized in some convenient manner and is stored, say, in a computer file; upon interrogation the manager retrieves a report and performs all subsequent analyses from inference to decision. Most accounting systems are of this elementary form, employing a linear transactions model of the organization and serving as simple data banks. Simplicity, *per se*, is not a criticism of such systems; their shortcoming in application is that typically they do not discriminate between vital information and trivia. Thus managers interacting with an elementary data bank system often become frustrated by the lack of relevancy in large volumes of data.

At the second level of maturity in development the data bank system has been expanded to include most of the activities of inference as part of the formal system. In addition to exception reporting, the system now includes the capacity to forecast and to artificially test the consequences of implicit decisions. The emergence of the fields of management science and operations research accompanied by computer-based models, particularly linear programming and simulation, has done much to facilitate the realization of these selective-inference information systems. Here the manager can interrogate the system with "What if . . ." questions, and receive an array of consequences in response for his evaluation. The hidden danger in this dialogue is that the manager is usually insulated from factual data in the system by a host of assumptions imbedded in the model which provides the inferences. While a seemingly obvious caution, it is surprising how readily individuals are lulled into believing "realistic-looking" output is fact.

At level three in development, evaluation activities have been programmed into the selective-inference structures so that the information system now encompasses action recommendation. Here the need for a decision is triggered within the formal system on the basis of monitored observations and predetermined rules or a time scheduled event. Procedures are programmed to evaluate alternatives against assigned goals as the situation requires, the "best" course of action is chosen, and the recommendation is communicated to the manager. At that point the manager

* The well-known antecedent for this model is, of course, the "scientific method." For an interesting and more elaborate taxonomy see Simon (1960).

* Analogies of this form have been proposed by others in similar contexts; for example, Chapter 15 in Gregory and Van Horn (1963) and Mason (1970), in particular.

either implements a decision based on the recommendation or he rejects the alternative and further analysis may be initiated. The most common form of this action-recommending information system in organizations today is the advisory staff group or committee. In this case line management delegates authority for a certain area of responsibility to a staff department, but retains final control for decision through review and certification. Another variant of this system has appeared in the form of large scale optimization models, particularly linear programming applications in industrial scheduling. In many of these cases, however, systems originally designed for "action recommendation" have over time reverted back to "selective-inference" systems as limitations of the model became apparent.

In the final stage of maturity the entire decision process has been automated within the information system. All activities from observation to choice and the ability to initiate action, commit resources and monitor results have been programmed. In effect the manager is now outside the structure having fully delegated his authority, although he retains the power to revoke the delegation at some future time. The simplest form of the automated decision system is the "standard operating procedure" in organizations; a more sophisticated example would be a computerized process control system in a petroleum refinery. Modern factory inventory control systems are another common example. Obviously, automated decision systems require extensive knowledge of the decision process for the given application and consequently their development has been limited to well-defined environments.

Figure 2 summarizes this overview of information structures in MIS. Concerning the classification it is important to recognize that the levels of development should not suggest a linear or necessarily sequential progression of system maturity. That is, the MIS in a modern organization today is not one of these information structures; it is a composite of all four types. Said differently, the two basic components of design in any information system are (1) a *model* of the user, and (2) a *data* store. The former defines the output interface or system application, and the latter constitutes the environmental image or system input. For MIS the user model reference is management decision processes. In the evolution from "data bank" to "automated decision" the user model becomes technologically more sophisticated, as more activities of the process are formalized and programmed into the system. But decision processes exist at all management levels in an organization hierarchy. Thus, one finds information structures of different maturity at different management levels. The most mature computer-automated information structures in MIS today are still confined to lower management levels.

Level of Development	*Information System Type*	*Decision Activity Model (Fig. 1) Formalized and Programmed*
1	Databank	Observation
2	Selective-Inference	Observation + Inference
3	Action Recommendation	Observation + Inference + Evaluation
4	Automated Decision	(All above) + Decision + Feedback

Figure 2—Classification of information structures in MIS

The preceding discussion provides a framework in which to assess the dimensions of MIS technology, the "gaps" today inhibiting implementation, and the direction of future developments. For present purposes I will confine these remarks to two dimensions: (1) the user model component and (2) the data (processing) store component.*

USER MODEL TECHNOLOGY IN MIS

The lackluster results vis-a-vis expectations realized in MIS to date can be attributed in part to the fact that the implicit model of the user has remained naive. As with more elementary information storage and retrieval systems, the user of a MIS can occupy two distinct roles either as a generator of system input or as a consumer of system output. In most cases these roles occur in different individuals in the organization and each interacts with the system differently. The structural interface of the system which facilitates communication between these respective roles is the data file.

Dating from the early 1950's the user model which typified first generation, computer-based MIS was *accounting* transactions. For most applications this model better served the system input role than the output requirements of managers. Consequently, management decision support was limited to a class of data bank structures for financial reporting, and system performance evaluation (when executed) was based on administrative (or clerical) cost reduction. With the development of operations research techniques and the evolution of second generation computer systems for MIS, accounting was supplemented by a series of user models based on *management* function, such as personnel administration, production-inventory control, mar-

* In Chapter 1 of Kriebel, et al. (1971) we have classified MIS research along five dimensions, however, space limitations here prevent a more extensive discussion.

keting management, and so on. In seeking to close the output gap in the user model and advance to selective-inference information structures, functional area managers in effect developed their own information systems. The counter-cries to this movement were the appeals for "integrated data processing" or (in some circles) "the total systems approach." System compartmentalization during this period aggravated a variety of development problems including data collection, data redundancy and inconsistency, and serious limitations on file cross-talk. System costs were often hidden in overhead accounts, data processing feasibility governed applications selection, and "management intangibles" dominated systems evaluation.

As total costs continued to increase in spite of gains in computer hardware efficiencies, the third generation systems of the mid-to-late 1960's saw a shift in emphasis towards consolidation—though not necessarily of the "total systems" variety. The output-oriented, management function user models in large measure were abandoned for an input-oriented *data base* model with the goal of data processing efficiency. The development orientation in MIS now focused on a corporate data bank which stressed input data format, flows, and files with little attention to the specific output requirements of end users. Working applications programs in the system were decoupled from data files through the imposition of file management software. Most formal information systems today are still in this stage of evolution.

From this brief history one sees that the user model technology in MIS has not progressed very far over the past fifteen years. At lower management operating decision levels where an OR model may be in good correspondence to the actual management problem, the decision mechanism often becomes an automated information structure in the MIS. But above the level of routine behavior, the user (output) model rapidly returns to a data bank structure. Today's "solution" to the issue of user output requirements is to maximize the flexibility for options at the output interface. Data managers and report generators are two common examples of such output flexibility. In effect specification of the user (output) model is now left up to "the user." Similarly, evaluation of the system benefit to the user is becoming *his* own responsibility. That is, in several large organizations today the computer-based resources of the MIS have been divisionalized into a "profit center" and, though not a freely competitive market place, the user is required to pay for services requested. The performance criterion for system operations is thus "simplified" to efficient utilization of resources.

This present stage of evolution raises several questions concerning future developments in the user model dimension of MIS technology. For example, the profit center organization is a move toward the information utility concept; but is "information processing" a homogeneous commodity? Divorcing the system design from specific user needs is an attempt to make the technology independent; but is MIS technology inert? The contemporary orientation on data input and EDP technology implies that resource efficiency is a major bottleneck; but has EDP utilization been the key barrier in MIS implementation? The data base model development of a MIS seeks to establish a corporate data bank, often building from the bottom up; but do information structures for managers draw upon common data?

In anticipating the next ten years, my first prediction is the demise of the present-day data base orientation as the dominant user model image in MIS development. Instead the development focus will shift back to an output orientation that is user dependent, though not as a return to the second generation MIS. The emphasis will be on basic decision processes and problems of the specific organization and manager without regard to the functional environment. Information structures will be developed to solve a particular manager's problems; some of the structures will be generalizable to other situations in broad outline. For example, one early attempt at such a structure for strategic planning decisions has been the so-called corporate economic simulation model.[14] The mixed results achieved by corporate simulators thus far can be attributed in part to the difficulty in implementation of securing top management attention and involvement. Another less publicized illustration of an information structure tailored to a specific decision problem is the concept of an "issue map" developed by McKinsey and Company for Mayor Lindsay of New York City.[7] Still another structure that I would include in this context was the original development and application of PERT (Program Evaluation and Review Technique) and CPM (Critical Path Method).

The user model image that focuses on *critical decision* processes for MIS development, however, is only one aspect of the new technology. Allied with the change in orientation will be a rise in the application of operations research and behavioral science in developing and implementing these information structures. It is common knowledge that many of the basic methods and known results in operations research are not being used by managers today, even though many of the techniques have considerable potential as decision aids.[8] This issue has been labeled a "communications gap," although some feel the problem is more fundamental.[3] I think a majority would agree that MIS technology is not inert, even though the computer might be. To achieve compatibility at the user/system (or man/machine) interface, technology can either (1) adapt the system to fit the user's requirements (or behavior patterns), or (2) seek to change user behavior to better match system capabilities.* Much of the effort by industry professionals to date has been directed at the second approach, particularly in the popularized education programs on "OR and computer concepts for executives." Results notwithstanding, the empirical evidence on MIS implementation suggests: (1) except for the most routine activities, managers actively resist attempts (real or perceived) to erode their authority base; (2) the executive's orientation is toward the "people" in the organization, his self-concept is as an individual who directs the activities of others; (3) there is relatively little understanding of upper management decision processes. Emerging information structures in the next decade will increasingly incorporate behavioral parameters in their design which reflect organizational associations, leadership style, and management attitudes as a means toward improving acceptance and effectiveness at the user/system interface.

For example, in the mid 1960's the experience of IBM with "executive terminals" for their own MIS led to the establishment of an Information Center at corporate headquarters with a human rather than a machine interface for the user, primarily because of dominating behavioral considerations (cf., Chapter 8 in Reference 10). Similarly, at Alcoa in developing their new Picturephone Remote Information System (APRIS) for executives, "the principal design criterion was ease of use . . . rather than provide just a tool, the goal was to provide . . . the service of better access to information."[4] The "complete" user guide for APRIS is printed on a 3″×5″ index card. More basically, perhaps, research is already under way to parameterize behavioral constructs in the decision process, such as "participation,"[16] to model how managers identify problems to be solved,[13] and to understand how humans process information in the act of solving problems.[12] Before the end of the decade I think these developments will impact on MIS design in the appearance of more "personalized" information structures which better match the users' needs and in the identification of new requirements for system technology. Within the data processing industry the emerging trend toward companies which provide "information services" will continue; they will be the developers of the new technology which solves the user's problems.

DATA PROCESSING TECHNOLOGY IN MIS

Although organizational information systems existed long before the appearance of the computer and EDP, the formal designation MIS is commonly associated with the modern information technology of the last twenty years. A company's decision to "establish" an MIS capability in this period contained two conditions of entry: (1) a large initial capital investment of $.5 million or more, and (2) a non-revocable commitment to EDP, since the "bridges" to existing manual systems were usually "burned" as new systems were developed and mechanized. Consequently, the initial stakes to play the MIS game were high even if amateur players did not always recognize them. But then so was the promise of payoff. The economic equation for management was simple: replace labor with capital so that as data volumes increase and technology improves the per unit cost of processing declines. The engine that would power this system (or the MIS) was the computer.

Computers have been successfully employed in engineering instrumentation, scientific data processing, military and space applications, and in business where the application involves large volumes of data and relatively straightforward computations, such as in communications switching or bank check processing. To secure the capital leverage of the computer in each case requires that the process involved be *formalized* and programmed. But the needs for different applications are different and, as discussed above, the absolute requirement to formalize management decision processes has been the key barrier to the computer's success in MIS. In my opinion this problem has been further compounded by the promoters of so-called "integrated systems."

EDP technology encompasses a broad domain beyond "the computer," from firmware to peripheral devices and communications, from POLs to data management software and hypervisors, from system configuration to systems analysis and people. Within the space available it is obviously impossible to cover all aspects or even do partial justice to the many contemporary developments. As a compromise, I will instead highlight a subset of the whole that I think holds particular significance for MIS in the future.

* I'm reminded here of the lament some years ago, by the EDP manager of a very large steel company who in responding to an inquiry by the Chairman of the Board was required to process some 90 million records over a two-day computer run. Apparently, the Chairman did not ask his "MIS" the *right* question.

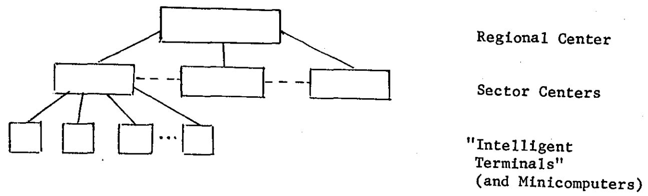

Figure 3—Distributed data processing grid

Perhaps the most distinguishing characteristic of third-generation EDP system operations was the emergence of teleprocessing, facilitated by multiprogramming and data communications technology. Although early time-sharing applications were restricted by the existing hardware and operating systems, considerable progress has been made in a relatively short time span. This development is significant for at least two reasons. First, it provided the basic framework for distributed data processing; second, it turned the centralized vs. decentralized operations debate into an academic issue to be decided on a relative basis by organizational philosophy. The distributed data processing (DDP) approach (see Figure 3) employs a hierarchy of EDP centers, ordered on the dimension of capacity and interconnected through direct communication lines. (Increasingly in the future these lines will be dedicated for data transmission rather than modifications of voice networks.) At the lowest level in the DDP grid the point-of-origin device for data capture and interaction will be an "intelligent terminal," ranging from a Picturephone-like* device to a minicomputer with local data processing capacity. Where online access and speed are not important data cassettes will provide communication linkages. In more sophisticated applications computer networking will be employed for direct communication between computers and multiprocessor centers. Although thus far the DDP concept has been employed primarily in experimental systems, I believe it will be commonplace in the future.

The distributed data processing approach in one sense is a natural outgrowth of the time-sharing principle to extend system utilization while capturing some of the economies-of-scale in hardware technology. However, experience has shown that the massive "universal" system approach rapidly leads to substantial diseconomies in software overhead and administration. By analogy, the computer is not a universal machine; "a truck, a motorcycle or a racing car each has a different engine which is designed for high performance and economy in the specific use intended."[1] The computer system and MIS that seeks to be all things to all people in one package is doomed to failure at the outset. The cost balance in configuration is between operating control over a fragmentation of diverse specialized systems which may be locally optimal but globally expensive, and the universal system "dinosaur."[9]

A critical problem to date has been technically with the integrated data processing approach—particularly in extreme applications for MIS which have attempted to "integrate" everything from customer sales transactions to the President's appointment calendar. The basic difference under DDP is not to integrate but instead to provide a well-defined interface for relatively independent sub-systems. Data managers have been a first step and in the future these systems will be dedicated to sub-set applications as required. What emerges then is a *portfolio* of technology (packages) optimized with respect to the portfolio of user information structures. Some of the elements in the overall portfolio will interact, some will not; however, all elements will be highly modular. That is, one application may periodically require augmented computer capacity from the sector or regional centers in "competition" with other applications, others may share certain master files for data, and still others may be locally self-sufficient. For example, the "executive terminal" might well become an information structure serviced by a minicomputer with limited communication to a corporate data bank via cassette.

The utility structure of the DDP grid recalls the previous question: Is "information processing" a homogeneous commodity? The purist would answer affirmatively at some level of computer science or, above the ISP (Instruction Set Processor) level, one could identify kernel processes. But the absolute answer to this question does not seem critical to me. That is, defining the requisite interfaces will begin to establish the standardization required to achieve plugboard modularity of sub-systems. For example, General Electric is currently addressing parts of this problem with "interprocessing" in which customers' computers and GE's network service are used jointly[5]—to cite one illustration. A more interesting issue, perhaps, for managers and EDP technology in future MIS now becomes the "make or buy" decision.

Earlier I remarked that the economic rationale by management in making the commitment to EDP and MIS was essentially to replace labor with capital and improve productivity. What has happened, however, is that total costs have increased. Even if one examines only the *apparent* costs of systems operations and development the capital/labor ratio advantage has

* Picturephone is a registered trademark of the Bell System.

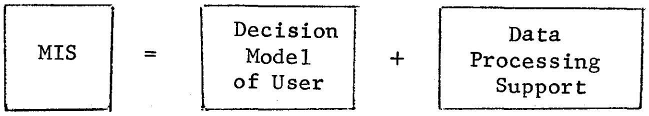
not materialized; equipment hardware cost continues to decline as a percentage of the total which includes systems personnel and administration—today ranging between 35 and 45 percent. Furthermore, as most of the trade literature reports, apparent costs are only the visible portion of the economic "iceberg" in MIS when we include such *hidden* cost factors as the drain on management time, inadequate priority analysis of competing applications (and the foregone opportunities), abandoned projects due to vacillating support, security in the EDP department, inefficient software, etc. The constant advance in the sophistication of the new technology will continue to raise the economic stakes for payoff in MIS as this total cost base expands. Sunk cost notwithstanding, the decision many companies are literally beginning to face is whether or not they can afford to be in the MIS business.

This economic crossroad in MIS is not to suggest that management is contemplating a nostalgic return to the Dark Ages. More realistically, they are weighing the practicality of making it themselves or buying it on the outside. Today information services companies sell pieces of an MIS; you can buy information problem solutions as a complete package and for a price contracted *in advance*. Often this opportunity does not exist inhouse and cost estimates are notoriously biased. The large corporations with the requisite capital base and absolute system constraints will retain inhouse technology for their MIS. Increasing numbers of companies in the $50 million annual sales or less category, however, are going to buy their MIS technology over the next ten years. Few companies today generate their own electrical power requirements; many companies buy their legal services as needed; most small companies buy their accounting services. The distributed data processing approach will facilitate a comparable opportunity for EDP technology. Management will decide how much of it to "buy" and how much to "make" in establishing an economically viable MIS. For the data processing industry: establishing the centers, developing the technology, and regulating operations will be determined in the market place by the user or the government or both.

CONCLUSIONS

Having reviewed the state-of-the-art in MIS technology contemporary developments indicate that the future holds no radical departure in the promise of a major technological breakthrough, although there will be change. The MIS as the computer itself is still in its infancy and progress in design and development is an evolutionary process that depends on how much is learned from past mistakes.

Perhaps the most significant change in the future from the perspective of results will be a reestablishment of purpose as information structures in MIS seek to solve the bona fide problems of users. In simplified terms we characterized system technology by the model:



We further stressed that the many information structures which in aggregate constitute a MIS range in their sophistication as a descriptor of management decision processes from a relatively naive "data bank" model to a complete and closed-loop program for "automated decision." As developers seek to advance the state of user model technology the MIS design focus will shift from a data base orientation to a focus on the critical decisions of line managers in organizations. More emphasis will be placed on education of both system analysts and managers to close the communications gap; design teams will be formed to better utilize the methods of operations research and management science. To further increase understanding and acceptance behavioral considerations will assume a dominant position in development, becoming parameterized where possible to better match the information structure to the user's problem. The MIS then will become a portfolio of information structures designed to solve the information requirements of a hierarchy of management decision processes.

Data processing support within MIS will also undergo change over the next decade in an evolution from current developments. One major outgrowth will be extension of the distributed data processing approach to delivering a portfolio of EDP support in MIS. Within this framework efforts on integration will diminish in favor of modularity in design to decouple and develop relatively independent sub-systems with well-defined interfaces for plugboard compatibility. Data management systems will become dedicated to improve the linkage between data base development and the user model portfolio's requirements. Communication within the distributed data processing grid will be over dedicated lines for data transmission or in some cases by data cassettes. The minicomputer will become commonplace as "intelligent terminals" in the grid. Finally, pressured by rising inhouse costs and the requirement for economic payoff, all but the large corporations will decide to buy their EDP technology from outside suppliers, in some cases retaining minicomputer terminals as the system connection.

In looking toward the future of MIS technology then, my view sees *payoff* and *portfolio* as the most descriptive adjectives. To me they are inevitable if MIS in the future is to include *progress*.

Selective security capabilities in ASAP— A file management system

by RICHARD CONWAY, WILLIAM MAXWELL
and HOWARD MORGAN

Cornell University
Ithaca, New York

Although the general requirements of data security in file management and retrieval systems are fairly obvious, and have been often stated[1,2] current practice does not provide even an approximation of these requirements and, in fact, current languages and operating systems, with few exceptions[3,4] make it relatively difficult to achieve these objectives when one tries to do so. Apparently, current languages and hardware serve as an informal security and privacy protection system that is more or less satisfactory for most current applications. While security and privacy controls are often discussed, they do not appear to be high on most managers' lists of pressing problems.

The authors' concern with security is limited to the systems implications which arise when one or both of the following circumstances exist:

1. A common file is used for two or more different purposes, e.g., an integrated management information system.
2. A file is directly accessible by those who are responsible for generating input, and those who use the information it contains.

Questions of physical security of facilities, tampering with hardware etc., have been treated elsewhere[5,6] and will not be discussed here.

At present, the programming languages and operating systems that are used for most file maintenance and information retrieval applications are sufficiently complex and esoteric that professional programmers and/or production controllers have been interposed between the ultimate users of the file and the file itself. Moreover, the majority of such applications are still handled by relatively conventional batch processing systems, without remote access devices being placed directly in the hands of the information supplier or consumer. Both the physical separation, and the necessity of human review of access to the file serve to provide an informal but adequate security system to protect against abuse by the information consumer. The programmers and production controllers in such a system, however, often have considerable freedom to attack the security or privacy from within. (How many data processing departments are able to keep salary information from their programmers?)

It is clear that remote access systems represent the future for such applications—the only question being how rapidly the future will arrive. It is also clear that user and problem-oriented languages now exist[7] and once data-consumers have experienced the power and convenience of these languages they will not willingly return to a situation in which they are at the mercy of a staff programmer. Both of these developments suggest that formal and explicit treatment of the questions of data security is rapidly becoming a necessity. The following describes the approach to these questions that has been taken by the authors in ASAP, a file maintenance and information retrieval system designed and implemented by the authors.

There are three principal questions associated with the security of a particular file:

1. Which people with physical access to the hardware containing the file should have access to any particular file?
2. What subset of the file is each authorized user permitted to access?
3. What types of processing operations are permitted to each authorized user?

ASAP approaches each of these questions by using a complete directory of authorized users which is appended to the master file in question. While ASAP cannot prevent the data-set that represents the master file from being processed by independent programs written in other languages, it can and does supervise all requests for information entry, update, or retrieval which are written in the ASAP language, and in doing so enforces the security restrictions that are explicit in the user directory. This directory contains, for each authorized user:

1. "password" identification information.
2. A description of the file subset accessible to this user.
3. A description of the processing actions this user is permitted.

RECORD SELECTION

The first method of specifying the subset accessible to a particular user is to describe which records of the file are accessible to him. This is done by including in the directory entry for each user a Boolean expression that describes by content those records to which he is permitted access. When a user makes a request, a monitoring routine based upon this filed Boolean expression is interposed between the file management utility routine and the user program. The result is unobtrusive, but absolute—the user program only "sees" records for which the Boolean expression is satisfied; other records essentially do not exist for this user. The syntax of ASAP permits the user to easily further restrict the selection of records from the file, but this individual Boolean constraint is automatically and invisibly 'ANDed' to the selection criterion for each and every request submitted by this user and there is no way he can override it without going completely outside of ASAP and obtaining independent access to the master file.

For example, consider a master student file at a university in which there is one record for each student. One user of this file might be the administrative office of the College of Engineering. (The system is, of course, quite content with such 'corporate' users, actually representing a number of different individuals.) The selection condition for this user would probably be something like:

```
COLLEGE='ENG'
```

where COLLEGE is the name of a field in the record and 'ENG' is one of the possible values of the field. The user representing the office of the Dean of Women might be assigned the selection restriction:

```
SEX='F'
```

and a user concerned with those football players on athletic scholarships who are in academic difficulties might be restricted with:

```
ATHLETICS='F'
              AND FINANCIAL_AID>1000.00
              AND GRADE_AVG<2.0
```

A complete program in ASAP could consist of the following statement:

```
FOR ALL STUDENTS WITH CLASS='FR',
  PRINT LIST: NAME, CAMPUS_ADDRESS,
              CLASS_RANK, ORDERED
              BY CLASS_RANK;
```

If this request were submitted by the College of Engineering it would produce a listing of all freshmen engineering students. Exactly the same request submitted by the Dean of Women would yield a list of all freshmen women.

While the primary purpose of providing this mechanism is to restrict the distribution of information to those users with a preestablished need-to-know, it has a secondary effect which may be more important and interesting than the security aspect for many applications. This is the fact that each user can deal with his accessible subset of the file exactly as if that constituted the complete file. He is in every sense unaware of the existence of other records and can employ the full facility of the language and the system for his subfile, without requiring any special treatment because it is a subfile. This means that most of the difficulties associated with multiple, decentralized files can be avoided without sacrificing their simplicity of use. One can avoid the currently typical situation in which an individual student is the possessor of a score or more records in different and separated files in various stages of update and decay.*

FIELD SECURITY

A second method of defining the subset of the file accessible to a particular user is to assign different 'security classes' to different fields within each record. When the record is defined each data element (field) is assigned to one of nine security classes. One class is called unrestricted and this is the default when no

* In conventional processing of sequential files the 'invisible' records in such a system would impose a prohibitive processing penalty on the user of a small subset. This is avoided in ASAP by simultaneously processing many independent requests in one pass through the master file.

explicit security designation is given; the others are designated 1, 2 . . . 8. The classes are independent, with no hierarchy implied by the level numbers.

When each user is enrolled in the system the security classes to which he has access are explicitly listed. While every user has access to unrestricted information, access to each of the other three classes must be explicitly granted or denied. Field and record security are multiplicative—a user may see only authorized fields in authorized records.

To continue the previous example, the fields of the student record might be classified in the following way:

Unrestricted information:
Name, campus and home address, telephone, college, class.
Security Class 1—Personal/biographical information:
Medical history, draft status, disciplinary actions, race, religious preference.
Security Class 2—Academic information:
Class standing, individual course records, standardized test scores.
Security Class 3—Financial information:
Treasurer's account, financial aid, family financial report.

Now the administrative office of the College of Engineering, whose access is already limited to records for which COLLEGE = 'ENG', could also be limited to the fields in those records that are unrestricted and class two information. Fields containing personal and financial information, as well as the complete records for students not in engineering are inaccessible to this user.

As in the case of record, a significant advantage of the system is the opportunity to combine several different types of information in a single master file, and keep that information out of reach of unauthorized users, out of the way of users who don't want it, and still have complete information readily available when it is required.

RESTRICTION OF PROCESSING OPERATIONS

A third, almost independent type of security concerns the type of actions that a particular user can perform. Actions are classified in the following way in the ASAP system:

1. Read only access
2. Read/write access to existing records
3. Record creation and deletion
4. Ability to extend language by adding definitions*
5. Attach read only external procedures
6. Attach read/write external procedures
7. Alter the record definition
8. Modify the user directory—add or delete users, or change the security restrictions for existing users

The directory entry for each user includes a list of the types of actions that are permitted to this particular user. Read only access to the accessible fields of accessible records is assumed; all other types of actions must be explicitly authorized. No hierarchy is implied in the above list so that, for example, the ability to extend the language does not imply write access to the file.† Obviously, the ability to modify the user list must be granted with great frugality since this implies the ability *to obviate the entire security* system.

IMPLEMENTATION

ASAP is a compile-and-go system—each run begins from source, and security tests are applied at the source language level. Since no object decks are ever produced by the system, there can be no opportunity for security to be obviated by an alteration to the object program. Although the compile-and-go strategy is unusual in the data processing environment, it does not exact the penalty in compilation time that might be expected. The compiler is very fast, and recompiles source in time comparable to, if not better than, time required to load the object modules of a corresponding program. (On a 360/40 ASAP compiles at card reader speed, on a 360/65 at 50-100 statements per second.)

The first card of each user program is an identification card bearing the user's password. This is used to search the user directory for the appropriate entry. When the user's entry is found, the record selection condition is passed, in source language form, to the compiler, along with two bit masks, one for field security, and one which specifies permissible actions.

The record selection condition is compiled into object code that is appended to the file management utility routines. This code is exercised for each record of the master file, thus representing some execution overhead. Since the compiled code is made part of each

*,† In ASAP, users may define report formats, input formats, codes, and other frequently used constructs. These are then catalogued for future reference. Often, therefore, users will extend the language by adding special reports or macros to the system, an action quite independent of the ability to write on the master file.

selection criterion, however, this often amounts to no more than two or three machine instructions per record. Only records that satisfy these conditions are passed on to the program representing the user-specified record selection criterion.

Both field selection and action restriction are entirely exercised at compilation time and represent no execution overhead whatever. Each entry in the symbol table, e.g., field name, report name, keywords, etc., contains a security mask. On each source reference to a field, the security class of that field is ANDed with a copy of the current user's security mask, and a simple test then decides whether or not the field is inaccessible to the user. If an attempt is made to reference a "classified" field, a condition code is set that the run is terminated after compilation. When processing definitions of entities which may include information from several fields, such as reports or summaries, the security of the report is simply the OR of the security classes of all fields mentioned. Thus, while each field of a record may only have a single security class, a report may require the user to have access to several classes before he can use it.

The permissible action checking is done in a similar manner. Each action is tested against the action mask for the user for whom the code is being generated, and an improper action will cause the run to terminate after compilation.

Since references to the symbol table are made for every symbol scanned, the overhead involved in checking the security classification is rather small. And, since it is only exercised during compilation, at rather low cost, a fairly large set of security restrictions can be enforced.

The different types of security are not quite independent in the ASAP system, although there is no technical reason why they could not be. When a user is permitted to attach an external procedure (which may be written in any programming language) the system does not attempt to enforce field security. Record security is still effective since the call to the external procedure is not made until after the record has been selected for processing. However, once the record is selected, the entire record is available to the external procedure. Although it would have been possible to pass an abbreviated copy of the record in which inaccessible fields had been blanked out, the substantial overhead this would require was considered unnecessary, since the use of external procedures requires a special security class which must be approved by the system controller.

The current implementation also includes a provision for encrypting the master files. This is performed using standard cryptographic techniques, with the keywords based on the system controller's passwords. The cost for encrypting or decrypting a 500 byte record on a 370/155 is about 500 microseconds of CPU time.

SUMMARY AND CONCLUSIONS

The security provisions of ASAP are rudimentary, but are relatively simple to understand and use. Since the language is compiled, rather than interpreted, and most of the security features are fully exercised at compilation time, rather than at execution time, the security aspects of the system are not expensive to use. It will be interesting to observe in time whether these simple and inexpensive features of the system will be widely exploited by users. If not, then perhaps security considerations have been overemphasized by those in research and development and do not constitute an important general problem. If they are used, it is likely that users will become more sophisticated in their requirements and these simple classifications may not long suffice. It is, of course, no problem to increase the complexity of record selection conditions, or the number of classifications in either field or action restrictions, but it may turn out that other types of security exist, with concepts unlike those here.

Clearly, the ASAP security system is mainly designed to prevent the casual user from gaining access to information he should not see, and the determined professional would have little trouble going around these security measures, using other languages.

It is interesting to consider the problems of implementing even this rudimentary security system for a conventional file—that is one created, updated, and interrogated by programs written in a contemporary general purpose language (PL/I, COBOL, etc.) and executed under a standard operating system. One might then conclude that the task is most formidable, and that if security is a real problem, the software now in general use is not up to solving it.

The CODASYL Data Base Task Group[8] has proposed language extensions which permit one to specify security and privacy restrictions. They allow for quite general restrictions, and would probably lead to a far more costly implementation of security than that of ASAP. A more general treatment of methods for reducing the cost of information security systems is forthcoming.[9]

A graphics and information retrieval supervisor for simulators

by JAMES L. PARKER

University of British Columbia
Vancouver, Canada

INTEREST IN SIMULATION

Interest in simulation by computer has grown steadily over the last ten years. This interest has become even more strong in the last couple of years with the advent of popular interest in environmental and social systems. Frequently the most limiting factor in the simu'ation and in the evolution of the techniques of simulation is not the ability to generate the programs to do the arithmetic. It is the ability to handle in an easy way the information flow which results from the simulation and to provide users—particularly those who are not intimately familiar with computers—an easy versatile, hands-on way of displaying this information.

The above need is felt in two ways. First when a new simulator is written a significant portion of the effort of its design and coding goes into that portion of the code which maintains the data base on which the simulator operates. Another significant portion of effort goes into the system which allows the simulator to communicate with a user. This repetitious diversion of energies and money from the primary interest of the people who write simulators (the arithmetic itself) is at this time severely limiting the growth of simulators. In addition the lack of easy graphics display and information retrieval makes it more difficult to correct and evolve the simulators. One can correct and calibrate a simulation more rapidly if one can see exactly what it is doing and if there is a system which allows a sort of throttle control over the activities of the simulator.

The current limited usefulness of simulators can partially be attributed to the fact that the real people who should use the results of the simulators are people who are not familiar with computing equipment. They frequently have only an intuitive feel for what they would like to display and how they would like to see it. Most simulators currently built are left to wither in the academic realm because there is no mechanism for communicating the powers of these simulators to the people who are really interested.

It is the purpose of this paper to explain an information retrieval and graphics supervisory system which will accept most forms of simulation and execute them as subsystems. It provides users with an easy and flexible way of maintaining the data output from the simulators and of displaying this information in graphic and tabular form.

THE IIPS PROJECT (Inter-Institutional Policy Simulator)

The work that is described in this paper was done with a particular simulation project in mind, even though the system itself is not simulator dependent. This project is the Inter-Institutional Policy Simulator project financed by Ford Foundation and as a joint effort between the University of British Columbia, the City of Vancouver, the Greater Vancouver Regional Board, and the Province of British Columbia. The purpose of this project is to involve several diverse institutions in the development of a simulation which can then be presented to the various governmental and social agencies in the Vancouver region. The project is characterised by having several groups working on diverse simulators which must interact. Also its ultimate audience does not in general have a high familiarity with computers. It is also a requirement with this system that it be independent of the types of devices on which output is to be displayed. This project therefore has made an ideal testing ground for the ideas presented in this paper since the variety of people and the variety of simulators involved makes a maximum test of the design of the system itself.

THE SUPERVISOR FROM THE USER'S POINT OF VIEW

This description from the user's point of view will freely use examples based on the regional project being done in the Vancouver area. This means that, because this simulation is basically over time and subregions of the study area, the dimensions of time and region will be used liberally in the following descriptions. As far as the simulator supervisor itself is concerned, time is not a dimension any different from any other dimension or key in the information retrieval system. The only exception to this is the fact that the simulation supervisor does assume that there is one dimension in the simulation which is unique in that the policy interventions explained below are over a certain interval of this dimension. In the vast majority of simulations being built today this dimension is time, so there is no confusion. This dimension could just as easily be distance, however. Let's say that one is simulat:ng a rocket trip from the earth to the moon. The dimension chosen might be distance rather than time. It is conceivable for the simulation of an electronic circuit that this unique dimension would be a voltage level. In the following discussion, however, it will always be assumed that this dimension is time over a subset of regions.

THE INFORMATION BASE

The user of this system sees three things. The primary aspect of this system from his point of view is a large data base which represents all of the available information about the system being simulated over a time interval in years which is chosen by the user. As far as the user is concerned all of the data base information is always present in the computer files. He simply has to display whatever aspects of the system are of interest to him.

The second element which the user sees is called the policy vector. This is a set of variables each of which has a name conveniently chosen for the user. The names themselves may be redefined by the user. Each variable can take on different sets of values over time. As an example, the interest rate prevalent in an economic situation would be a single variable which the user might want to set to different values for different subintervals of the time span in which he is interested. These variables which can be set by the user constitute the policy interventions which the user can make into the model. In this way the user can attempt to study the effect of certain policy decisions and to see the differences in the display for different policy values. Each policy variable has a certain default value at the time the user begins a session with the simulator. He can change this default value to any value he chooses over the entire time interval he is studying or over a subinterval. Assume that the time interval is 1970-1990 and assume that the initial value for the interest rate is 7 percent. The user can change this value over the whole time interval or he can change the value for a subinterval. For example, he could make the interest value 8 percent in the interval from 1980-1985. As far as the user is concerned the current state of the data base reflects the set of policy values which he has chosen and they also reflect the total situation over the whole time interval he is studying. He can also set the time interval that he wants to study.

The third element available to the user is the command language with which he requests displays and asks for changes in policy elements. Although these are the two main functions of the command language there are many other commands associated with the type of displays desired, the devices available, and with saving and restoring portions of the information base.

SOME SIMPLE EXAMPLES

Before describing in more detail the structure of the information base or the command language, it might be well to show a couple of examples of the types of displays a user might request. Let us assume that the user is aware that the figures for population for a set of regions in the study area are available in the data base. Assume that there is one population figure for each region and each year and one total figure called POPULATION for each year. In that case, he might make the following simple display statement.

DISPLAY POPULATION BY TIME

This produces a simple graph shown in Figure 1.

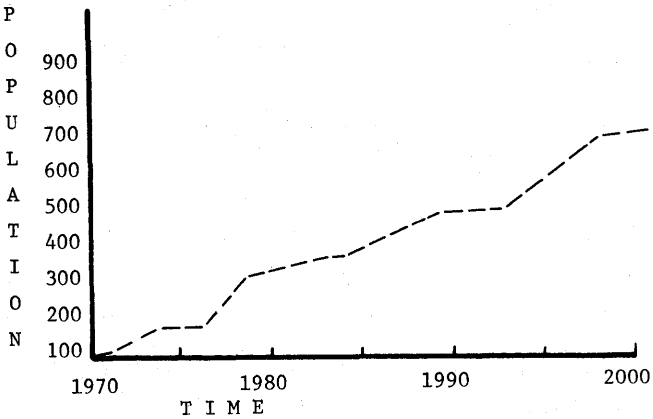

Figure 1—Simple display of population by time

Then let us assume that the user gives the command

CHANGE INTEREST RATE TO 8 PERCENT

He then repeats the first command. In this case, he would get the following graph in Figure 2 displaying the population figures reflecting his policy intervention. As in indicated later it is possible to split whatever device he is using for display into several areas. Using this feature, he could have displayed these two graphs one beside the other on his screen or his paper. He could then compare directly the two population figures. It was also possible for him to give the following command as his second display command and he would have the two graphs superimposed over each other. Thus he could compare them on the same area.

DISPLAY POPULATION BY TIME
SUPERIMPOSED

Or he might have given the following single command which would have produced the same results but with each graph marked by the corresponding interest rate:

DISPLAY POPULATION BY TIME
BY INTEREST RATE FROM 7
PERCENT TO 8 PERCENT

This would have produced the graph in Figure 3.

The simple examples give a clue to the power of the system by showing the direct control the user has over the actions of the simulator. It also suggests that there exists a wide variety of types of displays. The following shows how the user relates these displays to whatever devices he has available and what display types are available.

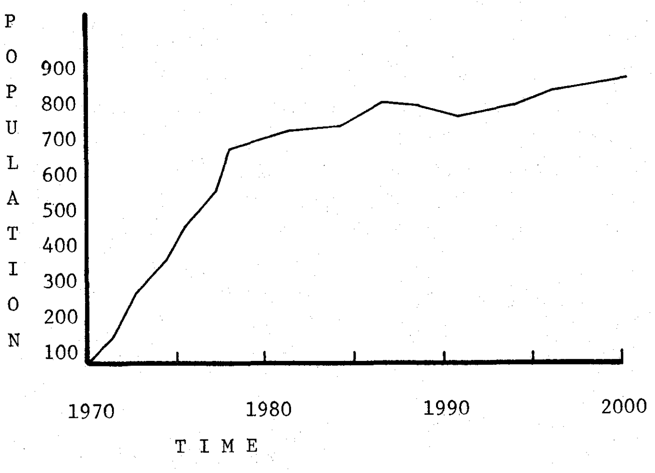

Figure 2—Re-display after policy change

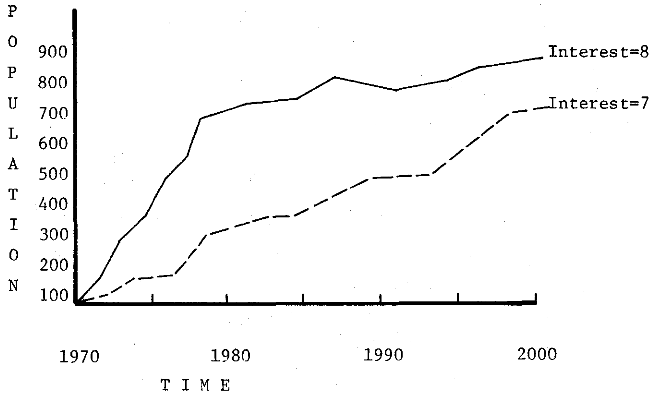

Figure 3—Use of policy intervention in display command

DISPLAY DEVICES

The system is set up so that no matter what sort of device the user is working from he can receive some type of display. The limits of the display for given device type are dependent on the quality of display that the device can support. If the user is sitting at a teletype, he can receive graphs of whatever resolution a typewritten line can support. Similarly, if he has a line printer available to him, he can receive plots on the line printer. If he has a scope available, then he can receive his displays with the much greater resolution and flexibility that a scope allows. Finally if he has a Calcomp, he can receive the same resolution as that of the scope but with the limitations that the use of paper obviously implies. The system as implemented at U. B. C. supports an Adage type non-storage scope, a Techronix scope, Calcomp plotters, line printer, 2260 display, teletype or 2741 disp'ays, and a dot printer.

The user has quite a bit of flexibility in the way in which he can relate his displays to the particular devices. In the above sample command, the defaults were all in effect so that the user did not have to worry about assigning the graphs to areas. For a particular device, the user is allowed to cut the face of the device into 1, 2, or 4 areas. This is most advantageous when using a Calcomp or storage scope. It is also possible that the user has more than one device available at any given time. If he has for example a scope and a Calcomp this allows him to develop certain images on the scope and then have them plotted on the Calcomp. In the case that the user has established multiple areas he must indicate the area on which he expects a display to appear. As was evident in the above examples, the user can cause a new graph to be superimposed on an old graph or he can start with a completely fresh image in an area. It is also possible in the command language for him to move a current display from one area to another. This allows an evolution of a display on a CRT type device and the creation of hard copy from a device like a Calcomp. In addition to this the graphic supervisor is set up so that it provides a memory buffer of images for each area currently in use. This implies that whatever images have been created for a given area, a user can always step back and review a previous image or move forward and again see the current image. The number of images contained in the memory buffer for each area is defaulted to five but it can be changed by an individual user.

RATES OF DISPLAY

It must be remembered that the whole purpose of this system is to display information quickly to a human being and in a form which he finds understandable and pleasing. In light of this it can be observed that a static display is not in general pleasing to a human being. It is much more intriguing and informative to see something that moves. For this reason, the displays on this system have been given a wide flexibility in the way in which they are displayed with respect to time. Naturally these methods of display with respect to time are much more flexible on a CRT but some of these principles are also applicable to paper graph displays.

Each graph is considered to be a subset of a graph with four dimensions. It may seem rather surprising to consider a graph as having four dimensions. However, if one can superimpose several graphs in one area, one already has three dimensions, as in Figure 3. In Figure 3, the three dimensions are population, time and interest rate. Do not confuse time as used here with the idea of the real time of the person using the system. Time here is simply one of the data variables from the information base. If a sequence of figures such as that in Figure 3 could be displayed where each frame in the sequence corresponds to the given value of some fourth variable, the display would effectively be showing the relation of four variables. Not only that, but it would be showing it in a way that would be fairly palatable to human understanding. If the user can see the change in his graphs from one frame to the next, it is actually a fairly good way of transmitting information to a person. The idea of the "rate" in these displays is based on these two ideas—that one can display a four dimensional graph and that the graph can be displayed through time.

THE RATE CLAUSE IN THE DISPLAY COMMAND

The general form of the display commands for graphs is as follows:

```
DISPLAY (SEQUENCED) BY X (SE-
QUENCED) BY Y (SEQUENCED) BY
Z (SEQUENCED) BY T AT RATE R
```

The above example does not include all of the features of the DISPLAY command but includes those which are relevant to the rate of display. It is intended that the SEQUENCED phrase can occur only in one of the four positions. These four positions represent the four dimensions which will appear on the graph. The variables X, Y, Z and T are to be replaced by data names from the data base. The form of the display is determined by which variable has the SEQUENCED phrase associated with it. If the SEQUENCED phrase is associated with the last variable T, then the system merely pauses after each complete frame. Note that it is possible to have less than 3 dimensions in a given display command. The rate R is in tenths of a second. If the word PAUSE is used, then a single frame of the graph is displayed and the next frame is not displayed until the user generates an interrupt on whatever type of terminal he is using. This allows the rate of display to be completely controlled by the user. He can then investigate the characteristics of a single frame before he proceeds to the next frame. Otherwise the image is built up at whatever rate he specifies. The benefit of this type of approach is that it allows one to display more information and to give a person a feeling of something growing. As the graph emerges, one gets the feeling of being able to see a process.

The SEQUENCED phrase can also be associated with any of the earlier dimensions. If it is associated with the Z dimension, then the individual frame of the graph is also built up with pauses in between its parts. Associating the rate with the X dimension also generates a different pattern or growth of the graph and different pattern of pausing. This will be particularly beneficial when using the model for instructional purposes, in which people can discuss a set of policy interventions and then test them out on the model. At this point one can guess what is about to happen in the graph as it grows. After seeing part of the graph one can make predictions as to what will happen next. This will stimulate discussion and the use of the individual's imagination as to what the simulator might do. For example, a policy intervention might require a period of several years in order to take effect. This will allow people to stop and discuss their ideas about how long it might be before the policy takes effect. Since one of the primary purposes of a simulation like this is to stimulate people's imagination, this rate or throttle control on the graph output is very valuable. Figure 4 shows the three different types of growths of graphs which can be displayed. In the succeeding paragraphs, other types of displays than graphs will be explained. Some of these can also have the rate associated with them. At this time no meaning has been associated with the concept of putting the SEQUENCED phrase on the Y dimension.

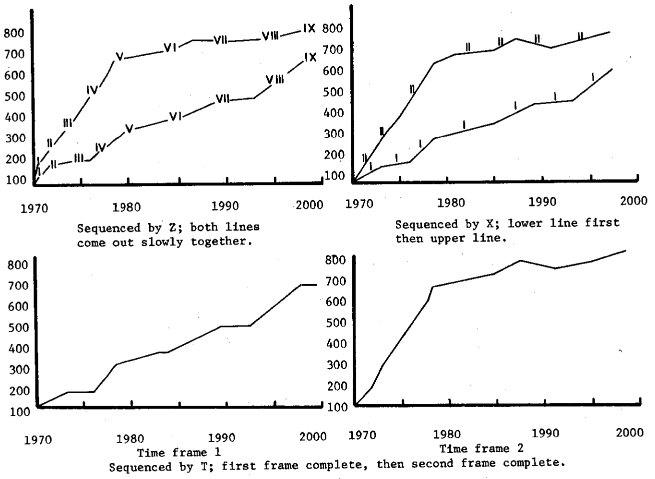
Lines marked with the same number of cross lines are displayed simultaneously. It is difficult to indicate motion as below by printing on a static sheet of paper.

TYPES OF DISPLAYS

There are actually more types of displays available to the user than those indicated above. Any graph may be superimposed on any other. The five types are:

1. Map
2. Point
3. Line
4. Bar
5. Contour

BAR: The bar graph is of a standard form. It is assumed that if more than two dimensions are expressed in the display statement for a bar graph that the third dimension will indicate different time frames. It does not make sense to have more than three dimensions for a bar graph.



Sequenced by Z; both lines come out slowly together.

Sequenced by X; lower line first then upper line.

Time frame 1

Time frame 2

Sequenced by T; first frame complete, then second frame complete.

Figure 4—Different sequences of display using rate with *x*, *z* or *t* axis

LINE: The line drawing is just the standard line graph which has been explained above. This can have from two to four dimensions.

POINT: If the display command is indicated to be of type POINT, the first two dimensions are taken to be the X,Y coordinates of the point. Point data may or may not be superimposed over a map. If the X and Y coordinates are the coordinates of some regions on a map, then it can be superimposed over a map. There are other cases, for example population versus unemployment over several regions, which would generate a scatter diagram for all of the points within the specified time interval and for all of the regions in the model. In a point graph, if the third dimension is given it is assumed to be a Z value and the numerical value is drawn in on the graph at the spot indicated by the X and Y coordinates. If there is a fourth dimension, it is assumed to always represent different time frames in a point graph.

MAP: Maps are generated from files in the data base which are the output of point digitizing equipment. They are currently all outline maps. Any point data can be superimposed over an outline map.

CONTOUR: This type of display is generated from point data with at least three dimensions. In this case the first two dimensions indicate the location of point on the map as in the point graph and the third dimension indicates the value to be used by the contour generating program. If there is a fourth dimension it is assumed to represent different time frames as always.

The form of the display command to indicate the type of display is as follows:

```
DISPLAY/X/BY/Y/BY/Z/BY/T AS MAP
                            BAR
                            LINE
                            POINT
                            CONTOUR
```

See Figure 5.

THE COMMAND LANGUAGE

The above examples have given references to various commands in the language. Although it is not the intention of this document to produce a user's guide to the language, several commands are explained below with their features to give an idea of the range and flexibility of the system.

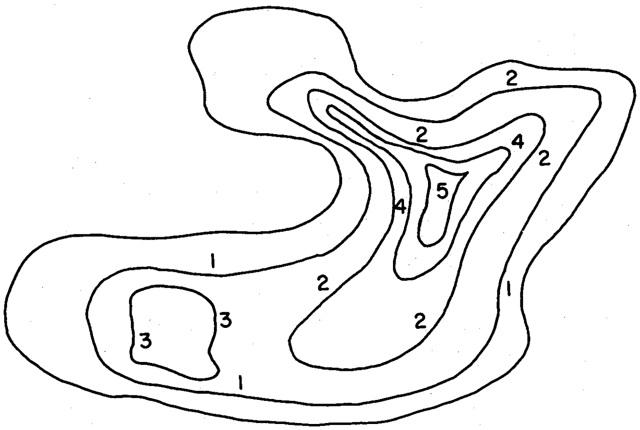


Figure 5—Map with overlaid contour lines. Contour may be formed using any data variable from the data base which has map origins

The commands are broken into three groups: display and data manipulation commands; systems and graph manipulation commands; and user aid and text formatting commands.

The display and data manipulation commands are LIST, DISPLAY, SAVE and RESTORE.

The LIST command has several options. It can list for the user any of the names in the system, such as the names of the policy vector interventions available to the user, the names in the information base, the file names into which the information base is organized, or any text replacement names which the user has defined. The list command can also output data from the information base in tabular form if this is more desirable than having it in graphic form.

The options on the DISPLAY command which have not yet been mentioned are that data may be summarized according to another variable which may or may not be in the display. For example, if population data is present in the information base by region for display purposes it could be summarized by time so that a single value would appear for the total study area for each time interval. Also on any one of the four dimensions, limits can be attached by typing FROM lower limit TO upper limit BY increment, where the increment value is simply the value used to step from the lower limit to the upper limit. Soon there will be added a feature to the system whereby any of the display dimensions can be replaced by an arithmetic expression. Then given unemployment, population and total population available in the data base, one could say 'DISPLAY UNEMPLOYMENT/POPULATION BY TIME,' and this ratio would then be calculated. It is also possible in a display command to introduce a policy vector entry. For example:

DISPLAY POPULATION BY TIME
BY INTEREST RATE FROM 8% TO 9%

It is very likely that the user, after developing a data base and a set of policies in which he may have invested quite a bit of time and money, may want to save all or part of the current status of the system. It is also possible that the user may also want to investigate a decision tree of his own policy strategies and to compare the results. In order to do this he must have the capacity to save all or part of the system in his own private files. This is the function of the SAVE and RESTORE command. The SAVE and RESTORE commands can save the total contents of the system, the contents of any one of the data files, or the symbol names that a user may have defined. See below for an explanation of the user defined symbol names.

SYSTEM AND GRAPH MANIPULATION COMMANDS

These commands set up the structure of a given session using the simulator supervisor and alter the status of the system. The ESTABLISH command initially indicates which devices are available to the system and how many areas each device should be broken into. This allows the use of multiple devices of different types simultaneously. For example, in one location in which the system is used, there is both a storage scope and Calcomp plotter available.

Since each area has a memory buffer, there must be commands for displaying images stored in this buffer. These are the GO BACK and GO FORWARD commands. These commands will also transfer an image from one area to another. This allows one to take a display from the memory buffer of a scope device and to display it on hard copy such as a Calcomp.

The ERASE command simply blanks the image on one area. The primary use comes when the system is being used for teaching purposes and one wants to have the viewer's attention directed elsewhere.

The SET command changes a variety of different system functions and defaults. This is used to set the number of images contained in the memory buffers, certain defaults about the way files are to be handled and so forth.

USER AIDS AND TEXT HANDLING COMMANDS

The EXPLAIN command can be followed by any of a variety of names. If it is a name of an item in the data base, a prewritten explanation of this item will appear. If it is a command name, a portion of the command manual will appear. If an error has occurred and the command says "EXPLAIN ERROR", a prewritten explanation of the error message will be printed out.

The HELP command currently supplies the user with information about where he can obtain various types of information about the system. It is hoped that this function will be greatly expanded in the future.

It is possible for the user to define any character string as any other character string and to have this text replacement occur in his command. The ability to redefine text allows each user to build up during the session the environment in which he operates. This means that he can redefine any name in the system to be a name more comfortable to his own way of thinking. He can also give names to graph descriptions which he feels he wants to display frequently. This will be particularly useful when users begin to generate arithmetic expressions which they do not want to repeatedly type out. The commands here are DEFINE, which defines one string as another string for replacement purposes, i.e.,

```
DEFINE POP AS POPULATION_VALUES
```

This would allow the user to use the characters POP whenever the full name was required. DROP followed by a string simply drops that string from the replacement table.

```
DROP POP
```

It will frequently be the case that a user discovers that he wants to name a whole description of a graph. So it is very convenient to have this built right into the display command itself. The command is then DISPLAY followed by the new name followed by the word AS followed by the usual graph description. This enters the name given in the replacement table and enters as its replacement the string describing graph as below.

```
DISPLAY P_GRAPH AS POPULATION BY
    TIME BY REGION AT RATE 40
```

THE SUPERVISOR FROM THE SIMULATORS POINT OF VIEW

One of the primary goals of this system is to make it very easy to add a new simulator and to minimize the burden of input/output command parsing and display on these simulators. For this reason the world into which the simulator fits is made extremely simple. As far as the simulator is concerned, the communication with the outside world consists of reading variables from files which are accessed by a file number and writing other numbers into other files. In case of an error there is a routine which is called with an error message number and which has some macro capabilities. The files that the simulator sees are basically sequential files with keys allowing either a sequential or random read or write. The file descriptions which define the names of the values which will be put in these values are written out in simple character format very much like the data description for any high level language. These file formats are shared by all the simulators in the system at one time, so that one simulator can read the files generated by another simulator. Since these file descriptions are in character format, they can be easily changed and evolved as the simulators themselves evolve. It is only required that (as in FORTRAN style input and output) the simulator assumes the function of each variable in each row that it reads in from the file. For one given file, the simulator must be aware when it is written that the fourth variable of this file is population.

MORE DETAIL ON THE INFORMATION RETRIEVAL SYSTEM

The information retrieval system is really the heart of the simulator supervisor. It must be able to access the files by key and it must be able to support a fairly complicated key structure within the files. For example, there will be files which are indexed by time and region and there will be some files which will be indexed only by region. Yet for display it would be necessary to relate these two files by region alone ignoring the time key on one of the files. There would also be files by time and region and other files by time region, and time of day. This effectively means that the information system must support a hierarchical data structure with multiple keys. However, the vast majority of accesses to the data base by the simulators are made in a completely sequential fashion. That is, very little of the structure is used in a hierarchical fashion. The possibility must be there when it is required.

In order to maintain this facility, the information retrieval system has been structured to operate on sequential files with fixed length records. These are designed to look like FORTRAN vectors; they are just a row of variables. In order to maintain the facility of multiple keys, each file may have several keys which are concatenated together to form a single key. If one wants to generate a facility for accessing the kind of structure mentioned above where one file is by time and another by time and region, the implementation must have two files with the information recorded by key in each file. To do this key lists are kept for each file which gives the key value and a line number or record number for locating the corresponding record.

Since it is possible to change policy variables over certain intervals of time it is also necessary that there be a mechanism for invalidating portions of the data base. For example, if the current data base had been computed from 1970 to 1990 and the interest rate were changed in 1980, it would be assumed that some of the output from some of the simulators would no longer be correct if they were influenced by the interest rate. Therefore those files would have to be erased beginning with 1980. This can be accomplished by simply erasing the elements in the key list which have year values after 1980.

This organization of the information retrieval system allows very simple access routines for the simulator. Yet it will allow a fairly complex hierarchical structure of keys if necessary. The fact that the user assumes all the data to be present at a given time and that the data is actually computed by the simulators only when it is requested for a display means that unnecessary computations never have to be made. Therefore the information retrieval system must be able to communicate to the supervisor what data is actually present in a file at a given time.

In order to explain to the system the structure of the files, and the interdependencies among the simulators for data, there must be a set of simulator descriptions and the file descriptions. These file descriptions as mentioned above are simply lists of the variable names that will be used by the user for referencing the data. It also includes other characteristics of the variables such as the maximum value that they should be allowed to obtain and the minimum. For each file there is a description of the simulator which writes the file and how to load that simulator in order to execute it. There is also a set of simulator descriptions which describe the files each simulator reads. This is sufficient information for the supervisor to decide on a given display command what data is required, what data is missing, which simulators must be called to generate the data and in what order the simulators must be called. The rule is that a single file may be written by only one simulator. This is required so that the supervisor can tell how to replace data which has been invalidated by policy changes or which may never have been computed in the first place. In order to generate missing data, the supervisor steps through the years in the current time interval and at each year runs the simulators required to generate data for that year. These simulators are dynamically loaded and are kept in core as long as possible until another simulator is required to run.

AN OVERALL FLOW DIAGRAM OF THE SYSTEM

The system is broken up into three major sections of code. The primary section is the supervisor itself. This code does the initialization work of reading in all the tables, reads in each command from the user, and converts the alphabetic strings in the command to integers which are merely reference numbers corresponding to the strings. This allows command interpretation to be done very easily. It is at this point that text replacement is also done. The commands then go through a large switch to individual subsections of the supervisor which process each command. The second section of coding are the I/O routines. These routines maintain the key lists for the individual files and do all of the sequential and random reading and writing requested either by the simulator or by the supervisor. At the time the simulator originally begins running it is assumed that each file that is non-empty is in a read-only master copy. As long as display commands are generated for these files this read-only copy is used. As soon as simulator wants to write a file a scratch copy is made. This copy can either default to a temporary file or can be put into a private file of the user, depending on a systems switch. Notice that the I/O routines, except for saving original data, treat observed data and simulator output exactly the same. There is no distinction between data bases which were

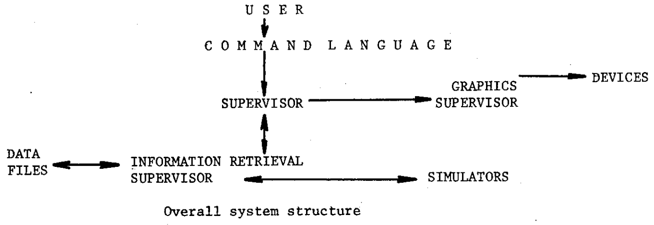

Figure 6—Overall system structure

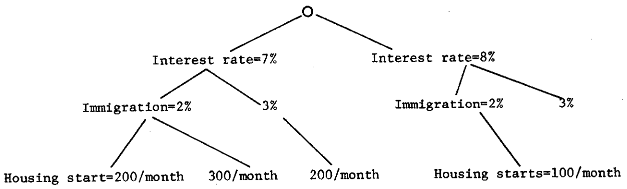
originally observed and which are modified by simulators, data bases which were written only by simulators, and data bases which were only observed. This symmetry of treatment coupled with the ability to describe files in format-like statements allows the structure of the files to evolve very easily.

The third piece of code involved is the graphics supervisor. This section of code maintains the current state of all of the display devices in the system. It also maintains the image buffers, the memories for each area of each display. It is the responsibility of this section of code to convert a standardized graph description which it receives from the supervisor into the proper display for each device in the system. It is also the responsibility of this section of code to OR the graph images together into single images when superposition has been requested. This part of the program also does the computations required for contouring and displaying of bar graphs and so forth.



```
DISPLAY POPULATION BY TIME
DISPLAY GEOGRAPHICALLY SINGLE_FAMILY_DWELLINGS AS CONTOUR
DISPLAY GEOGRAPHICALLY POPULATION SEQUENCED BY TIME AS CONTOUR
```

At each level display might be made of population, land use contours, etc.

Figure 7—A possible decision tree for investigating policy alternatives

EXTENSIONS

The most exciting extensions to this system will be in the area of providing facilities to the user for developing policy strategies. The first cut in this area will be to give him the ability to develop a decision tree of alternatives, and to compare and display data across these different alternatives. See Figure 7. At this point it would also be of value to be able to provide him an analysis of which variables in the data base are affected and at what level by changes in the policy variables. At first this can be done on a guesswork basis by knowing which data is invalidated by changes in which policy variables. Later on, however, it may be interesting to do more in-depth analysis by actually running the simulators for a short period, noting which variables change, and attempting to give some indication of the derivatives involved.

What would also be very interesting in this context is to generate a rudimentary artificial intelligence device which searches out policies which tend to satisfy certain goals set up by a user. In this case the interaction between the user's intuition in suggesting goals and a rudimentary artificial intelligence device might produce some very exciting results.

CONCLUSION

It is strongly believed that this system will bring the power of large interactive computer systems rapidly to users in two different ways. Primarily, it will provide an ability for an untrained user to investigate in great detail and according to his own experience the workings of a set of simulators. Secondly, by relieving the simulator writers of the burden of providing user interface and information retrieval it will allow the quality of the simulators and the types of the simulators themselves to be evolved very rapidly.

NASDAQ—A user-driven, real-time transaction system

by NAT MILLS

Bunker Ramo
Trumbull, Connecticut

INTRODUCTION

By Christmas time of 1970, 1200 brokers active in the Over-The-Counter securities market nation-wide, had had a new Bunker Tamo CRT terminal placed upon their desk. Through these "NASDAQ" terminals, they would be expected to watch and change all their quotations from then on. Within a month, they were confidently using the data in the system, that they were themselves updating, and turning their backs on almost all of the previous phone checking and "pink sheets."

By March, 1971, Barron's magazine had reacted to NASDAQ as follows: "To the amazement of virtually everyone, the complex network of cables, computers and cathode ray tubes . . . breezed through its shakedown period with scarcely a hitch. What's surprising (is) . . . the almost instantaneous success and acceptance NASDAQ has scored."

And before the new year was half gone, the talk had turned to the feasibility of automating the exchanges themselves. NASDAQ was becoming a model of how aptly a computer complex could serve a national trading community.

"BEATING THE ODDS" IN REAL-TIME SYSTEM CREATION

The NASDAQ system is but one of many large real-time, transaction processing configurations that have been attempted during the past 10 years and in most cases been completed, sooner or later, during the past 5 years. Many of our computing fraternity (and sorority) have been involved in these efforts, and many more will be immersed in similar efforts during the next 10 years. In this paper, we are offering the highlights of our own particular experience, and some of the reasoning behind the course we took, which did "beat the odds."

In fact, evaluating the design decisions made in building the NASDAQ system might well be viewed as one half of a very useful object lesson in the problems and pitfalls to be met in developing large on-line, real-time systems. The other half of this object lesson would then be the comparative evaluation of the design options chosen in less fortunate projects where the pit was fallen into. It would be presumptuous, and certainly not fitting for us to make a critical analysis of such projects. Therefore, we confine ourselves to presenting the following picture of our own effort.

THE SYSTEM IN PROFILE

The NASDAQ System is a nation-wide, real-time configuration now serving the quotation needs of the Over-The-Counter securities market. NASDAQ stands for the **N**ational **A**ssociation of **S**ecurities **D**ealers **A**utomated **Q**uotation system. It is centered in a pair of Univac 1108 multi-processing computers in Trumbull, Connecticut (see Figure 1). Radiating from this center is a network of data lines to Bunker Ramo Model 2217 CRT's in the individual offices of sub-

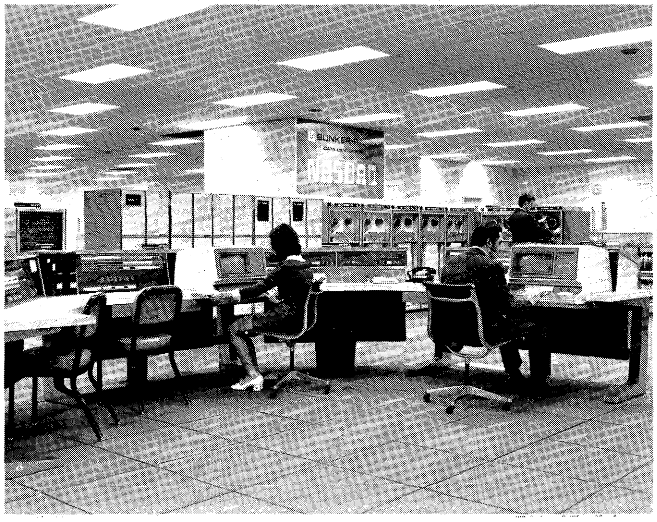


Figure 1

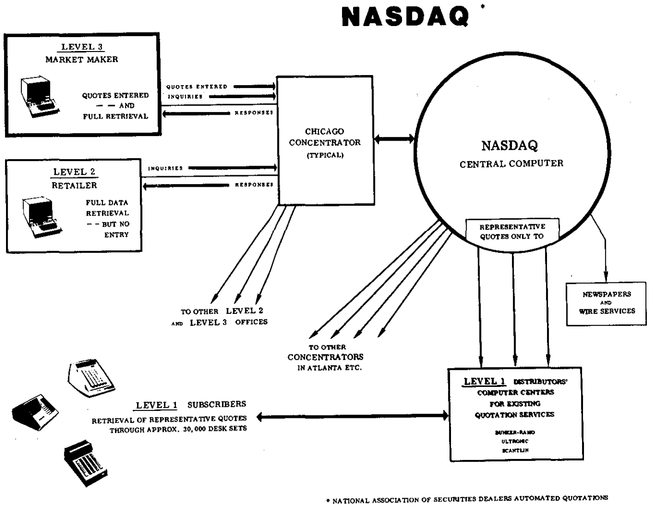


* NATIONAL ASSOCIATION OF SECURITIES DEALERS AUTOMATED QUOTATIONS

Figure 2

scribers. Controlling and concentrating the traffic in this network at four regional points are duplicate Honeywell DDP-516 computers, each with a Bunker Ramo designed Communication Control Unit as a front end interface (see Figure 2). In each office being served is at least one Over-The-Counter Control Unit (OCU) to support the terminals installed for NASDAQ (see Figure 3).

At the Trumbull Center, as units integral to the central processor, are a group of auxiliary memory devices and communication traffic handlers. In the hierarchical levels of the directly accessible storage is held the on-line data base, from which quotation, index, volume and other information is retrieved for remote display. The system restricts to a particular level of terminals in the offices of market makers and the NASD itself the functions of data base updating and control.

Activity is, as of this writing, averaging over 900,000 calls per day, and peaking at busy periods at over 110 calls processed per second. The size and scope of the system is still expanding. At this point, over 900 offices are tied into the system, with 1,400 terminals installed.

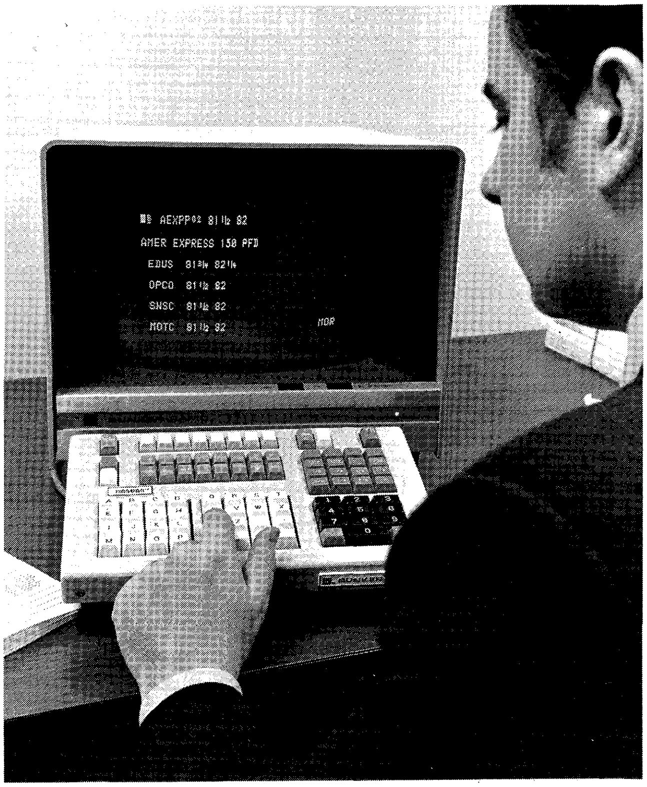
The data base is built around records for over 2,800 securities, active in the system on the basis of over 19,000 quotations by market makers taking positions in them. The volume of purchases and sales is being reported into the system daily and now exceeds that of all other exchanges combined, except the NYSE.

THE UNIQUE CHALLENGE FACING IMPLEMENTATION

Of course, this whole system and its functions did not arise haphazardly. The start of the design effort was the recognition that the implementor of NASDAQ faced a formidable task for several pivotal reasons.

- The direct users of the system would be brokers interacting amid their hectic daily trading. They would be entering, verifying, and retrieving the data upon which the data base itself would be built. No trained clerical personnel or computer operators could intervene.
- The whole process being automated would actually create an entirely new way of doing business for the Over-The-Counter Market. No precedents or earlier system existed.
- To support a viable market, the whole trading community, nation-wide, had to be on-line together at system start-up.
- A substantial portion of the expected users were reluctant and skeptical about being supported by automation. Any failures or ambiguities in function could be expected to be exploited to question the whole system's utility.

Recognizing the seriousness of these challenges, the system analysis effort began in earnest.



```

Figure 3

ESTIMATES OF TRAFFIC LOAD AND MIX

In the effort to provide a solid basis for all design decisions, there were studies in the field, simulations, and functional analyses of many aspects of the processes NASDAQ would automate. Particularly, in order to properly select and locate components of the communication network, we needed informed projections of traffic loads, geographic distribution, and mix of entry types.

With the decision already made to put the central site in Trumbull, Connecticut, the heaviest volume of traffic would obviously be between there and downtown New York City. Other traffic paths were mapped out and studied for potential service demand. Then formal network analysis was applied to the data, using "COPE," Bunker Ramo's own computerized analysis tool.

From the functional aspect, observation of O.T.C. brokers' activities indicated an approximate ratio of seven to one between the number of requests for the quotations in a security and the number of updates of those quotes. The human factors of location, style of work and data interaction were studied in the actual trading environment to obtain further data for the design decisions, which are described in the following sections.

THE CENTRAL SITE CONFIGURATION

For the central processor in the NASDAQ configuration, the Univac 1108 was chosen on the basis of its already proven reliability and the elements of its design which expedited real-time operation. Two units, as a multi-processing complex, were recognized as essential to carry the system's total processing load, though unit processing, when necessary, would be sufficient to maintain all on-line functions.

The total complex is controlled as a configuration by an Availability Control Unit (ACU), which allocates facilities in the multi-processing environment (see Figure 4).

Since swift accessing of a large data base would be critical, an hierarchy of random access storage devices was chosen from those in the Univac line. In this case, a wide range of high-speed and low-speed drums and common core has provided an adequate supply of random access storage for the data base, programs, tables, and dictionaries as needed. From these devices, individual record retrievals, program overlays or even remapping core has functioned with speed sufficient to keep within the specified response time on all transactions.

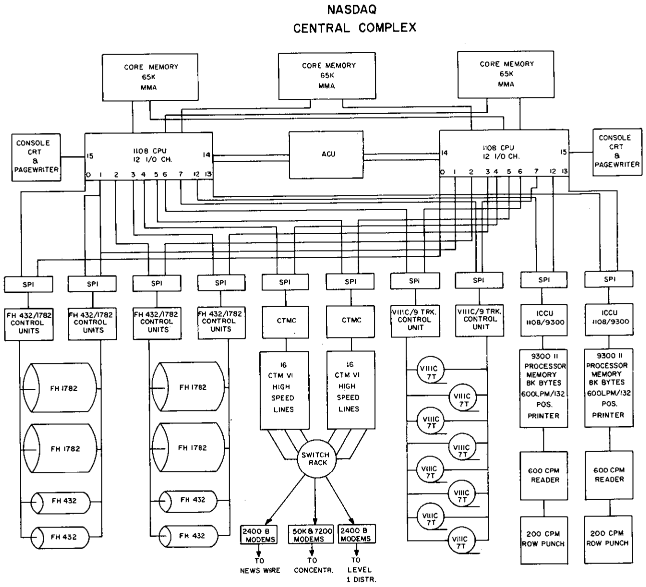

Figure 4

Auxiliary to the central complex is a normal complement of magnetic tape drives, consoles, two Univac 9300 processors driving printers, and card units. For environmental control, dual air conditioning systems have been installed. To assure continuous power, an Uninterrupted Power Supply (UPS) of batteries and a gas turbine motor stands by in permanent readiness.

At the center's terminus of the communication network, a Bell System exchange is installed on site, dedicated solely to handling NASDAQ traffic. Interfaced with the central processors are a pair of communication terminal module controllers (CTMC's) each with its own set of 16 communication terminal modules (CTM's) cross-switchable for carrying all traffic through the appropriate modems to the users via the regional concentrators and to the auxiliary services tapping the data base, such as the public quotation services and newswire distributions.

The upper limit for traffic through this present central configuration was pegged by original design estimates at 220 calls per second. However, built into the hardware plan (and the software design as well) is ample provision for expansion to handle growth in load, and changes or extensions in function.

THE DECISION TO INSTALL REGIONAL CONCENTRATORS

Those who have been close to the NASDAQ development effort from the start feel that the most important

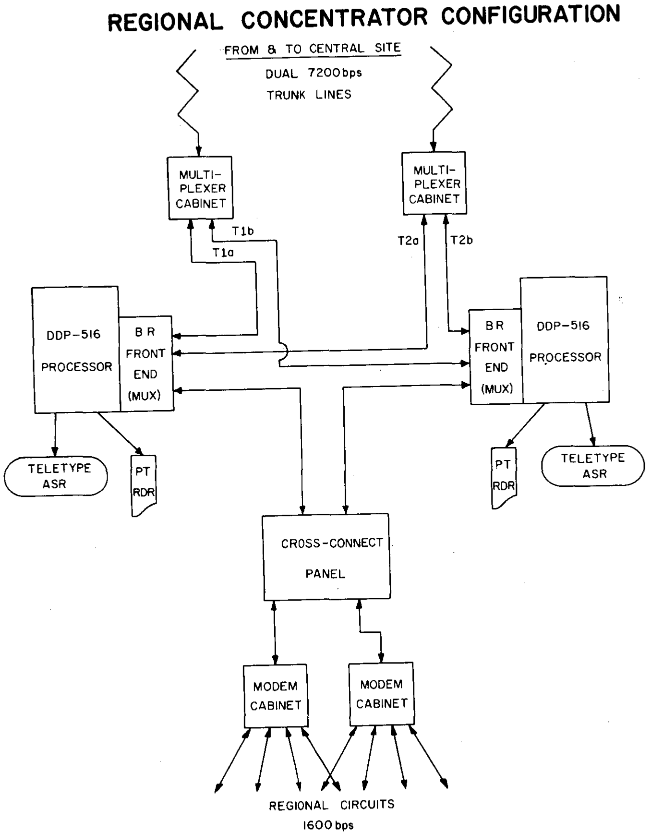

Figure 5

single design decision was that made to set-up regional concentrators for communication processing and polling. The danger of over-burdening the central processing complex with the details of terminal servicing was recognized early.

The network analysis indicated the economic benefits of concentrator placement at New York City, Chicago, San Francisco, and Atlanta. This divided the communication network of leased lines into two levels:

- dual trunk lines transmitting point-to-point between the central site and the concentrators synchronously at 4800 bps. (To and from New York City at 50 K bps.)
- regional circuits between the concentrators, and the control units in the brokers' offices, transmitting asynchronously at 1600 bps, as private line multi-point duplex data circuits. (Asynchronous in order to match the most suitable modem and the chosen line speed.)

At each regional concentrator site, the following equipment was installed (see Figure 5):

- A pair of unitary configurations each backing up the other with:
  —A Honeywell DDP-516 processor (16K Core)
  —A Bunker Ramo designed and built communication front-end interface
  —A paper tape reader
  —A teletype Model 35 ASR
- Connecting this pair of units with its regional lines are:
  —a cross-connect panel
  —two Multiplexer Control Cabinets
  —two Modem cabinets

With this concentrator structure, it was possible to introduce priority handling and line controls at the regional level. For instance, full duplex use of the regional circuits became effective with the introduction of nested polling initiated by the concentrator. With the multi-station local control units all riding their assigned regional circuits, polls could be nested into individual messages and be recognized by the proper addresses at a great saving in traffic load and message turn-around time. This technique also tends to equalize the service for all terminals, by giving priority in the polling process to control units in offices with multiple CRT's.

AUTOMATING THE OTC TRADER'S FUNCTIONS

An often somewhat neglected aspect of system design, the human interface, had to be studied carefully,

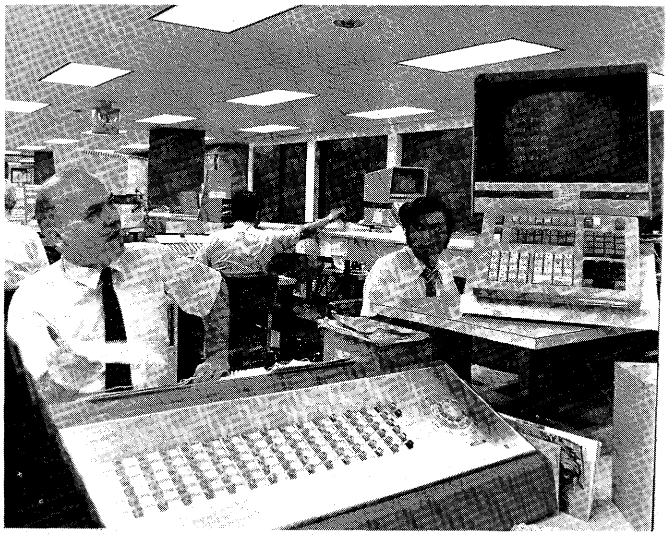

Figure 6

and be coped with realistically for this project to get off the ground. The extraordinarily hectic environment of the trading room of a busy brokerage house has to be seen and heard to be believed (see Figure 6—an unbusy example).

Of course, Bunker Ramo has had some experience in this industry, dating back to 1929 for the first automatic dissemination of quotations. But the direct input of data by the broker at his desk was something entirely new, and a somewhat frightening prospect for seasoned real-time computer professionals.

For NASDAQ, this meant first of all the keyboard layout, and the ease of entry message generation. Thus, a unique keyboard was designed from the table up for this new type of user (see Figure 7), which attempted to support his manner of operation, and to avoid appearing overloaded and baffling. Special function keys directly expedite the setting up of certain messages. In particular, the broker maintaining a quotation in the system is able to change it rapidly with a few keystrokes, or with little more than a directional character (↑ or ↓) to cause the normal change of ⅛th of a point. Other design advances contributed to an overall layout which sought to give the user a "congenial" keyboard. It seems to have succeeded.

The second terminal area to which human factors concerns were applied was the query/response display content. Actually the processing logic of the whole system became query/response oriented by conscious decision. No demand to respond to computer processes is put upon the user. The entries the user transmits are accepted as a whole and displayed as updated for the user to verify or are rejected with an explanatory message, which does provide some self-teaching interaction. The effect has been to enable the users to get what they want from the system with next to no training.

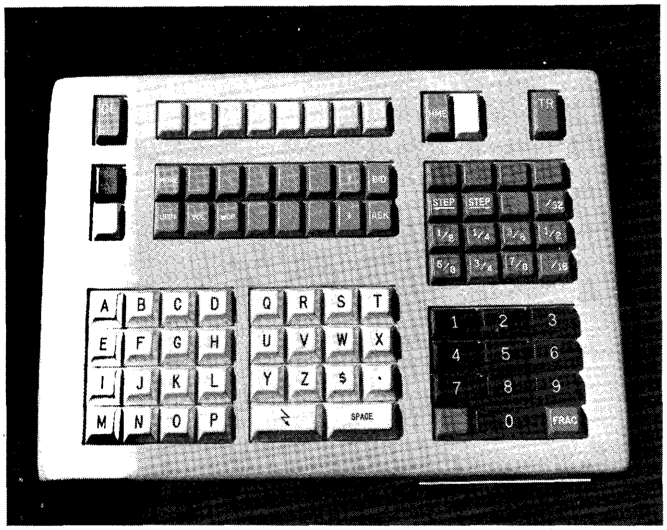

Figure 7

Just behind the individual terminal, supporting up to 24 of them per office, is the O.T.C. Control Unit (OCU). This unit handles the refresh, character generator and control logic for the CRT's. It also provides some by-product functions that assist the user. For instance, it generates a unique office and device address, which it prefixes to every out-going message, thus ensuring protection to the firm's quotations, and enabling office oriented services to be selectively implemented by software processes.

As an example of the flexibility of the OCU, there was the necessity to cope with a late addition to the functional requirements as originally specified. Some brokers wanted to be able to capture the changes in their own quotations as they were entered into a NASDAQ terminal, and post them on automated display boards in their own offices. This was implemented for such users by setting a special bit in the response which would signal the OCU, and by supplying a "Local Post" key on the keyboard to permit such local transmission when desired for non-NASDAQ securities.

This then completes a capsule description of the major hardware elements at each level of the system. It has proved to be a smoothly functioning, coherent complex. The next sections of this overview deal with the program structure which made the system function.

SOFTWARE ELEMENTS

The major NASDAQ components in the software category are the following:

- An expanded version of Univac's "EXEC 8" operating system, supporting multi-thread, real-time transaction processing with queued file accessing and updating. Bunker Ramo extensions to this system upgraded its real-time communication control features.
- The necessary set of on-line functional application programs, processing the full range of acceptable queries to, and required outputs from, the system.
- A hierarchy of recovery programs, designed to reallocate system elements, to restart, or to drop to degraded service as necessitated by conditions.
- A series of off-line processing programs to handle file maintenance tasks, report production, and pre-processing to optimize the file structure of the next day's on-line operations.

- A communications control program to function in each of the DDP-516's of the remote concentrator configurations for:

  —polling each control unit and servicing each regional circuit
  —store-and-forwarding message traffic
  —managing buffer resources and time clock functions
  —printing out (at NYC) the newspaper transmissions
  —monitoring circuits for error rates which might predict line deterioration, and alerting operations personnel to the need for intervention.

- An overriding time-monitoring program to initiate at pre-set times various activities such as:

  —opening or closing all active securities
  —calculating index values
  —disseminating data to news media
  —halting the volume reporting function

- A many-faceted program providing supervisory access of several types to the system and its data as follows:

  —on-line entries to cause immediate display or alteration of file contents
  —on-line intervention to change system parameters or time functions
  —on-line entry of file maintenance transactions for off-line processing
  —off-line batched transactions for normal file maintenance

CREATING A CLEAN MESH OF SOFTWARE

Developing all the elements of the total software environment required a staggering amount of coordination and attention to detail. The general principles followed were the standard ones for real-time programming such as:

—reentrant and reusable code
—dynamic buffering
—program overlays
—record lock-out during update
—automatic system recovery and restart
—queued file accessing within multi-thread logic
—multi-processing utilization of dual processors

On top of taking full advantage of the current "state of the real-time art," certain solutions to problems unique to this system deserve mention.

1. The analysis of expected traffic had highlighted the predominance of quote requests, and among them, for the "top of the list" for any security, that is, what would be the first quote frame on the CRT. The rest of the list of quotations is obtained frame by frame as a "MORE" key is pressed. To save processing time with this first frame frequency, it was decided to keep it always pre-formatted in the security record ready for immediate transmission.
2. In a similar effort to expedite retrieval response, the statistics of accesses for each security are used daily to order the next day's allocating of the address keys of the most popular securities to a core-resident dictionary, and all others to a drum-resident dictionary.
3. The security of the data base was guaranteed by the storage of two copies of all on-line files in cross-drum and cross-channel locations so that the availability of any record would not be affected by the failure of any one hardware component.
4. Buffers are grouped in different sizes and requests are queued first by buffer size needed, and then shifted away from the longer queues, if possible, to the queues of the buffers next in size. Access to a drum record is also shifted to that copy of the record which resides on the sub-system with the shorter queue.

The net result of these and many other techniques has been a quite unflappable system. The meshing of all the programmed modules was accomplished before start-up with the usual around-the-clock effort, but fortunately with a minimum of unpleasant surprises and crash patching sessions.

PUSHING EXEC 8 OVER THE HUMP TO ACCEPTABILITY

Even though the operating system for the Univac 1108 had been around for a while, it was clear fairly early to the NASDAQ implementors that it had its weaknesses, and some serious gaps for real-time system control. Therefore, a special effort was directed toward identifying all the problems that turned up, and all potential problem areas as early as possible.

With alacrity and concentration, the Univac program development staff in St. Paul, Minnesota went to work and produced the necessary enhancements. Some of the improvements, however, were developed by the NASDAQ crew itself, and most of these were then adopted as part of official versions of Exec 8.

The most significant modifications and enhancements to Exec 8 were the following:

—Protection against improper mass storage assignment.

—Ability to optimize drum utilization by using absolute addressing to allocate or access mass storage.

—Ability to bring up or shut down I/O paths and units initially and dynamically.

—The aborting of I/O queues at abnormal program termination to facilitate faster reload.

—Provision for extensive logging and accounting of I/O error events.

—Ability to get "immediate functions" performed by the Exec.

—Revising the drum read and write routines to shift from one in two interleaving up to one for one interface between drum and core. This particular stratagem significantly improved data transfer speeds. It had not been regarded as feasible for the hardware involved, but the step has proven to be sound.

—Ability to reconfigure any component at any time with or without manual intervention.

—Applying the processor monitoring capabilities of the Availability Control Unit (ACU) in order to detect CPU malfunctions.

—Utilizing automatic reboot, whenever possible, to reduce the amount of operator intervention required.

—An automatic dump to high speed drum when the system has to reboot.

—The detection of a rebooting loop and signaling for operator intervention.

—The monitoring for, and the correction of a real-time error loop by automatic program reload.

—Maintaining a Master Configuration Table in core and on drum, containing the current status of the system.

—Ability for an application program to be reloaded without losing its facilities allocations.

—Entry point to Master Configuration Table to enable application programs to obtain necessary recovery data.

—A variety of enhancements of the operator interface with application programs, including a display of the program mix functioning at the time.

—A repertoire of debugging aids such as core and drum traps, dynamic core and drum dumps, and a trace routine.

—The development of a "moving picture" of core displayed on the console CRT. This is a little gem of a monitor routine for debugging and analysis work. For instance, the rhythm and pattern of dynamic buffer allocation could be observed as its core locations changed on the display screen.

—A package of test routines to shake down new levels of the Exec itself.

—A variety of lesser improvements to clean-up and remove unnecessary code, and generally to reduce overhead.

It is not too much to say that this effort was as crucial as any to the success of the total NASDAQ implementation.

THE TACTICS OF IMPLEMENTATION

The NASDAQ project got under way with the contract signing in December, 1968 between the NASD and the Bunker Ramo Corporation. The completion date specified in that contract was two years later to the day.

Many things had to be set into motion. Hardware units had to be designed, checked out and scheduled for assembly line production. A new building had to be planned and built for the central processor site. Systems design, network analysis, and computer selection all had to be tackled in short order. The early installation of the central processors was a big help to all concerned.

One of the things that was not set into motion was the functional specification after it was carefully elaborated and clarified. Of necessity, it was frozen early and fortunately was able to stay that way almost inviolate.

A relatively small crew of engineers, system analysts, and programmers (approx. 50 in all) was assembled, mostly from within Bunker Ramo, to tackle the direct system creation. They turned out to be an extraordinarily dedicated and resourceful crew. Just before Christmas in 1970 they offered a functioning NASDAQ to the waiting world. It had arrived only four days late, and it stayed arrived.

THE PARCEL OF SUBSIDIARY FUNCTIONS

As in most such systems, a variety of subsidiary functions were included in the functional specification, and then turned out to require a major part of the effort. These bonus components, all of which were safely on board when NASDAQ started functioning included the following:

—A median quote, called the Representative Bid/Ask (RBA), for display on the top line of every quote frame, and for public dissemination.
—A set of indices for the OTC market, based on all the stocks in the system, for retrieval and dissemination.
—The display of news bulletins in response to requests from any terminal.
—The provision of direct transmission of RBA's and Indices to the quotation and newswire services.
—A full gamut of overnight off-line processing to prepare the data base for the next day with all file changes made, to produce regulatory reports for the NASD, and to provide statistics on system behavior.
—The support of all varieties of supervisory intervention and file adjustments entered on-line, with some requiring action immediately on-line and some held for off-line processing.

This last area generated the largest single module of programming and required extensive rearrangements in the overlay logic. These areas as a whole required more extensive testing than all the rest of the system combined. In fact, the last critical hurdle before start-up was the satisfactory completion of that part of the cycle which went through the off-line processing from the end of one day into the start of the next day.

THE TEST TO END ALL TESTINESS

To guarantee that the NASD and all its user-members would find nothing in the system to get upset about, a frontal attack on all aspects of the system was mapped out. The functional, supervisory and communication functions in all their complexity required exhaustive testing. The system's capacity also needed testing under over-loaded traffic conditions.

How could we throw every possible permutation and combination of query at the system and verify that we were getting the correct, prescribed response? The type and content of the response in turn depended on a multi-dimensional matrix of conditions, such as the brokers' type, the status of the security affected, the time of day, and the other quotations already entered. In other words, to predict any particular query/response pair, we would have to establish the content of the data base at that point in time for that particular interaction.

Only then could we expect to isolate those responses which might be proper in form but incorrect in content.

The immensity and crucial role of this stage of the system's development forced us to become the midwife of some unique methods to meet the necessity. We realized from the start that we would have to automate the process in some fashion in order to avoid the horrendous, error-prone chore of creating exhaustive (and accurate) test data input.

The possibility of writing a program to generate a full variety of test input in query form, without responses, proved on examination to demand an extraordinary programming effort, among other drawbacks. Even to check response messages on a print-out by eye, or on a dump by programmed comparison were each clearly prohibitive prospects. There had to be a better, yet absolutely thorough method of automating the check-out of system responses.

THE SOLUTION TO OUR PROBLEM

Since 99 percent of the live input data would be entered via the CRT keyboards, and most of the output would be displayed on the CRT screens, these terminals and their control units were the critical message-formatting modules of the system. A processable query and a displayable response would have to be sent from, and be returned to, this control unit.

The accuracy of the *visual* content of keyed entries could be checked on the display before being sent, and the content of the resultant response from the system could be *visually* verified in the same way.

Could we hold this query/response pair in their message formats and then, if correct as displayed, capture the paired record on tape, or if not, divert it for diagnosis? In the second case, the encoded messages would provide precise evidence for remedial action by either programming, systems, or hardware design staffs.

The equipment to handle this task was already at hand in the form of two communication concentrators located in the Trumbull Data Center, adjacent to the central processing unit.

Thus for the test, one of these concentrators performed in its actual NASDAQ role, but as the only *active* front end for the whole system. Thus the system configuration and its software did not need to be altered in any way for test purposes. As far as the NASDAQ system could tell, it was receiving and responding to

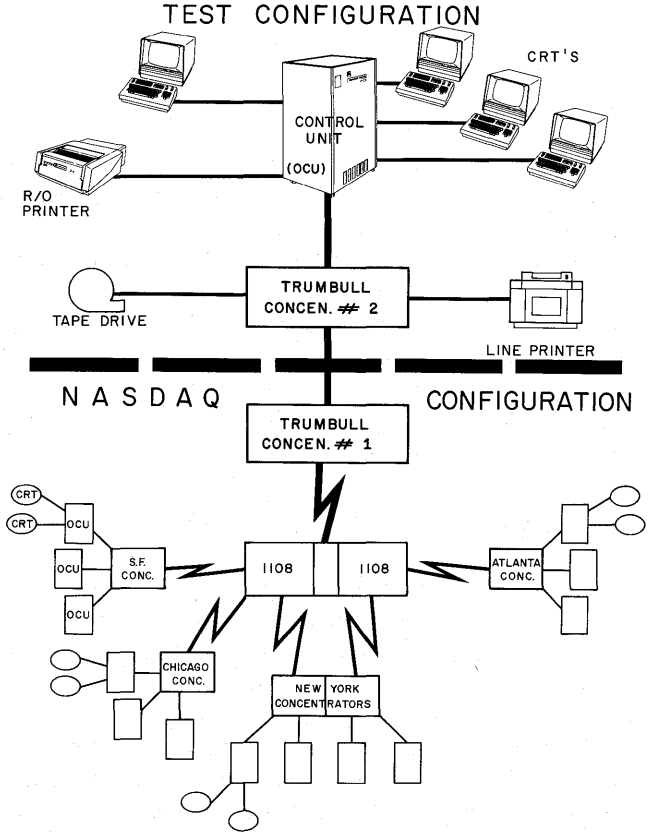

Figure 8

genuine activity from real users (see Figure 8 for a schematic of NASDAQ plus our test configuration).

The second concentrator was programmed as a test monitor and manipulator. This concentrator had to function in a two-sided fashion, appearing to the first concentrator and the central processors just like any one of many possible control units with terminals. On its other side, interacting with the test control units, it behaved as if it were the NASDAQ system itself. Among other facilities, this enabled us to circumvent the restrictive integrity of the NASDAQ design, which accepts file updates only when uniquely identified by the user's own hardware-supplied address.

For test manipulations in general, this programmed concentrator gave us the flexible control we needed. Its program responded to a set of control level entries from the test CRT terminals to trigger the verification capture, numbering, and printing, etc., of the test query/response pairs as created.

Early in the game we decided that we would have to simulate at least six days of system operation. This became necessary not only to allow for some gradation in complexity, but also in order to permit certain global conditions to be amply tested, such as a "delayed opening" of the market on a particular day.

We were equipped to map into core memory and drum files a check-pointed or start-of-day on-line data base which recreated a previous stopping point. Using this facility, we could push ahead with the testing effort in several different areas in parallel fashion. Otherwise with a linear check-out path, each bug would have hung us up until the necessary program patching was accomplished.

By allocating a different set of simulated securities to each major function, we were also able to work around any buggy area until it was ready to be tested again. Within each of these allocations, a spectrum of security types and market maker positions was developed in order to exercise every conceivable variation.

In addition, we set up separate charts to keep track of every scripted entry that generated a line on one of the required off-line, "overnight" reports.

CARRYING OUT THE TEST

Anyone who has ever been involved with the demonstration of an on-line process knows what happens next. With everyone crowded around to watch, the previously infallible gear or program begins to fall apart with a spectacular display of recalcitrance. Well so it went. We set the stage, everyone held their breath, and then the first query we keyed in proceeded to pull down the whole software structure.

Of course, with only six weeks to go before cutover, there was consternation, pandemonium, and dire forebodings from all sides. Scrutinizing the wreckage, the programming team quickly spotted and repaired the fatal flaw. It turned out to be precisely the type of problem that live volume testing or actual use would eventually have hung up on. The unique feature of that first frame was simply the use, in a particular function, of a security whose initial letter was beyond "S" in the alphabet. Our test scripting fortunately had the range of detailed variation to catch this situation.

When all the smoke had cleared, we resumed our testing effort and this time the scene settled into a more normal process.

The check-out continued right up to start-up time, and helped assure everyone that all was well with NASDAQ.

ACHIEVING RELIABILITY

The reliability of the NASDAQ system is by now an accepted fact of life for the OTC market. System performance has been on an uninterrupted basis for 99.92 percent of the scheduled time since January 1, 1971 (total down time of one hour and 57 minutes in 2,376 hours of operation).

Reliability is, of course, critical to the success of any such system after it becomes the functioning structure of a nation-wide market place. Its realization in the case of NASDAQ is the result of a web of carefully designed features.

On the hardware side, it has been due first of all, to the inclusion of units of already proven dependability in service. The long evolution of Bunker Ramo's on-line configurations for the brokerage industry now guarantees the production of terminals, control units and multiplexers which inherit a built-in reliability.

Bell Telephone lines are another matter, but in this area also, Bunker Ramo experience has served to enhance reliability. Predictions of line occupancy, by which selection of lines and transmission speeds were made, resulted in a communications network, which has:

- Provided response times averaging well under three seconds,
- Kept the message error rate, over conditioned lines, well within agreed limits,
- Provided as yet uninterrupted trunk line service by establishing dual lines with diverse routing,
- Allowed for future trunk line upgrading as needed, to 7200 and 9600 bps speeds.

Through the NASDAQ configuration, uninterrupted hardware performance has been ensured by the doubling of each processing unit for instant fallback support. Likewise, for the software side of NASDAQ, reliability has been designed into the functioning system itself.

Since non-technical users would be on-line to the system, entering data and updating files constantly in real-time, it was necessary to shield the processing from any disruptive entries. This is maintained by rigorous programmed control of all input. As a result, the system has not been "bombed" by any entry since regular functioning started.

Finally, the software provides extensive recovery facilities to get the system back-up and keep it running under a wide variety of adverse conditions, either temporary or of some duration. The fact that NASDAQ has been cited as "an outstanding engineering achievement" is due in large part to this reliability, now fully proven after nine months of service.

IS NASDAQ INVULNERABLE?

So it does seem as if Bunker Ramo "beat the odds" with the NASDAQ system. Despite all the things that could go wrong, everything seemed to click into place neatly. To observe the system functioning now at the Trumbull Center is to see nothing happening.

And, in that situation is hidden a new and potentially serious problem. The operators in the central site cannot avoid becoming extremely bored. There is a danger that their experience gained with a visibly struggling and trouble-loaded system in the days before start-up will now fade completely. What will happen to their ability to cope with future crises, which will, by that time, be unavoidably unique and complex? Achieving such a high level of automation can bring new problems in its wake. But since this new problem is already recognized, the remedy is on its way, we hope.

LSI Perspective—The last five years

by H. G. CRAGON

Texas Instruments
Austin, Texas

INTRODUCTION

An attempt to write the history of LSI over the past five years is a difficult task because of the lack of definition of just what is LSI—LSI means different things to different people; and there is little documented evidence on the successes and failures. I believe it is instructive to look back approximately seven years from the date of this conference to a document which, in my opinion, represents the first clear statement of the requirements for and goals of LSI.

BACKGROUND

On June 28, 1965, the Systems Engineering Group, Research and Technology Division, Air Force Systems Command issued a request for proposal for Large Scale Integrated Circuit Arrays. The problem statement and objective are quoted below.

Statement of the problem

The successful development, and subsequent production of silicon circuitry, has proven this technology capable of providing an order of magnitude improvement in reliability of systems utilizing this approach. Concurrent with this improvement in reliability has been a continuing reduction in circuit function cost. This reduction has progressed to the degree that package cost for these circuit functions represents approximately 50 percent of the final cost. It has been further shown that the intrinsic reliability of the silicon integrated circuit (SIC) is at least one more order of magnitude higher than that which is achievable with the circuits after individual packaging. This indicates that predominant failures are associated with bonding and lead failures within the circuit and multilayer wiring board or interconnection failures at the system level. These failures can be further eliminated by reduction of the circuit to circuit transfers required at the subsystem level. This in turn will greatly reduce the number of individual packages with their associated input-output terminations. Thus, it is readily apparent that if these higher order circuit functions can be achieved, today's level of reliability, cost, and size reduction can be further improved. It is the objective of this program to develop the technology for such an approach.

Objective

It is the objective of this program to accomplish as much as a ten-to-one improvement in reliability in electronic subsystem or systems over that presently available with today's integrated circuit capability. It is a further objective to achieve this improved reliability while simultaneously achieving enhanced subsystem performance and an overall cost reduction. These improvements will be accomplished through the sophisticated use of a large-scale monolithic integrated circuit array containing up to 1000 circuits utilizing either metal-oxide-semicondutor (MOS) or bipolar active devices with associated passive elements capable of being interconnected to perform logic for data processing, memory, and/or analog functions."

Several interesting points can be observed in these statements. First, the reasons for desiring LSI were to extend the reliability, reduced cost, and improved density factors that had been observed in the transition from transistor to integrated circuit equipment.

The second important point was that LSI was defined as having up to 1000 circuits using either MOS or bipolar devices for both logic, memory, and even analog functions.

Three contracts resulted in late 1965 from this Air Force initiative—one to Texas Instruments, one to RCA, and another to Philco-Microelectronics. The major thrust of the Texas Instruments effort was directed to the discretionary interconnection of the good cells on a bipolar slice for both logic and memory. RCA's program was to develop complementary MOS memory devices, while Philco-Microelectronics worked on the development of four-phase MOS shift registers.[1]

The conference proceedings of the AFIPS conferences provide a documented history of the computer industry; and, for this reason, most of my references are from this source. Many of the papers I will cite have bibliographies which will, in total, give an extensive reference to the field of LSI.

LOGIC IN LSI

The Proceedings of the Fall Joint Computer Conference of 1965 contain four papers dealing with cellular type array structures.[2,3,4,5] While these structures are interesting from an academic point of view, it is clear that the authors were concerned with devising a class of "standard" circuits which would perform the combinatorial logic function without a proliferation of part types.

Both the prospective user and the semiconductor manufacturer seemed completely preoccupied with this combinatorial logic problem during the period 1966 through 1968. L. C. Hobbs[6] stated in 1966 that "System designers must consider large-scale integrated circuits arrays as a new type of device that necessitates major revisions in systems design concepts, machine organization, and hardware software tradeoffs." At the same conference, Michael Flynn[7] made the assertion that "Integrated electronics should be much more than monolithic circuitry." Flynn believed that better solutions to the computer users problem would result if LSI were considered as a new component, and new computer systems could be devised which were based on this component.

The problems of unique parts and part types which LSI generates were studied extensively. Fubini and Smith[8] stated that "the total number of unique part numbers the industry may require for a typical group of different machine types may be as large as 100,000." They went on to suggest that the system reorganization would be useful to reduce this number of part types.

Robert Noyce[9] addressed the question of LSI cost and concluded that "Only standardization, plus the development of automatic design capabilities, will make integrated arrays available in the future at a substantial cost reduction compared with today's integrated circuits."

The recognition that an associative memory required standard logic distributed within the memory prompted several research projects in this technology. One such program was described by Ryo Igarashi and Tora Yaita[10] in 1967.

LSI MEMORY

Perhaps the seed of the first really successful LSI was planted when the computer designer's attention turned from the logic problem to the use of LSI in the memory function. Gibson's[11] paper on "*Considerations in a Block-Oriented System Design*" at the SJCC in 1967 discussed how a small but fast memory could be used to enhance the performance of a large but slow memory. In retrospect, it is obvious that this paper describes the "Cache" concept employed by IBM in some of the 360 and 370 computers. While the devices used in Mod 85 cache cannot be called LSI, a trend in the use of higher levels of integration was beginning to emerge.

At the FJCC of 1968, Conway and Spandorfer[12] discussed system enhancement applications for LSI where complete rethinking of the historical computer architecture art would not be required. Of the 10 enhancement application areas cited, 5 concerned random access memories and 1 the use of read-only memory for microprogramming.

This same conference in 1968 received a paper by Sanders[13] on semiconductor memory circuits and technology. He stated that "The manufacturing process for semiconductor memories is characterized by mass production of similar items." The industry had finally and clearly identified the first home for LSI! Since 1969, we have seen the cost per bit battle rage between the semiconductor memory manufacturer and the core memory manufacturer.

It would appear that most computer systems designers had not considered the significant cost reduction in the total cost of the hardware that would result by the use of low cost LSI memory devices. While observing that the memory represents 25 percent of a computer's main frame, we still struggled with the problems associated with replacing the 15 percent cost of the logic.[1] The core memory manufacturers were not ignoring this point, however, as core prices dropped by 30-50 percent during the 1969-1970 period.

Some of the first semiconductor memory devices were quite small; 16 bits. The technology has developed to the point where 1024-bit MOS devices and 256-bit bipolar devices are now being delivered in quantity by several manufacturers. As these devices contain the decoding logic, the problem of an excessive number of pins required for logic LSI has been circumvented.

We must conclude that these devices are true LSI as originally defined by the Air Force in 1965. We can expect that memory devices of greater capacity will continue to be introduced over the coming years.

The introduction of the IBM 370/145 with an all-semiconductor memory must establish that this technology is mature with the only question left being the upper limits on the number of bits on a chip. The memory device used is a 128-bit chip with four of these chips contained within a package giving a package of 512 bits.[15]

LSI LOGIC REVISITED

I wish to return to the question of logic in LSI. The concept of microprogramming advanced by Wilks[16] in 1951 is becoming a reality due to the availability of LSI read-only memory devices which make microprogramming an economic technique. The large number of mini-computers using microprogramming in conjunction with an ever expanding family of MSI logic devices is evidence of this success.

MSI logic devices are now being offered in excess of 100 device types by several manufacturers. These devices have provided the computer designer with the capability of designing very compact equipment using high volume production devices with the resulting low cost and high reliability. Many of size, cost, and reliability goals of the original LSI concept have been approached to a degree that seems to be acceptable from an engineer's point of view.

The quest for standard logic part types has made possible a new product that has swept the world in the last two years. This product is the electronic desk calculator. These calculators, in general, have one, two, or three MOS chips which make up the complete logic and memory function. It is difficult to trace this development in the computer literature because this product is not called a "computer." But, when one considers the complexity levels of the devices used in these calculators, one must conclude that LSI has scored another success. A typical single-chip calculator contains approximately 5000 MOS transistors on a bar having an area of approximately 25,000 square mils. This success has come about because there is a high volume requirement for a small number of part types having only a few pins. It is reported that 2,000,000 desk calculators of various types will have been produced in 1971. The fact that a device as complex as the desk calculator can be purchased for a few hundred dollars should revive the thinking on the distributed computer concept, but I will leave future projections to another author.

CONCLUSIONS

I can only conclude that LSI has been a success. When the manufacturer and the user worked together on real problems, then truly remarkable feats were accomplished. The one thousand bit memory device and the desk calculator stand as conclusive evidence. The search for applications of LSI in the logic section of the computer goes on and will perhaps find a solution which has economic justification.

Toward more efficient computer organizations*

by MICHAEL J. FLYNN

The Johns Hopkins University
Baltimore, Maryland

Two significant trends have evolved which will substantially effect the nature of computer organizations over the next ten years:

1. The almost universal use of higher level programming languages and corresponding decrease in the use of machine level programming.
2. The continued improvement in cost and performance of both logic and memory technologies.

These trends portend many changes. Most of them gradual, but certainly effecting the nature and perspective that we currently hold of computer organizations and their future evolution.

The machine language programmer of today does not program in assembly code for convenience. He codes almost exclusively for reasons of efficiency requirements, that is, the control of the physical resources in an optimal way. Ease of use is not as important a consideration in the development of a machine language as efficiency. This coupled with technological improvements, especially in the area of memory, portend the first significant change in computer organizations: the increase in use of parallel "or concurrent" operation of the resources of the systems. Since the hardware is inexpensive, units are made autonomous in the hope that their concurrent operation will produce more efficient program performances. "Efficient" in this sense is the respect to the user program and its performance, not with respect to the busyness of some internal subcomponent of the system.

There are several forms of parallelism: First, one may have concurrency of operation within a (internal) Single Instruction stream-Single Data stream (conventional type) program. In fact, this concurrency may or may not be transparent to the programmer. The second form of parallelism involves the use of multiple streams in programs.

IMPLICIT VS EXPLICIT PARALLELISM

Implicit concurrency or parallelism may be grossly characterized as that degree of concurrency, achieved internal to the processors, which is not visible to its programmer. Thus explicit parallelism is that concurrency of functional execution which is visible to the programmer'and demands his attention and exploitation. To date most attempts to take advantage of the two earlier mentioned trends have used a form of implicit parallelism. The machine designers attempted to achieve a certain concurrency of execution which is transparent to the problem program (machine language) by "wiring in" the concurrency control and preserving the use of older machine languages; thus the existence of the cache type[1] memory, as well as heavily overlapped computer organizations.[2]

Cache memory involves the use of high speed buffer memory to contain recently used blocks of main memory storage in an attempt to predict the subsequent memory usage requirements—thus saving the slow access time to storage.

The overlap organization involves the multiple issuing of instructions concurrently. When more than one instruction is in process at a given time, care must be taken that the source and sink data are properly interlocked.

Notice that much of the implicit parallelism is a direct result of the present nature of the machine language instruction. Rather than change the definition of the present machine language instruction to make it more complex, the manufacturers essentially standardize on it and use it as a universal intermediate programming language. Thus it has the aspect of transportability not usually found in other languages. Notice the ma-

* This work was supported, in part, by the U. S. Atomic Energy Commission under contract AT(11-1)-3288.

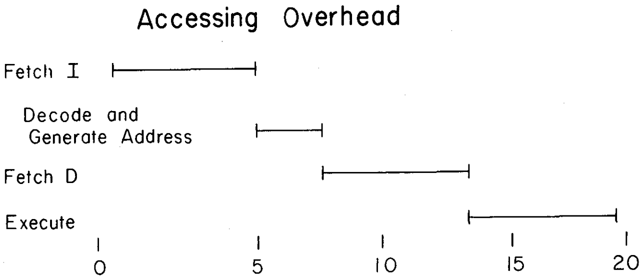

Figure 1—Conventional instruction

chine language instruction is not an ideal vehicle to allow one to control the physical resources of the system since the concurrent control is achieved automatically, without the possibility of any global optimization.

EXPLICIT PARALLELISM*

How can the control of the resources of the system be made visible to the programmer? First let us review the evolution of the machine language as we know it and compare it with microprogrammed systems.

An essential feature of a microprogram system is the availability of a fast storage medium. "Fast" in this sense is used with respect to ordinary logical combinational operations. That is, the access time of the storage device is of the same order as the primitive combinational operations that the system can perform—the cycle time of the processor. Another important attribute of modern microprogrammed systems is that this "fast" storage is also writable, establishing the concept of "dynamic microprogramming." It is the latter that distinguishes the current interest in microprogrammed systems from earlier attempts using READ-ONLY memory.[3–5] Consider the timing chart for a conventional (nonmicroprogram) machine instruction (Figure 1). Due to slow access of instruction and data, a substantial amount of instruction execution time is spent in these overhead operations. Contrast this with the situation shown in Figure 2, illustrating the microprogram's instruction. In Figure 2 there is an implicit assumption of homogeneity of memory, that is, that data and operands are all located in the same fast storage as the instructions. The latter assumption is valid when the storage is writable.

The preceding implies another significant difference in conventional machines and microprogrammed machines—the power of the operation to be performed by the instruction. In the conventional machine, given the substantial accessing overhead, it is very important to orient the operation so that it will be as significant as possible in computing a result. To do otherwise would necessarily involve a number of accessing overheads; thus we have the evolution of the rich and powerful instruction sets of the second and third generation machines. With dynamically microprogrammed systems (Figure 2), the powerful operation will do no more than a sequence of steps. Indeed, the rich instruction operation may (if its richness is done at the expense of flexibility) cause an overall degradation in system performance.

EXPLICIT INTERNAL PARALLELISM (see Figure 3)

In the traditional system, since the overhead penalties are so significant, there is little real advantage in keeping the combinational resources of the system simultaneously busy or active. This would mean that perhaps 17 or 18 cycles would be required to perform an instruction rather than 20—hardly worth the effort. A much different situation arises with the advent of dynamic microprogramming.[6] Consider a system partitioned into resources, e.g., adder, storage resources, addressing resources, etc. If the microinstruction can be designed in such a fashion that during a single execution one can control the flow of data internal to each one of these resources, as well as communicate between them, significant performance advantages can be derived. Of course these advantages come at the expense of a wider microinstruction. The term horizontal microinstruction has been coined to describe the control for this type of logical arrangement.

RESIDUAL-CONTROL IN DYNAMIC MICROPROGRAMMING

The preceding scheme sacrificed storage efficiency in order to achieve performance. Schemes which attempt

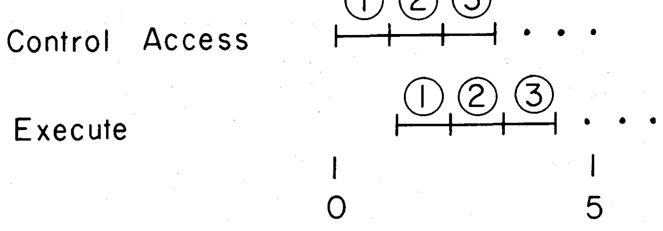

Figure 2—Microprogrammed execution

[*] The remarks on microprogramming are abstracted from Reference 15.

to achieve efficiencies both in storage and performance can be conceived, based upon an information theoretic view of control and storage. Much information specified in the microinstruction is static, i.e., it represents environmental information. The status remains unchanged during the execution of a number of microinstructions. Many of the gating paths and adder configurations remain static for long periods of time during the emulation of a single virtual machine. If this static information and specification is filtered out of the microinstruction and placed in "setup" registers, the combination of a particular field of a microinstruction with its corresponding setup register, would completely define the control for resource (Figure 4). This sacrifices nothing in flexibility—it allows for a more efficient use of storage.

EXTERNAL PARALLELISM—SIMD

Explicit parallelism may be internal as in the earlier discussion or external, that is, where the programmer directly controls a number of different items of data (Data Streams) or has a number of programs executed simultaneously (Instruction Streams). We refer to the first type of organization as a single instruction stream, multiple data stream (SIMD).[2] There are three kinds of SIMD machine organizations currently under development: (1) the array processor,[7] (2) the pipeline processor,[8] (3) the associative processor.[9]

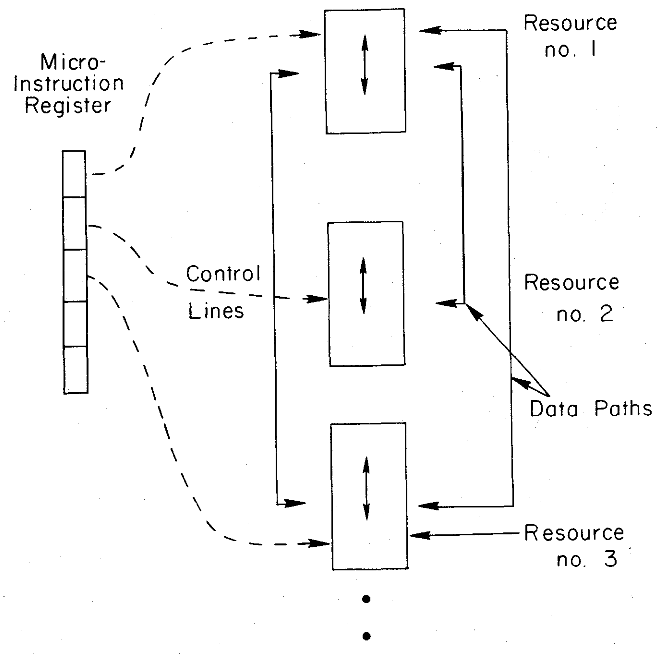

Figure 3—Simultaneous resource management

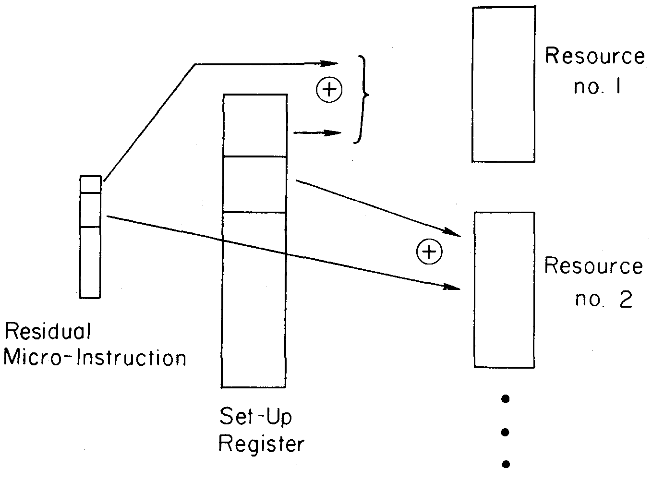

Figure 4—Residual control in microprogramming

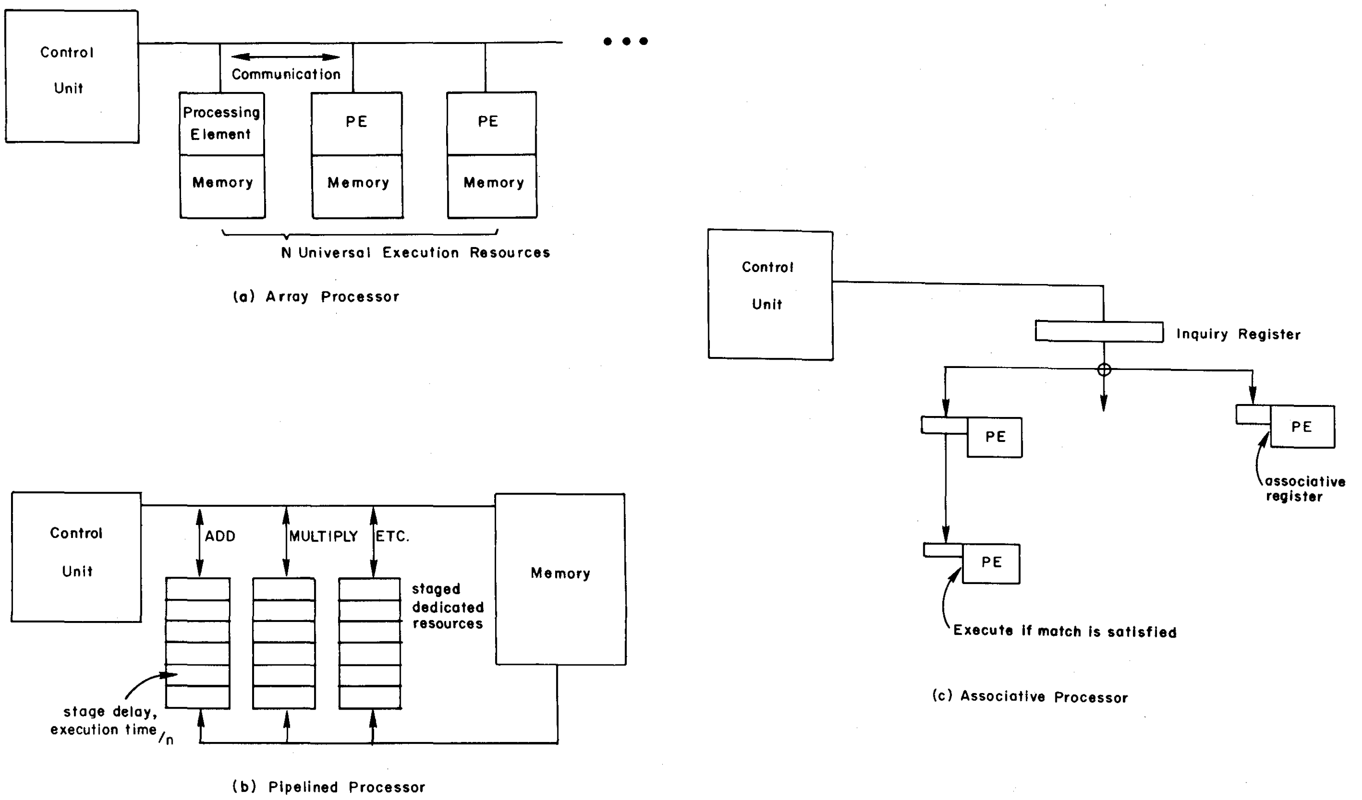
While these systems differ basically in their organization of resources and their communication structures, their gross programming characterizations are quite similar. One instruction is issued for essential concurrent execution on a number of operand data pairs. Figure 5 illustrates each of the three organizations. In the array processor the execution resources are replicated n times. Since each set of resources is capable of executing an operand pair, in a sense each resource set is an independent slave processor. It may indeed (and usually does) have its own private memory for holding operand pairs. Since each processing element is physically separate, communications between the elements can be a problem. At least it represents an overhead consideration.

The pipelined processor is in many ways similar to the array processor, except that the execution resources are pipelined. That is, they are staged in such a way that the individual staging time for a pair of operands is $1/n$ of the control unit processing time. Thus n pairs of operands are processed in one control unit time. This has the same gross structure (from a programming point of view) as an array processor. But since the pairs of operands reside in a common storage (since the execution units are common) the communications overhead occur in a different sense. It is due to required rearranging of data vectors in proper order so that they may be scanned out at a rate compatible to the pipelined rate of the execution resources.

Both array processors and pipelined processors work over directly addressed data pairs. Thus, the location of each pair of operands is known in advance before being processed.

The associative processor is similar in many ways to the array processor except that the execution of a



(a) Array Processor

(b) Pipelined Processor

(c) Associative Processor

Figure 5—Some idealized SIMD processor (a, b, & c)

control unit instruction is conditional upon the slave unit matching an inquiry pattern that is presented to all units. Matching here should be interpreted in a general sense, that is, satisfying some specified condition with respect to an inquiry pattern. Each slave unit contains at least one pattern register which is compared to the inquiry prior to conditional execution.

Each of these processor types performs well within a certain class of problem. The dilemma has been to extend this class by restructing algorithms. It has been suggested (by M. Minsky,[17] B. Arden, et al.) that instead of an ideal of n fold performance (on data streams) improvement over a sequential processor, the SIMD processor is more likely to realize

$$\text{Perf} \rightarrow \log_2 n$$

A possible rational for this is discussed elsewhere.[16]

EXTERNAL PARALLELISM—MIMD

The multiple instruction-stream multiple data-stream programs are merely statements of independency of tasks—for use on "multiprocessors." I believe that exciting new developments are occurring in the multiprocessor organization through the use of shared resources.

Two traditional dilemmas for a multiprocessor (MIMD) computer organization are: (1) that of improving performance at a rate greater than linear with respect to the increasing number of independent processors involved, and (2) providing a method of dynamic reconfiguration and assignment of the instruction handling resources to match changing program environments. Shared Resource Organizational arrangements may allow solution of these problems.

SHARED EXECUTION RESOURCES

The execution resources of a computer (adders, multiplier, etc.—most of the system exclusive of registers and minimal control) are rarely efficiently used. This is especially true in modern large systems such as CDC7600 and IBM Model 195. Each execution facility is capable of essentially processing, at the maximum rate, an entire program consisting of instructions which use that resource. The reason for this design is that, given that instruction I_{i-1} required a floating point add type resource, it is probably that I_i will also—rather than, say a Boolean resource. Indeed the "execution bandwidth" available may exceed the actual instruction rate by a factor of 10.

Another factor aggravating the above imbalance is the development of arithmetic pipelining internal to the resources. In these arrangements, the execution function itself is pipelined, as per the pipeline processor. This provides a more efficient mechanism than replication for attaining a high execution rate.

SKELETON INSTRUCTION UNITS

In order to effectively use this execution potential, we postulate the use of multiple skeleton processors sharing the execution resources. A "skeleton" processor consists of only the basic registers of a system and a minimum of control (enough to execute a load or store type instruction). From a program point of view, however, the "skeleton" processor is a complete and independent logical computer.

These processors may share the resources in space,[10] or time.[11, 12, 13] If we completely rely on space sharing, we have a "cross-bar" type switch of processors—each trying to access one of n resources. This is usually unsatisfactory since the "cross-bar" switching time overhead can be formidable. On the other hand, time phased sharing (or time multiplexing) of the resources can be attractive, in that no switching overhead is involved and control is quite simple if the number of multiplexed processors are suitably related to each of the pipelining factors. The limitation here is that again only one of the m available resources is used at any one moment.

We suggest that the optimum arrangement is a combination of space-time switching (Figure 6). The time factor is the number of "skeleton" processors multiplexed on a time phase ring while the space factor is the number of multiplexed processor "rings," K, which simultaneously request resources. Note that K processors will contend for the resources and, up to K-1, may be denied serivce at that moment. Thus rotating priority among the rings is suggested to guarantee a minimum performance. The partitioning of the resources will be determined by the expected request statistics.

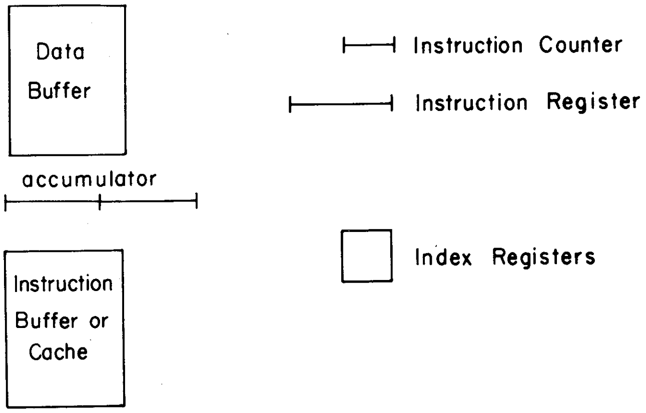


Figure 6a—Skeleton processor

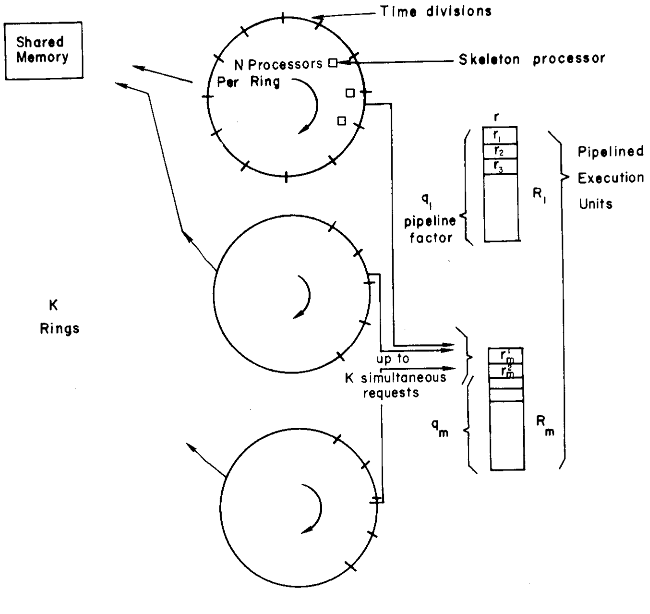

Figure 6b—Time-multiplexed multiprocessing

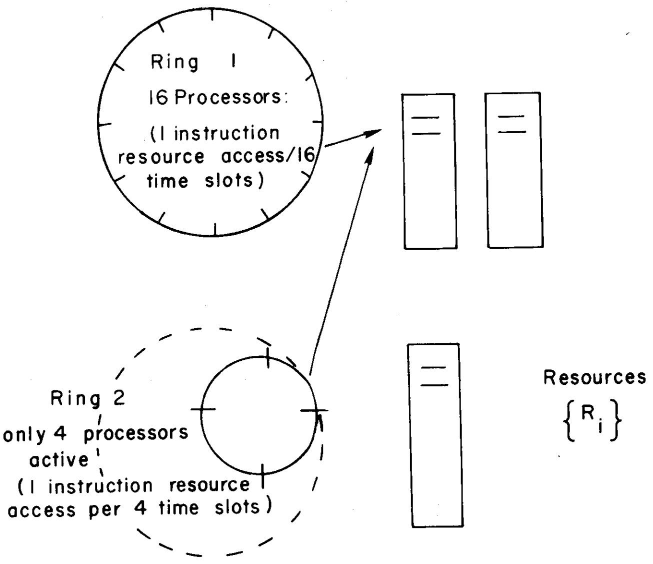
SUB-COMMUTATION

When the amount of "parallelism" (or number of identifiable tasks) is less than the available processors, we are faced with the problem of speeding up these tasks. This can be accomplished by designing certain of the processors in each ring with additional staging and interlock[14] (the ability to issue multiple instructions simultaneously) facilities. The processor could issue multiple instruction execution requests in a single ring revolution. For example, in a ring of $N = 16$

—8 processors could issue two request/revolutions or
—4 processors could issue four request/revolutions or
—2 processors could issue eight request/revolutions or
—1 processor could issue sixteen request/revolutions.

This partition is illustrated in Figure 7.



Ring 1
16 Processors:
(1 instruction resource access/16 time slots)
Ring 2
only 4 processors active
(1 instruction resource access per 4 time slots)
Resources
$\{R_i\}$

Figure 7—Sub-commutation of processors on a ring

IMPLEMENTATION AND SIMULATION

A proposed implementation of this shared resource multiprocessor is described elsewhere, together with a detailed instruction by instruction simulation.[13]

The system consisted of eight skeleton processors per ring and four rings per system. The execution resources were generally pipelined by eight stages. The proposed system had a maximum capability of over about 500 million instructions per second and was capable of operating at over eighty percent efficiency (i.e., performance was degraded by no more than 20 percent from the maximum).

THE TECHNOLOGY OF OPERATING SYSTEMS

Yet another type of parallelism involves the concurrent management of the gross (I/O, etc.) resources of the system by the operating system.

The evolution of very sophisticated operating systems and their continued existence is predicated on one essential technological parameter: the latency of access of data from an electro-mechanical medium. Few other single parameters in computing systems have so altered the entire face and approach of computing systems. Over the period of time, 1955 to 1971, access time to a rotating medium has remained essentially constant between 20 to 100 m seconds. Processing speeds, on the other hand, have increased by almost a factor of 10,000. Thus, originally we had a very simple system of scheduling. Data sets and partitions of programs were processed by simply waiting in turn as each request was processed. Today's situation requires scheduling essentially 1,000 times more sophisticated. In other words, if more than one instruction in 1,000 requires a machine to go to an idle state, we would have the same system performance, as we had in 1955. Thus the nature of the dilemma. If a technological solution, on the other hand, could be achieved with low latency for accessing large data sets, the whole need for sophisticated operating systems to sustain job queues and I/O requests would be diminished if not eliminated altogether. A great deal of time and money has been spent in analysis and synthesis of complex resource scheduling, resource control operating systems. I surmise that if a small fraction of these resources had been directly addressed to the physical problem of latency, physical solutions would have been found which would have resulted in much more efficient systems.

This remains one of the great open challenges of the next five years.

CONCLUSIONS

With the adoption of higher level languages for user convenience and the evolution of machine language for efficient control of resources, a departure in user oriented machine level instructions is seen. This coupled with the increasing performance of memory portends a major shift in the structure of the conventional machine instruction. A new structure will allow the program explicit control over the resources of the system.

With the increasing improvement in logic technology cost-performance, more specialized and parallel organizations will appear. For specialized applications SIMD type organization in several variations will appear for dedicated applications. The more general organization MIMD (particularly of shared resource type) appeared even more interesting for general purpose applications.

The major technological problems for the next five years remain in the memory hierarchy. The operating systems problems over the past years are merely a reflection of this. A genuine technological breakthrough is needed for improved latency to mass storage devices.
