INTRODUCTION

Although the last decade has seen the implementation of a very large number of compilers for every conceivable language, the literature on compiler writing is still unorganized. There are many papers on formal languages, syntactic analysis, graph theoretic register assignment, and similar topics to be sure. But, they are not very useful in helping the newcomer to the field decide how to design a compiler. Even the recent books in the field are more encyclopedic in nature than instructive. The best single book available is Gries,[1] which has a good bibliography for further study.

The few open descriptions of compilers that do exist rarely are candid about the mistakes that were made. This is, after all, human nature. Moreover the nature of scientific publishing is not conducive to papers of an evaluative or subjective nature. The principal reason, therefore, for writing this paper, is not to add to the basic body of scientific knowledge, but rather to provide a few value judgments on how compilers are being written and should be written. Since subjective statements should always be prefaced with "It is my opinion that", the indulgent reader will understand that this phrase should be applied to the entire paper.

There is an enormous amount of material to be studied in connection with compiler design. Most of it is very difficult to read. We refer to the listings of the compilers themselves and associated internal documentation. At present there is no alternative to obtaining a comprehensive knowledge of the field. Even if one is willing to put forward the effort, however, much of the material is difficult to obtain. The desire of computer manufacturers and software houses to protect their latest ideas interferes with a free flow of information. The result of this is the growth of an oral tradition for passing information much like the wandering troubadours of yore. Until this changes, there will be hardships worked on those who would like to learn the trade.

In order to reduce this paper to manageable size and to make generalizations more useful, let it be understood that we are mainly talking about so-called "production" compilers. By this we mean compilers for important languages that are intended for translating programs that are expected to be run extensively. Moreover, we restrict our consideration to compilers for medium and large scale general purpose computers. The subject of compilers for minicomputers and special purpose computers is deserving of considerable study on its own. Also research compilers, "quick and dirty" compilers, and pedagogic compilers will not be considered in this commentary. Finally, it is inevitable that someone's favorite technique will be given a short straw. For this we plead for tolerance.

SYNTACTIC ANALYSIS

In the area of syntactic analysis or parsing, the necessary solutions are clearly at hand. Parsers are now routinely constructed by graduate students as class projects. The literature on the subject is extensive, and new techniques are revealed regularly. Almost all compilers are written using only two of the many available methods however: recursive descent or precedence. Rarely are either used in pure form. Compilers that use both methods intermixed are common. Although both of these methods have their roots in the very earliest compilers, they remain the mainstays of the business.

Recursive descent

The basic idea in recursive descent is that there is a one-to-one correspondence between the syntactic units in the formal description of the language and routines for their recognition. Each routine examines the input text by either scanning for specified terminal tokens (usually produced by a separate lexical analyzer) or by calling other routines to recognize non-terminal syntactic units. Figure 1 is a flowchart of one such simple recognizer. Because most practical languages are defined recursively, the recognizers must themselves be

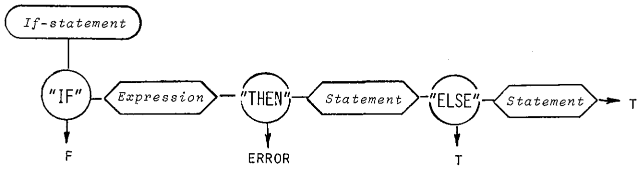

Figure 1—Recognition routine

recursive. Upon exit from each procedure, either the required syntactic unit has been recognized and the appropriate actions taken, or an error message has been produced.

Recursive descent analyzers are usually written so that it is never necessary to "back up" the input stream. If an impasse is reached, an error indication is given, perhaps a correction attempted, and the scan resumed at some readily recognizable token, such as ";". The knowledge of the context at the time an error is discovered allows more meaningful diagnostics to be generated than with any other technique.

The use of recursive descent usually requires the rearrangement of the formal syntax, since left recursions must be removed. Although this is not difficult, it does somewhat spoil the clarity of the approach. For peculiar grammars, it is easier to use recursive descent than to transform the grammar into a form suitable for precedence analysis. Although the methodology is basically ad hoc, recursive descent is the most widely used method of syntactic analysis.

Recursive descent has one further advantage for a language with a large number of productions. Precedence methods seem to require table sizes proportional to the square of the number of syntactic units, whereas recursive descent recognizers are roughly proportional to the grammar size.

Precedence analysis

The idea that operators have varying degrees of "precedence" or "binding-power" is quite old, and has been used in some of the earliest compilers. The formalization of precedence relations between operators actually started with Floyd[2] in 1963. Now it is more customary to define precedence relations between all syntactic units. While very few production compilers have used a formal precedence parser yet, the modern implementation of these techniques such as described by McKeeman,[3] is clearly destined for wider use.

The fundamental attraction of precedence methods lies in the automatic construction of analyzers from the formal grammar for the language to be analyzed. Parsers built in this way can be quickly changed to reflect language changes simply by changing the tables without modifying the underlying interpretation algorithm. Furthermore, if the tables are constructed by formal methods, the language accepted is exactly that specified and no other. This considerably simplifies the construction of bug-free parsers.

There are some drawbacks to parsers built wholly around precedence methods. For example, many languages in everyday use, such as COBOL and FORTRAN can simply not be made into precedence languages. Even PL/I can only be fit into the correct mold with considerable difficulty. Moreover, the tables required can be quite large.

A major problem with precedence parsing methods is the problem of recovery from source program errors and the issuance of good diagnostics for such errors. Several approaches to solving this problem have been tried with only modest success. Various techniques for reducing the size of the tables required, such as the introduction of precedence functions, serve only to complicate this problem.

Nevertheless, there are several conditions that suggest strongly that a precedence parser of some variety should be tried. If, for example, a parser must be produced in the shortest possible time. Precedence parsers tend to be easy to debug. A further advantage is gained if the language is being designed at the same time as the compiler, since the language can be made into a precedence language. Finally, a precedence parser is often a most suitable alternative when recursive procedure calls required for recursive descent parsing are either impossible (as in FORTRAN) or expensive (as in PL/I).

Mixed strategies

A number of compilers use the technique of recursive descent for analysis of the larger syntactic units such as statements, and turn to precedence methods for parsing expressions. In this case, simple operator precedence analysis is customarily used. There is no conceptual or practical difficulty in accomplishing this since the expression recognizer requires relatively small tables which may easily be hand constructed. The number of calls on procedures is minimized (normally a high overhead item) and perhaps the best of both worlds is achieved.

The idea of mixing parsing techniques can be generalized. It appears (with no theoretical foundation as yet) that a good partition is achieved when the subgrammar to be parsed with a precedence parser results in a relatively dense precedence matrix, and the subgrammar to be parsed with a recursive descent parser would result in a relatively sparse (for legitimate symbol pairs) precedence matrix.

INTERNAL REPRESENTATION

Generation of code occurs simultaneously with syntactic analysis only in very small compilers and quick and dirty compilers. In most compilers the results of syntactic analysis are stored for later code generation. A number of ways have been described for the internal representation of the results of parsing, two of which have attained really wide usage: tree structures (most usually a form known as triples) and late operator Polish notation. Figure 2 illustrates several forms of the representation of a simple expression. Form (a) is a binary tree, called triples when recorded in the tabular form shown, since each line consists of an operator and two operands. The result of each operator is known implicitly by the line number of the triple. Form (b) is a tree form with variable sized nodes. Form (c) is the Polish form and is actually the string that results from traversing the terminal nodes of a parse tree in a prescribed order.

The simpler compilers prefer the Polish representation since subsequent processing usually amounts to simply a linear reading of the text. Fortunately the order in which action is to be taken by the code generator is very nearly that of tokens in the Polish string anyway. Since this is also the order of generating the Polish string, the only advantage gained from deferred generation is that obtained by a full reading of all of the text, including declarations, implicit as well as explicit. Although optimization can be implemented on internal representations in Polish form, tree forms are much easier to work with.

1	C
2	D
3	A
4	B
5	$*_2$ (1)
6	$+_3$ (3)

Figure 2—Internal representations

A further advantage of Polish strings is that they may be easily written on and read from sequential data files, are conceptually simple, and require a minimum of additional space for linkage information. If memory space is at a premium or the simplest representation is preferred, Polish strings are recommended.

Complete representation of the source program in tree form is now growing in popularity, and has appeared in quite a number of the more recent compilers. It is especially prevalent in compilers for major languages for the larger machine in which optimization is important. The ease with which the program can be searched and/or rearranged is the primary motivation for this selection. For building a generation system based upon formal semantics, an internal tree representation is a good choice. Not only does it appear that code generation can be formalized but also that optimization strategies can be formalized utilizing the idea of transformation sets defined over trees.

SYMBOL TABLES AND DICTIONARIES

Considerable effort has gone into devising symbol table routines that have all of the desirable properties of compactness of storage required, speed of access, and simplicity of construction. The result is that almost all compilers use some variant of the hash link method. In this method, the symbol to be looked up is first hashed into a reasonably small range such as 31 to 512. This hash index is then used to access the head of a list of symbols with the same hash value. This is shown schematically in Figure 3. This hash chain is frequently ordered, say alphabetically, to reduce further the lookup time.

The dictionary information associated with each symbol may either be included directly with the external representation or be contained in a separate table. Since in a multiple pass compiler, the external representation is not required after the lexical analysis is complete, the separation of symbol table and dictionary has become customary.

It is becoming increasingly important to make provision for symbol tables and dictionaries to grow beyond the bounds of the available main memory. This presents no unusual problems for hardware systems that

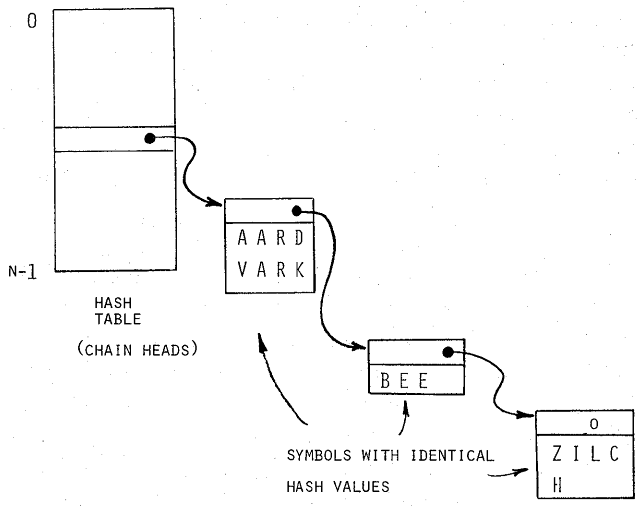

Figure 3—Hash chain symbol table

support virtual memory, but does require careful attention if it must be strictly software supported. The simplest and usual method is to divide the space required into pages and to address this space through an availability table. This method is used in the IBM PL/I compiler (F-Level) to allow the compilation of very large programs on a relatively small machine. In designing symbol table methods for use with software virtual memory, a premium is placed on minimizing the number of references to different blocks.

Compilers for block structured languages with immediate code generation usually allocate new dictionary entries in stack fashion. That is, new entries are placed in first position on the correct hash chain. Searching the hash chain then automatically gives the correct instance of the symbol searched for. At block closure, all the chains are pruned until an enclosing block number is found. The table is then shortened to the level that existed at block entry. In this way, symbol table entries that are no longer needed by the compilation are constantly discarded. Although PL/I is block structured, this very simple approach is not available without refinement. In PL/I, declarations may at any point be made in enclosing blocks. For examples, lables on entry statements belong to the immediately enclosing block, implicitly declared variables belong to the outermost block, and variables declared with the EXTERNAL attribute are scopeless.

TABLE MANAGEMENT

Early compilers had fixed size tables for storing information needed during compilation. Since the relative size of these tables could only be statistically determined, unnecessary limitation in the size of programs that could be compiled frequently occurred. During the 1960's however, dynamic allocation of storage came into widespread use. Although many techniques have been invented, only two have proven extremely popular: movable, contiguous tables, and block allocation.

Movable tables

The conceptual simplicity of having tables in consecutive memory locations is a major reason for adopting the idea of "floating" tables. The additional burden of referencing all entries indirectly through a current table base pointer is a small price to pay for this simplicity. First used in compilers by Digitek in a series of minicomputer compilers and by IBM in a COBOL compiler for the IBM 7090 in the early 1960's, the basic ideas have been widely adopted. Modern computer architecture that makes both base addressing and indexing simultaneously available makes implementation extremely simple.

Every table is allowed to grow (or shrink) independently. Before any table expands, a check is made to see if there is available space. If not, space is made available

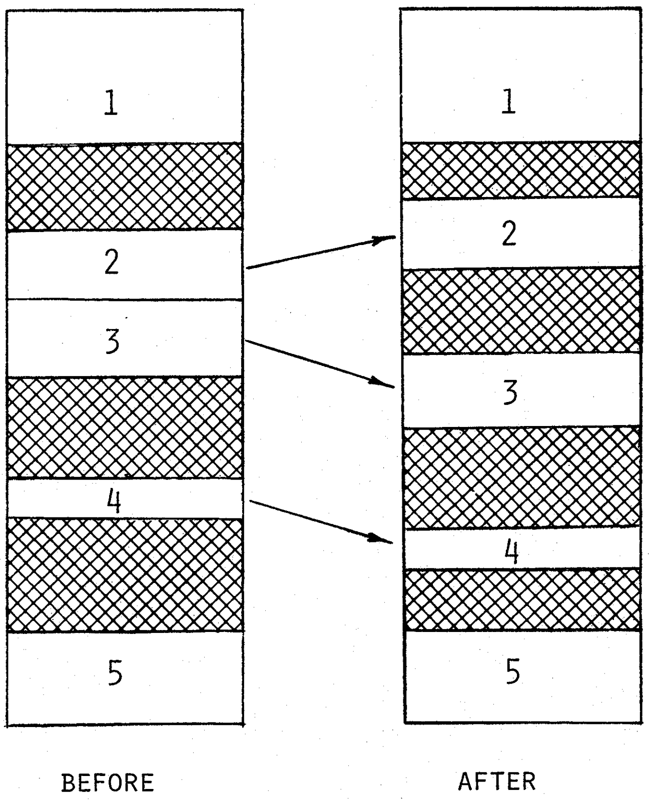

Figure 4—Movable table storage allocation

by actually copying the data items in the tables to be moved into another location in memory. Although copying data in memory to reorganize storage seems inefficient at first, it turns out to be quite satisfactory in practice since it occurs rarely. Figure 4 shows how tables are rearranged to allow available space for all tables to grow.

The interesting questions about this form of allocation revolve around deciding how much of the available space to allocate to each table. Garwick suggests that space be allocated in proportion to how much each table has grown since the last allocation. CITRUS (the storage allocation package in the IBM COBOL compiler) required specification of the desired increment of space. Most common is dividing the remaining space proportional to the current size of each table (with some prescribed minimum). All methods will run out of space only when there is absolutely no more. This may not be desirable, though, since considerable time will be spent trying to squeeze in the last item before overflow occurs.

Movable tables seem to work best for relatively small memories, for machines in which internal speeds are fast relative to I-O speeds, or for systems in which all available memory is allocated to the compiler at the start of any compilation.

List structures are complicated by the necessity to use relative links rather than absolute addresses and to identify the table pointed to.

Block allocation

Block allocation methods are the second most popular storage management technique. In this case, tables are not kept in contiguous locations, and information is usually linked together. Each routine that may add data to a table is responsible for requesting a block of suitable size (sometimes a system fixed size) for the purpose at hand. Usually space is allocated in multiples of the basic element size of the table at hand in order to avoid calling the main allocator too often. Since OS/360 implements this form of allocation as a primitive in the operating system, this form of allocation has been quite widely used on that machine.

This technique does have the principal advantage that since table segments are not moved after allocation, absolute pointers may be used in list structures. It suffers from the drawback that storage fragmentation can occur and may prevent usage of all available memory.

Block allocation is suggested whenever memory is a resource to be shared with other simultaneous users of the machine in a multiprogramming environment. This is because it is desirable to minimize the amount of memory required at any given time, and most main memory allocation algorithms supported by operating systems do not guarantee that additional memory will be allocated contiguously with previously allocated memory.

IMPLEMENTATION TECHNIQUES

Early compilers were invariably written in assembly language; most still are today. It was originally felt that only assembly language could yield the efficiency that was required in such a widely used program as a compiler, and that the required operations were not well supported by higher level languages. Although it has now been generally recognized that very little of any compiler needs to be "tightly coded" to achieve nearly the same efficiency, the tradition of assembly coding is dying a slow and painful death.

A second reason usually given for writing a compiler in assembly language was to minimize the space that the compiler required for its code. Factors of 1.5 to 3 have been cited. With the growth of main memory sizes available, the almost universal availability of random access secondary storage, and the common use of dynamic loading techniques, the requirement for small code has been considerably reduced in importance.

Advocates of coding in "higher level" languages have not always been completely candid in their arguments either. It is frequently stated that one of the main motives for using a higher level language is the gain in readability that occurs. Anyone who has tried to read a compiler written in FORTRAN knows that this simply is not the case. A much stronger case may be made for PL/I or ALGOL. The fluidity of these languages plus the natural benefits of block structuring generally result in code substantially more readable than assembly code.

A major drawback to most higher level languages for coding compilers is that the native data types manipulated in these languages are neither those required in either lexical scanning, nor those required for table management. Both of these are vitally important in compiling, and result in the construction of subroutines, frequently in assembly code, to support them. The linkage overhead in using these routines can be substantial.

By all odds, the most compelling reason for using a higher level language is the conciseness with which code can be written. The sheer laboriousness of assembly code is a major obstacle to its use. One of the best measures of the suitability of a language for a particular purpose is the number of characters that must be written to achieve the desired result. Since error rates in programming are almost independent of the language being written, concise programs will have fewer bugs than verbose programs.

Pops

One approach that has gained a number of particularly ardent adherents is that of writing compilers in an interpretive language. This idea seems also to have originated in the early 1960's. Although the COBOL compiler for the IBM 1410 was written in interpreted code, the main source of the popularity was the series of (mostly FORTRAN) compilers written by Digitek. A number of syntax directed compilers of the same vintage utilized an internal representation of a similar nature. The increased suitability of current computer instruction sets for compiler writing has caused the technique to largely fall from favor for large machine compilers in recent years. The technique has much to recommend it for some applications, though, and it is worthy of a few comments.

Since there have been no published papers on the Digitek POP system, which appears to be the most highly developed system, we will include here a somewhat more complete description than for the other ideas discussed in this paper.

The name POP derives from the *P*rogrammed *OP*erators on the SDS 910 for which the first Digitek FORTRAN compiler was written. These were a series of unassigned operation codes that caused a trap to a location distinct for each such op-code. This enabled the user to define the meaning of each of these op-codes by a subroutine. Subsequently, for other machines which did not have such a feature, a completely interpretive system was substituted.

The POP system consists of a set of operations that resemble single address instructions. The single operand in each POP is either a single data element (usually an integer but perhaps a pointer into a table, etc.), a character, a string of characters (this is handled indirectly), a table (movable), or a flag. Additional data types are defined as needed. Tables are implemented as contiguous, movable tables as previously described. A pointer is defined as having a table number part plus an offset into a table. Pointers are used for forming linked structures and for referencing data in tables if other than the last item is to be referenced. Tables are normally used like stacks. One table is distinguished as the main stack and is often used as an implicit second operand. Another table is distinguished as the stack used to save return addresses in procedure calls. Recursion is therefore quite natural.

To illustrate how this system is used, we will define several of the more common POP's. The first POP is LDS (Load Stack), and is written as:

```
LDS    A
LDS    B
```

This sequence of two POP's is interpreted as follows: First the data item A, a single work item, perhaps an integer, is placed on the main stack, extending it by one word in the process. Then the item B is added to the stack, extending it once again. At the conclusion, the stack appears as in Figure 5. The end of stack item is referred to as item 0 and the next item (A) is referred to as item 1.

The POP STS (Store Stack) is simply the converse. For instance:

```
STS    A
STS    B
```

stores the end item of the stack in cell A, and shortens the stack. The second POP stores the new end item in cell B and shortens it once again. The net effect of the four POP's we executed is to exchange cells A and B.

Similarly, the stack may be loaded with the end item on any table by MOF (Move Off) which has as an operand a table number. The effect of this is to lengthen the stack and to shorten the table specified as the operand of the instruction by moving one word of data. This operation is usually defined to set a global flag to FALSE rather than to move an item if the table specified is empty. The companion operation is MON (Move On). Hence to move the contents of one table into another, the four instruction loop suffices:

```
LA    MOF    TABLE1
      BRT    ALLDONE
      MON    TABLE2
      BRU    LA
```

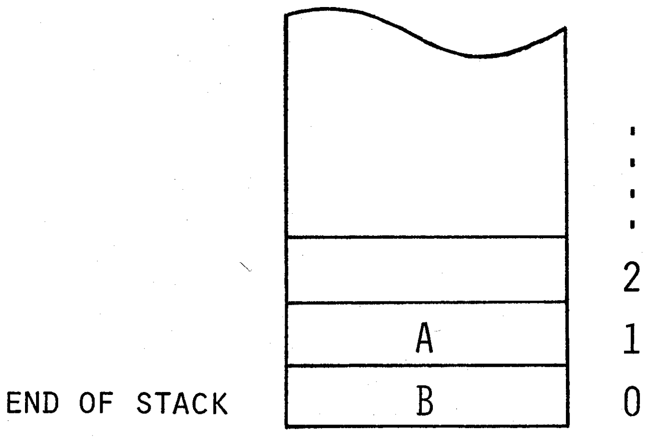

Figure 5—Picture of end of stack

The two new instructions above are BRT (Branch True) and BRU (Branch Unconditional).

Character scanning is done with primitives of the form

```
CHS      character
```

The POP CHS (Character Scan) has as its operand the internal representation of a character. If the specified character is the next in the character input stream, the input scanning pointer is advanced and a global flag set to TRUE. Otherwise the global flag is set to FALSE. Similarly a complete string may be matched with SCN (String Scan), as in

```
SCN      "BEGIN"
```

Subroutine calling is done with BRS (Branch and Save) which stores the return address in a stack. The natural implementation of recursion leads most POP written compilers to be of the recursive descent variety. For instance the sequence of code required to recognize the syntax SUM ::= TERM {+TERM}* is as simple as

```
SUM      BRS      TERM
         CHS      "+"
         BRT      SUM
         RET
```

The POP system is fleshed out with instructions for packing and unpacking data words, creating instructions, setting and testing flags, and so on almost ad infinitum. In theory, a POP compiler can be moved from one machine to another simply by writing a new interpreter for the next machine. In practice, this is not feasible because the bulk of the work in writing a compiler is in designing the code generation strategy, which must be rethought for any new machine in any event.

POP compilers are considerably more compact in code than machine coded compilers, especially where there is an addressability problem (such as in a minicomputer). Fortunately this is the place that compactness is needed most. POP written compilers are, however, slower than machine coded compilers not only because of the interpretive overhead, but also because of the redundant work done in moving data through the stack. This problem is masked in minicomputers since their computing power is very high relative to input output speeds of paper tape and teletypes.

The synopsis is that POPs are a fairly good way to write very small compilers for minicomputers and a poor way to write compilers for large machines.

Translator writing systems

As an implementation technique, the use of one of the many extant Translator Writing Systems deserves at least some mention. The idea of using a TWS is very appealing, but in practice the use of TWS has not proven much of a boon. The reason is quite simple. To date, TWS has done a good job of lexical scan, parsing, and the dictionary parts of a compiler, but has made few inroads into the most difficult parts, namely code generation and optimization. Even if the facilities provided by a TWS are valuable, the penalty of forcing a user into a prescribed mold has been too stiff for most production compiler writers to bear.

CODE GENERATION

Code generation has traditionally been one of the most ad hoc (and bug-ridden) parts of any compiler. There is some evidence, though, that this is changing rather rapidly. Formally, the generation of code is the attaching of semantics to specific syntactic structures. In the case of immediate generation, of course, opportunities for substantially altering the source order are minimal and conversion of the parse back into sequences of instructions proceeds strictly on a local basis. The actual generation of code is accomplished either by open sequences of code that construct the required instructions or by the equivalent of macro sequences selected by combination of the operator and the associated operand types. In the latter case, the macros are usually described in a format similar to the assembly language of the target machine. Conditional features similar to conditional features in macro assemblers are used to improve on the quality of code generated. Provision is normally made to test the state of the target machine as well as supplementary information about the operands. The macros also update the state of the target machine.

In multipass compilers, there is now a move to systematize code generation by formal tree transformations so that all data conversions, register loadings, and the like, are explicitly recognized in the tree structure. Most of the current work in formal semantics is along this line. Information may be collected during tree traversals which aids considerably in the production of high quality code.

Whether the code is produced by conventional or table driven techniques is far less important that the organization of the generation as a sequence of transformations rather than as a complex series of decisions based upon global data left as side effects of prior generation.

OPTIMIZATION

One of the most important differences between production compilers and experimental compilers is that most production compilers try much harder to generate high quality code even at the expense of considerably slower compiling. This tradition dates from the very first FORTRAN compiler. At that time, it was felt necessary to compete with hand generated code in quality in order to gain acceptance. Since that time much effort has gone into finding ways to improve the quality of code generated by compilers. Unfortunately, the matter is too tightly bound up with the specifics of the language at hand. FORTRAN, for example, is relatively easy to optimize. PL/I, on the other hand, is almost impossible due to the significance of side-effects in the language. If, of course, optimization information is supplied by the programmer (which is rarely done), the problem becomes more nearly like that of FORTRAN.

After carefully sifting through all of the forms of optimization that have been used however, there are only two areas of optimization that have sufficient payoff to warrant consideration, unless super-optimization is being attempted. That is, there are only two issues in addition to strictly local improvements in generated sequences. These two areas are register assignment and address calculation.

Optimal register assignment

Also dating back to the earliest compilers is the problem of optimal assignment of the registers available in the machine. If a computer has only one register of a given class, or a very large number, the problem is minimal or does not exist. However, for common machines with 3 to 16 registers in a register class, the advantage to finding the correct data items to maintain in registers can be substantial. This is particularly true of values used for array accessing. Although there have been numerous papers on this subject, the general problem is still unsolved. Even the most satisfactory approaches require an excessive amount of computation to find an optimal solution.

The consequence of this dilemma, is that most compilers that do not do flow analysis usually simplify the problem by merely keeping a simple record of register contents. Loads and stores are then done on a strictly local basis. This works quite satisfactorily for all except the most demanding requirements.

Address calculation

One of the most important forms of non-trivial optimization and one that requires at least a modicum of flow analysis is the calculation of subscripts within a loop by repeated addition of some precalculated value to an address rather than a full recalculation of the address. This is best shown by the simple loop:

```
DO    K = 2 TO 99;
   A(I, J, K) = A(I, J, K +1) + A(I, J, K − 1);
END;
```

The address calculations required can be drastically reduced with only two observations. First, all three array addresses are related to each other with only a constant difference. Second, consecutive executions of the loop body require only that the address be adjusted by a constant amount. The first of these simplifications is called common subexpression elimination. The second is called recursive address calculation. (It has nothing to do with recursion in the programming sense. Here it is really an iteration.)

Gear[4] reports on a reasonably straightforward way of accomplishing this by consecutive passes over the parsed program in alternating directions. Although his technique is applicable without alteration only to explicit loops in the program with no local branching to disturb the movement of code, with more extensive flow analysis this can be generally accomplished.

Although common subexpressions other than subscript expressions can be located and moved, the benefits are not impressive and there are perils. The necessity of avoidance of altering the side effects of the evaluation is often underestimated. For this reason, more general common subexpression detection is not often done.

Since programs that do considerable accessing of multidimensional arrays spend a large part of the time in address calculation, locating common index expressions and calculating addresses recursively in loops is recommended as one of the first targets in any compiler intended to produce very high quality code.

SUMMARY

This has been intended as a brief overview of the way in which production compilers are written at the present time as seen by one of the practitioners of the art. The word art is used here as little has been accomplished in applying engineering techniques to compiler writing outside of the areas of lexical and syntactic analysis. The parts associated with declaration processing and code generation and optimization are still very ad hoc. The need for researchers to find better descriptive devices for generation strategies and the miscellaneous problems surrounding the creation of real object programs is still great. The need for compiler writers to apply the best that is already known is perhaps even greater.

A laboratory for the study of automating programming*

by T. E. CHEATHAM, JR. and BEN WEGBREIT

Harvard University
Cambridge, Massachusetts

INTRODUCTION

We are concerned in this paper with facilities, tools, and techniques for automating programming and thus we had best commence with discussing what we mean by *programming.* Given a precise specification of some task to be accomplished or some abstract object to be constructed, *programming* is the activity of producing an algorithm or procedure—a program—capable of performing the task or constructing a representation of the object on some computing system. The initial specifications and the resulting program are both couched in some (programming) language—perhaps the same language. The process typically involves such activities as: choosing efficient representations for data and algorithms, taking advantage of known or deduced constraints on data and algorithms to permit more efficient computations, verifying (proving) that the task will be accomplished or that the object constructed is, in fact, the one desired, demonstrating that certain performance criteria are met, and so on.

The kind of facility currently available which might be characterized as contributing to automating programming is usually called a *compiler.* It typically translates an algorithm from some higher level (programming) language to a lower level ("machine") language, attempting to utilize memory and instruction resources effectively and, perhaps, reorganizing the computational steps, as implied by the higher level language representation, to move invariant computations out of loops, check most likely (or cheapest) arms of conditions first, and so on.

We are not here concerned with traditional compilers; indeed, we will assume the existence of a good compiler. We are concerned with facilities at a "higher level": translating specifications which contain much less commitment to particular data and algorithmic representations than is usual with higher level programming languages, and performing rather more drastic reorganization of representation, implied computational steps, and even implied method of computation than is done with traditional compilers. We imagine our end product to be programs in a higher level language. On the other hand, we must note that the line between the kind of facility we will describe and a good compiler is very fine indeed and we will suggest that certain kinds of transformations sometimes made by conventional compilers might better be approached with the tools and techniques described here.

The purpose of this paper is to describe a facility which we characterize as a laboratory for the study of automating programming. We view the laboratory as a pilot model of a facility for practical production programming. The time and expense invested in programming today and the lack of confidence that most programs today actually do what they are intended to do in all cases is surely dramatic evidence of the value of such a facility. The need is particularly acute when the task to be accomplished is complex and the resulting program is necessarily large. Such situations are precisely those encountered in many research areas of computer science as well as in many production systems software projects. Dealing with this kind of complexity, which is to say producing efficient verifiably correct program systems satisfying complex requirements is a significant, decidedly non-trivial problem.

The second section of this paper contains a critical discussion of a wide variety of work and research areas which are related; the third section is devoted to a broad general description of the laboratory; the fourth section then briefly describes the ECL programming system, the intended host for the laboratory; the fifth

section discusses, in general terms, a variety of program automation techniques to be employed; the sixth section describes the basic components of the initial laboratory; and the seventh section summarizes what we hope to accomplish with the laboratory and mentions several open problems.

RELATED WORK

There is a considerable body of work and a number of current research areas which are related to programming automation. Most of this work does not, at present, provide anything like a complete system; much of it does provide *components* of a system for automating programming and is thus directly related to and sometimes directly usable in the laboratory we will describe.

We have divided the work to be discussed into seven different areas: automatic program synthesis, mechanical theorem proving, automatic program verification, program proof techniques, higher level programming languages, equivalence of program schemata, and system measurement techniques. In each case we are discussing the work of several people; the bibliography cites the recent work we feel is most relevant.

Automatic program synthesis

The basic idea here is to construct a program to produce certain specified outputs from some specified inputs, given predicates asserted true of the inputs and the outputs as related to the inputs. The basic technique is to (mechanically) prove the theorem that there exist outputs satisfying the predicate and then to extract a program from the proof for constructing the outputs. It has been suggested that these techniques can also be utilized to transform programs, for example to transform a recursive procedure into an equivalent iterative procedure using the two stage process of first deducing a predicate that characterizes the recursive procedure and then synthesizing an equivalent iterative procedure which computes the outputs satisfying the predicate deduced.

We view the work in this area to date as primarily of theoretical interest and contributing to better mechanical theorem proving and proof analysis techniques. It is often more convenient to produce an (inefficient) algorithm than it is to produce a predicate; the two stage process proposed for "improvement" of programs is awkward and, we believe, highly inefficient as compared with the direct transformation techniques to be discussed below.

Mechanical theorem proving

The heart of any system for automating programming will be a facility for mechanical theorem proving. At the present time there are two basically different approaches to mechanical theorem proving and a realization of both these approaches provide important components of our laboratory. One approach is to construct a theorem prover which will, given enough resources, prove any true theorem in the first order predicate calculus with uninterpreted constants; the other approach is to provide a theorem prover which is subject to considerable control (i.e., allows one to employ heuristics to control the strategy of proof) and which utilizes interpretations of the constants wherever possible for efficiency. Mechanical theorem provers of the first sort are now usually based on the resolution principle. We term those of the second sort "programmable theorem provers".

Resolution theorem provers

Robinson's 1965 paper introducing the resolution principle has been followed by vigorous activity in implementing mechanical theorem provers based on this principle. Much of the activity has been concerned with developing strategies for ordering consideration of resolvents; at the present time the breadth-first, unit-preference, and set-of-support general strategies have been studied and other variations are being considered. It is clear that a powerful resolution-principle based theorem prover will be an important component of the laboratory.

Programmable theorem provers

In the PLANNER system, Hewitt provides a facility for programmable theorem proving in the sense that one can very easily utilize interpretations of the objects and operations entering into a theorem to control the strategy of proof, one can make the choice of technique used in any particular instance data dependent, and can very readily employ any general mechanical theorem prover, effectively as a subroutine. The use of a small subset of Hewitt's proposed facilities by Winograd (called micro-planner by him; see [Winograd 71], [Sussman 70]) in his program for understanding natural language gives dramatic evidence of the effectiveness of the approach. We thus include a programmable theorem prover on the style of Hewitt's and Winograd's as the basis for the theorem proving component of our laboratory.

Automatic program verification

The work in this area is concerned with mechanization of what we term "flow chart induction". Given a representation of some algorithm as a flow chart with assignments, conditional branching, and looping, one appends to the boxes of the flow chart predicates asserted true of the variables at various points in the computation and, in particular, of the inputs and the outputs. The procedure is then to attempt to mechanically demonstrate that the whole is consistent and thus that the program is correct.

Again, we view this work as primarily of theoretical interest. The theorem proving techniques utilized in King's system (see [King]) are particularly interesting, however, as they utilize interpretations of the integers and operations over the integers; while not general, they do provide rather more efficient methods for proofs concerning integers than is presently possible with the more general resolution-type proof methods which do not employ interpretations.

Program proof techniques

A number of workers have been concerned with developing proof techniques which are adapted to obtaining proofs of various properties of programs. These include some new induction methods—structural induction and flow chart induction—simulation techniques, and so on. This work provides a very important basis for proving the equivalence of various programs.

Higher Level Programming Languages

A considerable amount of work in the development of higher level programming languages has been concerned with providing languages which are particularly appropriate for certain application areas in the sense that they free the programmer from having to concern himself with the kind of detail which is not relevant to the application area in which he works. For example, APL permits a programmer to deal with arrays and array operations and relieves him of concern with the details of allocation, accessing, and indexing of the array elements. SNOBOL 4 directly supports algorithms which require back tracking, providing the mechanics automatically and permitting one to write theorem-proving, non-deterministic parsing, and such like algorithms very easily. SETL provides general finite sets as basic data objects plus the usual array of mathematical operations and predicates on sets; it thus permits one to utilize quite succinct statements of a wide variety of mathematical algorithms and to considerably ease the problem of proving that the algorithms have certain properties. ECL (which we discuss in some detail in a later section) provides a complete programming system with facilities which permit one to construct extended language facilities such as those provided in APL, SNOBOL 4, and SETL, and to carefully provide for efficient data representation and machine algorithms to host these extended language facilities.

Equivalence of program schemata

There has been considerable interest recently in studying various program schemata and investigating their relative power, developing techniques for proving their equivalence, and so on. Most of the work to date is interpretation independent and while, for example, many transformations from recursive specification to iterative specification of algorithms have been developed, it is clear that many practical transformations cannot be done without employing interpretations.

The most common use of interpretation dependent transformations is in "highly optimizing" compilers. There, a very specific, usually *ad hoc* set of transformations is employed to gain efficiency. Often the transformations are *too ad hoc*—under certain conditions they do not preserve functionality (i.e., don't work correctly).

System performance measurement techniques

It is a quite straightforward matter to arrange for various probes, monitors, and the like to permit measurements of the performance of programs, presuming that appropriate test input data sets are available, and a considerable amount of work has been done in this area. However, there are two further areas which are now the subject of investigation which we feel may yield important components for our laboratory. These are mathematical analysis of algorithms and automatic generation of probability distributions for interesting system parameters.

Mathematical analysis of algorithms

Several people have been working recently in the area of developing methodology and techniques for the mathematical analysis of algorithms to obtain estimates and/or bounds on certain critical parameters and for developing (and proving) optimal algorithms for certain functions. We envision the manipulation facilities of the laboratory as being readily adaptable to providing mechanical assistance in this activity, particularly in the area of aiding in the inevitable symbolic algebraic manipulation required in carrying out a mathematical analysis.

Automatic synthesis of probability distributions

Some recent work by Nemeth (see [Nemeth]) may, when it is developed further, provide an interesting and valuable component of the laboratory. What he is trying to do is to develop algorithms for mechanically generating probability distributions for various parameters from a computational schema augmented by given probability distributions for input variables and functions employed. Use of techniques like his should prove far superior to actually carrying out the computation for sample data values. A mixture of mechanical generation of distributions and carrying out portions of a computation might, in the earlier stages, provide a practical tool.

All the above work is related and relevant to automating programming, but none, in our opinion, is adequate alone. The need now is to integrate these facilities, techniques, and so on into a *system*—a laboratory for the study of automating programming.

THE APPROACH TO BE TAKEN IN THE LABORATORY

The goal of such a laboratory is a practical, running system that will be a significant aid to the construction of real-world programs. Automating programming entails transferring to the computer those facets of programming which are not carried out efficiently by humans. It is our contention that the activity most in need of such transfer is the optimization (in a very broad sense of the word) of programs. The orientation of the laboratory and the principal task to which it will be put is that of taking an existing program and improving upon it.

That optimization is, indeed, a key problem requires little defense. If "program" is taken in a sufficiently broad sense, it is easy to produce *some* algorithm which performs any stated task. Given just the right language, program synthesis is seldom a significant issue. For many problems, the most natural task description is precisely a program in an appropriate notation. The use of an extensible language makes straightforward the definition of such notation. For other problems, it may be that a predicate to be satisfied is a better task statement, but this too is in some sense a program. The line between procedural and non-procedural languages is fuzzy at best and it may be erased entirely by the use of theorem-proving techniques to transform predicates into programs (and conversely).

As we see the problem, the issue is not arriving at a program, but arriving at a good one. In most cases, programs obtained from theorem provers applied to predicates, from a rough-cut program written as a task description, or even from the hands of a good programmer leave much to be desired. Often, the initial program is several orders of magnitude away from desired or even acceptable behavior. The larger the program, the more likely this is to be the case. The reasons are generally such defects as inefficient representation of data, failure to exploit possible constraints, use of inefficient or inappropriate control structures, redundant or partially redundant computations, inefficient search strategies, and failure to exploit features of the intended host environment. Recognizing the occurrence of such defects and remedying them is the primary goal of the laboratory.

ECL AS A BASIS FOR THE LABORATORY

The ECL programming system and the EL1 language have been designed to allow rapid construction of large complex programs, perhaps followed by modification and contraction of the programs to gain efficiency. The facilities of ECL permit one to compose, execute, compile and debug programs interactively. The EL1 language is an extensible language with facilities for extension on three axes: syntax, data, and operations.

The EL1 language plays four roles in the laboratory: (1) it is the language used to construct the various components of the system; (2) it and its extensions are the language used to state algorithms which are to be manipulated by the system; (3) it is the target language for transformations (i.e., EL1 programs are transformed into better EL1 programs); and (4) it is the host language for the theorems constituting the data base.*

The features of EL1 and its host system, ECL, which are particularly relevant to the laboratory are the following:

(a) Data types (called "modes" in EL1) can be programmer defined using several basic data types (e.g., integers, reals, characters, etc.) and, recursively, several mode valued functions (e.g., construction of homogeneous sequences, nonhomogeneous sequences, pointers, etc.).

* That is, the parts of a theorem (i.e., the conditions, antecedent, consequent, and recommendation list as described in the following section) are couched in an extension of EL1 and "glued together" as an EL1 procedure by operators defined as extensions; of course, the theorems are not "executed" in the usual sense.

(b) Procedures can be *generic* in the sense that a given procedure (say that for +) can have a number of different bodies or meanings and the selection of a particular body or meaning to be used is determined by the mode(s) of the argument(s) utilized in some call of the procedure. Thus, for example, it is particularly straightforward to accommodate refinements in representation of some general data type (e.g., sets) without doing violence to algorithms defined on it by associating a new mode with a refinement and defining new versions of operators particularized to that mode via the generic mechanism.

(c) The compile-time, load-time, run-time, and the like kinds of restrictions employed in most systems are not present in ECL. In particular, the ECL compiler is a program which can be called at any time; it is given a program to be compiled and a list of variables (free in that program) whose values are to be taken as fixed. It then converts the program to a form which takes advantage of whatever efficiencies it can from the freezing of values. There is no distinction between compiled code and non-compiled (interpretive) code insofar as their discernible effect when executed.

(d) ECL provides storage allocation and reclamation mechanisms which are quite sensitive to space/time efficiencies. Thus, the so-called "data compiler" goes to some lengths to utilize memory efficiently when allocating a component of a complex data structure containing several "pieces".
The use of both "stack" and "heap" mechanisms for allocation and freeing of space is also provided.

(e) ECL provides for multiple concurrent paths and permits complete user control over the environment for each concurrent path. In addition to permitting strategies such as employing, say, a general resolution theorem prover to be applied to some difficult theorem in parallel with other undertakings, this feature makes it particularly straightforward to set up and run some program in an environment of ones choosing; for example, to gather statistics on its behavior in some simulated "real" environment.

(f) Error conditions (both system detected and those defined by user programs) are generally handled by setting interrupts and each interrupt is, optionally, handled by a user defined procedure. This feature is very helpful in test execution and evaluation of subject programs and permits construction of elaborate control mechanisms when appropriate, as might be the case in controlling the behavior of the programmable theorem prover.

There are two extensions of ECL which provide particularly convenient linguistic facilities for stating algorithms; these are an extension which permits one to deal with sets and set operations* and an extension which hosts non-deterministic programs.

OPERATION OF THE INITIAL LABORATORY

The laboratory, like ECL, is intended for interactive use. A programmer approaches it with a problem specification and a set of requirements on how the program is to perform. He and the system together undertake to produce a program which meets the specifications and requirements. The intention is that the laboratory be a practical tool for everyday use, i.e., that hard, real-world problems with realistic performance requirements be brought to and handled by the laboratory.

The problem specification may be an existing program written in EL1, possibly a long-standing production program. In this case, the presumption is that its performance falls short of that required and that the concern is with automating its tuning. Alternatively, the specification may be an EL1 program written in a very liberal extension and constructed solely as a concise algorithmic statement of the problem task. There may be little expectation that such a program will meet any non-trivial performance requirements. Significant improvements may be needed even to reach the desired order of magnitude. Finally, the problem specification may be a set of predicates to be satisfied. Here the laboratory begins by constructing an initial EL1 program using as its target an extension set designed for this purpose. Again, such a program may be several orders of magnitude removed from acceptable performance.

In very general terms, the laboratory is a man-machine system for transforming the initial program to an equivalent one which meets the stated requirements. The heart of the system is a set of transformations, actually theorems concerning the language, which preserve functionality while improving the program. Deciding whether an arbitrary transformation either preserves functionality or improves the program is, of course, impossible, but decision procedures for the gen-

* This extension permits us to capture most of the facilities proposed for the language SETL. See [Schwartz 70] for a particularly cogent argument for providing sets and set operations in a higher-level programming language.

eral case are not needed here. The laboratory will employ specific transformations which under appropriate circumstances—i.e., when their enabling predicates hold—maintain program equivalence. Constructing these transformations and verifying that the validity of the enabling predicates do insure functionality will be a task assigned to humans who may, of course utilize the facilities of the laboratory to prove the validity. While the *functionality* of the transformations may be assured, such is not the case for their *effectiveness.* To obtain a sufficiently powerful set of transformations it is necessary to include many whose utility is conditional, e.g., those which are effective only under circumstances which are difficult or impossible to verify analytically, or those which optimize performance in one metric at the (perhaps unacceptable) expense of another. In general, the transformation set will include transformations which are mutually exclusive (i.e., only one of some subset can be applied) and some which are inverses (i.e., applying two or more repeatedly will lead to a loop). Hence, choice of which transformations to apply is governed specifically by the performance requirements demanded of the program and the disparity between these and the program at each state of optimization.

Determining program performance is a crucial issue. There are two basic approaches, both of which are used in the laboratory. The first is *analytic.* The system derives closed-form expressions for program behavior based entirely on a static inspection of program structure and interpretation of the program operations. Then given a description of an input data set, e.g., as a set of probability distributions for possible input values, the system can describe the exact program behavior. Whenever such closed form expressions can be obtained, this is clearly the best certification of program performance. However, at present our analytical techniques are too weak for any but the simplest programs. The second approach is that of actually running the program on benchmark data sets, data sets provided by the programmer as part of his performance specifications. Between these two extremes lies the spectrum of simulation: those portions of the program which can be treated analytically are replaced by simulation blocks and the rest of the program is run as is. The large area of mixed strategy is particularly powerful since it allows one to use only partially representative benchmark data sets yet extrapolate meaningful results from them by the use of analytical techniques.

The utility of the laboratory will be governed principally by the specificity of admissible performance specifications and the degree to which they can be met on the intended machine. Performance specifications include the obvious bounds on execution time and space. Alternatively, they might be cast in the form: as fast or as small as possible. This is, however, only a rough cut. Few problems and fewer host machines are entirely homogeneous. In real time situations, optimizing total execution time may be far less important then attaining a certain minimum for particular sections. Similarly, the total space occupied by a program and its data is far less important than the distribution of this space over several storage devices of various capacities and access speeds. Also, the intended host machine may be a multiprocessor or provide multiprocessing capabilities by means of special processors (e.g., graphics) or remote processors (e.g., a network). Partitioning the computation among the various processors so that the computation load on each is beneath prescribed limits is another task of the laboratory.

The possible transformations for obtaining the desired performance vary considerably in scope, power, and effectiveness. A sketch of those which currently seem to have the greatest payoff may give the flavor of what may be accomplished.

The most straightforward are those for reducing the space occupied by data. Any field containing literal data restricted to N possible values requires, of course, no more than $[\log_2 N]$ bits. What may not be quite so obvious is that with an appropriate programming language, simply changing declarations is all that is required to control the storage allocated, perform the coding and uncoding on data access, and handle the necessary conversions. EL1 is such a language; hence, the class of transformations is readily obtained. In the case of sequences of literal data fields (e.g., character strings), further compression can be obtained by block encoding. Relations can be represented in a variety of ways and changing from one to another often results in significant economics. Sparcely populated arrays can be changed to lists or hash tables in which the array indices are retrieval keys. Conversely, the space occupied by pointers (e.g., in list structure) can be reduced if linked lists are replaced by arrays in which relations are represented by small integer array indices occupying only a few bits.

One candidate for optimization of both time and space is sets and set operations. There are a number of particularly efficient representations for sets applicable only under certain conditions (e.g., bit vectors when the number of elements is fixed and relatively small or lists in canonical set order when the generation of new sets is carefully controlled) or efficient only when the set operations are circumscribed (e.g., hash tables when the operations are union and intersection but not set complement). When such a representation is possible, its use will often produce dramatic improvement over standard list structure techniques.

Transformations for optimizing time are often subtle and require sophisticated techniques for manipulating program structures. Perhaps the best understood sort is the transformation of recursive to iterative programs. Even restricting attention to uninterpreted schemas, there are several interesting schema classes for which the transformation can always be carried out. By adjoining additional transformations which exploit the properties of specific common program operations, a very powerful tool for eliminating program recursion may be obtained.

Time can always be saved at the expense of space by substituting the definition of a routine for a call on it. Where recursion is absent or has been previously removed, it is possible to perform repeated back substitution until all calls have been eliminated. While too costly in space to be employed everywhere, it is very effective if performed on the most frequently executed portions of the program. Aside from the obvious virtue of eliminating the expense of function call, it has the more significant virtue of allowing each back substituted defining instance to be optimized independently—in the context of the text into which it is placed.

The principal class of time optimizations is the elimination of searches. A few such transformations are simple, e.g., the replacement of association lists by hashed structures or balanced trees, and the substitution of arrays for lists which are frequently accessed by indexing. Searching is, however, not confined to lists. Structures of all sorts—arrays, queues, strings, and so on—are frequently searched for an element or set of elements having some property. When the density of hits is small, blind search is inefficient. An appropriate method is to adjoin bookkeeping records to the given structure and add bookkeeping code to the program so as to keep track of what would be the result of searching. When the incremental costs of maintaining the necessary records is small compared to the search cost, this often provides a significant optimization. Determining what records must be kept and how to keep them are non-trivial problems, but ones which appear open to solution at least for many significant program classes.

A related class of program optimizations is based on reordering computations in operations on compound structures. Any operation on a compound object must be defined in terms of primitive operations or its primitive components. Given a sequence of operations on compound objects, it is usually possible to reorder the underlying sequence of primitive operations to reduce some computational resources. Galler and Perlis (see [Galler 1970]) discuss in detail the problem of saving the storage required for temporaries in matrix operations and mention that a variation on their technique can be used to minimize time. It appears possible to generalize these results to arbitrary data structures. First, recursion is eliminated from function definitions. Then each compound operator is replaced by its definition until only primitive operators appear (i.e., the back substitution optimization mentioned above). Then, program loops are merged to carry as many operations as possible on each loop. Finally, dependency analysis is used to find common sub-expressions and eliminated unnecessary temporaries. Any number of *ad hoc*, type dependent, transformations can be added to this basic framework. The basic technique, that of unwinding compound operations and then winding them up again in a more optional fashion, is broadly applicable.

Several sets of transformations are concerned with effective utilization of the particular host machine(s). These are therefore specific to the environment, but no less important than their general cousins. The most important is that of partitioning the computation among several processors. In so doing, the first step is to take a conventional sequential program and transform it to a representation which exhibits all the potential parallelism so that sequencing is dictated only by data dependency. The next step is to partition the transformed program among the available processors in such fashion that (1) upper bounds on computational resources demanded of each machine are obeyed; (2) communication between processors is carried out satisfactorily along the available data paths and (3) the entire configuration has the desired performance characteristics. Item (2) can be reduced to item (1) by treating each data path as a processor with its own (perhaps small) computational bounds. Item (1) is, of course, the heart of the matter. The work of Holt, Saint, and Shapiro provides a very promising approach to this and has already demonstrated some success in certain restricted applications (see [Shapiro 69]).

This set of program transformations is only representative. Others will be added in time as users of the laboratory gain practical experience with and understanding of program transformation. However large such a collection, it is only a beginning and its exact composition is only a secondary issue. More important is the problem of determining which transformations to use and where, given a program and a set of performance specifications. The first step is to refine the performance measurements so as to determine precisely where the specifications are not being met. Correlating the various measurements with program text is straightforward.

Given the program text augmented with resource utilization statistics, the next task of the laboratory is to find places in need of optimization, find one or more appropriate transformations, verify whether they are applicable and apply them. In choosing places to concentrate attention the laboratory starts simply by looking for the areas with the largest cost relative to that desired. Given these obvious starting places, the key problem is tracing back from these when necessary to the causes, perhaps at some point far removed in the program. In this step, and in the choice of transformation classes to be attempted, there will be the opportunity for explicit guidance by the programmer. If no guidance is given, the laboratory will doggedly pursue possible hypotheses but the search may be cut dramatically by human intervention.

Even with this assistance, the proposed transformations must be taken as tentative hypotheses to be explored. Few transformations always result in improvement. Many optimize one resource at the expense of others, while some transformations are of use only for certain regions of the data space. Hence, in general, it is necessary to continually verify that the transformed versions of the program are indeed improvements. Again, program analysis coupled with performance measurement tools will be employed.

In summary, the principal functions of the laboratory are choosing areas of the program to be optimized, carrying out pattern matching to determine the applicability of various transformations, performing these transformations, and arranging for explicit guidance by the programmer in this process. The laboratory consists of a set of components for carrying out these activities in concert.

COMPONENTS OF THE INITIAL LABORATORY

As we noted previously the laboratory is, essentially, one particular extension of ECL and that the internal representation for programs and data employed in ECL will be utilized for programs being manipulated (synthesized, transformed, proved to have some property, and so on). Here we will describe the several components in the initial laboratory—the several EL1 programs and/or ECL extensions which together constitute the initial laboratory. Before launching into the discussion, however, we want to note the influence of the work of Hewitt and Winograd on ours; the basic components of the laboratory have very much the flavor of the linguistic-independent components of Winograd's version of Hewitt's PLANNER system. Our discussion of the components is quite brief as our intention in this paper is to provide an overview of the laboratory and the general approach being taken. A detailed discussion of the current versions of the components is provided in a paper by Spitzen (see [Spitzen 71]).

Control

There is a top-level control path* which provides the interface between the user and the laboratory. It provides for input of the program to be manipulated and the associated performance criteria, if any. It then arranges that the program to be manipulated is put into a canonical form and sets up a parallel path which provides the manipulation strategy by calling for the appropriate theorem or theorems to be applied. The control path then provides for dialogue between the system and the user so that the system can request information from the user (e.g., verification that certain constraints hold in general, test data, and the like).

Programmable theorem prover

A "theorem" in the sense this term is used in the system consists of a condition which governs the applicability of the theorem, an antecedent, a consequent, and a recommendation list. Given some program structure, an instance of substructure matching the antecedent can be replaced by an equivalent substructure corresponding to the consequence so long as the condition holds. The recommendation list is basically a list of predicates which govern the use of other theorems to be used in manipulating the structure to match the antecedent in applying this one and it is the careful use of this "governor" which permits the theorem proving to operate in a practicable time frame. Note that in a very strong sense theorems are really programs effecting transformations which, through the conditions and recommendation lists (arbitrary EL1 predicates), can establish elaborate control and communication arrangements.

Data base

The theorems which constitute the basis for the transformations and manipulations performed by the system are housed in a data base. There is a continually growing static component of the data base which includes the "standard" theorems. In addition there may be a collection of theorems appropriate to certain particular investigations with which we will augment the data base at appropriate times. There is also a dynamic component which varies as a program is being manipulated. For example, if we commence dealing with the arm "$p_2 \Rightarrow e_2$"

* ECL provides multiprogramming; "path" is the ECL terminology for a parallel path of control.

of the conditional expression

$$[p_1 \Rightarrow e_1;\ p_2 \Rightarrow e_2;\ \ldots;\ p_n \Rightarrow e_n]$$

Then we would add the theorem appropriate to "$\neg p_1$" to the data base and arrange that it be removed when we get to the stage of treating the conditional expression as a whole in "higher level" manipulation of the program structure containing it.

The data base is quite large and, as various new facilities are added to the system, the data base will grow. Its size plus the fact that one wants to be able to select appropriate theorems (i.e., in accordance with a given recommendation list) from the data base efficiently, make it imperative that a certain amount of structure be imposed on the data base. Initially this structure basically amounts to a collection of "threads" through the data base, implemented by a combination of list structure, hash, and descriptor coding techniques. It is anticipated that getting an efficient structuring of the data base as it grows will pose a non-trivial research problem which we anticipate being attacked with the tools provided by the laboratory itself.

Pattern Matcher

The process of applying some theorem to some program structure involves matching the parts of the antecedent to acceptable corresponding parts of the structure; in general, of course, this will involve calls on other theorems to manipulate the structure into an appropriate format and/or the verification that certain conditions maintain. It is the pattern matcher which administers this activity; it will make tentative part-part matches, reject matches or attempt them in new ways when subsequent failure to match occurs, and so on.

Backtracking mechanism

The pattern matcher operates as a non-deterministic program in the sense that it makes provisional matches which must be "unmatched" and rematched when failure occurs to match some subsequent part of the antecedent to the program structure being manipulated. A backtracking mechanism must therefore be provided so that the effects of computations and variable bindings can be "undone." The method we use to accomplish this is to alter the basic EL1 evaluator so that, when backtrackable code segments are executed, any change to the environment is preceded by recording the appropriate modification to the environment which will undo the change in the event backtracking is required.

Measurement techniques

In addition to the usual facilities for inserting probes to provide measures of utilization of various functions and data elements provided in ECL and the usual ability to obtain measurements by sampling driven by a real-time clock there are two measurement components in the system which are less usual. Precise delineation of potential inefficiencies sometimes requires very exact timing data. Unfortunately it is usually impossible to get very fine-grained timing from most contemporary machines. Hence, the laboratory includes a machine language simulator for its host machine, i.e., a program which executes machine code interpretively and gathers statistics as requested. This permits programs to be run unchanged while collecting very precise data on the distribution of program execution time and storage requirements. This data, combined with that obtained by inserting measurement probes into the program permits performance measurements to be made to any level of detail. The second measurement component is an implementation of the "probability distribution computer" described by Nemeth.

GOALS OF THE LABORATORY

It must be stressed that the laboratory is intended for practical use, for the attainment of useful results which would be difficult to obtain without its assistance. It is the deliberate intention that one be able to approach it with a non-trivial program and obtain with it a significantly improved version. Such programs will include applications programs, system programs such as the EL1 compiler, as well as modules of the laboratory itself.

It appears that this will be achievable even with the simple approaches to be taken in the initial version of the laboratory. The use of *programmable* theorem provers and search techniques have made it possible to quickly endow the laboratory with considerable expertise, if not deep insight. On large production programs (which commonly are so complex that no one really understands their exact behavior) the laboratory may be expected to make significant improvements by more or less mechanical means. Such mechanical skill is precisely what is required to complement the high level programmer. Initially, the laboratory will serve as a programmer's assistant, suggesting possible areas of improvement and carrying out the transformations he chooses, but leaving the creative work to him. Even at this level the laboratory may serve better than the average junior programmer. Further, the initial laboratory will serve as a basis for developing more sophisticated control over the choice of transformations to be applied.

A topic which falls out as another application of this work is the modification or adaptation of programs. Given a program which does a certain job well, it is very common that it must be modified to handle a related task or work under changed conditions. Usually such modifications are done by hand, seldom with entirely satisfactory results. Hence, automation of the process is attractive. One method which has been occasionally proposed for performing this is to construct a system which when fed the existing program, deduces how it works, and then performs the specified modifications. This requires the system to dig the meaning and purpose out of the existing program—an operation which is difficult at best and perhaps impractically expensive. A solution which shows greater promise is to use the laboratory to combine man and machine. If programs are developed using the laboratory, then for any production program, there is an initial program from which it was derived. Given a statement of the new task to be accomplished, the programmer can make his modifications to the relatively transparent and simple initial program. This is still hand labor, but at a much higher level. Applying the laboratory to the optimization of the modified program results in a production program with the desired properties. This puts creative work in adapting a program into the hands of the programmer while freeing him from the drudge work.

It is anticipated that as the programmer gains experience with the system, he will develop his own set of optimization techniques. By making it convenient for him to add to the data base these transformations along with patterns for recognizing potential situations for their applications, we allow a certain degree of growth in the expertise of the laboratory. Given a clever population of users, the laboratory should grow to some considerable level of sophistication, at least in areas of interest to that user population. This scenario has, of course, its limitations. Merely expanding the data base would, in time, cause the system to flounder in a sea of possible but irrelevant transformations. Hence growth of the system must ultimately depend on significant improvements in global strategies, local heuristics, and theorem provers. In particular, the need for specialized theorem provers will very likely arise.

At present, it is not clear how to proceed in these directions, nor is this surprising. One of the purposes of the laboratory is to gain expertise in program manipulation, determine the limitation of current techniques, and advance to the point where the real problems can be seen clearly. The initial laboratory is a first step, but a significant step, in this direction.

Segmentation and optimization of programs from cyclic structure analysis

by JEAN-LOUP BAER and ROBERT CAUGHEY*

University of Washington
Seattle, Washington

INTRODUCTION

Modelling of computer programs by directed graphs, where the vertices represent the computational tasks and the arcs show the flow of control, has been used for optimization purposes,[1,10] parallel processing evaluation,[2,8] and segmentation.[7,9,13] All these studies are mainly based on the fact that a high proportion of the execution time of a program is spent in loops. Although the cyclic structure of programs can be theoretically complex, it has been observed that the nestedness is seldom very deep.[6] Thus if one wants to optimize programs written in a high-level language, the detection of cycles by the compiler and its use in an optimization phase may yield a definite improvement in execution time without having to pay too heavily for excess compiling time. In this paper we show how a compiler could make use of an efficient cycle detection algorithm[12] to model the embeddedness of cycles by an acyclic directed graph. The latter can then be used for packing purposes in case of a paging or "cache" memory system as well as for predicting the expected number of executions of a given statement for optimization purposes.

MODELLING OF FORTRAN PROGRAMS

For clarity of exposition we present the modelling process as a sequence of four phases. However, actions of phases 1, 2, and some of 3 are performed concurrently. The source program itself is scanned only once. The four phases are now described both functionally and in terms of the basic data structures. Detailed algorithms can be found in Reference 4.

Phase 1

Directed graph model—Instruction Sequences

The basic model is a *directed graph* $G(W, U)$ where W is the set of vertices $\{w_1, w_2, \dots, w_m\}$ and U is the set of ordered pairs (or arcs) $u_k = (w_i, w_j)$. Vertices represent computational tasks and arcs show the flow of control. Methods to analyze a FORTRAN source program and transform it into an equivalent—in terms of control—directed graph are now well-known. We shall follow Russell's approach[10] and therefore we assume the uniqueness of an initial vertex w_1 and terminal vertex w: as well as connectedness of the graph. Appendix I shows the vertices and arcs generated from the analysis of the current source statement according to its type. Figure 1 gives an example program (executable statements only) and its directed graph representation. Associated with each vertex w_i is a volume attribute v_i which represents the amount of memory words required for the machine code generated by the translated statement.

Thus given a source program, the first part of the modelling process yields $G(W, U)$ which can also be conveniently represented by an $m \times m$ (where $m = |W|$) Boolean connectivity matrix C,[9] and a volume vector $V(|V| = m)$.

For reasons which will become apparent in Phase 3 we now define the *Instruction Sequences* (I.S.) of a source program.

Let A be the class of all FORTRAN executable source statement types which do not have the attribute of implicit flow of control* and $\bar{A}$ its complement with respect to the class of FORTRAN executable source statements. Let $Z = S_1, S_2, \dots, S_i, \dots, S_n$ be the

* Present address: System Services Department, Snohomish County, Everett, Washington.

* I.e., these statements which have as a unique immediate successor the next statement in sequence.

Figure 1—Model of a FORTRAN program (executable statements only)

finite string of source statements which comprise a program, in the order (on ascending index) in which they are initially submitted to a translator. An instruction sequence I_k is a non-empty substring of consecutive elements of Z written as

$$I_k = S_{k1}, \ldots, S_{km}$$

such that:

(i) $S_{kj} \in \bar{A}$ for $1 \leq j \leq m-1$ and S_{k1} is called the initial statement of I_k

(ii) $S_{km} \in A$ and S_{km} is called the terminal statement of I_k

(iii) I_k is the substring of Z of maximum length which contains S_{km}.

Z is partitioned into instruction sequences and can now be rewritten as:

$$Z' = I_1, I_2, \ldots, I_i, \ldots, I_p.$$

Z' can also be represented by a directed graph $H(I, Y)$ where I is the set of vertices I_i representing the I.S.'s and $y_k = (I_i, I_j)$ is an arc $\in Y$ if the terminal statement S_{im} of I_i can transfer explicitly to a statement S_{jp} of I_j. This directed graph can also be represented by a Boolean connectivity matrix M.

Given Z the string of source statements, the determination of the I.S.'s and their interconnections is easy and not time consuming (Figure 2 displays these new structures for the example program of Figure 1). It follows the same algorithms as the one used for the generation of branch instructions by the compiler.

Phase 2

Identify DO-loops and their embeddedness

In this phase we record the membership of statements in DO-loops in the following way. Each DO-loop is represented by an m-dimensional Boolean vector, say d_i for the ith DO-loop, such that $d_{ik} = 1$ if the statement represented by vertex w_k is in the DO-loop and $d_{ik} = 0$

otherwise. At the same time, we build a (partial) embeddedness Boolean matrix E^+ which is such that $e_{ij}^+ = 1$ if DO-loop j is nested within DO-loop i.

The construction of the d_i's and E^+ is up to this point straightforward and mainly requires the same techniques as those used generally in the compilation of DO-loops, that is the maintenance of a stack of currently active DO-loops and their associated terminating labels. Figure 3 shows the d_i's and E^+ after DO-loop processing for the example of Figure 1.

Phase 3

Identify the remaining elementary cycles

A general algorithm to detect the elementary cycles in a directed graph has been recently published.[12] It is based on a path extension technique with each vertex of the graph being a potential starting point for a cycle. In our case, the searching time of the exhaustive detection—a function of the number of vertices and arcs in the graph—can be greatly reduced by the following two observations.

(i) Ignore the feedback arcs of the DO-loops since the corresponding cycles have already been detected.

19, 3	5, 6

(ii) In FORTRAN only a subclass X of statements ($X \subset A$) can be origin statements of cycles. This subclass X corresponds to statement types*:

GO TO K
GO TO L, ($K_1, K_2, \ldots, K_p$)
GO TO ($K_1, K_2, \ldots, K_p$), L
IF (E) K_1, K_2, K_3
IF (B) S where S is a GO TO statement

Only statements of type belonging to X can be starting points of cycles in $G(W, U)$, and they are necessarily terminal statements of I.S.'s. Thus we are going to reduce our cycle search by looking first for cycles in $H(I, Y)$ and then transform these into cycles of $G(W, U)$. This phase is going to be processed in three stages.

Stage 1. Reduce domain of search of elementary cycles of I.S.'s

A list of paired origin-destination statements, where the origin statements are the terminal statements of the I.S.'s and the destination statements are those referred to by the labels K_i, is built during the scanning of the source program Z. The forward reference labelling problem is dealt with in the same manner as the compiler must do for generating code. The corresponding list of origin-destination I.S.'s is also constructed (cf. Table I for our example).

* We restrict ourselves to the analysis of main programs or subroutines, that is we do not include CALL statements as statements which imply transfer of control.

Figure 4—Matrix M* and domain of starter I.S.'s

The domain of possible starter nodes for the cycle detection algorithm could be further reduced as follows. Let (I_k, I_j) be an origin-destination pair of I.S.'s. They will be part of a same cycle if and only if $m_{kj}^* = m_{jk}^* = 1$ in the reflexive transitive closure M^* of the connectivity matrix M. If these relations do not hold the origin-destination pair can be deleted. However, it is debatable if the gain incurred by this deletion surpasses the cost of generating M^*, a process of order greater than n^2.

Figure 4 shows M^* and the reduced set of I.S. starting vertices.

Stage 2. Find elementary cycles of I.S.'s

The algorithm already referred to[12] is used with the short-cut of skipping those vertices which are not part of the reduced set of possible starting points. Figure 5 lists these cycles.

Stage 3. Conversion of I.S. cycles to original graph cycles (G-cycles)

Each cycle of I.S.'s must be converted into cycles of the original graph (G-cycles). It is of course possible that a single I.S. cycle may yield several G-cycles. For example, the I.S.:

	Corresponding vertex number
10 A=B	1
20 C=D	2
IF (E) 10,20,30	3

which has one I.S. cycle, namely itself, yields two G-cycles $\{1, 2, 3\}$ and $\{2, 3\}$.

The conversion algorithm may be summarized as follows: Let $C_i = I_\alpha, I_\beta, \ldots, I\sigma$ be an I.S. cycle. Recalling the definition of an I.S. one can write $I_\alpha = S_{\alpha,1}, S_{\alpha,2}, \ldots, S_{\alpha,m\alpha}$. All $S_{\alpha,m\alpha}$ are part of all G-cycles generated by C_i. Let $(S_{\alpha,m\alpha}, S_{\beta,j})$ be a paired origin-destination statement leading from I_α to I_β. Now the sets d_i corresponding to G-cycles are obtained as follows:

1. Initialization step. $d_i^0 = \phi$ (the empty set).
2. Let α be the index of the first I.S. in C_i and β the index of the next I.S. in sequence (if there is only one I.S. $\beta = \alpha$).

$$d_i^\alpha = d_i^0 \cup \{S_{\alpha,m\alpha}\}$$

C_1 = (3)

C_2 = (3,4,5,6)

C_3 = (3,4,5,6,7,8)

C_4 = (4)

C_5 = (5)

C_6 = (7)

Figure 5—List of cycles of instruction sequences

3. For each origin-destination pair $(S_{\alpha,m\alpha}, S_{\beta,j})$ do:
   For each d_i^{α} do:

$$d_k^{\beta} = d_i^{\alpha} \cup \{S_{\beta,j}, \ldots, S_{\beta,m\beta}\}$$

4. $\alpha = \beta$; $\beta = \gamma$ (set to index of next I.S.). (If $\alpha = \sigma$, β is set to the index of the first I.S.)

If α = index of the first I.S. then stop; the d_i's are the last $d_k\beta$ generated; else go to step 3. Figure 6 shows the set of G-cycles generated in the Boolean notation adopted in phase 2.

Phase 4

Complete and reduce the embeddedness matrix E^+

We now want to complete E^+ which was defined and partially built during phase 2. If d_i and d_j are two G-cycles in Boolean representation, then let $f_{ij} = d_i \cap d_j$. Elements of E^+ will now be defined by:

—If $f_{ij} = d_i$ then $e_{ji}^+ = 1$, $e_{ij}^+ = 0$ (d_i embedded in d_j)

—If $f_{ij} = d_j$ then $e_{ji}^+ = 0$, $e_{ij}^+ = 1$ (d_j embedded in d_i)

—If $f_{ij} \neq d_i \neq d_j$ then $e_{ji}^+ = e_{ij}^+ = 0$.

Since the embeddedness of the DO-loops between themselves have already been recorded, these tests are done only for the pairs of cycles i, j where $1 \leq i \leq n$ (n number of cycles), $k < j \leq n$ (k number of DO-loops).

Now the E^+ matrix can be considered as the precedence matrix of an acyclic directed graph where the embeddedness property is the precedence relation, i.e., the vertex representing d_i is a successor of the one represented by d_j if $e_{ji}^+ = 1$. In the sequel we shall use strict embeddedness which is defined as: d_i is strictly embedded in d_j if it is embedded in d_j and there exists no d_k such that d_i is embedded in d_k and d_k is embedded in d_j. In order to find a representation of strict embeddedness one has to find the minimum connectivity matrix E such that $E^+ = \bigcup_{i=1}^{\infty} E^i$. Solutions to this problem can be found in Reference 3, 11. Figure 7 shows E for our example program.

This construction completes our modelling process. We now describe some possible applications.

Vertex Number

APPLICATION OF THE MODEL TO PAGING AND CACHE MEMORY SYSTEMS

The model can be used as an aid in packing code in pages in such a way that the number of interpage transitions due to instructions is reduced in comparison with the compiler's usual memory allocation technique. Other attempts at solving this problem range from a macroscopic approach[9] to the analysis of generated code.[5] We will follow a middle of the road route similar in its degree of detail to other studies.[7,13] We do not try in any way to achieve an optimal packing such as in Reference 14 which not only requires information that the model cannot deliver such as the cost of page faulting[15] but which would also take too much computing at compilation time. Our goal is to reduce the number of page transitions through easily implementable algorithms with the understanding that some gross assumptions may have to be taken. The basic philosophy is to pack first those statements which are in the most nested cycles. This was the purpose of obtaining the matrix E.

We need a few additional definitions. Extending the usual relations found in trees, we define the roots of an acyclic directed graph to be those vertices which have no predecessors. The immediate successors of a vertex will be its sons, its immediate predecessors will be its fathers, and sons of the same father will be brothers. Note that this last relation is transitive only in the case of a tree. The level l_i of a vertex w_i is the length of the longest path from a root to w_i. The maximum level ml_i is defined as $\max(l_i, l_j, \ldots, l_k)$ where $w_j, \ldots, w_k$ are the successors of w_i. These levels l_i and ml_i can be computed directly from E^+ or by performing a topological sort on the graph.

Traversal of the graph

Our first objective is to traverse the graph in an order reflective of the nestedness of cycles. A sort on levels l_i, which satisfies this criterion, is rejected because at the same time we want to keep as much as possible the image of the structure of the source program. To facilitate the traversal, the graph is going to be modified into a forest. If in the original graph the vertex w_i had more than one father, the one selected to stay is the one with greatest maximum level. That is for all columns i which have more than one bit set to 1 in matrix E, let j be the index such that $e_{ji}=e_{ki}=e_{li}=\cdots=e_{pi}=1$ and $\mathrm{ml}_j=\max(ml_j, ml_k, ml_l, \ldots, ml_p)$. Then set all bits of column i to 0, except for e_{ji} which is set to 1. After such a transformation is completed the levels and maximum levels have to be recomputed. The forest can now be represented in a tabular form[4] (cf. Table II) which aids in the traversal of the forest. This traversal, a variation on post-order is defined recursively by:

1. Order the sons of the root r by descending maximum levels in SONS$_r$, say $(r_1, r_2, \ldots, r_k)$.
2. Traverse the sub trees of roots $r_1, r_2, \ldots, r_k$ in that order. When a subtree is composed only of a single vertex, its root, the root is then traversed.

In the tabular form, the field USED is a flag showing those vertices which have already been traversed, DEGREE is a counter for the sons which have not yet been traversed and the other fields are self-explanatory. For our example, the algorithm yields {9147856} and {32} for the traversal of the two trees.

During the traversal of the forest, the volume of each individual cycle is computed as follows: Let d_i be a cycle, vd_i its volume, $(w_{i1}, w_{i2}, \ldots, w_{ik})$ its members and $(v_{i1}, v_{i2}, \ldots, v_{ik})$ be the volumes of the w_{ij}. Set d is the set of vertices which have yet to be traversed (initially $d=W$) and d_i is the cycle currently traversed. Then if $d_i'=d_i\cap d$,

$$vd_i=\sum_{w_{ij}\epsilon d_i} v_{ij}$$

and one suppresses from d all vertices belonging to d_i.

Assign vertices to pages

Given *i*) a page size p, ii) the order in which cycles are traversed per the above algorithm, say $T=\{d_{i1}, d_{i2}, \ldots, d_{ik}\}$ and iii) their volumes $VD=\{vd_{i1}, vd_{i2}, \ldots, vd_{ik}\}$ an algorithm to assign vertices to pages, a direct descendant of Lowe's,[7] is summarized here. The algorithm accesses the cycles in T consecutively left to right, assigning as many cycles d_{ij} (each cycle in its entirety) to a single page as the memory volumes vd_{ij} permit. By a cycle in its entirety is meant that a cycle in its vertex assignment is not permitted to run off the end of one page and have following vertices assigned to a subsequent page except when the cycle is the initial (and hence sole) cycle assigned to the page. Whether the cycle is assigned to a page as in the page over-run case or in aggregate vertex by vertex as in the former case, the assignment is reflected by a merger of graph vertices in connectivity matrix C and by the merger of memory volumes in the volume vector V (cf. phase 2 of the second section).

The algorithm consists of three parts. The first part deals with initialization for assigning a new cycle from T to pages. The second considers assignments to pages when a cycle is known to fit entirely within a page and is therefore not assigned to the page on a vertex by vertex basis. The third part considers the case when a cycle exceeds the length of a page and has its vertices assigned to the initial and following pages on a vertex by vertex basis. The algorithm terminates when the cycles in T have been exhausted.

A step by step description of the algorithm follows.

0. Set the current page size cp to 0. Set $h=0$.

A. [*Initialization*].

1. If $h=k$ (i.e., vector T completely traversed) then end.
2. Let h be the index of the next (initially first) cycle in vector T and d_j be the Boolean representation of this cycle.

$$h=h+1; \qquad j=T(h).$$

3. Let n be an index varying from 1 to m (the number of vertices in G). Set $n=0$.
4. If $cp=0$ go to step 7.
5. If $cp+vd_h \leq p$ (i.e., if the current cycle will not go over a page boundary) go to step 11.
6. Set $cp=0$ (Start a new page).
7. $n=n+1$.
8. If $d_{jn}=0$ (i.e., vertex n does not belong to cycle j) go to step 7.

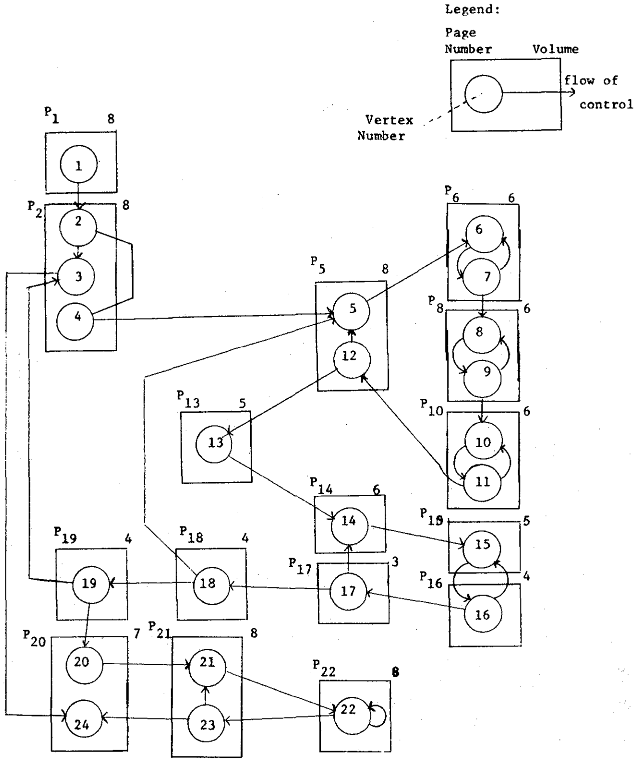

Figure 8—Vertex assignment for example program after first packing algorithm

9. $q=n$ (q temporary variable for last vertex traversed).
10. If $vd_h>p$ (if cycle does not fit entirely in a page) go to step 16 (part C).

B. [*The cycle fits in* (*remainder of*) *page*].

11. $cp=cp+vd_h$; $v_q=cp$ (This is part of the merging process).
12. $n=n+1$.
13. If $d_{jn}=0$ go to step 15.
14. $v_n=0$. Merge w_n into w_q (for an explanation of merging see below).
15. If $n=m$ go to step 1 (i.e., to part A) else go to step 12.

C. [*The cycle overflows a page*].

16. $cp=v_n$.
17. $n=n+1$.
18. If $d_{jn}=0$ go to step 22.
19. If $v_q+v_n>p$ go to step 21.
20. Merge w_n into w_q and v_n into v_q; $cp=cp+v_n$; Go to step 22.
21. $q=n$; $cp=v_n$.
22. If $n=m$ go to step 1 else go to step 17.

TABLE III—Volume Vector for Example Program

Vertex	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24
Volume	8	4	2	2	3	3	3	3	3	3	3	5	5	6	5	4	3	4	4	5	5	8	3	2

The merging process is defined by:

—To merge w_n into w_q replace qth row of C by the logical sum of itself and the nth row of C, and replace the qth column of C by the logical sum of itself and the nth column of C. Set the nth column and row of C to all 0's.

—To merge v_n into v_q replace v_q by v_q+v_n in the memory volume vector V and set v_n to 0.

The remaining task is to assign those nodes which are not members of cycles. It is done by following part C above, after first initializing both q and n to 1.

Figure 8 shows the result of packing for $p=8$ (a very small page size only for illustration purpose) and the volume vector of Table III. Although this algorithm is crude—and we see below how to improve it—it is worthwhile to compare its outcome with what would have been obtained by usual compiling techniques. Figure 9 shows how the code would be allocated in a straightforward manner with vertices allowed to run over pages.

As can be seen the total number of pages required for the generated code is smaller in the usual compiler's case (7 instead of 10). However, the goal of the packing algorithm is to improve the residency of the pages, i.e., the locality of the code. In general the number of data pages needed for efficient execution is much greater than the number of code pages; the packing algorithm thus helps in leaving more main memory space to data during long bursts of execution. For example, loops (w_6, w_7) (w_{10}, w_{11}) and (w_{22}) occupy one page instead of two. Moreover, as stated earlier, the packing algorithm can be improved. A first clean-up pass could be implemented as follows:

If after the merging process, $C_{ji}=1$ (i.e., pages i and j are connected) and $v_i+v_j \leq p$ (the sum of their memory volumes is less than a page), then merge w_i into w_j and v_i into v_j.

In our example, pages 16 and 17 would be merged, as well as pages 18 and 19, thus leading to a definite improvement in the second part of the main cycle.

A more sophisticated clean-up pass would be first to "squeeze" those elementary cycles which are leaves of the forest, by allowing vertices to run over pages. (In our example w_{16} would be in pages 15 and 16.) Then the clean-up pass defined above would be invoked. Figure 10 shows the results of the improved algorithm. The main loop requires now only 8 pages; the number of interpage transitions is diminished, and the locality of the code is improved.

EXPECTED NUMBER OF EXECUTIONS OF SOURCE STATEMENTS

The knowledge of the expected number of times a given source statement is going to be executed can be an important factor in the optimization of high-level source programs.[6,10] It allows replacement of compiler-generated code by a tighter hand-coded version in the

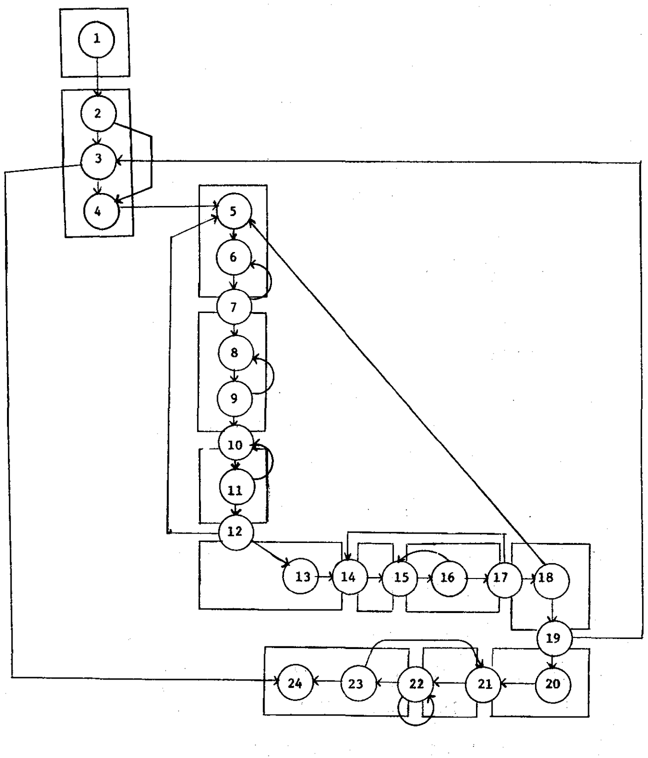

Figure 9—Usual memory allocation by a compiler (all pages have volume 8)

event of an often-repeated statement. In the context of the previous section, the traversal of the tree could be monitored by the maximum expected number of executions, instead of being directed by maximum levels, thus leading to a better residency of pages of code.

In this section we show how these numbers can be estimated when i) the probabilities q_i^j of traversing the arcs (w_i, w_j) corresponding to paired origin-destination statements are known, and ii) when the mean number of times the feedback arc of a DO-loop is set up to be traversed is known. These parameters of the source program will have to be "guessed" or instrumented.[10] In the former case they represent a first pass at the analysis of the program and only well-known sections of it should be optimized. In the latter, they correspond to an "a posteriori" optimization of a production run. In both cases, we assume that we have a Markovian process, i.e., the q_i^j stay invariant each time w_i is reached.

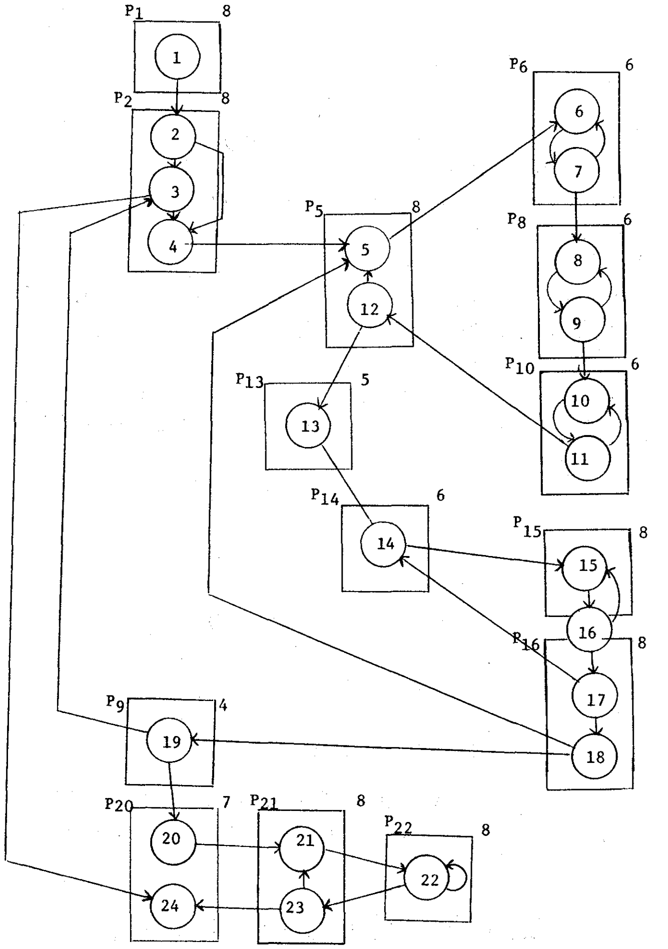

Figure 10—Parking after "squeeze" and "clean-up" passes

Traversal of the directed graph

The method we outline is an outgrowth of studies related to the prediction of performance of multiprocessors.[2,8] Let f_i be the expected number of executions of vertex w_i, p_i its probability of being reached from the initial vertex w_1 when all feedback arcs of the graph have been removed. In the case of a stochastic cycle, i.e., one which is not a DO-loop, this feedback arc is the one corresponding to the last paired origin-destination statement encountered when transforming the I.S. cycles to G-cycles, and of probability not equal to 1. After normalizing the probabilities of arcs incident out of vertices which are origins of feedback arcs, one computes the p_i as:

(1) $p_i = \sum_{j=1}^{k} p_j q_j^i$ where w_j $(j=1, \ldots, k)$ are the immediate predecessors of w_i. At initialization all f_i are set to 1.

The traversal of the directed graph represented by the original embeddedness matrix E is performed as follows.

1. Let $d_1, d_2, \ldots, d_k$ be the leaves of the graph. Partition these leaves into classes $E_1=\{d_1\}$, $E_2=\{d_2\}, \ldots, E_k=\{d_k\}$.
2. If two classes E_i and E_j are such that there exists $d_i \in E_i$ and $d_j \in E_j$ such that $d_i \cap d_j \neq \Phi$, let $E_i = E_i \cup E_j$ and suppress E_j.
3. Repeat step 2 until no suppression occurs.
4. Compute the f_i (up to that point) of each vertex member of a cycle belonging to one of the E_i left after step 3, as explained below.
5. Suppress from E all the leaves and repeat steps 1 to 4 until all cycles have been treated.

Steps 1 to 3 are facilitated by the use of the tabular representation of the graph. They involve mainly the partition of cycles into classes with the equivalence relation being "to have a common father with at least one member of the class."

Computation of f_i's corresponding to leaf cycles

Let $E_k = \{d_{i1}, d_{i2}, \ldots, d_{ik}\}$ be a class as defined above. We shall give expressions for the f_i of vertex members of d_{ij} in supposing first that the cycles are at their maximum depth of embeddedness.

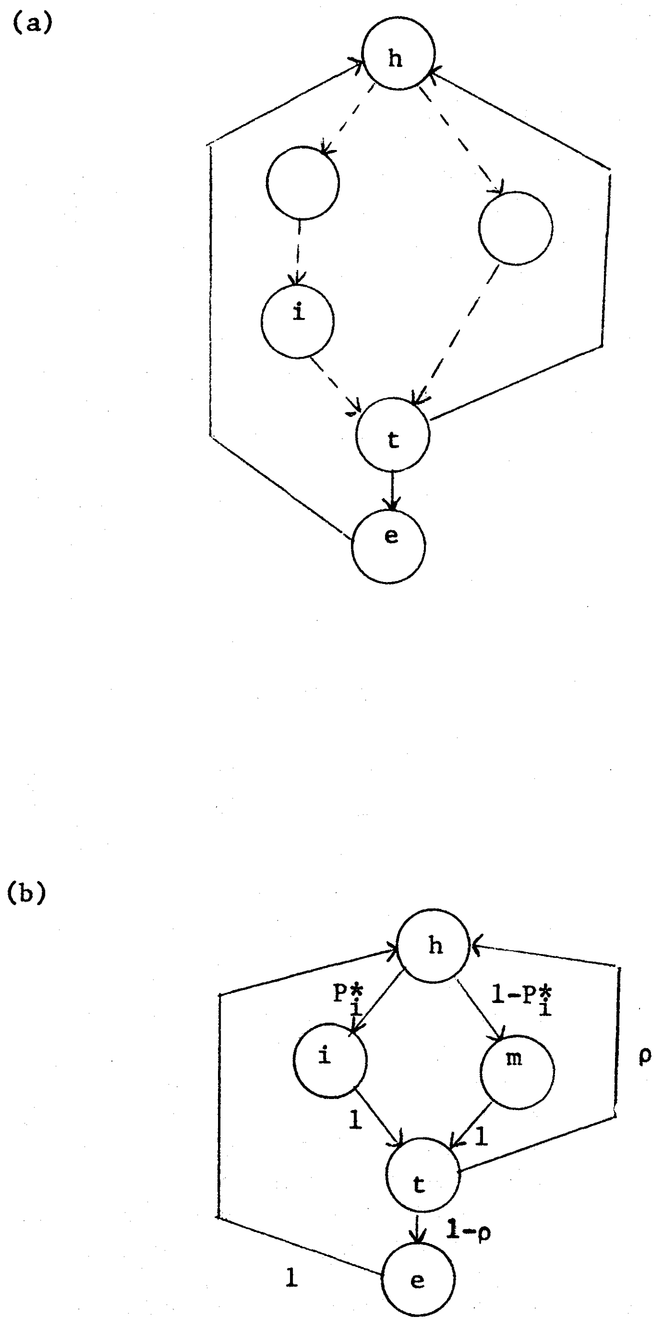

Figure 11—Regular Markov chain (subcase 1 of case 1)

Case 1. E_k has a unique member $d_{i1}=\{w_h, \ldots, w_i, \ldots, w_t\}$ where (w_t, w_h) is the feedback arc.

Let p_i^* be computed as in (1) in considering only the subgraph corresponding to d_{i1} and $p_h=1$. We note $\Pr[w_i(j)]$ as the probability of executing $w_i\, j$ and j times only.

Subcase 1. There is no branching out of d_{i1}, that is there exists no arc (w_i, w_i') such that $w_i \in d_{i1}-\{w_t\}$ and $w_i' \notin d_{i1}$.

Let $(N-1)$ be the mean number of times the DO-loop has been set up for and ρ the probability of the feedback arc of a stochastic cycle. For a DO-loop:

$$f_i=\sum_{j=1}^{N} j \Pr[w_i(j)]$$

and

$$f_h=N.$$

But

$$\Pr[w_i(j)]=\binom{N}{j} p_i^{*j}(1-p_i^*)^{N-j}.$$

Hence:

$$f_i=\sum_{j=1}^{N} j \binom{N}{j} p_i^{*j}(1-p_i^*)^{N-j}$$

$$=Np_i^* \sum_{j=1}^{N} \binom{N-1}{j-1} p_i^{*j-1}(1-p_i^*)^{(N-1)-(j-1)}$$

or

$$f_i=Np_i^*=f_hp_i^*.$$

For a stochastic cycle: the process can be considered as a regular Markov chain as shown in Figure 11.a. by introducing an extra arc of probability 1. Now if P is the regular transition matrix, $(\Pi_h, \ldots, \Pi_i, \ldots, \Pi_t, \Pi_e)$ the limiting probability vector, it is known that the mean first passage time to return to a given state is $m_{ii}=1/\Pi_i$. In our case, $m_{ee}=1/\Pi_{ee}$ represents the mean number of steps, and $f_i=\Pi_i/\Pi_e$.

If one is interested only in f_h, f_i, f_t, the graph is equivalent to the one in Figure 11.b. whose transition matrix is:

$$\begin{vmatrix} 0 & p_i^* & 1-p_i^* & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ \rho & 0 & 0 & 0 & 1-\rho \\ 1 & 0 & 0 & 0 & 0 \end{vmatrix}$$

and since $\Pi_i=p_i^*\Pi_h$, then $fi=p_i^*f_h$. Now f_h could be computed by the ratio Π_h/Π_e but directly one can see that:

$$f_h=\sum_{j=1}^{\infty} j \Pr[w_h(j)]=\sum_{j=1}^{\infty} j\rho^{(j-1)}(1-\rho)=\frac{1}{1-\rho}$$

Subcase 2. There is some branching out of total probability $1-Q$ where $Q=p_t^*$. In the DO-loop case:

$$\Pr[w_h(j)]=Q^{j-1}(1-Q)\ (j=1,\ldots,N-1);$$

$$\Pr[w_h(N)]=Q^N.$$

Hence

$$f_h=\sum_{j=1}^{N} jQ^{j-1}(1-Q)+NQ^{N-1}=\frac{1-Q^N}{1-Q}$$

Now

$$\Pr[w_i(k)]=\sum_{j=k}^{N}\Pr[w_h(j)]\binom{j}{k}p_i^{*k}(1-p_i^*)^{j-k}\qquad (k=1,\ldots,N)$$

and

$$f_i=\sum_{k=1}^{N}k\Pr[w_i(k)]$$

$$=\sum_{k=1}^{N}\Pr[w_h(k)]\sum_{j=1}^{k}j\binom{x}{j}p_i^{*j}(1-p_i^*)^{k-j}$$

$$=p_i^*\sum_{k=1}^{N}k\Pr[w_h(k)]\cdot$$

$$\sum_{j=1}^{k}\binom{x-1}{j-1}p_i^{*j-1}(1-p_i^*)^{(k-1)-(j-1)}$$

$$=p_i^*\sum_{k=1}^{N}k\Pr[w_h(k)]=p_i^*f_h.$$

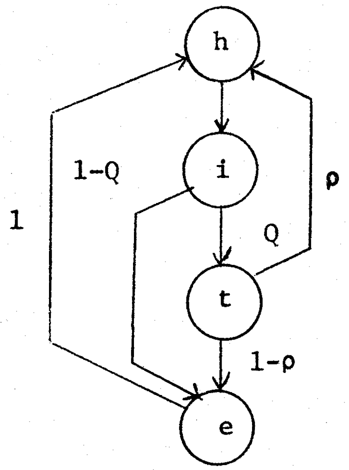

Figure 12—Regular Markov chain (subcase 2 of case 1)

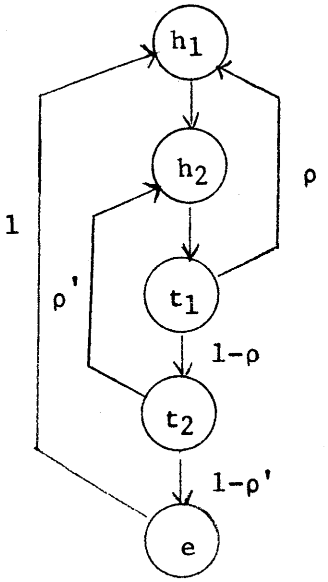

Figure 13—Regular Markov chain (subcase 1 of case 2)

In the stochastic case, the computation of f_h corresponds to the Markov chain of Figure 12 of transition matrix

$$\begin{vmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & Q & 1-Q \\ \rho & 0 & 0 & 1-\rho \\ 1 & 0 & 0 & 0 \end{vmatrix}$$

which yields

$$f_h=\frac{1}{1-Q\rho}$$

Analysis similar to subcase 1 would yield $f_i=p_i^*f_h$. In summary for this first case, the computation of the f_i involve only the computation of the p_i^* and of the f_h as given above.

Case 2. E_k has more than one member.

Subcase 1. All cycles are stochastic.

Again we have recourse to the Markov chain approach. Of interest are the f_i of the heads and tails of the cycles. A typical example is shown in Figure 12 of transition matrix;

$$\begin{vmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ \rho & 0 & 0 & 1-\rho & 0 \\ 0 & \rho' & 0 & 0 & 1-\rho' \\ 1 & 0 & 0 & 0 & 0 \end{vmatrix}$$

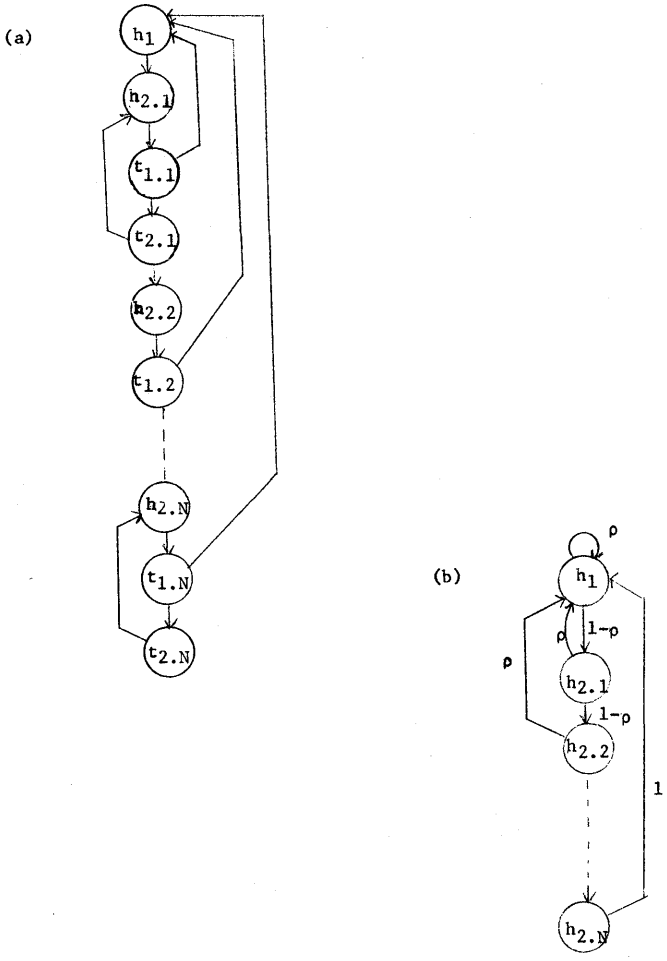

Figure 14—Subcase 2 of case 2

which yields

$$f_{h1}=1+\frac{p}{(1-p)(1-p')},$$

$$f_{h2}=f_{t1}=\frac{1}{(1-p)(1-p')}$$

and

$$f_{t2}=\frac{1}{1-p'}$$

Subcase 2. One member of E_k is a DO-loop (there can be no more than one due to the Syntax of FORTRAN).

Consider again Figure 13 but suppose now that the second cycle is a DO-loop. It could be possible by using methods of renewal theory to determine the f_i in this case. However we can still use the Markov chain approach. To do so an N-folding of the structure must be performed as shown in Figure 14.a. To obtain f_{h2} and f_{t2} a reduction as in Figure 14.b. is performed giving a transition matrix

$$\left|\begin{matrix} p & 1-p & 0 & \cdots & 0 \\ p & 0 & 1-p & \cdots & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ p & 0 & 0 & \cdots & 1-p \\ 1 & 0 & 0 & \cdots & 0 \end{matrix}\right|$$

which yields

$$f_{h1}=\frac{1}{(1-p)^N},$$

$$f_{h2}=\sum_{i=1}^{N} f_{h2\cdot i}=\sum_{i=1}^{N}\frac{1}{(1-p)^i}=\frac{1-(1-p)^N}{p(1-p)^N}$$

and $f_{t1}=f_{h2}$, $f_{t2}=(1-p)f_{h2}$ as in subcase 1.

If for both cases 1 and 2, the cycles are not embedded in any other cycle, the f_i are multiplied by p_h the probability of reaching the first head. If they are embedded in other cycles, the f_i computed at the next level will be multiplied by those just obtained until all cycles have been treated.

CONCLUSION

In this paper we have presented a model of Fortran source programs with particular emphasis on the cyclic structure. Applications of the model to segmentation and optimization have been introduced. Algorithms needed to extract information from the high-level language in order to build the model have been given. A packing algorithm, whose goal is to reduce the number of interpage transitions in a paging or cache memory system, has been presented along with its application to an example program. The cyclic structure of the program has also been used to compute the expected number of executions of each statement of the source program.

The results of the packing algorithm, which is meant to increase the locality of the generated code, could also be used in paging mechanisms with anticipatory control. The expected numbers of executions could serve in the packing of data into pages, the data with high correlation being allocated in the same pages. This latter problem needs more investigation and it is in this direction that extensions of the model and new algorithms should prove useful.

The interplay of computer science and large scale scientific calculations

by KENT K. CURTIS

National Science Foundation
Washington, D.C.

The history of computing has been characterized by the statement that what the manufacturer makes, the customer takes. To the extent that this is true, it is not only an interesting and perceptive comment on history but also a testimonial to the remarkable nature of the sequential, stored program, electronic computer. If that invention had not fit so well from the beginning to a wide variety of interesting problems, the development of hardware and software systems could not have proceeded as independently of scientific motivation as it did. Of course, scientific requirements have influenced systems design, but the prominent parameters such as speed or memory size could be understood without detailed knowledge of scientific problems or programs and the parameters which might depend upon the structure of programs could be ignored.

It is fortunate that that was true. There were important problems to solve in physics, chemistry, meteorology, etc. We could work on those without delay and let systems design take care of itself, with *ad hoc* software adjustments when things became intolerable. Computers worked so well there was no apparent need for guidance by scientists of system design. Better design might make an incremental difference but that increment was not sorely missed and barely worth an incremental effort.

Meanwhile, computer development followed an internal dynamic of its own. It was influenced by the fact that scientific requirements provided a ready market for computers which were big and fast, but the general purpose computer was a useful paradigm and rapid advancement of electronics technology kept many problems at bay. Computer engineers and businessmen could do their own thing in their own way, with unusual freedom. The computers they built have reflected principally their own genius in taking advantage of technological opportunity, and that, happily, has been sufficient.

In making these comments, let me note that they refer to the machines which have until now dominated scientific calculation. Other designs which attempt to reflect some additional measure of understanding of scientific calculations have been considered and some are of substantial current interest. Pipe-line systems and the ILLIAC IV, are among those which come to mind, but none of them has yet had opportunity to prove its value. Even they, however, are the result of adding only one more global observation to the design criteria, the observation that many scientific calculations have the common property that they involve the redundant use of identical operation sequences on ordered sets of data. Hence, their appearance and history does not vitiate the force of the earlier observation. On the contrary, they extend its force to the near future.

They do, however, raise several interesting points. First, the principal ideas of architecture underlying each of the machines which are now being physically realized are approximately ten years old. Still, these machines are only now being delivered and experience suggests that it will be some time yet until the systems will have been stabilized sufficiently and used sufficiently to be able to make a definitive evaluation of them from experience. This is a long gestation period. It suggests that we should not expect breakthroughs in large scale scientific computing due to new ideas in machine architecture in a short time scale. The machines which are now coming to life may be substantial contributors to scientific computing ten years from now, if they prove out, but it is unlikely that machines which are still on the drawing board will contribute until later.

It also suggests that unless we believe we already have discovered the only important concepts in machine organization (which is possible but would be most remarkable, if true) we should be very interested in reducing the time span from idea to realization. Ideas in machine organization spring from an environment of experience to meet a perceived need. They need testing to evaluate them. If the need is really important it will probably persist until an answer is found. But, on the other hand, if the need is important we would rather not wait ten years. This line of thought argues for research in such areas as description languages which can describe complex systems and be translated to a design and fabrication process and it argues for support by the scientific community for such research. I would like to return to this point later.

Second, a "paper machine" has very little weight. At an early stage in the development of the machine which is becoming ILLIAC IV, I spent some time with several people who were active in hydrodynamics and meteorological research to see what basis for estimating performance could be established from analyses of the actual codes which were of interest in those fields. My question was, to what extent does the parallelism which is available in this design offer an effective improvement in performance, considering the detailed structure of the computing algorithms, data management, and I/O processes that are used in these problems? I thought I understood how to do that kind of analysis, at least in part, including modifying the codes for parallel processing, but I did not know the codes. I hoped that someone who knew the codes could be motivated to undertake some analysis. I was impressed with the degree of interest in the machine and the lack of interest in attempting any analysis. I found a uniform response that if the machine existed, they would try it because it seemed intuitively attractive. No one was willing to attempt an analysis of his programs, however, with a view to justifying construction of the machine or influencing its design. In all fairness, they did not know how to do it and neither did I. The problem is harder and more subtle than I thought. The question remains open and, indeed, I still do not know how to find an answer with assurance except by extended experience. Responsible people still hold an honest difference of opinion. Fortunately, the continued development of that machine did not require the active support and involvement of the scientific community it was intended to serve. Technological opportunity supported by intuition and some analysis has been sufficient. The experience suggests, however, that there exists only a weak coupling between the community of natural scientists and the community of computer engineers. It also affirms the need to test new ideas in machine design by actual construction of machines and evaluation in a user environment.

Another interesting point which these machines have emphasized is that more than one schema may be applied to the solution of most problems and different computer architectures may favor different schema. This seems obvious but it required the actual development of parallel and pipe-line machines to stimulate such rethinking of problem formulation and algorithms. Now this offers a rich field of research for numerical analysts and computer scientists, where results may be of direct interest to scientists. I personally believe that this is a profoundly significant development which may portend the appearance of a new degree of influence by computers and computer science in our conceptualization of the scientific problems we attempt to solve. More immediately, however, it means that definitive evaluation of new ideas in computer architecture can only be made after good algorithms for those architectures are devised. Is this backwards? Should not the analysis of algorithms influence design? Is this not another example of weak coupling between communities with allied interests? Fortunately, we are beginning to make progress on the theory of algorithms which offers hope of benefit to both scientific computing and computer design.

Let us return, now, to the remarkable success of sequential computers in large scale scientific computing. If one considers the spectrum of activities which now comprises large scale scientific calculation one can observe a number of common features.

(1) The conceptual theory upon which the computations are based was firmly established before the invention of computers. That theory had been well verified using experiments and calculations which could be and were conducted without computers, providing a solid basis for faith that large investments of effort and money in computing would not be wasted.

 High energy physics might be considered to be one outstanding exception to this since conceptual theory in that field is being developed during the age of computers. If one considers the actual computing being done, however, the distinction disappears. The large scale computing is in analysis of data from experiments which are patterned in their design and analysis after particle physics concepts that were well established before computers were applied. Orders of magnitude less computation is used in theoretical investigation exploring the conceptual understanding of high energy physics. No theory commands sufficient faith to justify a larger investment of time and money.

(2) The conceptual theories are all expressible in well formed mathematical or statistical models.

(3) Based on the conceptual paradigms, it is possible to visualize, without using computers, interesting problems which can be solved with computers.

(4) Such problems can be solved, to a sufficiently good approximation to be interesting, using sequential machines operating for reasonable lengths of time.

(5) These problems enjoy a high national priority giving them access to the large amounts of money and effort which have been required for their study.

If you think about it, this is an interesting set of properties. It suggests the roles which have been played in fact by scientific motivation, technological opportunity, and public support in determining the course of development of large scale scientific computing. It provides a basis for understanding why scientific progress and the development of computer technology could be so vigorous, so symbiotic, and yet so independent. It provides a rationale for the observation that scientific inquiry has adopted the technology provided rather than leading or strongly cooperating in its development. At the same time, it points to certain limits, which have been observed by the course of events, in fact, on the regions of success in scientific computing. If one may have faith in continuity, it suggests some features which can be expected of developments in the near future.

One interesting observation which derives from this set of characteristics is that although computing has profoundly changed the style and methodology of research in some fields, although it has opened new questions for serious consideration, there has been no departure from already established concepts. Computing has not yet altered our paradigms of nature in a fundamental way. This is not surprising—the time constant for developing fundamental physical theory is much longer than the history of computers—but it indicates that we should not expect the short time scales associated with the development of technology to be reflected in any obvious way, if at all, in the rate we revise our fundamental understanding of nature. It also invites the question of whether computing should be expected to ever become an essential component of conceptualization. Are there interesting phenomena which cannot be described within the framework of mathematical or statistical models? Are there important questions to be posed which do not yield to analysis by sequential procedures? What would it mean to include a program operating in time as an essential element in our description of a model, as we now include time-dependent equations? It is an interesting conjecture. Considerations of real-time systems are suggestive.

Before going on, let us examine some possible inferences which may be drawn from the preceding characterization of large scale scientific computing. Certainly it is true that national priorities have strongly influenced the choice of fields of investigation and hence the visible progress. These priorities are changing and efforts in large scale computation in fields other than the physical sciences will receive more encouragement. Fields which have the property that they can take advantage of existing technology, have well posed questions based on well formulated mathematical paradigms, and have a sufficiently large community of interested and talented scientists who are beginning to emerge as partners with the physical sciences in large scale computing. The National Science Foundation is playing a role in this through its interest in the applications of computers to research in the natural sciences, in social sciences, and in applied research. One harbinger of change is the establishment of the Computer Research Center for Economics and Management Science by the National Bureau of Economic Research, Inc. with NSF support. We intend to take advantage of other opportunities as they arise.

If we note, again, that it has taken a decade to develop the new machines which are now appearing and that it will be some time, yet, before they can be adequately evaluated we may guess that the new fields which will join the ranks of large scale scientific computing in the next decade can be discerned now. They are not many. Few disciplines enjoy the advantages which the physical sciences have of almost universally accepted, well established paradigms which adapt well to existing computer technology. Advances in theory might accelerate the entry of one field or another in unexpected ways but advances in technology are unlikely to do so within a ten year time frame. I, myself, am not aware of many well formed problems embedded in widely accepted theory which are only awaiting a technological breakthrough to be solved. Even if they exist, it will take time to translate new ideas in technology into effective research application. The ideas must first be converted into actually realized tools, a task that may take more than ten years itself if we accept prior experience as a guide. The application of these tools must then be developed. Although there is overlap in these activities, a reasonable expectation would be that in ten years time we will be able to guess some still in the future impacts we do not now discern but the fully active members of the large scale computing fraternity which will then exist are already recognizable today as having accepted theories which are describable by mathematical or statistical models amenable to solution by sequential machines. The potential new members are distinguished from the present members primarily by the fact that they are only now adopting the mathematical methodology of the physical sciences and by the fact they they do not yet enjoy high national priority status. Technology notwithstanding, ten years is a short time in the development of human thought. Even quantum theory took much longer to evolve.

Another feature which emerges from considering this set of properties is the prevalence in successful scientific computing of certain mathematical or statistical models. Not only were the conceptual theories well established before computers entered the scene but the models used to describe those concepts and the approaches taken to solve them were also well established. For example, finite difference approximations of partial differential equations. We have always quickly exhausted the capacity of the machines we had to solve those problems in that way but we have not become frustrated because technology advanced rapidly enough to keep the game interesting. We have made substantial advances in discovering faster, more efficient algorithms for carrying out these processes and in understanding convergence and stability but basically we have worked, not only in the same conceptual but also in the same procedural framework that was common with desk calculators. (Monte Carlo techniques might be thought to be an exception. I think not. As with many things, computers made those already established techniques more effective.)

Now a new line of thought is beginning to emerge. I am aware of it in meteorology but it may be present elsewhere. Computers have enabled us to undertake "ab initio" calculations which could never be approached before. (Indeed, some chemists now believe that their theory is so sound and their computing techniques so accurate that they can place as much faith in the results of a calculation of a possible molecule as they can in an experiment. They have some substantial basis, as is evidenced by the story of the noble gas compounds but it reflects an interesting shift in attitude.) This ability has enabled us to undertake prediction with an accuracy never before possible and the long range weather forecasting which has become part of our daily lives is an outstanding result. But, perhaps we are beginning to push the limit of that ability using standard techniques. The predictive power of a given mathematical model rests ultimately upon the completeness and accuracy of the physical data we can provide even if the model is in principle perfect and we have infinite computing power. At some point, decreasing the size of the mesh or increasing the number of layers in a three dimensional atmospheric model multiplies the computational steps required without yielding a commensurate increase in useful results. It has been suggested that in atmospheric circulation problems, computers may be bringing that limit within sight. A couple of weeks may be a limit beyond which the model diverges from reality because of limitations in physics, not computing.

This observation is suggestive. The problem has been recognized before and some computer scientists have studied significance arithmetic schemes to provide continuous knowledge of the significance of quantities throughout a calculation. This work has not yet entered into practical application but interest may revive in it as we find ourselves pushing the limits of data accuracy more frequently. If true, it will offer a rich field for research relevant to computer users.

But the observation is also interesting in another dimension. It would be surprising if a conceptual theory can find mathematical expression in only one model or if that model can be solved in only one way. It would also be surprising if we have already chosen the best model for all situations. In atmospheric circulation, some of the questions one wants to raise may be answerable from a turbulence model which is statistical in nature and leads to a different computational problem. This could be a better way to obtain some results than solving the general field equations.

This phenomena is not new. Scientists have always reformulated models and changed approximations when they were unable to make further progress with one particular line of attack. Instead, the last twenty years have been unusual. Computers have increased the power of certain traditional lines of attack so much that we are only now approaching their limits. As we reach those limits, more attention may be paid once again to alternatives and to the real significance of the numbers we compute.

Finally, this set of characteristics of successful scientific computing can be helpful in anticipating the near term impact of new developments. They suggest that the most likely effect of technology will be to help scientists do better the things they already know how to do, perhaps, even stronger, the things they are already doing. Before discussing specifics here, however, it is necessary to make note of a new current which is beginning to influence the computing environment. While scientists and computer manufacturers each followed their own independent but mutually reenforcing interests, a third community, the community of computer scientists, was gradually emerging. This is the community whose imagination is captured by the intrinsic interest of complexity, systems, and computers and it is largely populated by bright young people who grew up with computers as a background. To the extent that computers have broken tradition, these people have the advantage of growing up with fewer ties to the old traditions. This community is now taking shape and beginning to find things to say which have relevance to both scientific calculation and computer design.

Neither the computer manufacturers nor the computer users have had much interest in computer science. They have been preoccupied with technology and have strongly flavored the definition of the term "computer science" with their own interests. For this reason it may be necessary to define more precisely what I mean. To some degree, one man's science may be another man's technology and neither can live in good health without the other. This is especially true if one looks at the actual occupations of people who call themselves scientists, the things they really do with their time and energy. The term science, however, has a commonly accepted meaning which involves the discovery and formulation of generalizations or principles that can be expressed in models describing phenomena. Computing has focussed attention on phenomena which are as old as man but which have been taken for granted; phenomena concerning information, complexity, and the processes for organizing, describing, and analyzing. Computer science is addressing itself to these phenomena. Its success will have meaning for all who are concerned with computers.

The conduct of computer science research is also interesting. There is reason to believe that it must be, at least in part, essentially complex and involve the concerted effort of research teams. Professor Jack Schwartz, of New York University, has used an analogy which I find fruitful. He notes that mathematics is a solitary occupation which can be compared to diamond mining. One digs through large quantities of dross but in the end one finds a jewel which is small, beautiful, and can be easily admired by all who have eyes to see. Computer science, on the other hand, is comparable to coal mining. One handles comparable or greater quantities of material but none of it can be thrown away. Everything must be preserved for use and the process is intrinsically complex. This does not preclude generalization and the discovery of principles but it does say something about the process of finding them and about the description of them which gives them meaning.

With this preamble, let us return to the consideration of new technology. There are several things which come immediately to mind. They cannot really be separated—each influences the others—but you can construct your own feedback loops.

(1) Machine architecture

This has already been discussed. The new architectural ideas which may affect large scale scientific computation within ten years are already being built in hardware. The long lead times involved make it almost certain that the impact of other ideas will not be realized in that time frame. New contributions inspired by the machines now being built will increase rapidly as those machines actually become available, however, and will influence their use. These will be in the areas of problem formulation, analysis of algorithms, data management schemata, operating systems, languages, and file management. I hope these machines will be available for computer science research. I think they cannot be properly evaluated without it.

(2) Solid state memory

It appears likely that we will soon have memories available which are comparable in cost to present core memories but comparable in speed to logic. This will change one of the parameters of machine design which has been nearly constant throughout the history of computers, the ratio of memory time to logic time, from about 100:1 to about 1:1. It would be most surprising if this does not have some effect. Programming would seem to gain a new degree of freedom. One possible effect may be more effective specialization of machine function without specialization of machine design. Floating point arithmetic might be programmed again, not wired, for example, to give greater flexibility of word size and significance arithmetic may have a better chance for effective implementation.

On the other hand, the forces influencing change are numerous, subtle, and complex. It is very difficult to forecast but fascinating to watch as events unfold. The foregoing statements assume that it is easier to program than to build machines. But one can also imagine ways in which this same memory development, with proper inspiration and motivation, might lead to simplifying the fabrication process. Modular building blocks for machines and systems of machines might then become part of our standard repertoire.

(3) Algorithms

This is an area where computer science will give us an undisputed benefit. Theoretical limits on the speed of algorithms will provide measures against which to compare performance and will inspire improvement. Analysis and classification of algorithms will begin to give formal structure to programs and guides to optimize design of both programs and machines. From this area will come the indispensable tools for understanding the information processes which are possible for us to use in solving problems.

The benefit will be felt, not only in increased performance on our present problems, which may be significant or not, but in providing us with constructive procedures for thinking about the information processes appropriate for our problems. It may seem facetious to suggest that the science of algorithms will usurp the role of calculus and numerical analysis as the primary tools for description and problem solving. It certainly is premature. But I will be interested to see what our attitude is about this at the end of this decade.

(4) Languages

In the short history of large scale scientific computing we have relied primarily upon one language, FORTRAN, and have accepted its limitations in the interest of pursuing the scientific problems at hand. Again, it has been the case that other languages might provide an incremental gain but that has not been worth an incremental effort by scientists to learn, to use, or to develop. Improvements have been made and will continue. Computer scientists are developing automatic code optimization procedures which may help performance and, perhaps, debugging. Monitoring schemes and performance measurement studies are making it possible to do time analysis of programs to increase the efficiency of codes. Factors of two, three, ten, or sometimes fifty improvement result. But with respect to learning languages, the scientific community has been conservative.

Now we may be reaching another kind of limit. Programming is a human effort involving a long chain of people and events before a complete program can be made to work satisfactorily. Programming time and the irreducible error rate at each step of the process places a practical limit on the growth of complexity of programs, generally by making the cost or time required to achieve a certain degree of complexity greater than we can, or want to invest. In spite of large programming investments and outstanding successes we are all aware of these limitations, and have had the experience of thinking of interesting programs which we were unwilling or unable to write. More significantly, some of the programs we have already constructed are maximally complex for our resources. FORTRAN is becoming a restraint that can be felt.

It is clear that this restraint can be relaxed since this is an area in which computer science has made progress since FORTRAN was developed. Iverson's APL, for example, is indicative as is Schwartz' SETL. In still another direction, Hearn's REDUCE is building a record of accomplishment. Within a decade, scientists will be multilingual and have greater freedom for scientific research as a consequence.

Another problem in the general area of languages which computer science is attacking is the problem of transportability of programs from one computing environment to another. Gradually, the structure of programs, compilers, and operating systems is becoming clear. We are learning how to isolate the essentially machine dependent portions of codes, and to bootstrap a system with minimum reprogramming effort. The benefits of this development are already being felt in economy of programming effort when changing machines. Ultimately, it may make an important contribution to scientific communication by making it feasible to exchange codes.

(5) Communications

This may make the most significant change in our daily working environment and seems to have large momentum, with stimulation from many sources. The National Bureau for Economics Research Center, which I mentioned earlier, is being established with remote operation in mind from its inception. So is the CDC-7600 installation at Berkeley for high energy physics. ILLIAC IV, at Ames, will soon follow and it seems likely that other centers for specialized disciplines with planned remote operation will soon appear.

The trend seems natural and inevitable. Research computing involves not only a computing machine but also a corpus of appropriate programs and an operating policy favorable to the work. Finally, and perhaps most importantly, it involves a group of scientists and support staff which can work well together and communicate freely to develop the research methodology. The success of this organization for research has been demonstrated in the national laboratories. It is not surprising that it carries over to computing with communications providing the means.

At the same time, this mode of operation is a departure from the organization of research computing which developed during the fifties and sixties when each institution built the local, general purpose computing capability which would best satisfy its overall staff requirements within the limits of its resources. This change requires an adjustment by all parties concerned and the transition will take time to accomplish. It will be interesting to see what changes in our working environment and relationships result.

These are several technological changes that may affect scientific computing in the near future. Others should be included, also. The availability of large data files, improvement in man-machine interaction, progress in data representation (including the question of what data should be stored and what should be reconstructed), and others will have a significant impact.

Yet each of these seems likely to have effects which are rather specific to particular fields of research, in the near term, and little influence common to all fields. Color graphics may be an exception.

One other project, which NSF is undertaking, should also be mentioned. That is a cooperative effort among several universities and national laboratories to analyze, certify, and document standard subroutines. The resulting library should give us greater basis for confidence in results and less trauma in carrying out research programs involving computing.

Before closing, I would like to mention the problem of publication. Scientific computing has labored under a handicap because it has not been possible to publish programs. A number of factors are relevant but I am not sure of their causal ordering.

(1) *Attitude*

Programming has been considered necessary but menial even though it has been the principal occupation of many scientists in terms of time and energy.

(2) *Language*

Mathematics has a language which is concise and makes the intellectual content clear. Often, the best description of a FORTRAN program is the program itself which is neither concise nor clear.

(3) *Utility*

A mathematical analysis of a theory or experiment can be universally understood, generalized, and used. A program is typically obscure, specific, and almost universally useless.

The belittling attitude toward programming, which is another carry-over of tradition, has certainly inhibited any attempt to solve the problem but failure to overcome the other hurdles does not encourage a change in attitude. It is a classical example of an impasse, one which natural scientists will not solve within the framework of their own disciplines.

It may be that computer science will make an important contribution here by developing the basis for describing and communicating programs in a really useful and general way. If that results, the benefit to science of improved communication may be great. It is interesting, though, that the path to this accomplishment will have been through byways such as automata theory, formal languages, perhaps set theory, the study of algorithms, and the structure of machines which have almost no discernible relevance to physical science.

We have seen that although progress in large scale scientific computing has been surprisingly rapid, it has also been bound by tradition. We have also seen that there is a long time constant in developing and absorbing technology. Both of these facts tend to become obscured by the activity around us but together they will continue to shape the near term future. At the same time, a new influence is emerging through the development of computer science which may provide the means to relax the constraints of tradition and expand both our conceptual and procedural horizons. The time scale for fundamental change, if it occurs, can be expected to be long but a decade may reveal the strength of the trend. It will be interesting to watch.

Computer architecture and very large problems*

by R. B. LAZARUS

University of California
Los Alamos, New Mexico

For the purposes of this paper, "very large problems" are defined by two properties: (1) There is an effectively unlimited amount of physics and of spatial detail which it would be useful to include if practical; and (2) the calculation must be completed in a limited number of hours. The best example is perhaps the global weather problem. We will obviously never put in all the energy sources or all the topography and we must obviously calculate faster than real time.

Such problems need big machines in the sense of operating as rapidly as possible on large numbers of variables which describe or pertain to a single region of space. It is the aim of this paper to consider questions of computer architecture in this context.

The questions of primary interest are (1) what computer architecture is best for such problems today, and (2) what architecture may be best ten years from now. These questions will not, in fact, be answered. The following comments may, however, indicate why the first question is unanswerable and help others in a search for the answer to the second.

To keep the problem within a reasonable scope, it will be assumed as a boundary condition that the cost per unit of arithmetic of the ideal computer for large problems must not be substantially greater than the cost per unit of arithmetic of, say, an IBM 360/195 or a CDC 7600. This assumption is intended to exclude an architecture which offers a factor of n in speed if the cost is up by a factor of, say, $3n$. This admittedly excludes an interesting area; if, for example, it becomes necessary to control Los Angeles air traffic by computer and the best available computer is too slow by a factor of three, then it would certainly be interesting to know whether the necessary computer could be built for a cost up by a factor of nine. Nonetheless, the restricted question would appear to be of sufficient interest, since many large problems, though important, command only limited funds.

Let us start by considering the role of logic elements. They differ in cost, speed, size, power dissipation, sensitivity, and reliability. In many cases, there are inherent trade-offs among these properties. Let us imagine an omniscient computer designer who has in mind all possible computer architectures—no, make that all possible computer designs—and who has full knowledge of all available logic elements. For all possible designs implemented with all available types of element, he wants to find that combination giving the maximum speed, subject only to the restrictions that speed-to-cost ratio be not much higher than what is now available and that the computer have a mean time to failure of many hours.

He would immediately realize that the problem is not well defined. He would ask what *kind* of calculation he is to maximize the speed of, and be told, "Large problems, as defined above." Noting that such problems have "large numbers of variables," he would fold into his task the consideration of the various kinds of memories available. He would then come up against the following major architectural problem.

Define access time as the time which must elapse between a decision to fetch an operand from a given address and the arrival of that operand at the desired function unit. Then, for all large-memory technologies today, the access time is long compared to the achievable average instruction execution time. (In other words, you can't win by rebuilding the IBM 704 with modern components.) What can be done? There appear to be only two things to do. First, one can try to minimize the number of operand fetches required during the solution of the given problem. Second, one can overlap the fetching of operands, both with each other and with computation.

It is interesting to ask whether these two things are in conflict with each other. For machines with internal

* This work performed under the auspices of the U. S. Atomic Energy Commission.

addressable registers, good coders (and compilers) exploit the first; by clever use of the registers, they try to minimize the number of times a given operand is fetched. For the upcoming vector machines, on the other hand, good coders will try to exploit the second; they will maximize overlap by favoring the vector commands, which stream operands from memory as fast as the memories and memory buses permit.

Is there, then, a conflict or not? There is a conflict only so long as the restriction on gate count (which may come from cost, size, power, or reliability) prevents us from having the best of both worlds. Here is precisely where the question gets so sticky. Are we discussing today's practical problems, or are we looking for fundamentals? This matter will be touched on again below.

In passing, it might be noted that this problem of long access time cannot be solved merely by development of a very fast memory, because transmission times for address and data would still be long. It is no help to postulate a general scaling down of the whole computer, so that all function units can be very close to the memory, because this will scale down the instruction execution time as well. A very restricted solution is suggested in the Appendix, but just for fun, since it certainly cannot be achieved within the next ten years. The long access time should probably be accepted as a fact of life.

At this point, our omniscient designer might note that, while memory access times are inherently long, it is relatively easy to achieve high bandwidth by a variety of methods. He might then pause to consider the methods appropriate to various architectures and note advantages and disadvantages.

The first technique uses a memory word which is two or more machine words in length. In all plausible situations, the number is a power of two and the machine words have consecutive effective addresses. For a given memory technology, this increases *potential* bandwidth as long as the read time increases more slowly than the size of the memory word. Whether or not it increases *realized* bandwidth depends on the mean number of *useful* machine words which are acquired by a fetch of a memory word. The technique is obviously appropriate for instruction fetching and for feeding streams of consecutive operands to a vector machine. With many independent memory boxes (see next paragraph), the technique is also quite powerful for most "naturally occurring" codes, if the boxes have fast registers to hold the last memory word fetched, or in the presence of a "cache" memory as in the IBM 360/85 and 195.

The second technique uses interleaving of many independent memory boxes. We may assume with no loss of generality that the number of boxes is a power of two and that they are interleaved on the low order bits of the memory word addresses. This technique is also obviously appropriate for feeding streams of consecutive operands to a vector machine. Let us examine the behavior of such a memory for a sequence of fetches from random addresses; for simplicity, assume there is only one machine word per memory word. Suppose we have an infinite list of random addresses, a clock, and the logic to pass one address per cycle to the appropriate memory box. If the order in which the fetches get accomplished is irrelevant (and if we have sufficient logic), then our steady state will either be one fetch per clock cycle or else all boxes working to capacity, depending on whether the clock is relatively slow or relatively fast compared to the memory cycle time. In either event, that steady state will constitute maximum available data rate.

If our list has precedence relations (as it certainly must when we mix in stores as well as fetches), or if we do not have facilities to queue up an arbitrarily long list, or if we do not have the logic to scan an arbitrarily long list in one clock cycle, then we will have conflicts and loss of data rate. It is probably not fruitful to derive results for random addresses, since there is a great deal of correlation in real cases.

It is worth noting that additional processors may be able to share a memory "for free" whenever a single processor leaves most boxes idle most of the time. Such idleness could be because of a relatively slow clock cycle or very many boxes, or it could be because of too many precedence relations in the work of a single processor (assuming that multiple processors have no, or at least negligible, precedence relations among each other).

The third technique uses separate memories serving separate processors. This is the technique of the ILLIAC IV, where each memory-processor pair works on a separate portion of the large problem. The potential bandwidth is simply the product of the number of such pairs and the bandwidth of an individual pair. The realized bandwidth is less by the mean fraction of processors doing useful work.

By this time, our designer, being merely omniscient and not divine, has developed a headache. He returns to his consideration of logic elements, having in mind that there are several ways to get whatever bandwidth he needs from memory. He takes a quick look at the possibility of using the best of everything. He imagines a design of eight super-processors with independent instruction streams, where each super-processor consists of 64 slave processors, each combining the arithmetic capabilities of a 7600 with vector streaming capabilities. Before bothering to add up the price, he sees that the mean time between failures will be a few minutes.

Concluding, then, that he must compromise, that he may use only a subset of the techniques which enhance speed for certain kinds of work, he realizes that his problem is still not well defined. He calls in a friend who knows all about programming, numerical analysis, and applied mathematics. He asks for guidance on the fundamental arithmetic and data flow requirements of the large problems under consideration.

Unfortunately, his friend points out two difficulties. First of all, there are trade-offs between the amounts of arithmetic and the amounts of data flow, at both the programming and mathematical levels. Second, the properties of any important computer which may come into existence will themselves influence the development of mathematical techniques.

The second point is brushed aside, and a new problem, this time well defined, is stated as follows. For all possible computer designs, implemented with all available types of element and applied to today's large problems with all well-known mathematical methods, which combination of design, implementation, and calculational method gives the fastest solution, subject again to cost and reliability restrictions?

Perhaps these gentlemen are busy somewhere solving this well defined problem. Unfortunately, they have not been heard from, and the problem is too difficult for ordinary mortals. What should be done?

What actually has been done in recent years is as follows. Various designers have chosen some medium-sized area in the design-implementation space, looked for a local optimum with respect to some set of pieces of problems, and proceeded to create a computer. During the creation time, mathematicians have made some exploration of the calculational method (and programming technique) space by analysis and simulation. After creation (if successful), programmers can be expected to find quite rapidly the actual optimum with respect to programming technique; over the years, the mathematicians will also move us steadily toward the optimum with respect to calculational method. In this way, points are located empirically in the space of interest, namely the design-implementation-method space.

It is time now to look more specifically at the present state of affairs. Consider the approximately 16 year interval between the IBM 701 and the CDC 7600. A typical large problem ran for about ten hours on the 701; a typical large problem runs for about ten hours on the 7600. The ratio of work being done is perhaps 1000; the cost ratio is perhaps five, leaving an improvement factor of 200. Most of this factor, which amounts to 40 percent per year, comes from raw component speed. The rest comes from improved design (architecture, if you wish), including floating point arithmetic, index registers, parallel input-output, sophisticated arithmetic engines, and, finally, parallelism among instruction decoding, addressing, data flow, and arithmetic. *Most* of what came from improved design was again due to improved component technology, being obvious enough in principle but requiring large component counts which, in turn, required cheap, small, reliable components. For the large problems, not very much at all, up through the 7600, came from what we would now like to call really new architectural concepts, like vector arithmetic, multi-processors, or parallel processors.

The reason why architecture has apparently played so small a role, to date, for large problems is precisely that 40 percent per year is very big. If implementation of a substantially new architecture requires a 50 percent increase in cost and a two year delay, one is giving away a factor of three to begin with. Furthermore, if the architecture moves us away from the optimum in method space (i.e., if new methods and/or reprogramming is required), one gives away a further factor; it is generally considered that at least a factor of four must be anticipated in order to motivate a substantial change in method or program for a large problem.

To say this again in other words: As long as 40 percent per year improvement keeps coming along "for free," the *short term* needs of the large problems under consideration here do not motivate a substantial architectural change unless the anticipated speed improvement is substantial. "Substantial" means a factor of four in speed-to-cost over the competition *after* correcting for delivery date at 40 percent per year, compounded.

There are, nonetheless, motivations. The first is the need to shift onto a more rapidly rising curve, if there is one, even if one takes an initial loss to do so. If routine improvements will come at a greater rate with some new architecture than with old architectures, then the short term loss from making the transition will eventually be overbalanced.

The second and more important motivation is the need to explore the design-implementation space in order to get ready for the time, which must come sooner or later, when nothing approaching 40 percent per year will be available in the implementation direction. The trouble is knowing where to explore, and how much to spend on such exploration.

To begin with, it must be noted that the manufacturers will continue to explore, through actual construction, architectures which look profitable. Although the nature of the expanding computer market is such that architectures will not look profitable if they are only good for large problems of the type considered here, some light will nonetheless be shed on our question of the best machine for such problems. It will not be shed optimally, but it will be shed, in some sense, for free.

There is a key difference in the importance of time between the commercial interest and the computer science interest. In the fullness of time, it will make no significant difference to computer science whether something was achieved a year or two earlier or later. But it can make quite a substantial difference to the company which achieves it first.

All in all, this author sees no valid basis for criticizing the nature of the action within the private sector. On the other hand, it will be appropriate from time to time for the Government to underwrite exploration of important areas where the chance for profit is too far off to attract private industry. Some comments may be in order on how such exploration should take place. The particular question of interest to this author is whether the exploration should rely on simulation or on machine construction.

Some years ago it was argued plausibly that the effective speed, for real large problems, of a new architecture could only be determined by implementing that architecture in a real computer as big and fast as anything else available. The argument was that only then would the appropriate people be motivated to optimize methods and programming. This may well have been true some years ago, but it is probably not true now. Two relevant things have increased in the last few years, namely the ability to do simulation at reasonable cost and the number of unemployed scientists.

CONCLUSION

To find the best computer, one must explore the space of computer design, componentry, mathematical method, and, programming technique. For a given computer design (or, at least, architecture), there has been substantial progress from improved componentry. This progress will continue for some time, but not forever. There has also been substantial progress from improved methods and programming techniques. This progress will also continue for some time, quite possibly forever.

On the other hand, one cannot say that, for a given componentry, there has been or is about to be substantial progress from improved architecture. Part of the reason is that the 40 percent per year of progress which has been available without architectural change puts a handicap on any development which requires more time (because it is breaking new ground) between choice of components and delivery. The rest of the reason must be that no new architecture has been invented which offers an order of magnitude improvement.

Some day, the rate of increase of component speeds must become small. At that time, architectural changes which give small improvements in performance will be profitable. In this area, it seems safe to assume that exploration by industry will be adequate.

If, on the other hand, as seems likely, the practical limit on gate count goes up by several orders of magnitude, substantial improvement will be available from architectural changes, and only from architectural changes.

It is on this basis of very large gate count that architectural exploration will be needed, in the opinion of the author. If such exploration is to be carried out be"ore the large gate counts are actually available, it must of course be done by simulation. The right time to begin is probably about ten years before the results are needed. Is that today? Was it, perhaps, a few years ago?

APPENDIX

If a memory technology came about which could give *one* function unit very fast access to all the words in a large memory, if there were an architecture with a crucial need for such very fast access from n function units, if such access to a small (e.g., register) memory were already in hand, and if the memory technology in question were so cheap that one could afford n-fold memory redundancy, then one might consider the following.

Let each function unit have its own memory, and let each memory start out with identical contents. Define two types of storing, A and B. A Type A store is the ordinary type, in which, logically, the old value of some variable is instantly replaced by the new value. A Type B store goes only to "empty" cell (i.e, it replaces dead, or garbage, information) and the information is not going to be refetchable for a long time. Then require all problems to restrict Type A stores to the small memory and make only Type B stores to the large memory.

Many readers will lose interest at this point; there are, nonetheless, many large problems which fit these rules. What is proposed, obviously, is that Type B stores be propagated from memory to memory at leisure. The whole thing would likely be of interest only if this propagation came from a natural diffusion inherent in the physics of the memory. For example, imagine that the binary storage element is a cell in a long filament. The filament is stable with all its cells zero or all its cells one. If any cell is changed, the change propagates along the filament in both directions. Each function unit gets at all the filaments at some convenient station along their length.

Scientific applications of computers in the '70s

by M. STUART LYNN

Rice University
Houston, Texas

It is still fashionable to predict that what happens in the future of computing will be a glorified extension of what has happened in the past. Thus, the last decade has seen an explosion in all uses of computers and therefore, so the fashion would dictate, this explosion must necessarily continue if the faith is not to be shaken.

There is no doubt that exciting new ways of putting computers to work will be found. This writer is in no better position than anyone else to forecast what these will be. It will, however, be the main thesis of this discussion that the explosive rate of growth will *not* continue, particularly in the area of scientific applications, but that the emphasis will be on making known applications work, and work in a more meaningful environment.

GOLDFIELDS

The gold-rush of the sixties is over—this period was characterized by taking a field of man's endeavor, any field, multiplying it by three and attempting to automate it, independent of whether or not such automation could in any way be justified. Support was easily available for anything and, as such practically every field of man's interest was a candidate for computer application. The fact that reality has fallen short of promise has left a skeptical, if not nasty, taste in many mouths. It is probably true, however, that we have been left with a more realistic perspective as to the meaningful uses of computers and, even more importantly, the limitations of such usage.

The gap between promise and reality is, for example, evident in application areas dependent upon modelling or simulation. Ten years ago it was customary to insist that we were on the verge of modelling the world and its component parts to fifteen decimal places; all that was required was another substantial injection of federal or other support to achieve the necessary breakthrough. In application after application a similar pattern was followed: early promise with highly simplified models indicated great things to come, only to be followed in time with the limitations of reality, as the complexities of highly nonlinear or otherwise complex problems and indeterminate data circumscribed the bounds of possibility. The debris left behind in many of the goldfields became depressingly familiar.

Now we no longer attempt fifteen decimal places. We talk instead of provoking lines of thought which might not otherwise have occurred. This is probably a healthy trend, although it is perhaps unfortunate that we are still not learning from the past in some newer application areas.

INDUSTRY TRENDS

In addition to the effects of left-over skepticism, trends in the computer industry will also mitigate against a continuation of the applications explosion. It is certainly highly probable that the current computer overcapacity in this country, when combined with the decreasing cost/performance curve of computer systems, will cause considerable pressure on the industry to underwrite new applications as a means of supporting continued expansion of the industry. However:

- It is likely that the most acceptable applications will be those whose economic pay-off is readily justifiable in the short-term, in view of past management experiences and of the current economic climate. This would tend not to favor scientific applications.

- The effects of unbundling have already moved the onus of applications research and development more than ever on to the end-user. This will continue. Whereas this has little impact on the traditional user of computers, it reduces the prospects of important uses of computers materializing among new user classes.
- The increasing pressure for rapid economic justification lessens the changes of serendipity yielding new applications. The principal opportunities for serendipity will continue to move back to the universities; this is probably not a bad thing, except that universities are not always in the best position to judge user needs over the long-term.

WHAT WILL HAPPEN?

This writer suggests that the following are likely to be characteristic of scientific applications of the next decade:

(1) The areas of application familiar today are unlikely to change substantially. The relative emphasis between areas is, however, likely to change as a reflection of society's changing priorities, as has already been observable over the past three years. Thus, for example, as a reflection of NASA's changing priorities, the use of computers in support of this nation's activities in space will shift toward the many possibilities involved in applications relating to the Earth Resources Program, a shift that has already begun to take place. Again by way of example, the ability to simulate ever more complex molecules and chemical reactions will have important applications in the petroleum, chemical and pharmaceutical industries.

(2) Basis technological developments in support of applications will not mature at anywhere near the pace of the sixties. The emphasis will shift toward making fuller use of existing technologies and in making them support each other. Thus, for example, the concern of the sixties for speed and compactness in algorithmic processes will have diminished importance in the complex environments of present and future operating systems and as the cost of computing continues to decrease. On the other hand, the unnatural boundaries between such areas as numerical analysis, mathematical programming, computational statistics, signal analysis, pattern recognition and control theory will continue to become less well-defined.

(3) There will be more emphasis on total systems implementation of known applications so that they are economically (or otherwise) useful to the end-user. This will include careful exploration of computing environments in order to minimize overall costs and to maximize, *inter alia,* user productivity and convenience. In this context there will continue to be an increasing emphasis upon reliable systems. Substantial investment in research and development of scientific computer applications will be closely geared to their proven practicality and utility in society as a whole.

(4) Basic methodologies already well understood in established application areas will be brought to bear upon newer areas. Examples of this are to be found in the electric power industry and in water estuarial modelling where only too often the simulation techniques currently used are primitive by comparison with what has been developed in other application areas.

(5) The computer will continue to be brought to bear, only with ever increasing emphasis, in making the scientific research process itself more efficient. Advances in the technology of interfacing with computers will become sufficiently reliable and efficient that the use of such technology will become widespread (many scientists use computers today no differently than they did ten years ago, in spite of the changes that have taken place). The ability to interact efficiently with large data bases, the growth of extensible languages, the development of special processors configurable by the user to meet his particular requirements, are examples of technologies which will have an impact upon ways in which scientists use computers.

This appraisal is not intended to be pessimistic. Within the above confines, the opportunities for using computers in exciting ways should be as great, if not greater, than ever before. The challenge, however, is one of turning more of the promises of the past decade into accepted reality.

The functions and elements of a training system

by B. A. JONES

Bankers Trust Company
New York, New York

"From a systems point of view, the design of an operation which can successfully carry out the training function becomes a problem of creating a system to accomplish a given end result or objective. In the case of training, this end result is to effect a group of planned and predetermined behavior changes in the organization."[1]

The following are five basic functions that I feel are essential for an effective training system that will allow you to effect that group of predetermined behavior changes:

I. Training Analysis
II. Educational Consulting
III. Training System Support
IV. Public Relations
V. Management

The elements of each of these functions become the procedures necessary for the successful operation of the entire training system. To better understand these five basic functions it is necessary to look at their elements.

The training analysis function (Figure 1) and its elements is the critical activity in determining training requirements.

We begin the analysis by gathering valid data. That is, in terms of performance, what is it you want the trainee to do that he is not now doing, or what is it you want him to do better? Determine whether these are basic skills and knowledge he should possess or whether they are supplemental skills and knowledge that will upgrade his proficiency. This may determine the priority of training.

The second element in the training analysis function is to address performance standards by conducting a deficiency analysis. At this point the following determinations *must* be made:

1. Is this a training problem?
2. Is this a feedback problem?
3. Is this an attitude problem?
4. Is this due to a lack of resources?
5. Is this due to a lack of reinforcement?
6. Is this a procedures problem?

When this element of the training analysis has been completed, the suggested solution to the initial request or desired end result may be made. If the suggested solution is to develop a training curriculum, the third element in the training analysis, that of stating the terminal behaviors, begins.

Once this has been accomplished, the design of the training curriculum proceeds. It is at this point that the cost of training, the length of training, the media, the method of evaluation, may be determined.

The implementation and evaluation of the training curriculum *may* end the analysis function. If the desired end result was not obtained, it may be due to a bad analysis or a poor design. Whichever is the case, a reiteration through the process is essential. If the desired end result has been met, the final element is to maintain the material. That is, if it is a one time only curriculum, it is placed in a history file. If it is an ongoing curriculum, it is kept up-to-date.

When the suggested solution, the second element, is *not* the design of a training curriculum, the Educational Consulting function becomes crucial. Figure 2 illustrates the elements of this function. It differs from the training analysis in that the training person acts only as an advisor, i.e., he can suggest solutions but is not accountable for implementation or evaluation. Figure 3 lists some of the skills and knowledge necessary for successfully performing the consultation function. The questions asked during the follow-up emphasize the advisory capacity of the consultant.

The third function of the training system, Training System Support, is basically an administrative and maintenance activity. However, the support is essential for a training division if it is to effectively serve and

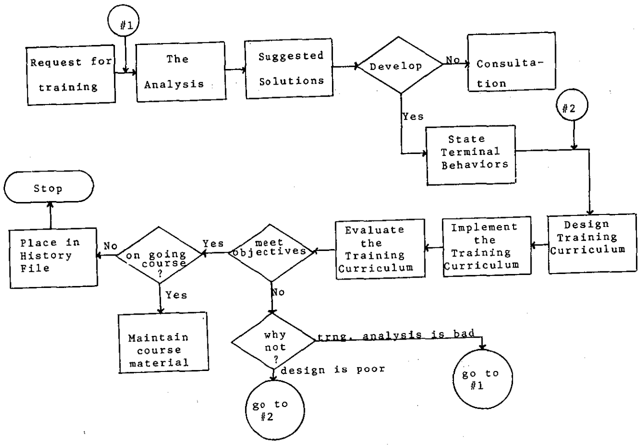

Figure 1—Training analysis function

assist its users. The elements of this function are exhaustless, but three of these elements are vital.

Record keeping provides an historical reference for each student and aids in defining what courses he must yet complete in terms of his career development. Record keeping is of great importance also in prepar-

Equipment maintenance is necessary for an effective and efficient training facility. It doesn't matter if the facility has only a one person training staff, a conference room, and an overhead projector, or is a large scale multi-media facility with a full-time training staff. Calvin R. Gould, put it this way:

> A national meeting of professional communicators was ending its second day with a banquet that featured a learned and distinguished individual. Before the banquet, the speaker's assistant set up a pair of 35mm projectors and a screen. This person would be the projectionist and would work from a cued copy of the speech. While this practice requires that the speaker read his material, it is more effective than asking for each slide, and if well rehearsed, can be professionally done. The audience quite properly expected a worthwhile message from the speaker, a vice president of a large manufacturing company. They weren't to be denied. His initial remarks, charging the audience with their responsibility to world communications, proved he was going to be a dynamic speaker. As the first slide was projected the house lights went off right on cue. Everything was working like clockwork, even the pause that followed the first slide seemed effective and timely . . . except it seemed to be longer than necessary . . . really too long. Finally the audience, the projectionist, and the speaker all seemed to realize simultaneously that the speaker's lectern light went out with the house lights. The fifteen minutes interruption required to recover from this unfortunate situation was enough to seriously damage the communications effectiveness of this presentation. I was in the audience, and I have long forgotten the message.[2]

A schedule for the maintenance of equipment must be established, fully documented and enforced. It should include timetables for the changing of bulbs, the cleaning of equipment, periodic maintenance checks, etc.

Inventory control is important, since in the majority of installations the training division has equipment that can be borrowed by other departments. The unavailability of equipment can often lead to the cancellation of a class. The availability of existing equipment should be documented by an inventory and status report form. Figure 5 illustrates the form used at Bankers Trust.

DESCRIPTION	QUANTITY	CONDITION	AVAILABILITY

The Public Relations function has two distinct elements. Within the organization, communication is with users of data processing training. The promotion of in-house courses and the *selling* of services are necessary in order to establish and maintain credibility. The external element is, on the one hand, *to let the rest of*

the world know what your organization is doing, and, on the other, to make sure that you yourself are not re-inventing the wheel.

The fifth function, that activity which permits the combination of time, people, and money to efficiently achieve the desired end result, is the Management function. It has four major elements: Planning, Organizing, Leading, and Controlling. Within each element are specific activities.

Since most data processing training staffs are not expert in management philosophy or management development, yet find it necessary to *manage* a training system, I offer the following descriptions of the four elements in the management function from Louis A. Allen, president of Louis A. Allen Associates, Inc.

I. Planning

"Planning is the work a manager does to master the future. Planning requires that a manager think before acting. In the process of doing this, he will map out beforehand what he expects to accomplish, how he can best do it, and the limits of cost and other factors that are significant. The principles of planning stress the importance of current decisions in limiting our potential range of action in the future.

They point out that the further we project a plan into the future, the more unstable and undependable it becomes. A key principle emphasizes the tendency of people to resist changes. Resistance to change can be overcome primarily by providing for participation and communication in the planning process. Plans are considered in terms of the specific activities of forecasting, establishing objectives, establishing programs, scheduling programs, allocating resources, setting policies, and establishing procedures."[3]

Figure 6 illustrates how our training staff at Bankers Trust interprets this element.

II. Organizing

"Organizing is the work a manager does to arrange and relate the work to be performed so that it can be carried out most effectively by people. An organization is not people but the mechanism arranged to enable people to work most effectively together. An organization chart is helpful but the chart itself is not the work of

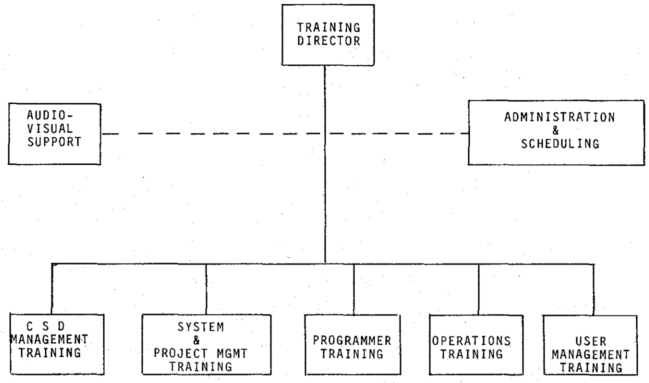

Figure 7—E.D.P. training division

organizing, for this is how one insures that the most work is accomplished by the fewest people at the least cost."[4]

Figure 7 illustrates the organization of our training division.

III. Leading

"Leading is the work a manager performs to get people to take required action. Leading is the energizing function that makes planning, control, and organizing possible. In studying what it takes to lead, we find that there is no one best management personality. The proper blend of authoritarian and democratic leadership knowingly applied is best. The specific activities within this function are decision making, communications motivating people, selecting people, and the development of people. We are at the present time within our element of control. A lot of work has yet to be accomplished so that these two elements of management will relate directly to our responsibilities."[5]

IV. Controlling

"Controlling is the work a manager does to assess and regulate work in progress and completed. The control is the manager's means of checking up.

While control by personal observation is often necessary, the most desirable method is control by exception. Here the principle of Least Cause and the principle of Point of Control are important to ensure that the greatest amount of control is applied where it will do the most good. The significant activities inherent in good control are establishing performance standards, performance measuring, performance evaluating, and performance correcting."[6]

It is apparent that, due to the sheer length of the process, a training staff of more than one is desirable. However, given that the training needs are clearly defined and not too abundant, and that time and money are available, such a process can be implemented effectively by a minimal staff. To a great extent, this is due to the increasing availability of vendor-supplied training materials, and also to new, multi-media techniques for its presentation.

To properly select media that will meet training objectives, one must understand the advantages and disadvantages of each. The most commonly used (and misused) media are the spoken and written word. Several studies have indicated that we retain only 20 percent of what we hear. It has also been cited that the average student possesses a reading level of eighth grade or lower. Therefore, it is necessary for the trainer to know his students' abilities and to adjust his communication methods accordingly.

The studies on learning further suggests that we retain 80 percent of what we see and as much as 95 percent of what we both hear and see. Thus, it appears that a lecture supported with various media would allow us to satisfy our objectives in the most efficient and effective manner.

It has been my experience, being fortunate enough to have access to a very sophisticated multi-media training facility, that the integration of various media into our training system has accomplished several things:

1. This integration makes use of two or more senses and
2. More easily establishes a relationship between the unknown and the known.
3. Often, visuals can save teaching time because they add to the student's ability to arouse and retain interest in the subject.
4. Visuals tend to create a sense of involvement and participation.
5. When color is used in visuals, the retention rate is vastly increased.

There are certain obvious drawbacks when a training facility is heavily involved with the use of audio/visuals. I have stated earlier that the record keeping function is essential in the smooth and effective operation of a training facility; I would like to emphasize this importance when using audio/visual media. The hardware required for the use of audio/visuals must be maintained as "Operational" at all times. It is *most desirable* to have backup for each piece of equipment you are using; the consequences are self-evident.

Staff resources must often be increased to support a multi-media facility, e.g., for maintenance and administration. However, once standards and procedures are developed for maintaining and scheduling equipment, the advantages one can attain from the use of multimedia are considerable.

In summary, when selecting media for communicating to the learner, consider the following procedures:

1. Determine your training objectives *first*, then determine the means whereby you can convey them to the student.
2. Consider the physical constraints; how will they affect the media you have selected? How many students will you have at one time? Where will they be trained?

3. Determine as best you can the collective backgrounds and abilities of your students, and which media will have the greatest appeal and effectiveness for them.
4. Examine carefully the economics of the ideal system, i.e., look carefully at the cost of alternatives.

SUMMARY

A Training System (the process) is a methodology with established functions, procedures, and activities one can follow to effectively and efficiently achieve a desired result.

A properly evaluated multi-media system, when well maintained, will improve the learner's ability to comprehend and retain the training supplied. This will allow the training division to accomplish its objective, that of giving the user of its services what he wants, when and where he wants it.

Planning data processing education to meet job requirements

by JAMES O. HAMMOND

IBM Corporation
White Plains, New York

The greatest single expenditure that a data processing organization has today is for its human resource. This has been dramatically illustrated in several well-known studies. The cost of human resources continues to rise in data processing. Computers and systems are becoming more and more complex. It has become extremely difficult for programmers and analysts to know all the essential things about a system. This is especially true with the large, widespread teleprocessing networks. This complexity of sytems is forcing more and more specialization in computer technology. At the same time, small computer staffs find that although a few staff members may know all that is required to support a system, it is frequently difficult to identify job responsibilities in such a way that maximum efficiency can be attained for the benefit of the business.

Most data processing organizations have major effects on their parent company's ability to meet the needs of its business. It becomes of vital importance, therefore, that the data processing or information systems department, as they are frequently called, be managed as efficiently as possible providing the business support to its parent company in the most optimum fashion. Obviously, the management of any data processing department is an important key factor in its success. In this day and age of national economic lull and austerity moves in business to get more for the dollar spent, it has become even more important that management exercise its very best judgment at all times to run the data processing department more as a business and not just as a support function. In other words, have as valid justification that the money spent is worth what is being gained from the output.

There is another extremely important factor to consider in maintaining a high efficiency level in a data processing organization. This factor is the utilization of the staff employees or the bulk of the human resource. If the data processing staff is selected and trained to meet the requirements and needs of the business of the parent company, then a data processing organization has gone a long way toward solving efficiency problems not to mention personnel problems and potential large cost savings that can be gained.

The staff human resource portion of a data processing organization is the one addressed in this paper. More specifically, ways of defining and structuring data processing skills and job responsibilities are explained. Approaches are included on ways of defining an education program to provide the knowledge and skills that may not currently exist in the skills mix of the data processing staff.

Keeping in mind that all the other key factors of operating an efficient, productive data processing organization have not been forgotten, concentrate for a moment on how we might go about putting some form and rationale to human resource selection and training.

One of the most effective ways of relating data processing skills requirements, and in turn DP education, to a data processing organization is to start with the process being used to develop and implement data processing products. Relating skill requirements to the process is especially effective because the process is normally a well established one with which most company management are familiar both inside and outside the DP organization. Since the DP process is the mainstream around which the majority of all other DP activities in a department revolve, it is most likely a well defined and valid process. If the DP department is just being organized or for some other reason the process to be used is not well defined, then first things should be first—the process should be clearly resolved and defined.

The major steps of the DP process will vary from one DP organization to another and, of course, from

Figure 1—DP process steps

one company to another. This is expected and even desired if the organization is being primarily tailored to meet the needs of the parent company's business.

Figure 1 shows a selection of DP processes chosen from the DP organization of several companies in the United States. It can be seen, as was just mentioned, that the steps in the processes do vary. It is interesting, however, to notice that in spite of variations in the steps of the process and that some of the steps are called by different names with essentially the same meaning, that there is a thread of commonality through all the processes. There are some process steps that are common to all data processing organizations regardless of size, complexity, systems types, or structure. Three of these common steps are design, install, and maintain.

It is important that the major steps of the process be clearly defined in any given DP organization where the human resources are being studied. Once this is done a framework is established around which the human resource requirements can be structured. The process shown in Figure 2 has been selected for the purpose of illustrating how we can go about relating the human resource requirements to a DP process.

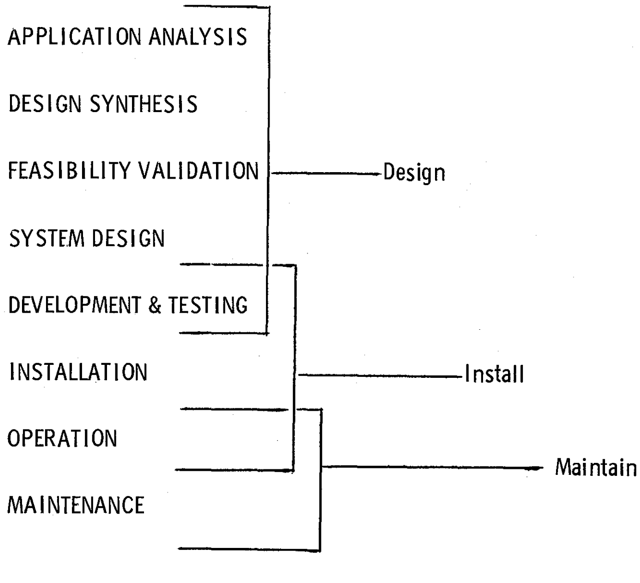

Figure 2—The process

Considering the common thread through the processes again—design, install, and maintain—these general terms can now be expanded into the selected process.

Before we go further in skills requirements structuring, we must make sure that each step of the process is defined well enough so that there is no miscommunication. I have attached the following definitions to each step of this process. Keep in mind that there is no hing fixed about the process and the associated definitions that are being used in this example. Although, according to surveys made, this is one of the more common processes, the steps and definitions may be different for various DP organizations.

So that we may continue our analysis, here are the definitions that will be used.

Process Steps

I. Applications Analysis
II. Design Synthesis
III. Feasibility Validation
IV. System Design
V. Development and Testing
VI. Installation
VII. Operation
VIII. Maintenance

Definitions

I. Applications Analysis

This first step includes defining the problem, analyzing and documenting the existing system, describing the processing, defining output and performance requirements, estimating the value of what is required, and developing and presenting the initial specifications to management for their review and concurrence.

II. Design Synthesis

This step includes establishing project planning and control, checking and refining the systems requirements and initial specifications, developing preliminary design alternatives and selecting a solution that is most economically feasible and best meets the requirements specified (with supporting analysis from Feasibility Validation). The system solution is then proposed to management where a decision must be made whether to proceed into System Design or consider alternative solutions.

III. Feasibility Validation

This includes the processing testing the performance, technical feasibility and validity of design alternatives or existing solutions by creating prototypes, models or through simulation. Major cost and performance improvements can be made possible by the application of standard solutions and generalized program designs already available. Adaptations of existing systems or generalized programs may be entirely adequate solutions; therefore, no further design work would be required.

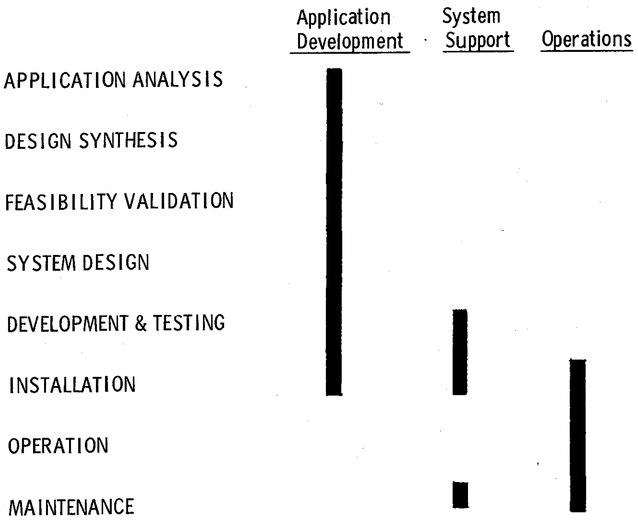

Figure 3—The process expanded

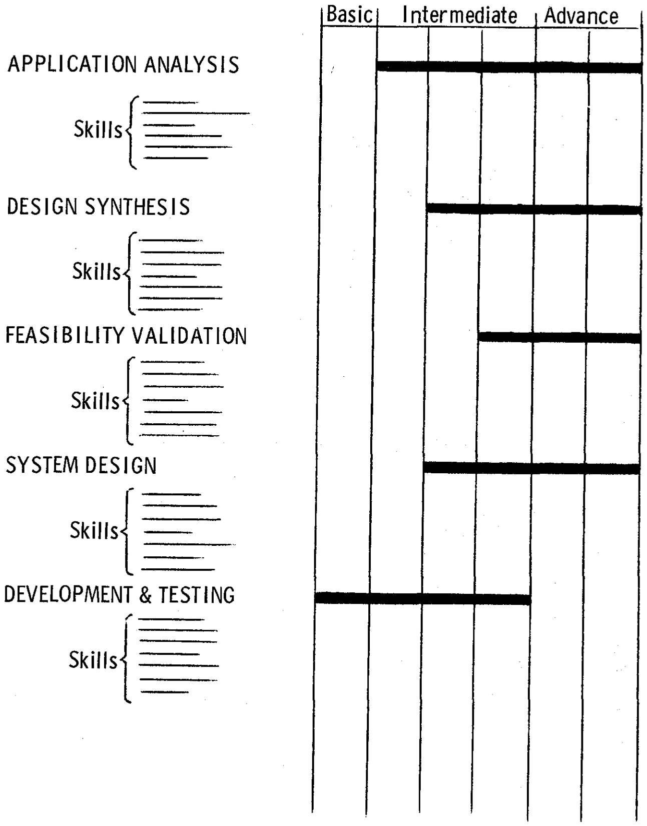

Figure 4—Application development

IV. System Design

This step includes planning and designing the details of the systems solution using the output from Design Synthesis and the feasibility model, selecting hardware and software, developing the new procedures and test plan, and identifying each program.

V. Development and Testing

Here the process is completed and proved by translating the system and program specifications into machine-readable code, testing and debugging this code and documenting each program module.

VI. Installation

This step includes converting data files, transactions, software and hardware used by the existing system to meet the requirements of the new system.

TITLE:
SENIOR ASSOCIATE PROGRAMMER, DEVELOPMENT.

GENERAL CONCEPT:
AN ACTIVE MEMBER OF AN INTERNAL DATA PROCESSING SYSTEM APPLICATION TEAM, RESPONSIBLE FOR DEFINING PROBLEMS, PROPOSING SOLUTIONS, DEVELOPING AND TESTING THOSE SOLUTIONS.
HE IS QUALIFIED TO SPECIALIZE IN THE AREA OF PROGRAM MODULE DEVELOPMENT.

SPECIFIC RESPONSIBILITIES:
(1) THE PRECISE DEFINITION OF PROGRAM MODULES (INPUT, TRANSFORMATION, AND OUTPUT) WHICH WILL IMPLEMENT THE SYSTEM DESCRIBED IN SYSTEM DESIGN.
(2) THE DOCUMENTATION, FLOWCHARTING AND CODING OF THE MODULES SPECIFIED.

COMMUNICATES WITH:
TESTING SPECIALIST FOR RESULTS OF MODULE AND SYSTEM TESTS.
SYSTEM DESIGN SPECIALIST TO REQUEST MODIFICATION OF SYSTEM SPECIFICATIONS, IF THEY ARE FOUND UNCLEAR.
MANAGER TO REPORT PROGRESS AND RECEIVE ASSIGNMENTS.

APPROPRIATE TOOLS, TECHNIQUES AND SKILLS:
ADVANCED PL/1
MODULAR PROGRAM DESIGN
PROGRAMMING TECHNIQUES
OPERATING SYSTEMS INTERFACE

PROMOTION POSSIBILITIES:
STAFF PROGRAMMER, DEVELOPMENT AND TESTING
SENIOR ASSOCIATE PROGRAMMER, SYSTEM DESIGN

Figure 5—Job description

VII. Operation

This step includes running the designed and tested system (or application) on the computer.

VIII. Maintenance

This includes the maintenance of the software systems programs and applications programs, e.g., changes, extensions, and optimization.

There are specific skills, tools and techniques that must be known and applied to accomplish each of the steps in this process. If the organization is a large one, a staff member might specialize in one or two of these steps and be required to master a smaller number of tools, but be able to apply these with considerable expertise. A small DP organization would not have a requirement for such extensive expertise; the staff member may, therefore, be skilled enough to perform several of the steps in the process to a much less level of complexity.

At this point the DP organization functions and job responsibilities can be related to the process that has been described. The organization functions can be identified as being three main segments of activity:

1. Application Development
2. System Support
3. Operations

Figure 3 shows how these organizational functions can be related to the process. Notice the overlap among the functions. For example, the system support function overlaps the application development function in the development and test step and installation step of the process. In large installations where a high degree of specialization may exist, these overlaps indicate the points where responsibilities are passed from one person or group to another. It is extremely crucial that these key points of communication are identified and the responsible staff members are made aware that this "passing of the baton" so to speak, is an important part of their responsibility. It is equally important that they be adequately trained to carry out these tasks with great efficiency.

Now take another cut at the same process from the individual staff member point of view. For the purpose of analyzing how this might be done, consider the applications development function alone for a minute. The staff working within this function of a DP organization

Responsibilities/Skills
(Be Able To:)

Application Analysis

Analyze existing system/applications
Document system
Define system requirements
Development and present initial specifications

Design Synthesis

Refine initial specification
Develop conceptual solutions—design alternatives
Identify and select known/existing solutions
Specify details of each design alternative
Estimate development, conversion, installation and operating costs
Test and evaluate alternatives and select best solution
Present proposed system solution

Feasibility Validation

Create and test prototype systems
Construct and analyze or simulate models
Compare prototype or model to required systems performance

Systems Design

Development systems design work plan
Document system in detail
Design forms and reports
Finalize record and file requirements
Define data editing and validation rules
Select final hardware configuration and software
Document controls, audit trails, back-up procedure
Write new and revise old procedures
Plan system test and prepare test data
Prepare computer operations work flow
Document computer flow and identify each program

Development and Testing

Define program modules
Flowchart, code and document program modules
Design and implement program module tests
Implement system tests specification in system design

Technical Strength Definitions

0 has no knowledge
1 understands capability and applicability
2 can use technique effectively
3 can maintain, modify and create new features
4 can synthesize and evaluate to reduce or eliminate analysis, machine runs, development or tests based on his wide knowledge of alternatives and depth of experience.

Figure 6—Programmer/analyst in application development environment

is made up for the most part of one of three types of personnel: analysts, programmers, and managers. The analysts are known as systems, application or program in most cases. The analysts' job responsibilit'es can range across the analysis, synthesis, validation, and design of DP systems and applications. Programmers are generally of two primary types, applications and systems. Applications programmers program and test primarily business applications whereas system programmers program primarily control and system applications. There are a wide range of job responsibilities performed by programmers at all levels of complexity. The managers referred to here are technical managers. It is important to identify the job responsibilities of higher management along with all the other members of the organization but higher managements' job responsibilities are broader, less technical, and more administrative. For this reason they have been excluded in the sample being used in this paper. The technical manager is one who has direct supervision over a small staff of programmers or analysts and is able to understand technical detail, at least within his assigned responsibilit'es.

There are numerous titles for programmers and

Figure 7—Programmer/analyst in application development environment responsibility (skills) matrix

analysts. It is best, of course, to define job levels using the titles of a given DP organization. In Figure 4, the levels—basic, intermediate, and advanced,—have been used to relate job levels to the process. The bar graphs under these levels give an indication of the approximate average level required to perform the job responsibilities in the corresponding process steps. For example, most senior staff personnel have had experience and/or training in development and testing before advancing to more senior positions in either systems design, feasibility validation, or design synthesis. This type of structuring forms a rather neat array of potential career paths.

Job levels, titles, and major responsibilities are traditionally structured into a job description. Job descriptions can range in form from the one sheet summary shown in Figure 5 to very detailed descriptions. In all cases, it is worthwhile specifying the

Technical Strength Definitions

0 has no knowledge
1 understands capability and applicability
2 can use technique effectively
3 can maintain, modify and create new features
4 can synthesize and evaluate to reduce or eliminate analysis, machine runs, development or tests based on his wide knowledge of alternatives and depth of experience.

Figure 8—Programmer/analysts—Responsibility matrix expanded

knowledge and skills required as well as promotion possibilities. This information is valuable to management both in utilizing the employees best talents and planning for his career advancement.

A further expansion is necessary of the knowledge and skills required to do the jobs within each step of the process. If some type of job analysis has not been performed on the data processing organization in question, then now is the time. What the job involves, the complexity of the technical level, the associated responsibilities, and, last but not least, the knowledge and skill level required to do the job all must be defined to fulfill the requirements specifed in the steps of the process. Much of this information can be structured on the job description summary sheet that was just described.

Job analysis should be done by professionals who have had experience in making such analysis. This type of study is usually performed for a fee by an outside consultant. If the consultant is carefully chosen the results will be well worth the money but be sure that he has extensive data processing expertise on his staff to participate in the analysis. Also make sure that his analysis is going to be provided to you in a form that fits your needs and is tailored to the process in your organization.

There are many good approaches to job analysis Most of them involve some type of general experience questionnaire and the observation and interview of selected employees doing their job. It is important to make sure that the employees have a good underst'nding of what is being done and why job related questions are being asked. Employees quickly become skeptical and concerned when a lot of questions are asked about their job and how it is performed. The cooperation given by the staff in programs such as this will be much better and with a more positive attitude if the reasons are first clearly explained.

Under each of the process steps the major skills, actions, and knowledge are identified that are important in accomplishing the step in the DP organization. Try to refine these major items as much as possible so they will be concise yet descriptive of the responsibility. Sometimes it is difficult to express all the items purely in the terms of skills. For this reason be practical and realistic about the results by using a mixture of skills, actions, and knowledge. This approach seems to render a better level of definition.

Figure 6 shows how this expansion can be accomplished. Keep in mind that we are talking about the application development function of the DP organization and the associated programmer and analyst staff. For this reason the expansion shown is for the first five steps of the process.

The technical strength definitions below show how knowledge levels can be identified. Once again these definitions should be prepared with the requirements of the organization in mind. There must be an adequate range in the knowledge levels. With programmers and analysts it is especially desirable to be able to identify whether they can explain a concept and apply it as well.

Technical Strength Definitions

0 has no knowledge
1 understands capability and applicability
2 can use technique effectively
3 can maintain, modify and create new features
4 can synthesize and evaluate to reduce or eliminate analysis, machine runs, development or tests based on his wide knowledge of alternatives and depth of experience.

You will notice that these levels are primarily for programmers and analysts so that we may continue to expand our definition of the application development function.

All the data that is needed to put together a summary skills matrix of a selected DP organization should now be available. The data includes:

1. Definition of the steps in the DP process to meet the needs of the business.
2. Definitions of job responsibilities to meet the process requirements.
3. Association of these job responsibilities with defined jobs.
4. Identification of the level and possibly the title of each of the defined jobs.
5. List of the major relevant skills, actions, and knowledge to meet the defined job responsibilities.
6. Define the strength levels of the skills and knowledge requirements.

A summary skills matrix can now be constructed by inserting the strength indicators required for each defined activity of each process step. The strength indicators are placed in the appropriate job title or level column.

Figure 7 shows how the technical strength indicators are added to the System Design step of the process. The strength level definition and the job level to which it is associated is determined primarily from the data obtained as a result of the job analysis and survey of the staff's skills.

When the summary skills matrix is constructed for all members of the DP organization, it becomes an invaluable management tool in planning and obtaining the required skill mix. The skills matrix also acts as a key index in planning tailored education for the staff. This can lead to significant savings in education expenses to a company.

Using the summary skills matrix and data from the job analysis and knowledge surveys, a trained industrial educator can determine what additional knowledge and skills are needed to enhance that already possessed by the staff. The identification of the missing skills and knowledge is the foundation on which future training

Name:
Business System Design

Duration:
Five days

Audience:
Those with the responsibility for the detailed design of a business system.

Prerequisites:
Experience in program development and testing or successful completion of the development and testing curriculum.

Objectives:
Upon successful completion of this course, the student will be able to:
Develop cost estimates and a work plan for scheduling and controlling the work through the design phase.
Define the record content, file organization, storage requirements and access methods.
Define data editing and validation rules, controls and audit trails.
Design the necessary forms and reports.
Complete the detailed documentation of the system, specifying the input, output, processing and file requirements of each program.
Prepare the systems test plan.

*Topics**	*Hours*
Systems design cost estimating planning and scheduling	2
Detailed record design, file organization and access method specification	4
Editing, validation, controls and audit trails	2
Forms and reports design	2
Procedure writing	2
Systems test planning, test data and file preparation	4
Program specification and documentation	4
Estimating programming development time	2
Case study	8
Total	30

* These topics teach to the 2 and 3 technical strength levels.

Figure 9—Course specification

can be based. Much of this needed training can be accomplished on the job or through self-study. Some of it will require more formal classroom education. In any case, the education will be tailored toward the business needs and requirements since it is based on a foundation geared toward that same goal.

Regardless of whether the training program required is going to be developed in-house or contracted out to an education company or computer manufacturing company, it is good to have at least a general specification of the type of training needed.

Using the related job responsibilities boxed in on Figure 8, a training specification can be written. Job responsibilities that are related should be clustered together so that eventually a series of topics or modules can be defined to teach the relevant subjects. Related topics, in turn, are normally grouped together to form a course.

The course specification shown in Figure 9 is one designed to teach to the 2 and 3 strength level on all the job responsibilities boxed in Figure 8. Notice that the course specification identifies the most pertinent facts about the training needed. The audience, prerequisites and a clear definition of the objectives are the most important items. Individual topics that make up the course and the approximate duration of each can be included when they are needed. The purpose for using a duration on each topic is to give some indication of the depth that topic covers.

I said at the beginning of this paper that surveys show that the greatest expenditure that a data processing organization has is for its human resource. Actually it is the knowledge that is being purchased. This statement applies equally as well to most all human resource requirements in industry. In Peter F. Drucker's recent book, *The Age of Discontinuity*, he treats knowledge as one of the four discontinuities. Mr. Drucker says, "Knowledge, during the last few decades, has become the central capital, cost center and the crucial resource of the economy."

Since knowledge is a very valuable and expensive commodity it should be treated as such. Planned education according to the needs of a business will impart knowledge where and when it is required.

Modular training—A new emphasis

by ROGER W. KLEFFMAN

United Air Lines
Englewood, Colorado

INTRODUCTION

During 1970 and early 1971, United Air Lines and IBM implemented a PARS-based (Programmed Airline Reservations System) reservations system. This system is written in Assembly Language Coding for the IBM 360/65. The software is special purpose, dedicated to providing very fast response to remote airline reservations inquiries including: schedules and availability between cities, passenger name data, and related information. At the start of the project, there were virtually no United personnel with PARS experience, and the implementation phase included the development of a comprehensive training program. The principle objectives of this program, over and above that of preparing United programmers and operators for participation in the project, included the capability to be completely self-sufficient for PARS training at United, the ability to administer training as personnel became available to the project, and the desire to maintain a minimal staff of professional trainers.

To achieve these objectives 12 special courses were developed using the guidelines described as modular training. These courses, developed by IBM for United, were according to specific guidelines and standards. The standards emphasize that courses should be developed in short, self-contained parts, bring the student into direct contact with source information and use other media (e.g., video tapes, audio tapes, slides) to amplify material being presented to the student. This assists the student in advancing at an individual pace, and encourages self-sufficiency.

The basis for this paper is that an in-house training program can be developed which is self-sufficient. The need for outside training may exist for course development. However, generally development can be accomplished by line personnel with technical competance designing training courses in accordance with well-defined standards and objectives. Once developed, it is possible to administer the training on an "as needed" basis, and to accomplish training on second or third shift, or even on a part-time basis.

The balance of the paper presents the details relating to this particular project. This includes principles of course development, course descriptions, and the required training sequence for positions on the project. It should be stressed that no really new principles or techniques are offered, only a new emphasis or applying some old methods (and not so old, such as video modules) is advocated here.

MODULAR TRAINING

Modular training is the term used by United to describe training in terms of courses divided into specified units. A course is defined as: a set of objectives that should be achieved by a target audience together with training material, a time duration for the course, and a plan for accomplishing the training. Training courses are tutorial for programmers and operators on this project in that training is viewed as the transfer of information necessary for the student to carry out job responsibilities in a defined area. This is in contrast to training in a seminar environment by means of exchange of ideas among participants. Under the modular approach, the responsibilities for programming and computer operator positions have been keyed to the courses. Each position has an identified sequence of training courses through which a student progresses prior to full-time work assignment.

Under this modular training approach, each course is administered to a student by an advisor, an experienced person with successful completion of the course or with extensive experience within that area. The governing elements of the course are a student guide and an advisor's guide.

The student guide is a document which coordinates the student's progression through training material. It is designed to give the student the information

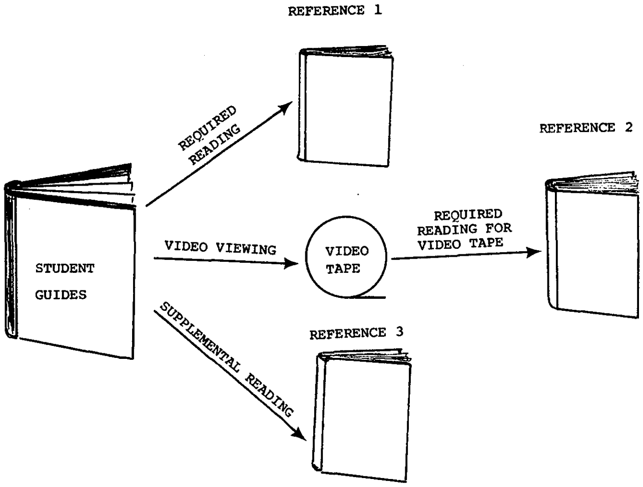

Figure 1—Student guide

necessary for a thorough understanding of the subject, as illustrated by Figure 1.

The intent of the student guide is to direct the student through applicable training material in a given order. This includes readings in references not contained in the guide itself (technical manuals, professional journals), or viewing video tapes (including local productions keyed to specific elements of the project), as well as utilizing the guide itself for tutorial material.

In particular the video tapes are a valuable means for producing training material. Use of video tapes is to deve'op standard, lecture-type modules and eliminates the requirement for an instructor to repeatedly give the same stand up lectures. Video is also useful in explaining standards and procedures, which can be presented to the student as dictated by students responsibilities to the project. The advisor, however, must always be available to answer questions or exchange dialogue with the student on the basis of the information in the video tape.

By design the student guide cannot and does not function alone as a self-sufficient course, such as in programmed instruction. The advisor is a necessary and vital part of the course in modular training.

The format of the student guide includes:

A. Introductory Section
   1. Course description and intended audience.
   2. Course objectives.
   3. Prerequisite training and/or related experience.
   4. Recommended duration of the course.
   5. Advisor/student relationship.

B. Reference Material
   This section identifies all other manuals and documents needed in the course.

C. Detailed Assignments
   This section presents the series of steps which lead the student through the material. It includes reading assignments, identifies lectures, designates participation in workshops, and tests to determine how well the student is learning and applying the material. In courses involving programming, actual coding experience is accomplished by assignments which are processed on the computer.

A history log is maintained for each course containing questions raised by students during the course. This information is used to develop additional explanatory material, quizzes, or more detailed references to aid the student in acquiring a better understanding of the subject.

COURSE ADVISOR

The second key element in modular training is the Course Advisor. By design the course can be administered to a single person, to a formal class of students, or to several students who have started the course at different times. Except for formal classes, the advisor performs this roll on a part time basis. As a result, line programmers can function as advisors as well as having normal job responsibilities.

Under United's approach, only one person devotes a full-time effort as the advisor for basic courses, and line programmers act as advisors for advanced courses. Each manager furnishes the advisor for advanced courses for students who will receive assignments in that manager's area. Only senior, experienced personnel are used as advisors. This represents one of their job responsibilities, and is a means of providing further experience in the management aspects of dealing with people.

The advisor has three primary responsibilities:

1. To serve as a point of reference for any questions the student may have on the course material. The advisor may not be able to answer every question, and may have to get the answer from another source. In any case, the response is on a timely basis.
2. To administer quizzes and exams to the student as required in the course sequence. The results are always reviewed with the student to insure complete understanding.

3. To emphasize the most pertinent parts of the course relative to the student's work area, and to evaluate the student's understanding of the course. Here, the advisor's function is to tailor the course to the student's needs. The advisor takes the initiative in discussing the important aspects of the course instead of passively waiting for the student to ask questions. By probing the student's thought process the advisor can fill in any areas of weakness and correct misunderstanding. Normally, the advisor spends ¼ to ½ of the student's assigned course time, depending on the advisor's familiarity with the course and the extent of the student questions. For example, if a student is training on a half-time basis, the advisor can expect to spend ⅛ to ¼ of that time in an advisory capacity. The advisor also provides up-to-date technical information on the system, which minimizes the problems associated with technical obsolescence of training material.

CAREER PATHS AND COURSE PROGRESSION

The United PARS project provides training for programmers, data base personnel and computer operator personnel. This section describes each job and the training sequence required.

There are seven areas of programming responsibility:

1. Application Programmer
   Develops programs in a real-time environment which accomplish the airline reservations functions. These include display of airline schedules, availability of seats inventory control, flight information, and programmatic exchange of information with other airline reservations systems. Programming is done in ALC, the assembly language used for coding on the IBM 360 series.
2. Schedule Change Programming
   Includes an understanding of batch processing as well as real-time programming, and has significant impact on many system data records. These include modifications to flight schedule information and development of information used to reaccommodate passengers. Programming in ALC under DOS and OS is included.
3. System Support Programmer
   Has responsibility for the generation and maintenance of systems, both OS and DOS, PARS off-line support, together with file maintenance and management reports. Programming languages include P L/I and FORTRAN.
4. Control Program Programmer
   Has assignments in input/output for disk and tape, CPU scheduling, queue processing for input, ready and deferred lists, interrupt handling and on-line data collection.
5. Communications Programmer
   Is involved with control and coordination of communications between remote sites with CRT terminals as well as with the other computer systems. There is heavy involvement with hardware such as IBM 2703, WE201B modems or equivalent, IBM 2948, and the IBM 2915 or equivalents.
6. Performance Evaluation Programmer
   Analyzes the PARS system performance by measuring and interpreting system characteristics including input/output message size, program core residency time and execution time, file accesses and queueing. Simulates the system by means of model(s) and predicts system performance relative to proposed modification.
7. Coverage Programmer
   Has primary responsibility for the diagnosis and immediate correction of on-line software malfunctions, as well as monitoring on-line system software integrity. Programming occupies a relatively small amount of time.

Two Data Base jobs pertain to information records in both the on-line and off-line systems. Programming experience is not required for these jobs:

1. Data Base Specialist
   Has the responsibility for the integrity of all passenger information in the on-line system. This can involve restructing parts of the data base as a result of airline rescheduling as well as corrections to erroneous on-line information.
2. Data Base Coordinator
   Has responsibility for maintaining airline schedule information, pilot data information and communications tables. These are processed in the off-line system.

Computer Operations involves three tasks:

1. Data Control Clerk
   Receives and monitors off-line processing jobs, maintains tape and disk libraries, and JCL card decks for off-line jobs.
2. Computer Equipment Operator
   Operates all equipment in the off-line-system

R = Required
D = Desirable

Subscript indicates course sequence number

***Not required for all System Support Programmers**

Figure 2—Career path training sequence

and assists in monitoring the on-line system activities.

3. Console Operator
Has responsibility for operating the hardware in the on-line system. Monitors and controls system configuration, and applies corrective action for hardware failures.

The training required for these positions is summarized in Figure 2. IBM/360 training is also shown in presenting the training progressions. The total training days associated with the IBM/360 training and the PARS training identify the time needed before an individual is ready to accomplish productive work.

For example, a programmer with no 360 computer background would require both IBM/360 and PARS training. For applications programming, 40 training days would be required. If the programmer already had IBM/360 experience and no PARS experience, 25 training days would be required. The description of PARS training courses is given in the Appendix. Both the training results and the training duration are good as evidenced by high comprehension rate and mininal training period.

SUMMARY

As a part of the implementation of a PARS system, United Air Lines has developed a comprehensive training program using the modular method with three objectives:

1. United is self-sufficient for PARS training (Note: PARS training requires IBM 360 knowledge as a prerequisite).
2. Training is administered as people are available.
3. Training is accomplished with a minimal professional training staff.

Twelve courses were developed to achieve these objectives for the different job responsibilities within the project. More than sixty students were successfully trained with this method.

An advisor is a key element in administering modular training. The advisor is responsible for tailoring the basic course to reflect the content of the student's assigned area, and to monitor the student's progress. Drawn from the line organization, the advisor is proficient in the assigned area and monitors the student's progress by answering questions, administering quizzes, and probing the student's understanding of the subiect matter.

Modular training with professionally competent personnel acting as advisors eliminates the need for formal classes, and training can be administered on an "as available" basis, although a class can easily be accommodated with this method. In addition, the advisors have line responsibilities and thus the need for a large, dedicated training staff is eliminated. Currently, at United one person has full-time basic training responsibility for the 70-80 project programming staff.

Advanced training advisors are furnished by the area to which the student is assigned.

Generally only senior persons are advisors and represent a part of the responsibilities of a senior position. Being an advisor usually affords first exposure to working with people in a management mode, which is good experience if further advancement along supervisory lines is desired.

In particular, however, it was found that:

1. An advisor is indispensable to the program, and cannot be passive. The advisor must actively monitor and encourage the student's progress. Experience has shown this method has favorable results.
2. Prior to starting the training, there should be a review meeting between the student, the assigned manager and the advisor. The review will include the sequence and duration of the courses for the student, the approximate expected progress (relative to whether the student will be in training full-time or part-time), and the role and responsibility of the advisor(s).
3. Practical problems, and quizzes which reflect the course objectives are essential, especially for programming courses. A simulation of the real environment is necessary for coding and debugging problems. The course content must be tutorial and serve as a transition into the work environment.
4. Insofar as possible, training, especially the advanced training, should be on a part-time basis. This gives the student a better opportunity to assimilate the many new concepts and terminology as training exposes them. In fact, terminology is a major factor on this project, because the student is not only using EDP terms, but also the special vocabularies associated with airlines and with the PARS system.
5. Update of course content caused by system change is best accomplished by line personnel. In this case they act as advisors but without students, and have the responsibility for updating the applicable course content.
6. The student guide/advisor functions best in a non-development environment. In a totally developmental environment, scheduling is a problem. Estimates of required program development time always seem to neglect factors which were not expected to occur (sickness, machine downtime, etc.) In either case, the line must be staffed to accomplish both programming and training requirements.

Overall, modular training has worked reasonably well for the United Airlines PARS project. The primary objectives have been satisfied by a minimal professional training staff and utilization of line personnel in the training function. The advisory responsibility takes time, however, and an advisor's schedule must include time for training in addition to normal line responsibilities if modular training is to function properly.

This same method should also be able to work for other projects. A student guide need not necessarily be a reference unto itself, it may be a series of references to other manuals, documents, video tape, et al. Video tapes, in particular, afford the means of augumenting course material and making it available for training around the clock. There currently exists a dearth of organized information and material which can be used to construct a course. There is no prophet for rewriting a document which can be used in its present format with directions as to applicability. Both the student guide and the advisor furnish this direction to the material and provide tailoring specific to requirements.

APPENDIX A

Course descriptions

This Appendix presents a description of the 12 courses that were developed at United Air Lines. These specific courses are applicable only to a relatively small group of PARS users.

It should be noted that because the courses are tutorial, quizzes form an important part of the course, being geared to the course objectives. The student is expected to achieve certain defined objectives, and the quiz results represent, in part, how well the material has been learned, as well as performance evaluation.

Training in PARS requires a knowledge of the IBM 360 hardware and Assembly Language Coding (ALC). These are prerequisites for all the PARS Programming Courses. Commercial video taped courses, augmented by material particular to United's needs, satisfy these requirements.

The PARS courses are divided into two sets; a basic set which all programmers attend, and the advanced courses, which are attended on an "as needed" basis. The first three courses listed below are the members of the basic set; all others belong to the advanced set for programming except the operator course, which is independent. Sixteen video tapes have been produced by United to augment the basic PARS training. These were produced based on an evaluation of the information in the history log, an invaluable tool for developing training modules such as programming techniques, project procedures, and the like. In addition, the video modules are always available to the student on an around the clock basis, thus helping to free training from the prime shift dependency.

1. PARS System Description—3 days
   This course presents the basic PARS hardware and software descriptions, as well as concepts and terminology associated with the airline industry as well as PARS system. Emphasis is placed on providing the fundamental information concepts and terminology needed in other courses.
2. Applications Programs—5 days
   This course presents the functions of all PARS application program packages including programs within each package, and describes the data records required by each program explaining how these records are accessed and data is manipulated. It relates airline reservations agent actions and needs to the manipulation of the applications programs and the data records.
3. Airlines Programmer Environment—17 days
   This course is divided into three major areas corresponding to the types of programmer activities in this real-time PARS environment:
   1. Program Development
      The availability and use of programmers tools such as: entry control block, macros, and conventions.
   2. Program Maintenance
      The PARS Program Library System, the steps involved in entering programs, the inputs necessary for program maintenance.
   3. Program Testing
      The concepts and procedures used in testing, in generating test inputs and in interpreting test results.

   The course environment is designed to resemble, as closely as possible, the expected environment in the development group. The subjects discussed at length are those dealing directly with the job of application programming.
   Upon completion, the student is capable of productive assignment in applications programming within the PARS environment.
4. ACP Fundamentals—5 days
   This course introduces the programming techniques such as queuing, priorities, message flows, and related items used by the Control Program.

Upon completion the student is able to relate the functions of the ACP program to his present assignment.

5. ACP Internals—15 days
Airline Control Program Internals is concerned with program listing level discussion, by topic, of each of the functional units of the airline CP. This includes communications, hardware input/output, and services and facilities provided to application programs.
Upon completion the student is prepared to accept assignment in any functional area of the Control Program. The student will lack only what can be gained through experience.
6. Schedule Change Input Data Preparation—3 days
Editing and validation of modified schedule information is the main objective of this course. Upon completion the student is able to prepare the input data required for Off-line Schedule Change.
7. Off-Line Schedule Change—5 days
Topics covered include concepts of off-line schedule change; off-line schedule change input and processing, and a detailed analysis of the off-line schedule change programs.

   Upcn completion the student is able to communicate in the language of schedule change with non-programmers and other PARS Application Programmers, use to use the appropriate documents to extract the details of the schedule change programs assigned as the student's responsibility.
8. On-Line Schedule Change—5 days
This course presents the functions of all the on-line schedule change programs, defines the data records affected by the on-line schedule change and describes how they are affected, explains the four logic phases of the on-line schedule change, and relates the programs and data records involved to each phase.
9. Communications—5 days
This course presents PARS Communications in general, and specifically as applied in United's PARS System. This system exchanges communications with two other United Air Lines On-line Computer Systems. In addition PARS Communications is covered from the functional level to a detailed program level which describes the interrelationship of the programs, tables and data records involved.
10. Data Collection—5 days
This course describes the functions of the Data Collection Programs and defines the facilities provided by these programs, explaining how system, file, program and message variables are collected on-line, and reduced off-line. It identifies listing variables which are out of line from data collection reports and determines from these variables how system performance can be improved.
11. Data Base Management—20 days
Data Base Management covers four major file support functions and data base generation. These include: Pool Directory Generatiɔn and Maintenance, Recoup, Capture/Restore, Fixed File Reorganization and System Test Compiler.
12. System Operator Training—5 days
This course describes, in general terms, a typical PARS hardware configuration and the PARS software system. In addition performance of the following operator tasks is explained: program library maintenance and update, testing, system load, all other off-line and on-line operator activities, interpretation of error messages, and use of functional messages appropriate to a given job.

Computer training, present and future

by GORDON A. SMITH

Jet Propulsion Laboratory
Pasadena, California

INTRODUCTION

Before beginning this discussion, I would like to make a few remarks concerning the Jet Propulsion Laboratory (JPL). The Jet Propulsion Laboratory is responsible to the National Aeronautics and Space Administration (NASA) for unmanned missions in deep space. A worldwide tracking network encompasses Goldstone, California; Madrid, Spain; Johannesburg, South Africa; and Woomera and Tidbinbilla, Australia. In addition to the deep space missions, there are a great number of scientifically oriented projects throughout JPL. The Laboratory has approximately 4,100 employees, as well as some support contractor personnel.

All levels of personnel in JPL, as well as contractor operations personnel, are involved with the educational programs, starting with "Introduction to Computing" through management training in the data processing field.

Within almost every government organization, and certainly within every NASA facility, a considerable workload rests within the administrative and financial operations. These are nonscientific endeavors which hopefully will lead toward improved management information system controls. A commercial enterprise, financial operations organization has a number of similarities.

To begin with, I have prejudices against classrooms of stand-up instruction only, or classrooms of video-taped lecturers only, or instruction in any single medium. Therefore, I will spend a few moments reviewing some of the products of educational firms today leading toward a multimedia approach to the education and training of commercial programmers, systems analysts, or obviously, into some of the scientific fields.

Let me cite a few examples of ideas that have come out of some commercial firms. For instance, there is one firm in Ohio that has developed a course titled "ADP Terminology." This course consists of 16 audio tape cassettes and a small workbook for those who want to become familiar with data processing terms. One of the major banks in Arizona has required its 132 branch managers to review this course while traveling to and from work. It is also an excellent device to augment stand-up instruction for a new student. Several firms today have canned video-taped courses along with workbooks as a self-instructional means to replace the very widespread utilization of PI or programmed instruction textbooks. To my way of thinking, there is nothing more boring, and less motivating, than sitting down with a workbook, and saying I am going to learn by myself and teach myself something, whether it is data processing or any other area of interest.

Another firm, in addition to its video taped courses in basic computer programming—COBOL, FORTRAN, and so forth—has a considerable library of animated motion picture films, along with associated workbooks and other materials as a self-teaching means in support of standardized automatic data processing (ADP) curricula. Some of the films are excellent, and, in some cases, we have utilized them to augment our classroom course "Introduction to Computer Technology." A firm in Illinois has developed a systems analysis course, as well as courses in operating systems (OS) with a thorough interaction between video tape, audio tapes, and workbooks—none of the media being used for more than 15 minutes at a time. There is a constant transfer from one medium to another which provides not only motivation but reinforcement. More of the physical senses are used in the absorption of educational material. Of course, motion picture films are also used; films themselves are a bit more cumbersome, but if intermixed with other media, may become a viable means of instructional transfer.

I believe that audio tapes, video tapes, motion picture films, and animated cartoons can effectively be used in a learning carrel. A carrel is nothing more than an enlarged desk with various devices in it; one can

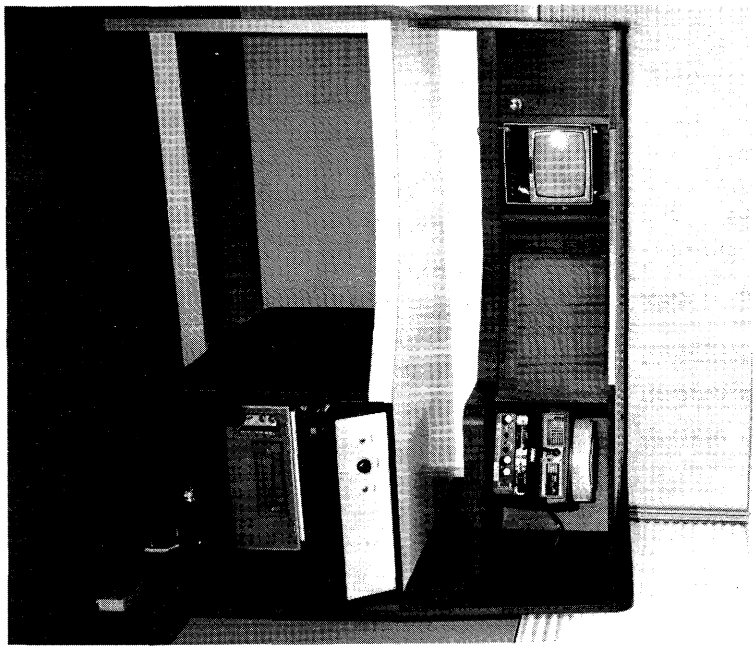

Figure 1—JPL training carrel

instruct himself at his own speed, and hopefully, improve his motivation if he has a goal in mind (see Figure 1). This type of self-instruction is extremely worthwhile if it is also reinforced by a senior programmer or analyst. The multimedia approach will create greater motivation.

For a moment, let's look at the benefits. In classroom training, the teacher is usually responsible for maintaining a norm at the average class level. Very often the faster student becomes quite bored because he is ahead of the group, whereas the slower student is having a problem keeping up, and thus becomes rather discouraged. Most schools in the data processing field require the student to write, run, and debug test programs on whatever type of equipment that school may possess. There is a danger at times if the "school" has only the equipment of one manufacturer and is not able to provide good classroom direction where students can effectively learn the differences between equipment of various manufacturers—either small-scale computers or large-scale systems.

A list of the computer courses available at the Jet Propulsion Laboratory, along with the computer selection procedure, is given in Appendix A; a set of computer-related job descriptions from the *Computer Education Directory* published by Edutronics Systems International, Inc., Los Angeles, Calif., is presented in Appendix B.

COMPUTER-ASSISTED INSTRUCTION

Computer-assisted instruction, or CAI, is a relatively new medium to augment the other media I have discussed; however, I am certain all of us will be influenced by it over the next few years. I feel we are missing a very worthwhile and cost-effective tool. Helen Lakin at the University of Wisconsin noted there are 1,264 program descriptions in the publication *Index to Computer-Assisted Instruction.* These descriptions are from sources in the United States, Canada, Europe, and Japan, representing elementary and secondary school systems, colleges, and universities that have complete CAI courses for credit. As an example, the University of Southern California recently instituted a complete course in Programming Language I by CAI for three units of credit. Many universities are using CAI as a self-teaching method very successfully for both direct teaching and remedial education. In none of these situations does it mean that there is not a teacher available to answer questions or at least to cover the highlights that may be misunderstood. In the government area, certainly throughout the Department of Defense, there are any number of programs that are offshoots of simulation programs as well as specific courses in CAI. Many of the programs, however, are tailormade to the particular command or to the organization.

It is extremely important that data processing organizations thoroughly evaluate available software systems in today's market, whether they are proprietary or in the public domain. For the programmer or systems analyst, where it can be shown to be cost-effective, there is no better system than one with immediate feedback. From a motivational standpoint, the one-to-one relationship without outside distraction can be made a very viable and successful means of instruction in this field. It seems strange that there are not more schools or private firms teaching programming, systems analysis, or data processing management on a computer terminal.

Briefly, from the principal title of the session, let's consider the capability of the computer in CAI. In August 1970, a test project was instituted in the Communications Electronics School Battalion at the Marine Corps Recruit Depot in San Diego, California. Twelve terminals were connected by data link to a UNIVAC 1108 computer some 75 miles away. A stand-up class was run concurrently with the CAI classes. Individuals were psychologically matched, and each student proceeded through the course of instruction at his own pace. Of considerable importance, the Marine instructors wrote their own courses for the computer after only two weeks of instruction from the manufacturer. A system of positive or negative reinforcement of learning experience was presented to the student immediately. The immediate benefits of the teaching experience were the objectivity, data collection and reduction, and standardization of instruction. Cathode ray tube terminals were employed. The results demonstrated substantially increased learning in the CAI class; and subsequent to the test, far greater retention was achieved. This demonstration has convinced Headquarters Marine Corps to initiate formal schools in CAI at the Marine Corps Station at Twenty-Nine Palms, California. Sixty terminals will be employed, course time will be reduced by 20 percent, and instructor requirements by 75 percent of instructor manpower.

In the universities, there is a strong tendency to tie CAI courses with other portions of the curricula. There is a major tendency, of course, to deal primarily with the fields of scientific uses of the computer, or, in other words, its applications to physics, chemistry, biology, genetics, etc., rather than to the straight business approaches; however, some universities are improving their curricula, from computer programming on into the area of management information systems. There is an excellent marriage between business management and the tools the computer can provide.

GOVERNMENT USE OF COMPUTERS

The government was the first major user of computers, in the late 1940s and early 1950s. Commercial data processing centers have become increasingly widespread. Subsequent to unbundling, the government agencies developed their own schools and separate series of grades within the Civil Service Commission to handle the various levels of computer programmers and systems analysts. One of the problems of government, as well as of all large business operations, is frequently a lack of communication among similar services and organizations. The Office of Management and Budgets in Washington is examining improvements in communication among similar elements of government, where both can utilize the same software, hardware, or systems approaches. Where there is coordination among government entities, cost savings are very substantial. Due to a low turnover, many large government entities also realize that their management personnel, as well as their programming personnel do not effectively utilize the tools available today.

Many of the leading computer manufacturers emphasize more now than before the need for improved management training which, in a sense, goes beyond the scope of this present paper. However, when speaking of education for computer programmers and systems analysts, we must consider the people who are directing the needs for this education and training. These needs definitely stem, and should stem, from a better understanding by management of their own specific needs. When management understands these needs and can define them, then indeed they will do a much better job in hiring personnel. This will establish the type of training curricula these personnel should have had before being hired.

As a lesson from the government's interest in this field, communicating between commercial firms possessing similar interests can assist industry in setting standards or norms of personnel. In Appendix B are a number of what I feel to be excellent definitions of programmers and systems analysts. There is a need throughout the United States today for an improvement in semantics of all facets of ADP terminology in the entire field. Personnel firms should seek for a common understanding, thus setting some type of definition of various grades of programmers for the systems analysts. In large industries, of course, these have been indicated. However, they vary considerably from industry to industry. By an improvement in definition, understanding, and attainment, the individuals in this field should become more professional in their community.

THE IMPORTANCE OF PRETESTS

Obviously, any paper may reflect the bias of the individual writing that paper, who may promote those things that are the most successful in improving his responsibilities. Both with beginning programmers or systems analysts, or with those who wish to enter this field, I am a firm believer in computer pretests. Large schools have pretests of one type or another. However, when they are selling courses, their pretests may not be as restrictive as a pretest would be within my organization or within other organizations depending upon a profit motive.

Pretests can aid in determining a person's ability to absorb a particular instructional level. He takes the test, analyzes the test himself, and, from the results, he himself should be mature enough to state whether he has the ability to go ahead as a computer programmer, as a systems analyst, or in some other field of data processing, or whether his capability in fact rests somewhere else, and not in the ADP field at all. Many of the personnel with whom I have been associated who have taken these pretests have suddenly decided they should not take FORTRAN or COBOL, but rather should go back into a program we have titled "Introduction to Computers," or, in other words, the basic groundwork—"What is a computer, what does it do, how does it operate, how does it function, and what are the various fields to which it could be applied?" The next step (shown in Figure A-1) analyzes his particular functional responsibilities, and, from there, determines the type of course toward which he should direct himself: in other words, what computing system should he be addressing? This last step is extremely important, since a person who is completely educated in one type of equipment, and then is thrown into another organization with an entirely different type of equipment, normally has some problems adjusting. This can be prevented if his training is directed toward the type of equipment he is going to use in the first place. Within an organization, a person's immediate supervisor is responsible for determining whether company time should be devoted to such courses or whether the individual would improve himself by taking courses outside of his office hours.

FUTURE DEVELOPMENTS

Let's consider some probable areas where changes in technology should considerably influence ADP education in the next decade. Increasing capability in the multiprogramming aspects of large-scale computers will permit a more economical approach toward computer-assisted instruction. Initially, however, it should be treated primarily as an augmentation or reinforcement of courses rather than as the stand-alone desire of some CAI enthusiasts. There will be an increasing need for studies into the motivational aspects of all levels of individuals, whether students are from grammar schools or high schools, or are personnel in government or industry.

According to the ETV Newsletter of July 26, 1971, as an example of the future development (and one that I believe will be widespread some years from now), the MITRE Corporation of Bedford, Massachusetts, is conducting a feasibility study utilizing TV/CAI through cable TV distribution. In this instance, both the voice and the still pictures are transmitted via microwave and on cable TV to homes equipped with special terminal and TV set combinations. The company is using its time-shared interactive computer-controlled information television (TICCIT) system to display selective material on individual TV sets. Thus, 600 TV sets can receive separate information provided by the computer at a typical rate of one frame every 10 seconds. The viewer is then in a position to communicate back to the computer through a 12-button telephone. The overall software for the system is designed under the sponsorship of the National Science Foundation, which can provide individualized educational courses for home and school use. Over courses that have a broad-scale interest in the future, therefore, it is quite likely that up to 10,000 TV sets in one local area could conceivably be tied into one major system with a number of different programs being selectively addressed.

Microcomputers of the future, costing as low as \$2 to \$3 K with keyboard and tape cassette units and a small TV light display, could be utilized by a number of commercial and governmental operations where specific instruction is required.* I believe the cassette will play a large part in the future.

Along with educational programs, we consider the terminal hardware development. Keyboards have varied from the standard typewriter keyboard to color-coded keys for some special studies. It is possible the lightweight, touch-sensitive surfaces instead of keyboards may be utilized. Common phrases that could have a general application to a number of educational uses may be designed into either system.

Pictorial or handwritten input may be one area of the future, as well as the very early development of voice input (Culler Harrison, Inc., in Goleta, California, and the Bell Telephone Labs), and, lastly, one I am certain a number of you have seen demonstrated, the plasma array terminals developed by Dr. Donald L. Bitzer of the University of Illinois in conjunction with Owens Illinois Glass Co. As some of you may recall, the view plate which replaces the video tube consists of three layers of glass with gold wires and an X/Y axis, imbedded in an electrolyte containing neon gas. The dots of stimulated neon gas, 3600 per square inch, may display pictures without computer regeneration, allowing both the computer and the user to modify the display. A number of these terminals are presently in manufacture by The Magnavox Co. for the University. I feel this type of approach will contribute a great deal to the ability of fairly small computers having a capability to relate through educational systems to a number of terminals.

The software field also has a major impact upon the future of education and training to systems analysts and programming personnel, in that language capa-

* F. W. Blackwell, *The Probable State of Computer Technology by 1980, With Some Implications for Education*, P-4693 R, The Rand Corporation, Santa Monica, Calif., Sept. 1971.

bility should certainly be on higher level than it is at present, including switchable microprograms, very large memories, associative memories, and other variables at an economical cost which could contribute considerably to a multi-user access. In a sense, with the technological changes, both in hardware and software, the aspect of the present programmer training should change markedly from the existing languages and the present direction. One of the interesting fallouts in teaching FORTRAN to a group of high school students on the West Coast recently resulted in improved ability of the students in their other courses. Apparently there is some relationship to the logical display of FORTRAN which overlapped into an improved understanding by these students in other subjects within their curricula.

Another aspect of the future is the multitude of libraries of application programs available to all facets of industry, government, and the educational community. With improved library maintenance and cross correlation, hopefully, many users of the future will be prevented from "reinventing the wheel" concept, and will be forced to thoroughly review the application programs available before they attempt to develop training programs on their own. Therefore, extensive markets exist for personnel to improve the development of such a compendium. Along with these application programs, however, and one of the aspects that is not as thoroughly covered today, is that of computer costs associated with each application program. This type of data will definitely have to be included in any compendium of library programs (similar to COSMIC,* which is operated today).

In communications, I feel many of us have seen limitations in our present telephone equipment; however, in the near future, firms similar to DATRAN, whose microwave towers will be completely devoted to data processing centers throughout the United States, as well as improvements in our present communication equipment and satellite interface, will aid considerably in the more economical aspects of computing, as well as the education and training in a CAI approach throughout major time-sharing networks.

In summary, there will be a considerable change in programming languages, major changes in terminals and hardware equipment, and a greater interest and acceptance of computers.

RECOMMENDATIONS

For the educational, governmental, or business organization involved with its own educational development, it is essential to seek a multimedia mode of educating personnel. Do not rely on self-instructional manuals for the individual to develop an ability on his own. Upon completion of internal or external schooling, maintain an open view to periodic reinforcement of whatever course the individual attends.

Whenever possible, seek or have developed pretests to determine the level of investment your organization would make with the individual. It is normally wiser to allow management personnel the prerogative for self-correcting to determine their level of instruction. I feel that senior and middle management are too often neglected in the general concepts of computer technology.

Be aware of the developments in the university and governmental areas in education and training as they may very often be obtained without cost to your organization. The NASA data bank (COSMIC) is an example of this.

Lastly, in returning to the major subject of this session, that of training of commercial programmers and systems analysts, a thorough review of the commercial school, in addition to the very excellent training offered by the major computer manufacturers, should be made. University or high school evening classes very often may be an economical advantage in this evaluation. Maintain an awareness of the development of CAI as it is being used in grammar schools, secondary schools, and universities. Most important of all, to the prospective programmer or analyst, be aware of the "state of the art" changes to prevent ccmplacency.

ACKNOWLEDGMENTS

This paper presents the results of one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology, under Contract No. NAS 7-100, sponsored by the National Aeronautics and Space Administration.

APPENDIX A—COMPUTER COURSES AT THE JET PROPULSION LABORATORY, CALIFORNIA INSTITUTE OF TECHNOLOGY

GENERAL INFORMATION

Definition of terms

Pretest. These are self-administered, self-graded tests whose purpose is to help the individual determine that

* The Computer Software Management and Information Center (COSMIC) is maintained for NASA by the University of Georgia and provides a national data bank of software programs developed and debugged by government agencies and in the public domain.

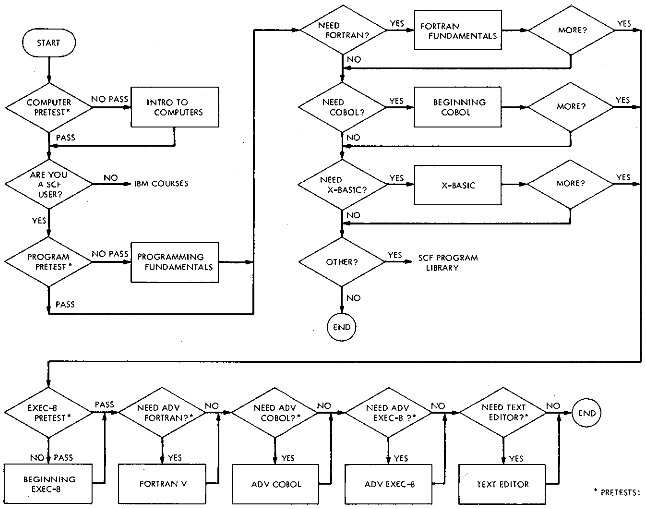

Figure A-1—JPL computer course selector

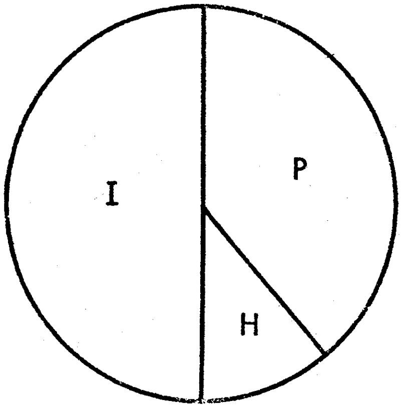
the course is correct and that the individual is neither underpowered nor overpowered for the course material. The pretest also provides a general feeling of course content.

Time distribution charts

Each pie chart indicates the approximate distribution of the total time of the course required both in and out of class. The symbol "I" refers to Instruction, "P" refers to Participation, and "H" refers to Homework.



Certification

Certificates of completion are issued and recorded in the personnel file. They are based either upon attendance or upon the demonstration of proficiency in the techniques or skills taught.

Survey

The courses were developed in response to the major needs expressed and measured through the Training Needs Survey.

Schematic

A diagram of the courses available is shown in Figure A-1.

INTRODUCTION TO COMPUTERS

For Whom: Those with little or no knowledge of computers. Quota limited.

Prerequisites: None.

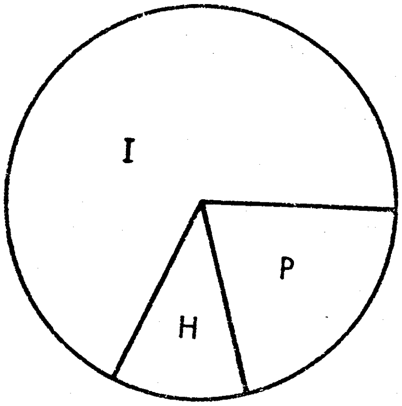
Description: Description and explanation of computer purposes, parts and functions, computer languages, programming concepts, and the computers at JPL.

Objectives: To gain a general understanding of computer-related technology and terminology.

Text Provided: Handouts.

Pretest: Recommended.

Time Distribution:



Instruction: Lectures with audio-visuals.
Participation: Discussion.
Homework: Simple problem assignments.

Schedule: Four 2-hour sessions; 2 weeks. A new class to be held each month during the year.

PROGRAMMING FUNDAMENTALS

For Whom: Those with no computer programming background who plan to take other courses in computer languages. Quota limited.

Prerequisites: None.

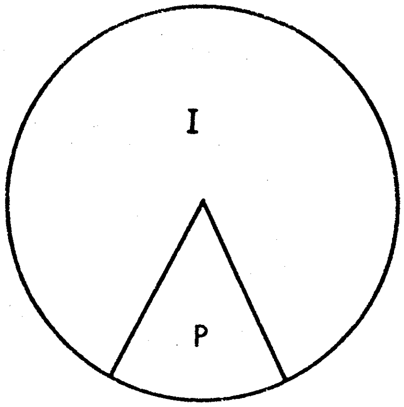
Description: Introduction to computer programming, its logic, elements, terminology, and procedures. Preview of FORTRAN, COBOL, and X-BASIC.

Objectives: To gain general awareness of computer programming concepts and languages.

Text Provided: None.

Pretest: Recommended.

Time Distribution:



Instruction: Live and video-taped lectures.
Participation: Discussion.
Homework: None.

Schedule: Four 2-hour sessions; 2 weeks. Classes to be held each month during the fiscal year.

FORTRAN FUNDAMENTALS

For Whom: Beginning FORTRAN programmers who will use the Scientific Computing Facility. Quota limited.

Prerequisites: "Programming Fundamentals" course.

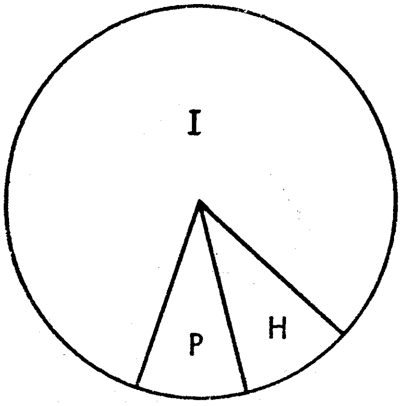
Description: Introduction to the elements of FORTRAN and the methods of writing programs in it. This course includes several illustrative problem assignments.

Objectives: To gain ability to write simple programs in FORTRAN.

Text Provided: FORTRAN IV primer—class notes.

Pretest: Recommended.

Time Distribution:



Instruction: Video-taped lectures.
Participation: Discussion.
Homework: Problem assignments.

Schedule: Twelve 2-hour sessions; 6 weeks. Classes to be given on a bimonthly basis.

FORTRAN V

For Whom: Scientific Computing Facility users. Quota limited.

Prerequisites: FORTRAN Fundamentals and "Beginning EXEC-8" courses and experience using the UNIVAC 1108.

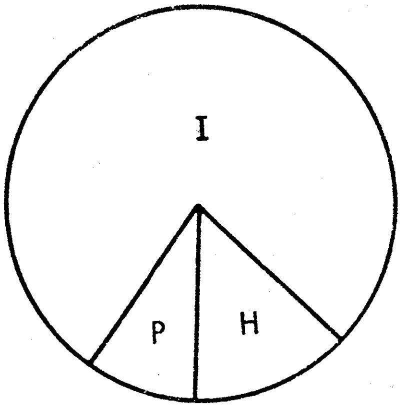
Description: Review of FORTRAN Fundamentals. Explanation of more extensive capabilities of FORTRAN for advanced programming technology.

Objectives: To gain ability to write sophisticated programs in FORTRAN.

Text Provided: FORTRAN V Reference manual.

Pretest: Recommended.

Time Distribution:



Instruction: Lectures.
Participation: Discussion.
Homework: Program assignments.

Schedule: Ten 2-hour sessions; 3½ weeks. Six to eight classes per fiscal year.

BEGINNING COBOL

For Whom: Those who will use the Administrative Computing Facilities. Quota limited.

Prerequisites: "Programming Fundamentals" and "Introduction to Computers" courses or equivalent.

Description: Introduction to the elements of COBOL and methods of writing programs. Several illustrative problem assignments are included.

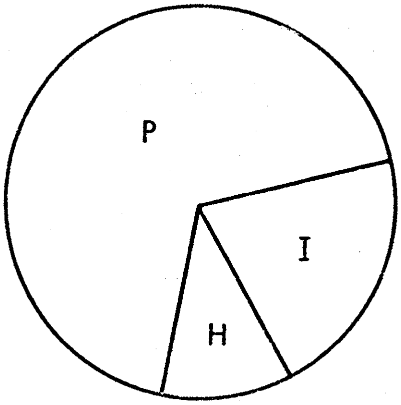
Objectives: To gain ability to write simple programs in COBOL.

Instructor: Self-study program with group discussion.

Text Provided: 1108 ANS COBOL—Programmers Reference Manual.

Pretest: None.

Time Distribution:



Instruction: Discussion leader and films.
Participation: Self-study.
Homework: Simple problem assignments.

Schedule: Four hours self-study approximately, plus 1-hour group discussion per week; 7 weeks. Four classes per year scheduled.

BEGINNING EXEC-8 CONTROL LANGUAGE

For Whom: Beginning users of the Scientific Computing Facility. Quota limited.

Prerequisites: Ability to use X-BASIC, FORTRAN, or COBOL.

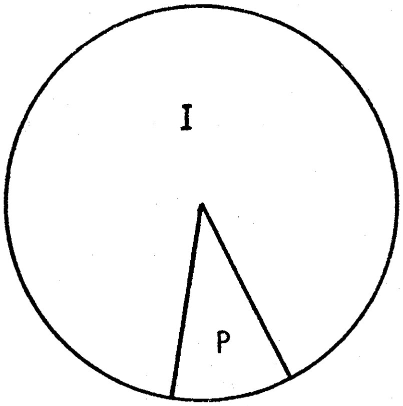
Description: "Introduction to EXEC-8," the Command Language of the UNIVAC 1108 System. Preparation of run streams, compilation of programs, assignment and manipulation of files.

Objectives: To gain ability to prepare simple jobs for running on the UNIVAC 1108.

Text Provided: EXEC-8 Student Handbook.

Pretest: None.

Time Distribution:



Instruction: Lecture.
Participation: Discussion.
Homework: None.

Schedule: Four 1½ hour sessions; 2 weeks; classes to be held each month.

EXEC-8 CONTROL LANGUAGE

For Whom: Scientific Computing Facility users.

Prerequisites: Extensive experience with the SCF computer system.

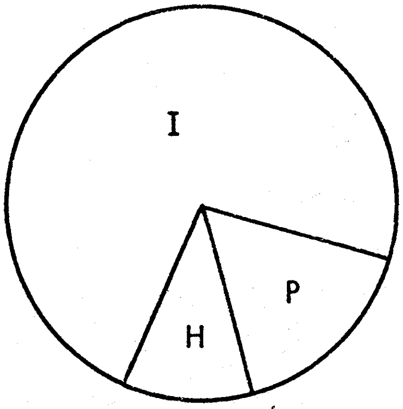
Description: Explanation of the full capabilities of the EXEC-8 Control Language, system file formats, and programming debugging aids and methods.

Objectives: To gain ability to prepare jobs for the UNIVAC 1108, utilizing the full capabilities of the system available to higher level language programmers.

Text Provided: EXEC-8 OPERATING SYSTEMS—Programmers Reference Manual.

Pretest: Recommended.

Time Distribution:



Instruction: Lecture.
Participation: Discussion.
Homework: Problem assignments.

Schedule: Ten 2-hour sessions; 5 weeks; four classes/year.

TEXT EDITOR FOR THE UNIVAC 1108

For Whom: Scientific Computing Facility users with access to conventional terminals. Quota limited.

Prerequisites: "Beginning EXEC-8 Control Language" course and experience in use of conversational terminals.

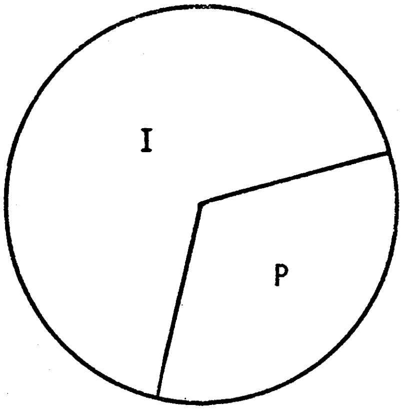
Description: Explanation of features of the UNIVAC 1108, Text Editor and its use at demand terminals, creating and modifying data or files.

Objectives: To gain ability to utilize more powerful and convenient methods of manipulating Source Files from conversational terminals.

Text Provided: Text Editor.

Pretest: None.

Time Distribution:



Instruction: Lecture.
Participation: Discussion.
Homework: None.

Schedule: Five 2-hour sessions; $2\frac{1}{2}$ weeks; two classes/year.

ADDITIONAL COVERAGE IN ADP COURSE CAPABILITY

1. Systems Analysis and Design Course: This is a 30-hour course of self-study, utilizing textual, audio, and video media (no single medium over 15 minutes at one specific period). It is an extensive, self-study program to develop skills in systems work for data processing personnel (DELTAK, Schiller Park, Illinois).
2. ADP Terminology: This is a course completely in audio, on audio tapes for personnel who wish to become familiar with data processing terminology. One of the recommendations for taking this course is to utilize a tape unit in a car going to and from work, listening and repeating the words, as well as the explanation following. This course was developed by a firm in Ohio, and is being utilized throughout the United States (DYNAPHONICS, Dayton, Ohio).
3. JPL/OS: The operating system for IBM's 360/75 computers. This program is completely on video tape for self-instruction or reinforcement, primarily to be used by the computer personnel having advanced knowledge of computer programs.
4. FORTRAN Fundamentals: In addition to the classroom presentation, this course can also be taken on a self-instructional basis by video tape.
5. Additional Courses: Additional courses are given in integrated circuit design, computer-aided circuit analysis, integrated circuit application, speed reading, telephone practice, computer concepts, and techniques, utilizing audio/video (animation) program, and workbooks on various subjects in the computer field in self-study mode, self-study audio cassette/workbook in BASIC, FORTRAN, and a computer technology course put out by the AIAA discussing computer technology media in the next decade.

APPENDIX B—COMPUTER-RELATED OCCUPATIONAL DESCRIPTIONS*©

OCCUPATIONAL DESCRIPTIONS

The occupations described on the following pages are considered to be the basic occupations most directly concerned with electronic computing. These occupations, however, are still fluid.

Hiring requirements and qualifications for employment have not yet been fully standardized. As a consequence, a certain amount of overlap and duplication of job duties and responsibilities will be noted among the various occupational descriptions. The occupational data, however, were assembled from many different sources and are a reflection of the existing situation. Since the data reflect the occupational situation as it exists in varied localities and establishments, the descriptions must be considered as composites of jobs, and cannot be expected to coincide exactly with any job in a specific organization. It will be necessary, therefore, to adapt descriptions to fit individual jobs before they can be used with complete accuracy.

The job descriptions are arranged in seniority order of their main titles. The wording of the title that appears at the head of each description is a reflection of common usage. Other titles, by which the job is known, also appear at the head of each description in small type. Between the main and alternate titles appears the code number which identifies the job within the present classification structure of the U.S. DICTIONARY OF OCCUPATIONAL TITLES.

The narrative portion of each job description is arranged as follows:

Occupational Definition—This provides a brief description of the duties involved in a particular occupa-

* © Edutronics Systems International, Inc., 1969 (Reprinted, with permission, from *Computer Education Directory*, Edutronics Systems International, Inc., Los Angeles, California, 1969.)

tion. It provides an understanding of the tasks that are performed, and the skills and knowledge that are necessary to the performance of those tasks.

Education, Training, and Experience—This section provides an indication of the amount of education and the level of training and experience usually required by management for employment in the occupation. As previously mentioned, the various occupations and the qualifications are not standardized, and considerable variation exists among employers as to required education, training, and experience. However, an attempt was made to indicate the range of such hiring requirements.

Special Characteristics—This section provides some estimate of the worker trait requirements pertinent to the specific occupations. It has long been believed that the ability of an individual to adjust to specific types of work situations is as significant as the education and training qualifications he brings to the occupation. This seems particularly significant when dealing with a group of relatively new occupations. Consequently, judgments have been in terms of a number of components consisting of aptitudes, interests, temperaments, physical activities, and environmental conditions to which individual workers have to adjust.

Aptitudes—These are the specific capacities or abilities required of an individual in order to facilitate the learning of some task or duty. This component is made up of 11 specific aptitude factors, and is a modification of the aptitudes contained in the General Aptitude Test Battery developed in the U.S. Employment Service. Those aptitudes were selected which seem to be significant in the occupation and were identified in terms of specific work situations. The factor of intelligence, however, was not rated because of the difficulty in writing meaningful descriptive statements.

Interests—This component is defined as a preference for a particular type of work experience. It consists of five pairs of bipolar factors, arranged so that a preference for one factor in a pair generally indicates a lack of interest in the other factor in the pair. Those factors were identified which seemed to be significant to the job in question, and were identified in terms of specific worker situations.

Temperaments—The temperament component consists of 12 factors defined in terms of specific work situations that suggest different temperament trait requirements. Each work situation describes a type of activity that demands a different adjustment on the part of individual workers. Those temperament factors were selected that appeared to be significant in the occupation, and were identified in terms of specific work duties.

Physical Activities and Environmental Conditions—This refers to (a) the physical activities required to be met by the worker; and (b) the physical surroundings which make specific demands upon a worker's physical capacities. There are six physical activities factors and seven environmental conditions factors. Those factors were selected that were significant in the occupation in the sense that they met established criteria for successful performance.

MANAGER, DATA PROCESSING—(169.168), DIRECTOR, DATA PROCESSING

Occupational definition

Directs and coordinates planning and production activities of electronic data processing division. Consults with management to define boundaries and priorities of tentative projects, discusses equipment acquisitions, determines specific information requirements of management, scientists, or engineers, and allocates operating time of computer systems. Confers with department heads involved with proposed projects to ensure cooperation and further defines nature of project. Consults with SYSTEMS ENGINEER, ELECTRONIC DATA PROCESSING to define equipment needs. Reviews project feasibility studies. Establishes work standards. Assigns, schedules, and reviews work. Interprets policies, purposes, and goals of organization to subordinates. Prepares progress reports to inform management of project development and deviation from predicted goals. Contracts with management specialists or technical personnel to solve problems. Revises computer operating schedule to introduce new program testing and operating runs. Reviews reports of computer and peripheral equipment production, malfunction, and maintenance to ascertain costs and plan operating changes within his department. Analyzes data requirements and flow to recommend reorganization or departmental realignment within the company. Participates in decisions concerning personnel staffing and promotions within electronic data processing departments. Directs training of subordinates. Prepares proposals and solicits purchases of analysis, programming, and computer services from outside firms.

Education, training, and experience

Two years of formal post-high school training in data processing with courses in business administration and accounting or engineering, or equivalent practical experience is necessary for small computer installations. College graduation with major in one or more of the above fields is preferred for large installations. Experience in systems analysis, programming, and computer operations is desirable. In installations offering more sophisticated services, such as operations research and engineering simulation, a college mathematics major coupled with experience listed above is desirable.

Special characteristics

Aptitudes:

Verbal ability to translate technical terminology into terms understandable to management and department heads.

Numerical ability to apply knowledge of linear or differential equations in evaluating work of department, preparing reports and proposals for management, and selling services to outside users.

Spatial ability to read engineering drawings, charts, and diagrams; to understand presentations, proposed solutions, and progress reports of business or engineering problems.

Form perception to see pertinent detail in drawing charts, diagrams, and other presentations.

Clerical perception to detect and avoid errors in reading and preparing reports.

Interests:

An interest in scientific and technical subjects to cope with wide range of technical and scientific problems processed through computer.

A preference for business contacts with people in directing activities of computer department and to sell ideas or services.

Temperaments:

Must be able to direct, control, and plan the operations of the division, bringing together knowledge of operations and information needs of departments, such as accounting, purchasing, engineering, sales, and inventory control.

Required to deal with people such as management, department heads, and manufacturers' representatives to exchange information and ideas, discuss equipment and their uses, elicit information from departments, and to answer inquiries from department heads.

Ability to influence management and department heads to enlist their support for acceptance, expansion, and sophistication of computer systems; and ability to sell excess computer time and services to outside clients.

Required to make judgmental decisions concerning equipment needs, scope of assignments, allocation of computer time, and organization of departments.

Required to make decisions based on factual data to evaluate progress or success of computerized projects.

Physical Activities and Environment:

Work is sedentary.

Occasionally walks to various departments and offices; stands during conferences and discussions with management, department heads, and supervisor of computer operations.

Talking and hearing required in conferences and during exchanges of information.

Near visual acuity and accommodation required for reading reports and charts.

Work is performed inside.

PROJECT DIRECTOR, BUSINESS DATA PROCESSING (020.168), BUSINESS-SYSTEMS COORDINATOR; LEAD ANALYST; PROGRAM MANAGER; PROJECT PLANNER; SENIOR SYSTEMS ANALYST, BUSINESS

Occupational definition

Plans, directs, and reviews business electronic data-processing projects, coordinates planning, testing, and operating phases to complete project with maximum balance of planning and equipment time, man hours and new equipment expenditures. Prepares project feasibility and progress reports. Confers with department heads who provide input and use output data to define content and format. Schedules and assigns duties to OPERATIONS RESEARCH ANALYSTS based on evaluation of their knowledge of specific disciplines. Coordinates activities of workers performing successive phases of problem analysis, solution outlining, solution detailing, program coding, testing, and debugging (error elimination). Reviews output data and related reports, applying knowledge of systems, procedures, methods, and data requirements of management and other output users to ensure adherence to predetermined standards and devise techniques for improved performance on similar future projects. Directs revision of continuous control project to adapt it to new data requirements or improve operations by using new techniques or equipment.

Education, training, and experience

A bachelor's or master's degree in business administration, with extensive course content in accounting and mathematics or statistics often is required. Employers frequently waive academic training requirements for currently employed workers with extensive systems analysis, design and followup responsibility in electronic data processing, and supervisory experience in tabulating-machine departments. Employers frequently require a degree or equivalent experience either in industrial engineering, or the engineering discipline most directly related to their manufacturing processes, when expanding business data processing to an integrated system that includes production forecasting, planning, and control.

Background knowledge and experience usually include a minimum of one to three years' experience in systems analysis and concurrent familiarization with structure, work flow requirements, and standards of the employing organization.

Current trend is toward greater mathematical sophistication than previously expected of workers at this level. The need for advanced mathematics becomes more urgent as computer applications become involved not only with normal business data-processing, but also with the involved problems of operations research.

Special characteristics

Aptitudes:

Verbal ability to elicit information and discuss project intentions, problems and progress, and to prepare reports.

Numerical ability to analyze problems and develop systems statements in form capable of being programmed. Mathematics varies from arithmetic and algebra for simple, single-purpose systems design to differential equations and mathematical statistics for complex systems involving optimization, simulation, or forecasting.

Spatial ability to develop, interpret, or integrate operational workflow diagrams and charts.

Clerical perception to recognize pertinent detail and avoid perceptual errors when working with verbal material, which often is in highly contracted and conventionalized form.

Interests:

A preference for prestige-type activities, and for business contact with others to participate in conferences with management, advise and inform others regarding the potentialities, limitations, and alternative methods of data processing, supervise analysts and coordinate their activities.

A preference for activities that are technical in nature to read and keep informed of computer development and, new or more refined systems and procedures techniques.

Temperaments:

Ability to perform a variety of duties involving frequent change, ranging from direct involvement in problem analysis to coordination of subsequent work processes until each project is operational.

Must be able to direct and plan an entire area of work activity, assigning subordinates on the basis of knowledge of individual specializations and abilities, and control activities through personal contact and reports.

Must be able to deal with people in nonsupervisory situations requiring considerable tact, to secure cooperation from management and all personnel affected by project.

Required to make decisions on a judgmental basis when supervising others and developing approaches to problems on basis of past experience. Evaluates fixed cost, time, manpower allocation, and output specifications to judge efficiency of project development and operation.

Required to make decisions based on factual data, as in planning proposed system around capabilities and limitations of a specific computer system.

Physical Activities and Environment:

Work is sedentary, with occasional standing and walking required.

Occasionally lifts and carries books, charts, diagrams, and other records seldom exceeding 10 pounds.

Talking and hearing to discuss problems and progress.

Near visual acuity to work with reports, charts, and diagrams and other printed or written records.

Work is performed inside.

SYSTEMS ANALYST, BUSINESS DATA PROCESSING—(012.168), COMMERCIAL-SYSTEMS ANALYST AND DESIGNER; DATA-METHODS ANALYST; SYSTEMS AND PROCEDURES ANALYST, BUSINESS DATA PROCESSING

Occupational definition

Analyzes business problems, such as development of integrated production, inventory control and cost analysis, to refine its formulation and convert it to programmable form for application to electronic data processing system. Confers with PROJECT DIRECTOR, BUSINESS DATA PROCESSING and department heads of units involved to ascertain specific output requirements, such as types of breakouts, degree of data summarization, and format for management reports. Confers with personnel of operating units to devise plans for obtaining and standardizing input data. Studies current, or develops new systems and procedures to devise workflow sequence. Analyzes alternative means of deriving input data to select most feasible and economical method. Develops process flow charts or diagrams in outlined and then in detailed form for programming, indicating external verification points, such as audit trial printouts. May work as member of team, applying specialized knowledge to one phase of project development. May coordinate activities of team members. May direct preparation of programs.

Education, training, and experience

College graduation with courses in business administration and accounting usually is required for entrants without prior experience in data processing. Some employers, while requiring a college degree, do not require a specific major or course content. A successful college record is regarded as proof of ability to reason logically which is considered more important for successful performance than knowledge of techniques acquired in any specific area. Many employers waive the formal education requirements for those workers employed in their establishments who have had several years' manual and machine systems experience prior to computer conversion. Business programmers without a college degree can, through experience, acquire a background in business systems and procedures and may thereby advance into systems analysis. Currently, the trend is to require a knowledge of advanced mathematics because of the rapidly increasing sophistication of business systems. Continuing education, through specialized courses, self-study, and participation in activities of professional associations, is the rule rather than the exception in this occupation, as in all higher level occupations related to the computer.

Special characteristics

Aptitudes:

Verbal ability to discuss problems and progress, prepare reports, and make annotations for graphic representations of work.

Numerical ability to select from alternatives to develop optimum system, procedures and methods. Mathematical investigation of such factors as variation in volume of input data, and frequency of appearance of exceptions to normal workflow in processing is often necessary. Level of mathematics varied from business arithmetic and algebra to differential equations.

Spatial ability to visualize, prepare, and review two-dimensional graphic representations of workflow.

Form perception to identify nonverbal symbols on records such as block diagrams and flow charts.

Clerical perception to avoid perceptual errors and recognize pertinent detail in the recording and identifying of letters and numbers that often occur in abbreviated or acronymic combinations.

Interests:

A preference for activities that are technical and analytical, and those that are abstract and creative in nature to devise new or to modify standardized computer-oriented systems to meet the specific needs of an organization.

Temperaments:

Ability to confer with personnel from other departments, develop flow charts, devise workflow sequence, and prepare reports.

Required to deal with people in conference and interview situations.

Required to make judgmental decisions to select from alternatives when devising optimal system.

Required to make decisions on basis of factual data to design system within machine capability.

Physical Activities and Environment:

Work is sedentary, with occasional standing and walking. Occasional handling of source documents, books, charts, and other records that seldom exceed 10 pounds.

Talking and hearing to discuss and confer with management and technical personnel.

Near visual acuity to prepare and review workflow charts and diagrams.

Work is performed inside.

OPERATIONS RESEARCH ANALYST—(020.088), MANAGEMENT-OPERATIONS ANALYST; OPERATIONS ANALYST

Occupational definition

Formulates mathematical model of management problems by application of advanced mathematics and research methods to provide quantitative basis for planning, forecasting, and making decisions. Analyzes problems in terms of management information requirements. Studies problem, such as selecting from competitive proposals a plan that affords maximum probability of profit or effectiveness in relation to cost or risk. Prepares mathematical model of problem area in form of one or several equations that relate constants and variables, restrictions, alternatives, conflicting objectives, and their numerical parameters. Gathers, relates, and identifies data with variables in model by applying personal judgment and mathematical tests. Specifies manipulative and computational methods to be applied to formulations and refers to data processing division for solving equations, programming, and processing. Reviews operations and testing of model to ensure adequacy or determine need for reformulation. Prepares written, nontechnical reports to management, indicating problem solution or range of possible alternatives in rank of desirability and probability of success when there is no single solution. Writes followup reports, evaluating effectiveness of research implementation. May specialize in research and preparation of contract proposals specifying the competence of an organization to perform research, development, or production work. May develop and apply time and cost networks, such as Program Evaluation and Review Technique (PERT), to plan and control large-scale business projects. May work in areas associated with engineering, as when analyzing and evaluating alternative physical systems, such as production processes, in terms of effectiveness and cost. May work alone or as member of a team.

Education, training, and experience

College degree with emphasis on advanced mathematics and statistics is usually the minimum educational requirement. A combination of advanced degrees in mathematics and business administration is especially desirable. A doctorate in mathematics is frequently required. Specific training in operations research at the graduate level is rapidly becoming a standardized requirement, as more schools offer courses in this interdisciplinary occupational area. Many workers have acquired the necessary background in mathematics through education and experience in engineering and the physical sciences, and knowledge of specialized techniques through self-study and participation in activities of professional organizations.

Special characteristics

Aptitudes:

Verbal ability to understand technical languages of various professional disciplines such as engineering and accounting, to give oral reports and to prepare written reports on results of research in lay terminology to management.

Numerical ability to understand and work with such mathematical specializations as game, queuing, and probability theory, and statistical inference to prepare formulations, specify manipulative methods and evaluate effectiveness.

Spatial ability to prepare and interpret charts, diagrams, graphs, and maps.

Clerical perception to recognize pertinent detail in compilation and analysis of statistical data, and to avoid perceptual errors in working with higher forms of mathematics.

Interests:

A preference for activities that are technical in nature to apply analytical, experimental, and quantitative techniques in the solution of management problems such as long-range forecasting, planning, and control.

Interests in devising mathematical equations, analyzing the methods used for their manipulation, and evaluating their practical effectiveness.

Temperaments:

Requires ability to perform a variety of tasks related to the solution of various problems on all departmental levels. This involves conversing in several professional disciplines with personnel at all operating levels to gather and relate data and opinions relevant to problem under study.

Must possess ability to make judgmental decisions such as probability of continuity or change in conditions, and assign arbitrary weights and values to problem factors when conventional statistical methods are not applicable.

Must possess ability to make decisions based on verifiable data, such as tabular records of previous organizational experience.

Physical Activities and Environment:

Work is sedentary, and occasionally involves lifting and carrying books, ledgers, and statistical tabulations seldom exceeding 10 pounds.

Talking and hearing to discuss organization goals and priorities with management and acquire data pertinent to the problem from other organizational personnel.

Near visual acuity to read and work with a variety of data from many sources, and to refer to texts and technical papers.

Work is performed inside.

CHIEF PROGRAMMER, BUSINESS—(020.168), COORDINATOR, COMPUTER PROGRAMMING; LEAD PROGRAMMER

Occupational definition

Plans, schedules, and directs preparation of programs to process business data by electronic data processing equipment. Consults with managerial and systems analysis personnel to clarify program intent, indicate problems, suggest changes and determine extent of automatic programming and coding techniques to use. Assigns, coordinates, and reviews work of programming personnel. Develops own programs and routines from workflow charts or diagrams. Consolidates segments of program into complete sequence of terms and symbols. Breaks down program and input data for successive computer passes, depending on such factors as computer storage capacity and speed, extent of peripheral equipment, and intended use of output data. Analyzes test runs on computer to correct or direct correction of coded program and input data. Revises or directs revision of existing programs to increase operating efficiency or adapt to new requirements. Compiles documentation of program development and subsequent revisions. Trains subordinates in programming and program coding. Prescribes standards of terminology and symbology to simplify interpretation of programs. Collaborates with computer manufacturers and other users to develop new programming methods. Prepares records and reports.

Education, training, and experience

Graduation from a technical school or college with training in business administration, computer programming, data processing mathematics, logic, and statistics is the usual educational requirement. Usually, a minimum of two years' experience in programming for same or similar computer system, on broadscope and complex projects is required. Experience should indicate knowledge of organization structure and workflow, and also reflect proven ability to supervise others and coordinate work activities of the group supervised with that of other organizational units.

Special characteristics

Aptitudes:

Verbal ability to present oral and written reports and recommendations and to read technical literature about changes in techniques and equipment.

Numerical ability to program at level of linear and Boolean algebra (logic) to minimize expensive programming and debugging time. Mathematics at level of differential equations and probability theory frequently required when an organization is developing or using sophisticated, integrated management information and forecasting systems.

Spatial ability to interpret systems statement, develop general and detailed computer flow charts, and prepare block diagrams that indicate hardware configuration.

Form perception to see pertinent detail in charts, diagrams, and code sheets composed of symbols.

Clerical perception to refer to manuals and written instructions and to review own work. This requires accurate identification of numbers, letters, words, and acronyms as well as ability to grasp general content.

Interests:

A preference for activities that are technical in nature to apply mathematics and logic in converting proposed business systems to computer-processable form.

Temperaments:

Ability to perform a variety of duties, covering problems from different but related areas of business activity such as production and inventory control, and sales analysis.

Must be able to direct, control, and plan development of business data processing programs that will meet current and future needs. This involves direction of activities, such as program testing and revising, and coordination of all phases of business programming activities to meet schedules.

Required to deal with subordinates for purposes of control and coordination, and with systems analysis and management personnel to resolve questions of intent and programming difficulties.

Required to make judgmental decisions based on experience to assign personnel and select and apply techniques that will produce least cost, fastest, or most flexible programs.

Required to make decisions based on factual data to evaluate adequacy of completed program by comparing program, test and operating runs with prescribed standards of terminology, and time.

Physical Activities and Environment:

Work is sedentary. Lifts and carries source and output data, books, charts, and diagrams seldom exceeding 10 pounds.

Stands, walks, talks, and hears in instructional and conference situations.

Near visual acuity to prepare, integrate, or modify complex programs, using a variety of charts, diagrams, and handbooks.

Work is performed inside.

PROGRAMMER, ENGINEERING AND SCIENTIFIC—(020.188), PROGRAMMER, TECHNICAL

Occupational definition

Converts scientific, engineering, and other technical problem formulations to format processable by computer. Resolves symbolic formulations, prepares logical flow charts and block diagrams, and encodes resolvent equations for processing by applying knowledge of advanced mathematics, such as differential equations and numerical analysis, and understanding of computer capabilities and limitations. Confers with engineering and other technical personnel to resolve problems of intent, inaccuracy, or feasibility of computer processing. Observes or operates computer during testing or processing runs to analyze and correct programming and coding errors. Reviews results of computer runs with interested technical personnel to determine necessity for modifications and rerun. Develops new subroutines for a specific area of application, or expands on applicability of current general programs, such as FORTRAN, to simplify statement, programming, or coding of future problems. May supervise other programming personnel. May specialize in single area of application, such as numerical control, to develop processors that permit programming for contour-controlled machine tools in source-oriented language.

Education, training, and experience

College degree with major in mathematics or engineering is usually the minimum educational requirement. A master's degree or doctorate in mathematics or engineering is a common requirement where analysis or programming is extremely complex or where work duties involve basic research in mathematics or programming. From two to four years of on-the-job training, with gradually decreasing amounts of supervision and with increasingly complex work assignments, are regarded as necessary for the worker to become familiar with at least one class of computer, programming language, and applications area. Short (one to four weeks) training sessions are given by employers and computer manufacturers to provide basic training and (later) specialized training. Current trends toward simplification of programming languages and greater applicability of generalized programs, and requirement of basic computer orientation and programming courses for college degree in physical sciences or engineering will reduce on-the-job training time.

Special characteristics

Aptitudes:

Verbal ability to discuss problems and equipment requirements with other technical personnel, to prepare computer flow charts, written records, reports, and recommendations and to read technical publications.

Numerical ability to interpret mathematical formulation, to select from alternative computational methods, to frame program within limitations of the computer to be used, prepare logical flow charts and diagrams, to convert program steps to coded computer instructions, and to review work. Level of mathematics may vary from arithmetic and algebra to advanced differential equations in the course of writing a single program, and may also include applications of numerical analysis.

Spatial ability to prepare logical flow charts specifying sequences of operating instructions and flow of data through computer system, to design input and output forms, and to interpret detailed drawings, diagrams, and other graphic data.

Form perception to see pertinent detail in charts, diagrams, and drawings, and distinguish symbols in subject matter areas such as physics and electrical engineering.

Clerical perception to avoid perceptual errors in recording of alphanumeric and special symbologies.

Motor coordination to operate calculator or computer.

Interests:

A preference for activities technical in nature to use mathematics to reduce formulations to computer-processable form.

Temperaments:

Required to make decisions on a judgmental basis, using past experience and knowledge to select best method of programming and coding a problem and thereby avoiding costly, time-consuming analyses of alternate techniques.

Required to make factual decisions, such as evaluation of program accuracy by computer acceptance, presence of error messages or obvious output distortions.

Must be able to conform to accepted standards and techniques in developing and testing programs, and in writing instructions for digital-computer operator.

Physical Activities and Environment:

Work is sedentary, requiring occasional lifting and carrying of source data, books, charts and diagrams seldom exceeding 10 pounds.

Talking and hearing to confer and collaborate with other technical personnel.

Near visual acuity to prepare logical flow charts from lengthy mathematical statements of problem, and to convert program steps to coded computer instructions.

Work is performed inside.

PROGRAMMER, BUSINESS—(020.188), DIGITAL-COMPUTER PROGRAMMER

Occupational definition

Converts symbolic statement of business problems to detailed logical flow charts for coding into computer language. Analyzes all or part of workflow chart or diagram representing business problem by applying knowledge of computer capabilities, subject matter, algebra, and symbolic logic to develop sequence of program steps. Confers with supervisor and representatives of departments concerned with program, to resolve questions of program intent, output requirements, input data acquisition, extent of automatic programming and coding use and modification, and inclusion of internal checks and controls. Writes detailed, logical flow chart in symbolic form to represent work order of data to be processed by the computer system, and describe input, output, arithmetic, and logical operations involved. Converts detailed, logical flow chart to language processable by computer (PROGRAMMER, DETAIL). Devises sample input data to provide test of program adequacy. Prepares block diagrams to specify equipment configuration. Observes or operates computer to test coded program, using actual or sample input data. Corrects program error by such methods as altering program steps and sequence. Prepares written instructions (run book) to guide operating personnel during production runs. Analyzes, reviews, and rewrites programs to increase operating efficiency or adapt to new requirements. Compiles documentation of program development and subsequent revisions. May specialize in writing programs for one make and type of computer.

Education, training, and experience

Minimum requirements are high school graduation with six months to two years of technical training in computer operations and in general principles of programming and coding, or equivalent job experience in these areas. Current trend is to hire college graduates for promotional potential with training in accounting, business administration, and mathematics, and provide them with a year of on-the-job training to qualify them for programming. In installations concerned with the application of the computer to more complex areas such as market research and statistical forecasting, a college degree in mathematics is preferred.

Special characteristics

Aptitudes:

Must possess verbal ability to understand and analyze oral or written statements concerning a variety of business problems and to discuss them with others.

Must possess numerical ability to interpret workflow charts, program problems, and understand machine logic. Level of mathematics varies from arithmetic and algebra for simple business data processing problems to differential equations and mathematical statistics for involved problems such as forecasting or optimization.

Must possess spatial ability to interpret diagrammatic representations of workflow, and to visualize flow of data through computer system to prepare computer block diagrams and logical flow charts.

Must possess form perception to see pertinent detail in symbols when reading, interpreting, or preparing charts, diagrams, and code sheets.

Clerical perception to detect errors in letters, words, and numbers recorded on charts, diagrams, and code sheets.

Interests:

An interest in activities technical in nature to effectively analyze problems, and to design logical flow charts and block diagrams.

An interest in activities that are carried out in relation to processes, techniques, and machines to plan sequence steps, to prepare instructions, and to test programs.

Temperaments:

Required to make judgmental decisions to plan logical sequence of steps and prepare logical flow chart for a project, keeping in mind capacities and limitations of computer and integrated machine units.

Must be able to conform to accepted standards and techniques in developing and testing programs, and writing instructions for computer operators to follow.

Physical Activities and Environment:

Work is sedentary, requiring occasional lifting and carrying of such items as source materials, run books, and documentations seldom exceeding 10 pounds.

Talking and hearing to communicate with systems, program coding, and operating personnel.

Near visual acuity and accommodation required to review statistical data and interpret charts and diagrams.

Work is performed inside.

PROGRAMMER, DETAIL—(219.388), JUNIOR PROGRAMMER; PROGRAM CODER

Occupational definition

Selects symbols from coding system peculiar to make or model of digital computer and applies them to successive steps of completed program for conversion to machine-processable instructions. Reads and interprets sequence of alphabetic, numeric, or special characters from handbook or memory for each program step to translate it into machine language or pseudo (symbolic) code that can be converted by computer processor into machine instructions. Records symbols on worksheet for transfer to punchcards or machine input tape. Marks code sheet to indicate relationship of code to program steps to simplify debugging of program. Confers with programming personnel to clarify intent of program steps. Usually works as understudy to PROGRAMMER, BUSINESS performing such additional tasks as converting flow charts and diagrams of simple problems from rough to finished form, or making minor changes in established programs to adapt them to new requirements.

Education, training, and experience

Must be high school graduate. Some training in programming, coding, and computer operations at technical school level is desirable. Experience in computer operations is preferred, but six months of job experience, most often in a clerical capacity, to become familiar with company operations, workflow, standards, and terminology is the minimum requirement. One to four weeks classroom training in coding for specific computer is usually provided by employer or computer manufacturer. Some employers favor college graduates in order to enhance the worker's promotion potential.

Special characteristics

Aptitudes:

Verbal ability to recognize programming and coding language consisting of abbreviated words, grouping of numbers, symbols, or mnemonics.

Numerical ability to convert decimal numbers to binary or other number systems.

Form perception to recognize and remember graphic symbols (arrangement of lines and curves).

Clerical perception to select from handbooks codes acceptable to computer, which involves accurate identification and recording of numbers, letters, and words.

Interests:

A preference for activities of a routine, concrete and organized manner to code programs, using standardized codes.

Temperaments:

Ability to perform repetitive tasks according to set procedures, to refer to source books for symbologies and select appropriate codes for each detailed step in program. Steps may number into the thousands.

Required to work to precise and established standards of accuracy in recognition of steps of detailed program and in selecting and recording codes. Any mistake can introduce error into programs and either prevent processing or distort output of program when processed.

Physical Activities and Environment:

Work is sedentary. Work sheets and code books seldome exceed five pounds.

Continuously handles pencils, work sheets, and code books while interpreting program steps, finding representative coding, and posting codes to work sheets.

Near visual acuity to select correct alphabetical, numerical, or special symbols to convert detailed program to machine-processable form.

Work is performed inside.

SUPERVISOR, COMPUTER OPERATIONS—(213.138), CHIEF CONSOLE OPERATOR; SENIOR CONSOLE OPERATOR; SUPERVISOR, DATA PROCESSING; SUPERVISOR, ELECTRONIC DATA PROCESSING

Occupational definition

Supervises and coordinates activities of workers who operate electronic data processing machines. Assigns personnel and schedules workflow to facilitate production. Directs training or trains personnel in operation of computers and peripheral and off-line auxiliary equipment. Works with programming personnel in testing new and revised programs. Develops operating methods to process data, such as devising wiring diagrams for peripheral equipment control panels, and making minor changes in canned (standardized) programs or routines to modify output content or format. Directs insertion of program instructions and input data into computer, and observes operations. Aids operators in locating and overcoming error conditions. Makes minor program and input data revisions through computer console to maintain operations. Notifies programming and maintenance personnel if unable to locate and correct cause of error or failure. Revises operating schedule to adjust for delays. Prepares or reviews records and reports of production, operating, and down-time. Recommends changes in programs, routines, and quality control standards. Consults with MANAGER, ELECTRONIC DATA PROCESSING about problems, such as including new program testing and operating runs in schedule and arranging for preventive maintenance time. Coordinates flow of work between shifts to assure continuity. May supervise personnel engaged in keypunching, data typing, and tabulating.

Education, training, and experience

High school graduation is the minimum requirement. Usually a minimum of one to three years' experience in operating computers, peripheral, and off-line equipment is required. A familiarization with programming and coding techniques usually gained through experience in computer operation or a course in programming are additional prerequisites. However, a two-year post-high school training course in electronic data processing may reduce experience requirements. Training in business administration, mathematics, and accounting is regarded as particularly desirable. Some employers require a college degree, particularly in large installations where work duties are largely administrative, and also in order to enhance the worker's promotion potential. Experience in supervising personnel is desirable.

Special characteristics

Aptitudes:

Verbal ability to train and supervise subordinates, confer with other supervisory and technical personnel, and prepare records and oral or written reports.

Numerical ability to level of arithmetic and algebra to cope with error or stoppage situations in computer operations; to plan operating changes; and to prepare variety of reports, often on a daily basis such as revision of average time requirements for processing data or cost allocations to departmental users.

Spatial and form perception to prepare wiring diagrams, wire control panels for peripheral machines, and operate equipment.

Clerical perception to review records of production, operating and down-time, and recognize pertinent detail in computer printout dumps.

Interests:

A preference for business contact with others to confer with management, technical personnel, suppliers of input data, and users of computer output, and to supervise and train subordinates.

A preference for activities that are technical in nature to keep informed of new techniques for operation of current machines.

Temperaments:

Ability to perform a variety of tasks subject to frequent change, such as training and assigning personnel, accommodating changes in production schedules to meet priority runs, maintaining records, and developing new operating procedures.

Must be able to direct, control, and plan the activities of computer operators, satellite input-output computer operators, on-line and off-line peripheral equipment operators, and tape librarians.

Required to deal with people such as other departmental supervisors to resolve problems concerned with the scheduling, adequacy, and accuracy of input data.

Required to make decisions on a judgmental basis to set up work assignments that make maximum use of workers' knowledge and ability, and most effective and economical use of computers and peripheral equipment.

Required to make decisions on a factual basis when developing schedules for processing programs, relating such factors as date of program receipt, priority assignment, estimated run time, and available computer time. Compares output requirements against available equipment, and existing programs, routines, wiring diagrams, and control panels to determine need for developing or modifying operational methods, or altering operating schedule.

Physical Activities and Environment:

Work is light, requiring frequent standing and walking and occasional lifting and handling of reels of tape, decks of punchcards, and control panels weighing up to 20 pounds.

Talking and hearing to give oral instructions, assign work, and train personnel. Confers with management and others, discussing such items as budget requirements and staffing, machine capability, and production problems.

Near visual acuity to frequently analyze records, prepare reports, study program run books, and read technical literature.

Work is performed inside.

COMPUTER OPERATOR—(213.382), COMPUTER OPERATOR; CONSOLE OPERATOR

Occupational definition

Monitors and controls electronic digital computer to process business, scientific, engineering, or other data, according to operating instructions. Sets control switches on computer and peripheral equipment, such as external memory, data communicating, synchronizing, input, and output recording or display devices, to integrate and operate equipment according to program, routines, subroutines, and data requirements specified in written operating instructions. Selects and loads input and output units with materials, such as tapes or punchcards and printout forms, for operating runs, or oversees operators of peripheral equipment who perform these functions. Moves switches to clear system and start operation of equipment. Observes machines and control panel on computer console for error lights, verification printouts and error messages, and machine stoppage or faulty output. Types alternate commands into computer console, according to predetermined instructions, to correct error or failure and resume operations. Notifies supervisor of errors or equipment stoppage. Clears unit at end of operating run and reviews schedule to determine next assignment. Records operating and down-time. Wires control panels of peripheral equipment. May control computer to provide input or output service for another computer under instructions from operator of that unit.

Education, training, and experience

A high school education meets the minimum educational requirements of some employers, but an increasing number of employers are demanding an additional several months to two years of technical school training in data processing. This training usually includes such courses as data processing mathematics, accounting, business practices, elementary programming, and operation of computers, peripheral equipment, and tabulating machines.

The employer or computer manufacturer usually provides one to three weeks of formal instruction for the specific computer system the worker will operate. Length of subsequent on-the-job training and experience required to achieve adequate performance ranges from a few months to one year because computer systems and equipment vary in complexity and need for operator intervention. Except in small units, a minimum of three to six months prior experience in operation of peripheral equipment frequently is required.

Special characteristics

Aptitudes:

Verbal ability to comprehend technical language of operating instructions and equipment manuals and to explain clearly any operating problems and difficulties in interpreting program intent.

Numerical ability at level of arithmetic to prepare operating records, time computer runs, and adhere to fixed operating schedule. While not always an operator requirement, an understanding of data processing mathematics (the number systems used, algebra and logic) is almost essential to discuss operating difficulties with programming personnel, and to progress from routine production runs to the testing of new programs.

Spatial perception to wire control panels for peripheral equipment.

Form perception to identify flaws in input and output materials.

Clerical perception to avoid perceptual errors in preparing operating records, and to recognize alphabetic, numeric, and mnemonic symbols.

Motor coordination, to rapidly set up machines and to move keys and switches to quickly correct errors or stoppages.

Interests:

A preference for working with machines and processes to continuously operate and monitor the equipment that comprises the computer system.

Interest in activities of concrete and organized nature to operate machines according to specific and detailed instructions.

Temperaments:

Work situation requires ability to perform a variety of work tasks subject to frequent change in the simultaneous operation of a console and a variety of peripheral equipment, the integration of which varies from program to program, or even during a single operating run, and which demands rapid transfer of attention from one piece of equipment to another.

Accuracy required to operate system effectively and minimize down-time and rescheduling of runs. Carelessness in following written and oral instructions can cause extensive rebuilding of program or input data, or even lead to irrecoverable loss of data.

Physical Activities and Environment:

Work is light. Lifts, carries, and positions tape reels, punchcard decks, output forms, and control panels seldom exceeding 20 pounds.

Stands and walks frequently when loading and monitoring machines.

Reaches for and fingers switches and keys on console and peripheral machines. Wires control panels, loads and removes input and output materials.

Talking and hearing to frequently exchange information concerning program and system requirements with other workers and to receive or give instructions.

Near visual acuity and accommodation to follow detailed operating log, monitor computer and peripheral machines for signs of malfunction, and analyze console messages or high-speed printer output for cause of error or stoppage.

Color vision to distinguish between colored wires when wiring control panels, to identify color-coded cards or forms and to monitor colored display lights if used.

Work is performed inside.

COMPUTER-PERIPHERAL-EQUIPMENT OPERATOR—(213.382), ASSISTANT CONSOLE OPERATOR; TAPE HANDLER

Occupational definition

Operates on-line or off-line peripheral machines, according to instructions, to transfer data from one form to another, print output, and read data into and out of digital computer. Mounts and positions materials, such as reels of magnetic or paper tape onto spindles, decks of cards in hoppers, bank checks in magnetic ink reader-sorter, notices in optical scanner, or output forms and carriage tape in printing devices. Sets guides, keys, and switches according to oral instructions or run book to prepare equipment for operation. Selects specified wired control panels or wires panels according to diagrams and inserts them into machines. Presses switches to start off-line machines, such as card-tape converters, or to interconnect on-line equipment, such as tape or card computer input and output devices, and high-speed printer or other output recorder. Observes materials for creases, tears, or printing defects and watches machines and error lights to detect machine malfunction. Removes faulty materials and notifies supervisor of machine stoppage or error. Unloads and labels card or tape input and output and places them in storage or routes them to library. Separates and sorts printed output forms, using decollator, to prepare them for distribution. May operate tabulating machines, such as sorters and collators.

Education, training, and experience

High school graduate. Post-high school training in operation of electronic or electromechanical data processing equipment is desirable. Employers frequently regard worker as understudy to computer operators and apply same education and aptitude standards to them.

Special characteristics

Aptitudes:

Verbal ability to read written instructions and handbooks and to communicate with supervisor about operating functions.

Spatial ability to follow diagrams to wire control panels, position and thread tapes onto spindles or position decks of cards in hoppers.

Clerical perception to identify and record, without error, data such as dates, program numbers, departments, and routings on forms.

Motor coordination and finger and manual dexterity to load and unload machines quickly and minimize down-time, to thread ribbons of tape over guides and through rollers, and to handle cards and tapes deftly without bending, tearing, or otherwise damaging them.

Interests:

An interest in activities concerned with machines, processes, and techniques to operate various machines. Preference for activities of a routine and organized nature to follow well-defined instructions for any of several different machines.

Temperaments:

Worker must be adept at performing a variety of tasks requiring frequent change to operate a number of machines in varying combinations and sequences.

When operating peripheral equipment, must adhere to established standards for accuracy, such as observing printer output forms for defects in alinement, spacing, margin, and overprinting. Immediate response to indication of error in operation of peripheral equipment is vital.

Physical Activities and Environment:

Work is light, involving frequent standing and walking when operating machines and lifting and carrying tapes, cards, and forms not exceeding 20 pounds.

Reaches, handles, and fingers to mount tapes onto spindles, position decks of cards in hoppers, and thread tape through guides and rollers of peripheral units or wire control panels.

Near visual acuity to read labels on reels, to wire plug boards from diagrams, to scan printout for error, and to read operating instructions and handbooks.

Color vision to distinguish between various colors of wires to ensure correct wiring of control panels.

Work is performed inside.

CODING CLERK—(219.388)

Occupational definition

Converts routine items of information obtained from records and reports into codes for processing by datatyping or key-punch units, using predetermined coding systems. Manually records alphabetic, alphanumeric, or numeric codes in prescribed sequence on worksheet or margin of source document for transfer to punchcards or machine input tape. May be designated according to trade name of computer system as CODING CLERK, UNIVAC; IBM CODER.

Education, training, and experience

High school graduation usually is required. Training of a day or two in a classroom situation or under the direction of an experienced worker usually is provided by the employer. Achievement of adequate speed, and particularly the development of a high degree of accuracy, takes from one to three months. Achievement of speed involves memorization of many of the codes. Familiarization with standard business terminology and abbreviations, and with special conventions used by the employer can reduce the time necessary to achieve adequate performance.

Special characteristics

Aptitudes:

Verbal ability to understand written and oral instructions, business terms, abbreviations, and mnemonic contractions, and to explain difficulties to supervisor.

Clerical perception to scan and extract pertinent detail from source documents, and to avoid and detect perceptual errors.

Interests:

A preference for activities of a routine, concrete, organized nature to code according to a predetermined, standardized system.

Temperaments:

Work activities are repetitive and short cycle in nature. Converts each item into the equivalent code in the allowable time cycle of a few seconds.

Must follow specific instructions to convert items to their coded equivalents which are indexed in tables or handbooks.

Physical Activities and Environment:

Work is sedentary. Reaches for, lifts, and handles handbooks, papers, and forms seldom exceeding five pounds.

Near visual acuity to read and convert items to codes.

Work is performed inside.

TAPE LIBRARIAN—(223.387)

Occupational definition

Classifies, catalogs, and maintains library of magnetic or punched paper tape or decks of magnetic cards or punchcards used for electronic data processing purposes. Classifies and catalogs material according to content purpose of program, routine or subroutine, and date on which generated. Assigns code conforming with standardized system. Prepares index cards for file reference. Stores materials and records according to classification and catalog number. Issues materials and maintains charge-out records. Inspects returned tapes or cards and notifies supervisor if worn or damaged. May maintain files of program developmental records and operating instructions (run books). May operate key-punch to replace defective punchcards and produce data cards to identify punchcard decks. May work in computer room performing such tasks as loading and removing printout forms, reels of tape, and decks of cards from machines.

Education, training, and experience

High school graduate, preferably with commercial background. Three to six months experience as catalog clerk, file clerk, mail clerk, or messenger with the company is desirable.

Special characteristics

Aptitudes:

Verbal ability to read information on labels describing contents of decks of cards and reels of tape and read catalogs that contain standardized codes and abbreviations.

Numerical ability to count, add, and subtract numbers to perform inventory functions.

Clerical perception to note pertinent detail on labels, cards, or work schedules, and in code books to detect error and avoid misinterpretation.

Interests:

A preference for working with things and objects, following routine and organized patterns to classify, catalog, store, and fill requests for cards and tapes.

Temperaments:

Follows specific instructions and established procedures to receive, store, issue, and purge materials.

Physical Activities and Environment:

Work is light, involving frequent standing and walking to carry reels of tapes or trays and drawers of cards weighing less than 20 pounds between desk, handtruck, file cabinets, and racks.

Reaches for and handles tapes and cards to store them.

Near visual acuity to read and assign identification symbols and inspect materials for damage.

Work is performed inside.

KEY-PUNCH OPERATOR—(213.582), CARD-PUNCH OPERATOR; PRINTING-CARD-PUNCH OPERATOR; PRINTING-PUNCH OPERATOR

Occupational definition

Operates alphabetic and numeric key-punch machine, similar in operation to electric typewriter, to transcribe data from source material onto punchcards and to reproduce prepunched data. Attaches skip bar to machine and previously punched program card around machine drum to control duplication and spacing of constant data. Loads machine with decks of punchcards. Moves switches and depresses keys to select automatic or manual duplication and spacing, selects alphabetic or numeric punching, and transfers cards through machine stations. Depresses keys to transcribe new data in prescribed sequence from source material into perforations on card. Inserts previously punched card into card gage to verify registration of punches. Observes machine to detect faulty feeding, positioning, ejecting, duplicating, skipping, punching, or other mechanical malfunctions and notifies supervisor. Removes jammed cards, using prying knife. May tend machines that automatically sort, merge, or match punchcards into specified groups. May keypunch numerical data only and be designated KEY-PUNCH OPERATOR, NUMERIC.

Education, training, and experience

High school graduate preferred with demonstrated proficiency in typing on standard or electric typewriter. High school or business school training in key-punch operation is desirable. Frequently, one week of training is provided by employer or manufacturer of equipment.

Special characteristics

Aptitudes:

Verbal ability to understand oral and written instructions, such as manufacturers' operating manuals, and to learn operation of machine.

Clerical perception to perceive pertinent detail in tabular material consisting of combinations of letters and numbers, and avoid perceptual error in transferring this data to punchcards.

Motor coordination to read work sheets and simultaneously operate keyboard of approximately 40 keys to punch data on cards.

Finger dexterity to move switches on machine.

Interests:

Preference for organized and routine activities to transfer data onto punchcards.

Temperaments:

Must be able to perform repetitive duties of operating key-punch machine.

Ability to follow specific instructions and set procedures to transfer data onto punchcards.

Required to work to precise and established standards of accuracy to key-punch data at high rate of speed.

Physical Activities and Environment:
Work is sedentary with infrequent lifting of decks of cards when loading machine.

Reaches for and handles code sheets, business records, and decks of cards; fingers switches and keys to operate machine.

Near visual acuity to read copy when key-punching.

Work is performed inside.

The future of minicomputer programming

by D. J. WAKS and A. B. KRONENBERG

Applied Data Research, Inc.
Princeton, New Jersey

> *"Here is Edward Bear, coming downstairs now, bump, bump, bump, on the back of his head, behind Christopher Robin. It is, as far as he knows, the only way of coming downstairs, but sometimes he feels that there really is another way, if only he could stop bumping for a moment and think of it. And then he feels that perhaps there isn't."*
>
> Beginning of *Winnie-the-Pooh*, A. A. Milne

INTRODUCTION

The minicomputer syndrome

The programming of minicomputers to date has resembled Pooh Bear coming downstairs because although we feel that there really is another way, we rarely stop bumping. Programmers for small computers have long exhibited what we call "the minicomputer syndrome", which is a very low expectation of program support and facilities on a minicomputer and a lack of appreciation of the hardware and software tools one can employ to attack and solve a programming problem.

Minicomputers came on the market when it was first realized that small general-purpose stored-program computers could be competitive with complex hard-wired systems built from general-purpose logic modules. Not at all surprisingly, the manufacturers of logic modules quickly became the leading developers of minicomputers. Since the programming process was viewed as an unfortunately necessary step in making the mini behave like the hard-wired system it was replacing, very little general-purpose programming support was provided with the minis. Thus, the minicomputer syndrome—the belief that primitive computers require primitive programming support—was born virtually at the same time as the mini itself.

Computer manufacturers have fostered this syndrome by typically providing little general-purpose software* with their minis. Although manufacturers have recently attempted to provide reasonable program-creation software, the majority of available assemblers still lack such desirable features as macros, conditional assembly, literals, and multiple location counters. Program-execution software for most small computers is often so weak that the user usually is left to write his own disk handler, communications package, or real-time executive. Even in cases where a manufacturer does provide such software, it usually requires a configuration that is uneconomically large.

The manufacturers' software planners seem to exhibit the minicomputer syndrome more than many of their customers. They continue to design separate, single-application monitors apparently assuming that the user will employ his mini only for real-time applications, file processing, communications, or report writing. Thus, the user who wants a single monitor system to support some combination or all of these must either adapt a manufacturer-supplied monitor or build one from scratch.

This lack of coherent manufacturer software support has also been characterized by a lack of standardization and conventions or standardization of poor or unworkable conventions in the software. This in turn has led to a proliferation of software to dismay any ecologist. For example, how many different assemblers now exist for the DEC PDP-8 family? We were able to count a baker's dozen in two minutes of trying; there must be an equal number we didn't think of or don't know about.

Finally, this lack of standards and conventions has resulted in incompatibility from one user to another. Software modules created for one user's executive and assembler can be neither assembled nor run at another user's site. We have been involved in more than one

* General-purpose software can be classified as either program-creation software (text/file editors, language processors), or program-execution software (monitors, device drivers, real-time executives).

project requiring that a program be manually transliterated from one dialect for a computer to another.

What is a minicomputer?

The paper is intended to describe programming for minicomputers. What do *we* mean by "minicomputer"?

Let us begin by characterizing the *small computer* as having:

(a) A short word and register length, aiways 18 bits or less; a small computer, therefore cannot perform *single-precision* floating-point arithmetic through either the hardware or software.
(b) A main memory provided in modules of 8K words or less (typically 4K words).
(c) An instruction set and, commonly, its addressing mode which are restricted, usually having a rather short operation code field in its machine-language structure.

One more characteristic is required to define what we mean by a mini: if a machine passes the test for a small computer, and you can't ordinarily buy it without an ASR Teletype®, it is a *mini*. If you can't ordinarily buy it without a *card reader*, it *isn't* a mini, it's just a small computer.

The virtual machine and the extensible machine

Let us digress for a moment and define some useful concepts we will refer to throughout the remainder of this paper. The concept of the "extended machine" was first propounded by Holt and Turanski;[1] we will use the term "virtual machine" interchangeably with extended machine. Here we are using the term "virtual" in its dictionary[2] sense: "Virtual, apparent, as contrasted with actual or absolute." That is, the virtual or extended machine is what the computer user, on some level, sees and uses. Another way of saying this is to describe it as the *set of primitives* with which he must work. Watson[3] defines a "virtual processor" in a timesharing system in a similar way. The "virtual memory" concept in paged computers is a similar derivation.

As it is, the computer user rarely sees or uses the "actual or absolute" machine. To do so, he would have to write all his code in machine language. Language processors, executive systems, device drivers, *et al.*, are all extensions to the machine which substantially affect the user's view of the machine. For instance, a minicomputer with a disk operating system appears to be a very different machine from one with only paper-tape-oriented software. A mini with a manufacturer-provided real-time executive appears to be a very different machine from one without it to the user with a data acquisition and reduction problem. In this sense, then, all available software and hardware options act as real extensions to the "actual" machine.

When certain types of extensions are preplanned into the computer hardware and software design, the resultant machine is considered "extensible"—to the extent that such extensions are planned. We characterize these extensions as being expansions of primitives on three distinct levels: the hardware or "firmware" level; the system software level; and the applications software level. On each level, the user can implement new extensions, typically visible at the next higher level (further away from the hardware) although sometimes available at the same level.

The *first* and *lowest level* of extensibility is at the *hardware* or *firmware* level. By hardware extensibility, we mean the ability to add new operation codes, typically for I/O but also for CPU purposes. Thus, a *supervisor call* facility was added to a PDP-8 four years ago to provide for user-supervisor communication in a real-time system for TV control room automation. This form of extensibility is designed-in, and encouraged, although only rarely used to augment CPU primitives. By firmware extensibility, we mean extensions through modifications or additions to microcode on those computers (such as all machines in the Interdata family) which have a two-level (micro and user) programming structure.[6] This ability to modify or augment the instruction repertoire of the machine is a powerful way, albeit rarely exploited, to extend the machine at the lowest level; the new primitives thus created are fully comparable to the original instructions of the actual machine.

The *second level* of extensibility is at the software level through creation of *system software*. By system software, we mean such obvious extensions as operating systems, device drivers and interrupt handlers, and any program-creation software, especially language processors, which can drastically change the primitives available to the end user. *Planned* extensibility at this level implies such hardware features as:

(a) A user mode/supervisor mode distinction, providing a trap of some kind against the execution of reserved instructions in user mode, and providing some kind of "supervisor call" facility.
(b) An approach to I/O on the hardware level which

® Teletype, a registered trademark of the Teletype Corporation.

provides for substantial compatibility of the I/O mechanisms from device to device, particularly with respect to interrupts and status information.

(c) Some method for extended address mapping which provides for hardware protection and relocation, thus relieving the mini user of his worst problem—severe limitations on addressing.

The *third* and *highest level* of extensibility is on the user software level. Planned extensibility provides the end user with the capability of augmenting the apparent set of primitives he uses in writing his programs. Such long-used techniques as subroutines and macros both constitute expansions of primitives, particularly when used together, e.g., a macro used to generate a calling sequence for a subroutine which performs some complex function.

Many sophisticated programmers for minis, particularly those coming from a large-computer background, habitually define large numbers of macros to provide extended primitives comparable to those found in the actual instruction set on large machines. In this way, the experienced programmer of a minicomputer views the problem of programming a mini as being no different from that for a large computer, effectively countering the purveyors of the "minicomputer syndrome" by using the same techniques, approaches, and skills developed for large computers. The manufacturer can plan for extensibility on this level by providing the user with macro features in the assembler and by providing flexible hardware and software techniques for invoking subroutines.

Let us close this introduction by noting that each layer of extension, although providing a new set of primitives to the next higher level, may also reduce the original set of primitives available on that level. A set of device drivers for I/O handling, once defined, usually prevents the user from writing code to use a new I/O device in a substantially different way from that standardized by the drivers added as extensions; he also loses, in the process, any capability of doing I/O operations himself, since attempts to do so are trapped by the hardware.

Additionally, a Basic system—editor, compiler, and operating system combined—gives the Basic user a different and more powerful set of primitives than he has in assembly language, but deprives him of the ability to perform operations in assembly language, even though this might be far preferable for some aspects of a given problem. Thus, the extended machine may look to the user quite different from the original machine, with some primitives added and others deleted, at the extender's discretion.

The remainder of this paper is devoted to describing many kinds of extensions which we see occurring now and in the future. Since this paper is principally about software, we will concentrate on extensions to the second and third levels. However, we feel that current hardware developments will encourage software-like extensions at even the lowest level, and we will discuss these implications also. Hopefully, viewing the minicomputer as more closely related to the large-scale computer than the hard-wired controllers it was originally designed to replace will lead to alleviating the underlying symptoms of the minicomputer syndrome.

THE MINI AS A GENERAL-PURPOSE COMPUTER

We will first discuss the minicomputer as it may be viewed by the applications programmer in the future. To do this, we will first examine a significant difference in the evolution of larger computer software as opposed to minicomputer software.

Both scales of computers developed from the same base: machine-language programs loaded into memory via manually produced media (cards or paper tape) followed by console debugging with the user setting switches and reading lights on the computer. In the history of large computers, the first executive systems were batch monitors, which were quite widely developed by 1960. These batch monitors provided for submitting "jobs" on decks of cards to the computer center where they were eventually entered into the "job stream" and run. All programming and debugging tools developed for large computers during most of the 1960s were oriented to batch operation; and today virtually all operating systems for today's large computers are optimized for batch processing. Nearly all commercial programming, and most university programming, is today done using batch monitors on computers including the IBM 360 and 370, the Univac 1108, and the CDC 6600 and 7600. Recently, a trend has started toward providing some sort of support for interactive programming, debugging, and program execution. Except for several large computers explicitly designed for interactive operation in time-shared applications (specifically the XDS 940 and the DECsystem-10, both produced by companies previously known for minis), the machines were originally designed for batch operation and modified in both hardware and software to support interactive operation. The IBM 360/67 is a modification to the 360/65, the Honeywell (GE) 645 to the 635, the Spectra 70/46 to the 70/45. These machines seem to have been grudgingly provided by the manufacturers to meet what they saw as a small, uneconomical, but prestigious market; none of them provide nearly as good interactive operation as machines and software designed to be interactive from the beginning. In particular, a system like the DECsystem-10 can provide program interaction with the user on a character-by-character basis through the user's teletypewriter; no machine based on a 2741-type terminal can possibly do so, since the terminal and its supporting computer-based interfaces are designed to operate strictly on a half-duplex, line-at-a-time basis. But the trend would appear to be toward expanded interactive and conversational uses of large computers, particularly as management information systems make terminal access to data bases desirable in real time.

Minicomputer programming started in the same way as the large computers. Paper tape was the primary I/O medium, read in by an ASR-33 Teletype®, with the computer console used for all debugging. Since minicomputers cost so much less than large computers, there was much less pressure to get away from console debugging, particularly as it was recognized as being a very cost-effective tool for a competent programmer. When it became clear that it was possible to create software tools to facilitate debugging, it was natural to use the Teletype®, which was there anyway (recalling our definition of a minicomputer), as the I/O device around which to design the "monitor." The first interactive programs for minicomputers, using the "console teletypewriter" to provide interaction with the user, were symbolic editors and debugging tools (particularly DDT,[7] a debugging system produced at MIT for the PDP-1). Many other interactive systems for minis are described in an earlier paper by one of the authors.[8] Interactive systems of all kinds are common today on virtually all minicomputers. In addition to symbolic editors and debugging .systems, there are full-scale Basic systems for one or several users on many minis; several minis have Disk Operating Systems designed for conversational control from the console teletypewriter, single-user and multi-user interpretive systems derived from JOSS® running on one or more terminals, etc.

Now that minicomputer configurations often include peripherals, such as mass storage on removable disk packs, card readers, line printers, magnetic tapes, formerly found only on large computers, we see a trend toward the use of batch operating systems on minicomputers. Such systems, typically based on RPG and/or Fortran as higher-level languages, are closely modeled after large-machine batch systems. *The resulting virtual machine thus looks almost, if not completely, like the virtual machines erected on larger-machine bases.* A user programming in Fortran or RPG, both relatively standardized languages, cannot tell, when he submits a deck and gets back his reports, whether it was run on a large computer or on a mini (except, perhaps, by the size of the bill!).

Thus, large computers and minis are becoming more and more alike—at least from the point of view of the applications programmer. The authors hope that the significant advantages of interaction between the user and the computer, so prominent in the development of minicomputer software, will not be disregarded by the mini manufacturers in their seemingly headlong rush to "me-too" compatibility with larger computers and their batch operating systems.

THE MINICOMPUTER EXTENSION SPECIALIST

Until now, the people who have played the largest role in extending minicomputers have been the system software designers and implementors and the hardware engineers. We feel that the systems software designers will have an increasing role as extension specialists in the future by becoming knowledgeable in hardware techniques.

Hardware/software extensibility

Already, the manufacturers of minis are providing richer instruction sets and more designed-in extensibility in their newer computers. As an example, the DEC PDP-11 provides a rich instruction set, a novel I/O structure, and virtually a complete elimination of the addressing problem which once plagued most minis. The Interdata Systems 70 and 80 provide substantial encouragement for the user to employ microprogramming to extend the base machine, i.e., to produce firmware. Almost all new minis provide modular packaging, in which a hardware function, to add a new primitive, can be easily wired on a single module and plugged into the machine.

We see the continued growth of microprogrammed processors, built around Read-Only Memories (ROM's), as being in the vanguard of user-extensible machines. The newest hardware facilities include Programmable ROM's (PROM's) which can be written by the user on his site; Erasable PROM's—which can be manually

® JOSS, a registered trademark of the RAND Corporation.

erased after being written; and Writable ROM's (slow write cycle compared to read, intended to be written relatively infrequently), sometimes called "Read-Mostly Memories" (or RMM's). All of these lead us to see a trend toward making this form of extensibility available by design, rather than by accident.

Thus, the extension specialist will be encouraged to work on all levels of extensibility. He will be able to add firmware in the form of lower level programming (microprogramming) or as pre-wired primitives which he can literally plug in as new functions (as on the GRI-909 family). Writable ROM's promise additional extensibility, even providing the systems programmer with the ability to optimize the instruction set for each application by loading a writable ROM from his system initialization code. Thus, he might choose an instruction set built around four-bit decimal numbers to run Cobol or RPG programs, one featuring binary floating point on multiple-precision numbers for Fortran or Algol, one with extensive byte manipulation for Snobol, and one with primitive expression evaluation for PL/I.

Systems programmers will become more competent at lower-level extension work, either by the firmware being brought closer to the user in the form of writable ROM's, or by the software designer being cross-trained in hardware techniques. For many minicomputer systems programmers, an oscilloscope is a familiar tool in debugging complicated programs and systems. Every sign indicates a growing encouragement for the systems programmer to create his own desired environment through extensibility. The DEC PDP-16 carries this to its logical extreme by letting the user build his own computer from a pre-determined set of modules using software tools to aid the design and implementation process.

Thus, we predict that the systems designer of the future will increasingly be at home in both cultures—hardware and software.

Programming automation systems

We also see a substantial growth and extension to what we call "programming automation systems"—techniques that provide the programmer with computer aids in the programming process.[9] All programming systems are designed to help the programmer through the critical loop of program development, i.e., program modification, language processing, debugging, and back to modification. Thus, systems such as Basic and JOSS® provide for complete control over the critical loop within the context of a single system with a single language used to control all three functions. On minicomputers, symbolic editors, language processors and debugging aids are provided to "automate" these three steps. For the systems programmer working on logically complex and large programs, however, the minicomputer does not really provide an optimum environment. Unless it provides bulk storage and a line printer, it is not well suited to editing and assembly. Unless it has a console much better designed than most mini consoles, it is also not particularly well suited to debugging (and the newest consoles are even less useful for debugging). Thus, there seems to be a trend toward the use of larger computers, particularly time-shared systems, for supporting programming automation systems designed to support smaller machines. A large-machine-based editor and assembler can do a lot to facilitate the creation of programs, particularly since the assembler does not have to be restricted in either the features or the number of symbols which can be accommodated. A good simulator, designed for debugging, can significantly improve the productivity of a programmer by providing him with the necessary tools to debug a program without the limitations of the smaller machine. The authors have invested quite some time over the last few years investigating this approach;[10] several other organizations have also done so, with some success. Several new computers, notably the GRI-909 and the IBM System 7, accentuate this trend; they are only supported by larger host computers; the actual machines are configured only to run programs, not to create them.

For years, systems programmers for small machines have felt, like Pooh Bear, that there must be a better way than assembly language to write programs for small machines. The so-called "implementation languages" have been in use for some time on larger computers; languages such as AED,[11] BLISS,[12] PL/I and ESPOL[13] have been used to create systems software, including compilers and operating systems, for large computers. We regard it as unlikely that implementation languages will soon be operational on minicomputers, due to their high initial cost and inefficiency of generated code. (Only if substantial computer time is invested in optimizing time and space will minis be able to support such implementation languages.) We do feel that the trend toward using larger computers to support minis will continue, and that it will soon be possible for systems programmers to use large-computer-based implementation language processors and debugging systems as accepted tools of the trade. Already a compiler for the BLISS language, an implementation language developed at Carnegie-Mellon originally for the DEC system-10, has been produced to generate code for the PDP-11 on the DEC system-10.

THE MINI AS A BASE FOR DEDICATED SYSTEMS

Over the past five years (which represents virtually the entire history of the minicomputer in terms of number installed), there has been a noticeable shift in the hardware/software tradeoffs in pricing and using minicomputers in dedicated system applications. Several people have long maintained that the price of the software for a dedicated system should, as a rule of thumb, equal the price of the hardware. Although apparently true four years ago, this cannot possibly be true today. Hardware costs of minicomputer mainframes and memories have been decreasing exponentially at an apparent rate of about 25 percent a year, while software costs have been slowly rising, at the rate of inflation. Thus, if the hardware/software cost ratio was around 1/1 four years ago, it is more like 1/2.5 today, and the gap is steadily widening.

All of the extensibility promised by recent hardware developments, including the modular construction of the new machines and the increasing use of ROM's, should have an accelerating affect on the applications of minis to dedicated systems, steadily reducing the cost of the hardware required for a given task.

We see implementation languages beginning to relieve the trend toward higher software costs and hope they will continue to do so in the future. But we see problems in the high cost of training existing programmers to use implementation languages, the lack of acceptance by lower-level programmers, and general questions arising as to whether such languages and compilers really appropriately solve more difficult problems (such as those that are space and/or time critical).

We predict that in the next few years the current problems regarding implementation languages will be vigorously attacked on several fronts, and we feel reasonably certain that they will be increasingly used in dedicated systems, particularly those which are neither space nor time critical. For critical systems, we feel that some time will be required before compilers for implementation languages, and indeed the languages themselves, are improved and tested to the point that they can be of real value.

Several people, including one of the authors, have used interpretive languages to simplify the construction of dedicated systems. In this technique, an existing interpreter, for a language such as ESI[14] or FOCAL,[15] is modified so as to minimize the core requirements for the interpreter by removing unwanted features and adding additional ones. The resulting extended machine is thus an ESI machine, or a FOCAL machine; the user program in the higher level language is stored in memory and executed completely interpretively. John C. Alderman, in a paper presently in manuscript form, has referred to such languages as "plastic languages", in the sense that the systems programmer, in designing the dedicated system, can modify the interpreter for the language, and thereby change the virtual machine, in much the same way as writable ROM's can be used. Indeed, the two approaches can easily be combined; one could wire the interpreter in an ROM and plug it into the computer, thus creating an unalterable virtual machine for FOCAL or ESI.

It should be noted that the use of the "plastic language" technique is limited to those systems which are not time critical, since the interpretive nature of program execution makes the resulting virtual machine relatively slow. One of the authors has been quite successful in applying this technique to a proprietary dedicated system, where its advantages are quite significant particularly regarding ease of modification of the higher-level application code.

SUMMARY AND SOME SPECULATIONS

In closing, we would like to summarize a few points made earlier, and to exercise our license to speculate a little on the near future of minicomputers.

First, the user of minicomputers for the solution of general-purpose applications in data processing, scientific programming, or engineering, will find minicomputers increasingly indistinguishable from larger computers. With luck, he will not find that interactive control, which now distinguishes most minis from larger systems, has been thrown out in the wash.

Second, the cost/performance ratio of minicomputer hardware will continue to improve at the same rate as it has over the last five years.

Third, the minicomputer user will continue to receive the benefits of cost/performance ratios through decreases in cost for the same, or slightly improved, performance while the large computer user will generally continue to receive more performance at the same cost.

Fourth, and as a consequence of the above, all applications of minicomputers will become increasingly more economical. Thus, many applications which are not performed on minis today, or many which are not done on computers at all, will utilize minis in the near future as prices continue to drop.

It might be argued that time sharing could just as easily be used in the future to solve problems which do not use computers at all now. It is undoubtedly the case that time sharing will continue to be used for those problems which require its unique assets, i.e., essentially as much processor time, as much I/O, as much core and disk space as required, when you need it, purchased on an "as you use it" basis. But even at the most favorable rates available today, time sharing is *much* more expensive than using a mini. The lowest price we know of for time sharing is about $8 an hour for as much time as you can use, though this is on a relatively small system with quite heavy loading and a lot of contention.

On the other hand, even at today's prices, a mini can be bought for $5000. If this is written off over three years, and used 40 hours a week, an effective price of only about one dollar an hour can be approximated. A few years from now, this should drop to around 25 cents an hour.

We see the possibility of people providing a variety of "plug-in packages" for popular minis, quite likely software provided in the disguise of ROM hardware to provide the supplier with proprietary protection, product standardization, and integrity against unauthorized user changes. Some of these standard plug-in packages might be:

(a) The COGO virtual machine for the civil engineer.
(b) The JOSS® virtual machine for the engineer and statistician, replacing today's electronic desk calculators.
(c) The small business virtual machine, providing the retailer with a small machine capable of performing routine bookkeeping.
(d) The homemaker virtual machine, providing the busy housewife with a menu planner, household controller, alarm system, and checkbook balancer.

In conclusion, if the designers and product planners of minis think more clearly on what minis can do in both program creation and program execution, we may see an end to the minicomputer syndrome.

The current state of minicomputer software

by JOSEPH F. OSSANNA

Bell Telephone Laboratories, Inc.
Murray Hill, New Jersey

INTRODUCTION

No one who has watched the spectacular growth of the minicomputer industry needs to be told that people are finding new small computer applications at an astonishing rate. Undoubtedly there are many reasons for this striking increase in minicomputer utilization. Certainly one reason is the increasing sophistication of minicomputer software. This paper will summarize the development of this sophistication, and will try to characterize its present state. Minicomputer hardware evolution will be discussed because of its effect on minicomputer software evolution. The range of minicomputer uses and users will be characterized along with their varying software organizations. Commentary on techniques of minicomputer software development is included. A number of examples of both past and present minicomputer software systems are presented.

MINICOMPUTER HARDWARE

A minicomputer is a "minicomputer" by nature of its hardware which is relatively simple, physically small, and comparatively inexpensive. This is accounted for by the following general characteristics compared to the "ordinary" large computer.

- Shorter wordlength
- Smaller memories
- Fewer and simpler instructions
- Simpler input/output capabilities
- Minimal features
- Fewer peripherals

In addition to the above, limited software support by the manufacturer and lower marketing costs have contributed to the lower price of the minicomputer. Wordlengths range from 8 to 24 bits with 16 bits being the most common in currently available machines. The range of memory sizes available in a typical current machine is from 4K words (K=1024) to 32K words. Basic instruction sets typically lack multiply and divide, decimal and floating-point arithmetic, arbitrary shifting, and fancy character string manipulation. Although minicomputer memories are smaller than those of large machines, the memory cycle times frequently are similar, with the result that computing speeds are similar in applications where a smaller word size and the absence of some types of arithmetic are not a factor. Basic input/output structures usually employ a single time-shared bus with limited device addressing and with limited parallelism during data transfer. Features such as memory protection, relocation, and segmentation are usually nonstandard or unavailable. Often few fast registers are included. The selection of peripherals standardly interfaced to a given machine typically has been limited. In the past, the only reliable peripherals available have been expensive ones originally designed for the larger computer systems.

To some extent, what has just been said above is becoming less true with time. The spectacular advances in integrated circuit technology in recent years have resulted in dramatic price declines. Core memory and peripherals have also become less expensive. The price of a basic system consisting of the central processor (cpu), 4K×16 bits of core memory, and a Model 33ASR teletypewriter has dropped from about $25,000 in 1966 to about $8,000 in 1971.[1] The circuit technology advances have also made increased system capability economically attractive. The following amendments to the list of minicomputer characteristics are presently apropos.

- Instruction sets improving; fast multiply, divide, and floating-point optionally available. More and better addressing modes being designed.
- Memory protection, relocation, and segmentation becoming optionally available.

- Larger sets of fast general registers becoming common.
- New bus concepts are providing better input/output structures.
- Priority interrupt structures and interrupt vectors are becoming standard.
- Smaller and well designed peripherals are available at reasonable cost.
- Less expensive disk storage is becoming available in sizes commensurate with small machines.

Manufacturers have achieved this and are providing increased software support without noticeably stemming the price decline.

These recent improvements in small machine architecture have attracted more sophisticated applications and more sophisticated systems designers. The advent of inexpensive disk storage is probably the most important occurrence influencing minicomputer software evolution.

A tabular summary of currently available minicomputers and their characteristics can be found in Reference 2. Similar information along with projections of the future of the minicomputer industry are given in Reference 1.

MINICOMPUTER USES AND USERS

Most minicomputer systems consist of a general-purpose small machine configured in a way suitable for some particular application. Tailoring the size and complexity of a system to the requirements of a particular job can result in an economy of specialization that outweighs the economy of scale of using a part of a larger machine.[3,4] Accordingly, one would expect the range of applications to break down in a way that reflects this economic bias. Auerbach[1] reports that in 1970 minicomputer dollar sales were divided as follows.

45%	Industrial and process control.
3%	Peripheral control (COM, OCR, line printers, etc.).
20%	Communications control (concentrators, switching).
10%	Computations.
22%	Data acquisition and reduction.

Process control and data acquisition often involve intimate connection to distributed sensors or laboratory instruments. This is often infeasible for centrally located large machines, especially when coupled with the necessity for rapid control by the user and his program.

In a survey conducted within Bell Laboratories in the Spring of 1971 of approximately 200 minicomputer systems the following usage breakdown was reported.

31%	Computerized testing of equipment and devices.
19%	Data acquisition and reduction.
18%	General-purpose computing, some with data acquisition.
15%	Peripheral control (plotters, cameras, displays, unit-record equipment).
9%	Intelligent graphic terminals and interactive graphic systems; general-purpose graphic-oriented computing.
7%	Process control.

It is possible to observe different software organizations across these various types of users. Some of the differences are clearly due to the nature of the applications. Many are due to the nature of available software support, to the software experience of the programmers involved, and to hardware limitations. In the next section these differences are characterized.

SOFTWARE ASPECTS

The choice of a software organization for a minicomputer system can profoundly affect hardware requirements, general efficiency, the range of applications, extensibility, and the ease of software maintenance and modification. The best organization in a particular case depends on which considerations are paramount. Other considerations include the following.

- Are the application programs to be run under an operating system?
- Is there to be on-line secondary storage?
- Are there crucial real-time response requirements?
- Are there to be multiple simultaneous users?
- Is the system to be self-supporting—i.e., can the application programs be developed and maintained on the system?
- Is there a justification or need for core protection, relocation, or some sort of virtual memory?

An "operating system" is a collection of basic and frequently used utility programs essential for convenient and efficient use of a machine. For many people this loose definition means the sum of all the programs they use that were written by someone else and consequently not easily modified. Most minicomputer operating systems are simple and basic compared to those used on large machines. The most basic form of operating system consists of programs to perform physical input/output and handle code and/or format conversion of the transmitted data, and a program to bring the user's program into core and give control to it. If the minimization of core usage is paramount, the generality of even a basic operating system may need to be foregone and only the absolutely necessary input/output programming be included directly in the user's program. Such inclusion of operating system functions in application programs is not uncommon on small machines.

If the same machine is to be used to develop the user's programs, other support programs are needed. An editor is needed to create and modify the user's source text (unless he is doing it manually, for example using cards). An assembler or compiler is needed to translate this source text into executable machine code. Optionally a debugger is useful for analyzing program troubles. Operationally, the first two are run like user programs, and the latter is usually combined with the user program if needed.

If there is justification for on-line random-access secondary storage such as a disk or drum, a different perspective is possible. The less frequently used portions of any operating system and of the user's program need not be permanently core resident, and core requirements can be minimized without foregoing the convenience and generality of an operating system. Further, support programs like those mentioned above can be stored on disk for handy use (by disk will usually be meant any such secondary device). Additional support in the form of libraries of user and utility programs can be easily kept along with a binder program that can search libraries and combine collections of program modules into executable units. Greater convenience is obtained when the operating system provides organized access to the disk by means of some sort of a file system. A well designed file system is usually the foundation of the better general-purpose operating systems.

Real-time response requirements can have strong implications for software system design. By real-time we do not here mean the requirements of controlling conventional peripherals such as disks, tapes, unit-record equipment, or most communication lines. In these cases a too-slow response usually causes retries and degrades efficiency but is not ordinarily fatal. What is meant are the response requirements of controlling such things as a steel rolling mill, a linear accelerator, or an oil refinery. Industrial process control systems typically receive a variety of external stimuli requiring a wide range of response times. This necessitates a hierarchical priority structure for the interruption and execution of programs. When there is more than a few such programs the scheduling can become quite complex. Operating systems for such situations are usually different than general-purpose ones; process control systems are discussed later. Data acquisition systems and communications control systems can have real-time response problems, if peaks can occur that would temporarily tax their processing capacity and it is important that no data be lost.

Unlike a process control system which supervises known external processes with generally known chari acteristics, a multi-user system such as a general-purpose time-sharing system faces user submitted tasks of more-or-less unknown characteristics. For example, resources such as processor time, core space, and file system space demanded by the user processes vary dynamically, and the system generally must schedule adaptively and enforce various limits on resource utilization. Even if a minicomputer system is economically justified when wholly committed to some application, a multi-user capability can permit software development to take place while the main application is running. An example of a multi-user system is given later.

Core protection is a hardware feature that enables the operating system to make sensitive regions of core storage inaccessible, thereby protecting those regions from damage by being written or preventing information from being read. This feature is uncommon in minicomputer systems that operate with debugged programs, but is usually mandatory in multi-user systems that permit users to write and execute arbitrary programs. Relocation is a hardware feature that permits a program to be loaded at any convenient place in core memory, and to be moved (while interrupted) to another place. This feature can be a great asset to, for example, a process control system trying to juggle a myriad of different sized programs between disk and core. Virtual memory[5] is a concept where a program can think it has more core than it really has or even than there is.

RETROSPECTION

When one looks at the minicomputer systems being used in the early 1960s one sees minimal hardware with typically no disk storage and minimal software support in the form of operating systems, compilers, editors, etc. The temptation was therefore great to make use of the nearest computer center with its big machine, big disk, and varied software support.

One of the first minicomputer applications that the author came in contact with at Bell Laboratories circa 1964 was an experimental remote graphical display system called GRAPHIC-1.[6] The hardware consisted of a Digital Equipment Corporation (DEC) PDP5 computer with 4K×12 bits of core, a modified DEC Type 340 display scope, a 4K×36 bit display memory, a light pen, Model 33ASR teletypewriter, and a card reader. In addition there was a high-speed connection to the direct data channel of a nearby IBM 7094. Support software consisted of an assembler and postprocessor to assemble, merge, and link relocatable programs to form executable units for the PDP5, a display material assembler, and a library of input/output and inter-computer communication programs. These support programs ran on the 7094 and produced cards that were read into the PDP5. End users of the system could write in a higher-level graphical language called GRIN[6] which also ran on the 7094, and could use the system to submit a regular batch job to the 7094. This dependence on the local big machine was a natural yielding to the temptation to do software development in a convenient environment.

GRAPHIC-2[7], a successor system to the one above, emerged in 1967 and is notable for its relatively sophisticated software. It is implemented on a DEC PDP9 computer with 8K×18 bits of core, a fast fixed-head disk, display, light pen, fast paper tape reader/punch, and a dial-up 2000 bit/sec link to the local big machine. As in the preceding case all the software for the PDP9 was written using support programs on the local computing center large machine, a Honeywell Information Systems 635. The end user is provided with a graphical programming language called GRIN-2[7] and an assembler, both of which run on the 635. In the next version of the system these will run on the PDP9 itself. GRIN-2 provides the ability to control the man-machine interaction, to create and edit graphical data structures, and to control the display. The system may be used in a stand-alone mode or it may be connected to the 635 and used in a mode where programs executing in the 635 send over programs or data on demand to the PDP9. One of the more interesting aspects of the software in this system is that it provides a form of virtual memory to the user program. To do this, each user's program and data is broken up into blocks which are assigned unique identification numbers (IDs). All references between blocks are in terms of this ID and an offset within the block. When a block is referenced it is retrieved from disk or possibly from the big machine. Only the currently needed blocks are actually in core at a given time. The user is relatively free from worrying about the size of core; one user application program consists of nearly 60K PDP9 words.

Another example is a small laboratory computer system used for the acquisition and reduction of data from a spectrometer. It originally consisted of a DEC PDP8 with 4K×12 bits of core, a Model 33ASR teletypewriter, a DEC Model 34D display, a home-made analog-to-digital converter, an extended arithmetic element, and interfaces to laboratory equipment. The user wrote his own application software in a few months using a DEC supplied editor and assembler on the PDP8 itself. Both user and support programs were stored on paper tape and had be be loaded using the reader on the 33ASR. How long does it take to read 4K×12 bits at the rate of 10 8-bit characters per second? This user eventually got 128K×12 bit drum primarily to facilitate the acquisition of more data than would fit into core. He now uses a DEC supplied disk-based operating system for program development and to run his application. This system is typical of quite a few minicomputer systems within Bell Laboratories.

A more recent (1968) example of a laboratory computer system designed for self-service by a variety of users at Bell Laboratories is described in Reference 8. The hardware consists of a Honeywell DDP224 with floating-point instructions, 32K×24 bits of core, two disk drives for 2.4 million word removable disk packs, magnetic tape, a card reader, analog-to-digital and digital-to-analog converters primarily for speech and music, a console typewriter, various graphical input and output devices, and miscellaneous devices such as a piano keyboard. Extensive software support is provided for the user in the form of a simple disk operating system with utilities for all the various devices, an assembler, a Fortran compiler, an editor, a loader, and a large library of useful programs. A simple file system is provided along with disk utilities for physical disk accessing. Disk conflicts are avoided by informal agreements and by many users having their own disk packs. The operating system will bring whatever program the user wants into core from disk but the user must manually transfer control to its starting location. This machine has been very successfully used by more than a dozen users for various research projects. A main drawback is the necessity for users to sign up for time on the machine, and a limited multi-user capability would undoubtedly be welcome. The system is much like a user-operated batch processing system. Even though some of the applications involve real-time response and are demanding of the processor, such tasks as file editing and compiling could go on at a lower priority or be done concurrently with less demanding tasks. Such an ability would require a better file system for user isolation and some scheme for rotating user programs through or sharing core. In this system, such additions would be tantamount to a complete redesign.

INTROSPECTION

Just as in the case of software design evolution on big machines, the evolution of software on small machines has not been homogeneous throughout the field. The inertia inherent in the use of successful software can last for times comparable to the current age of the minicomputer era. Most of the systems described earlier are still working. There probably isn't any early software design or development techniques that isn't still being practiced today. The major impetus for software design improvement comes from the introduction of more advanced machines and from the infusion of fresh software techniciars. Attracted by the newer small machines and often experienced on big ones, these fresh workers are beginning to achieve on the minicomputer a decree of software design sophistication previously seen only on larger machines.

In the next section an attempt will be made to characterize minicomputer software currently in common use and to describe some forefront efforts.

CURRENT EXAMPLES

Industrial process control

All indications are that this field will be one of the largest users of minicomputers.[1] Work in this field, not all involving minicomputers, is relatively extensively documented.[9,10] As indicated previously, process control applications often involve a wide range of real-time response requirements. Control algorithms involve the operation of complex multi-loop negative feedback systems. Most systems involve two forms of control: direct digital control in which the computer directly controls process variables; and supervisory control in which the computer sets the operating points of otherwise independent analog controllers. The response required in direct digital control ranges from milliseconds to seconds, while that required for supervisory control ranges from seconds to minutes. In addition, there is usually an overall optimizing and adaptive control function that slowly modifies the control algorithms. On top of this response time hierarchy can be management information and long-term scheduling functions involving delays measured in days or weeks. Direct digital control tasks are usually many in number but relatively simple while supervisory control tasks are fewer in number but relatively complex.

The number of task-oriented programs is usually sufficiently large that economy dictates that they not all be core resident; thus programs need to be brought into core when needed. The existence of the shorter real-time requirements as well as the desire for reasonable efficiency dictates that several programs reside simultaneously in core. Thus a process control system takes on the appearance of a multi-programmed time-sharing system. In contrast with time-sharing systems, the scheduling of the execution and interruption of programs is more complex in process control systems.[10] The relative priority of programs is typically dependent on process conditions, operator intervention, and even such things as the time of day. While the general technique is to respond to hardware interrupts and place programs into execution priority queues, provision must usually be made for certain high priority programs to purge certain other low priority programs from queues and for low priority programs to inhibit their interruption at certain critical times. Some sort of organized provision is required for the interlocking of shared data bases. Although most of the programming is done in assembly language and in Fortran, a number of process control oriented languages have been developed and used.[11] The process control field has in some ways reached a greater level of sophistication than other fields of application.

Communications control

This field includes communication line concentrators and controllers used as communication front-ends for large computer systems, as nodes in communication networks, and as message switching centers. The latter application requires secondary storage while the others do not. Data line concentration and control can usually be done less expensively and more flexibly with a minicomputer than with wired hardware controllers.

An example of a minicomputer front-end is the line concentrator used to interface varied terminal equipment to the Michigan Time-Sharing System.[12] This system was experimental and its hardware complement is not necessarily optimized. It consists of a DEC PDP8 with 12K×12 bit of core memory, a Model 33ASR teletypewriter, a high-speed paper tape reader/punch (to facilitate software development), an extended aiithmetic element, an interface to the local IBM 360/67's multiplexor channel, and interfaces to standard telephone data sets operating at all the standard speeds. The lower speed interfaces are bit buffered and the faster ones are character buffered. The system performs a limited form of terminal type identification of low speed asynchronous typewriter terminals and handles a variety of IBM and teletypewriter terminals. Because the speed of operation of each line is program controlled, statistical sharing of the access lines reduces the required number of telephone ports. The system-terminal interface is better human engineered than that obtained using standard IBM hardware line controllers. Full duplex operation of teletypewriters is standard and read-ahead of the terminal keyboard is provided.[13]

While such a system is less complex than many process control systems, the bit and/or character completion interrupt rate is high and the responding programs can't dawdle. The low number of distinct tasks combined with the high task rate dictates that the software all be core resident. The system described above was equipped to serve 16 low speed asynchronous lines and 4 voice grade synchronous lines; however, a system of this kind more typically can serve between 32 and 64 low speed lines along with several voice grade lines.

Paper tape operating systems

The above heading may overdignify the collection of software that it refers to, but this kind of software support is one the oldest and is still common. If one has a typical basic minicomputer configuration consisting of a processor, 4K words of core, and a teletypewriter with paper tape handling, one either does his software development using support programs stored on paper tape or uses some other machine for development and reserves the basic machine to run the application. The main drawback with paper tape based support is the slow rate of reading and punching paper tape. This drawback can be largely mitigated by adding a high speed reader/punch. Surprisingly enough, the convenience of working on your own machine and the fact that a cycle of editing, assembling, and reloading may be shorter than the time required to travel to and wait on the local computer center, may make the use of a paper tape operating system feasible. Of course, access to a good time-sharing system with the right kind of program support or to another machine like yours but bettei equipped is probably preferable.

An example of a current paper tape system in DEC's paper tape software for the PDP11.[14] It provides an absolute loader for reading in all programs, a reasonable text editor, an assembler, floating-point simulation, a math package, a collection of input/output utilities, and an octal debugger. The editor is used to create and edit programs at the teletypewriter; during editing, the old copy of the source is read off paper tape a block at a time, edited, and then punched. Assembling a program consists of reading in the assembler, feeding the source program to the assembler twice, and receiving an executable object copy of your program from the punch. Your program can then be tried by loading it; after loading the loader will transfer control to it automatically. If it works, fine; if not the octal debugger can be loaded into vacant core (if any) and used to poke around in the remnants. All of this is or is not as awkward as it seems depending on the alternatives open to you. With enough core a simple core resident operating system containing all the support programs with some core left for the user would be even more convenient; the additional cost is comparable to the cost of the smaller disks.

Disk operating systems

It has been observed several times previously that the addition of disk storage to a minicomputer system makes a world of difference. Even the simplest disk-based operating system greatly magnifies the convenience of working on your own machine, which becomes like using a one-user time-sharing system. Multi-user systems are possible and desirable and are discussed later. Much of what is possible with disk is possible in a slower more restricted way using randomly accessible magnetic tapes such as DEC's DECtape,[15] or even small tape cartridges.

An example of a recently available (circa 1968) disk operating system for a machine that has been around in some form for awhile is the PS/8 operating system for the PDP8 family of machines.[16] It requires 8K words of core and a disk *or* DECtape.

Another example is DEC's disk operating system for the PDP11.[17] It requires at least 8K words of core, a small disk augmented by DECtape, or a larger disk, a high speed paper tape reader/punch, and a console typewriter. The support software includes a command interpreter, a reasonable text editor, an assembler, a Fortran compiler, an octal debugger, a file utility package, floating-point simulation, a math package, and a linker to combine programs. The operating system provides a reasonable file system and does input/output for the user. Core is divided into five regions: a small region at the bottom containing the interrupt vectors which indicate the location of interrupt handling programs; next a small area for the resident monitor; an area for the user program at the top of core; below that the stack (where parameters are stored temporarily during the transfer of control between programs); and a free area divided into blocks and used for buffers, temporary tables, and device drivers brought into core.

To invoke a system support program such as the editor or a user program written to run under the system, the user types a request on the console keyboard which can include information about which input and output devices are to be used during the run. User programs can be used interactively and can be interrupted for debugging.

Multi-user time-sharing systems

It is an accepted fact nowadays that the time-shared use of a computer is one of the more effective ways of increasing the productivity of a group of users in need of computing service. The advantages of "working on your own machine" are effectively extended to the whole group at once. A multi-user system is inherently more complex than a single user one; it is necessary to multiprogram and/or swap user programs between disk and core and to keep track of everyone's input/output and machine conditions. It is helpful too, if users can be prevented from injuring each other and the system.

We shall present here, as an example of a multiuser system, a system recently developed (primarily by K. L. Thompson) at Bell Laboratories which is felt to be at the forefront of minicomputer software design. This system utilizes a DEC PDP11/20 computer with 12K×16 bits of core storage, a 60 cycle clock, a 256K work fixed-head disk, a disk drive for 1.2 million word disk cartridges, a dual DECtape drive, 8 low speed asynchronous line interfaces for remote typewriters, and a little-used paper tape reader/punch.

Core is divided into an 8K word/region containing the totally core resident operating system and a 4K word region for the user program and his stack. The system space includes about 2K used for a pool of dynamically allocated buffers. The operating system maintains an excellent file system, creates and manages user processes executing core images), does input/output for the user, and performs all scheduling functions. Scheduling is by placing ready-to-run users on one of three queues, depending on whether the user has interacted (has just typed an action character on his console), some pending input/output has completed, or the user has run out of time allotted for execution. All users are swapped between the fixed-head disk and the same region of core.

The main feature of this system is a versatile, convenient file system with complete integration between disk files and all input/output devices. There are three kinds of files; ordinary disk files, directories, and special files representing physical devices. A directory is like an ordinary file except that only the system can modify it. The file system is a tree structured hierarchy originating at a root directory. Any type of file can occur at any level. Files have names of eight of fewer characters. At any given time a user process is associated with a particular current directory. When the user program wishes to open or create a file, it gives the system the file name of a file in the current directory or it gives a path name which either specifies the absolute location in the tree or the location relative to the current directory. If the reference is successful, the system returns a file identification number to be used for future references. File system protection consists of associating with the file at time of creation the name of the creator and permitting him to specify whether he and others can read and write the file. Files are formatless and are regarded as strings of 8-bit bytes.

Another feature of the system is the ability to initiate asynchronously executing processes from within a program or from command level. Commands are normally terminated with semicolons or new-lines; the command interpreter creates a process to execute the command and waits for its completion. If the command is terminated instead by an ampersand, the same thing occurs except that the command interpreter doesn't wait. Argument strings typed with a command are made available to the program by placing them on the stack.

The name of any executable program can be used as a command. The name is first searched for in the current directory and if that fails it is then searched for in a system library. A myriad of commands are available including those for listing directories, moving, copying, and deleting files, changing the owner and mode of a file, and changing the current directory. Other programs available include a context text editor, an assembler, a symbolic debugger, a linking loader, a dialect of Basic, Fortran, a text formatter, games such as chess, and various experimental languages.

The system operates 24 hours a day, seven days a week. A user community of about a dozen people access the machine regularly although it is not a service offering. The group that owns the machine uses it heavily for preparing documentation using the editor and text formatter. The maximum of eight simultaneous users (limited by the number of lines) does not tax the machine's capacity. Because of the lack of core protection, any user can write, assemble, and run a program that could damage the system and cause a system crash. However, since most users use debugged programs like the editor or text formatter, and because those few who develop new programs are careful, surprisingly few crashes occur. A future version of this operating system will be developed for a version of the PDP11 having core protection and relocation.

Virtual memory systems

One of the more interesting areas in minicomputer software is the use of virtual memory to manage the core and secondary storage of a small machine. A system in an earlier example, GRAPHIC-2, supported a form of virtual memory without the use of special hardware. Another similar example is a small time-sharing system on a Honeywell DDP516[18]. A different example involves the use of hardware assisted segmentation and paging on a specially modified Interdata Model 3[19].

CONCLUSIONS

There has been a decided evolution toward greater sophistication in the design and use of minicomputer software during the relatively short years of the minicomputer era, although many of the earlier methods are still in use. A major force toward software improvement has been the introduction of new and better machines and the advent to relatively inexpensive disk storage. The expanding minicomputer field has benefited from the attraction of fresh software design talent often with large machine experience. Some recent forefront efforts are yielding minicomputer operating systems with features previously found only on large machine systems.

Real-time fault detection for small computers*

by J. R. ALLEN

INTRODUCTION

Advancing technology and declining costs have led to a sharp increase in the number and variety of small computers in use. Because small computers are readily suited for many real-time applications, a great deal of work has been directed toward simplifying the interface between the computer and its peripherals. Hardware interrupting capability and a specially designed I/O bus are required for peripheral device interfacing in a real-time environment and such things as direct memory access, data channels, and multilevel hardware and software interrupt capability are common. These machines tend to be parallel, synchronous computers with a relatively simple architecture.

In a real-time environment, fault detection can be of major importance. Much of the past work has been directed toward the design of additional hardware, internal to the computer, which allows critical feedback loops to be controlled and often inserts special registers for the maintenance task.[1-4] These techniques require that the maintenance circuitry be designed concurrently with the computer itself and have access to components internal to the computer. Many problems can arise from attempting to modify an existing computer. For example, critical timing and gate fan-out can be disturbed, and most warranties become void if unauthorized modifications are made to a computer.

Other techniques cannot be used for real-time fault detection because they require manual intervention, excessive storage, noncontiguous memory locations or excessive execution time.[5-7] Much of the previous work attempts to locate faults as well as detect them. While fault location is desirable, it is more expensive and requires much more time and storage than fault detection. Many applications do not require fault location. It may be more feasible to either interrupt the task or perform the task manually during the diagnosis and repair interval; the most important thing is to recognize that the computer may be performing the task incorrectly.

An earlier technique attempted to simulate each instruction using different instructions and comparing the simulation result with the actual result.[7] This technique requires that the computer be somewhat operational and that it be capable of comparing the two results. A means is needed for determining that the test routine is executed periodically.

In this paper, we propose a real-time fault detection scheme for small computers which is effective for faults in the central processor unit (CPU), core memory and I/O bus. It requires an external monitor which is simple, inexpensive, and interfaces to the computer's I/O bus just as any other peripheral device. The monitor periodically triggers a program interrupt, causing the computer to execute a predefine test routine. During the course of the routine's execution, several key bit configurations are transmitted to the monitor. If the computer fails to respond or if the bit configuration does not match the one that is expected, then the computer is assumed to be faulty and the device may either cause a power down or sound an alarm.

The proposed technique compares favorably to the previously referenced techniques in fault detection. Certain faults will not be detected, however, because

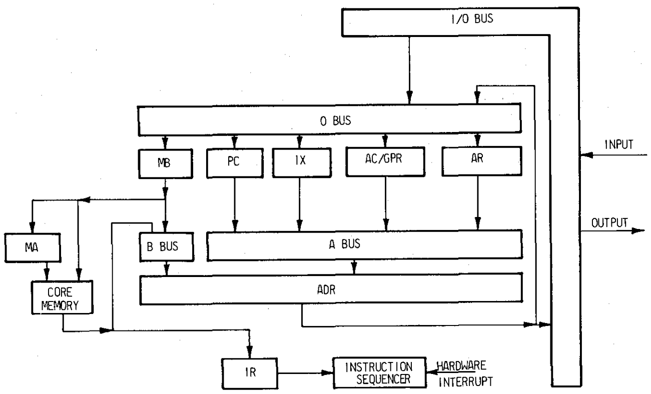

Figure 1—Typical computer architecture

internal modification to the computer is not allowed. In the past, real-time fault detection has carried a price tag comparable to the cost of the computer itself. A major advantage of this technique is that its low cost makes a great deal of fault detection possible in applications which would not previously have been cost effective. The fact that the technique assumes that no modification may be made to the computer means that many existing systems could make use of the method without extensive modifications.

COMPUTER ARCHITECTURE

The proposed fault detection method may be used with a variety of small computers, all of which are very similar in architecture. Included in this class of computers are such machines as Digital Equipment Corporation's PDP-8, PDP-9/15; Hewlett-Packard's HP-2100; Honeywell's DDP-516; Data General's Nova-1200 and Nova-800; Xerox Data System's Sigma-3; and Hitachi's HITAC-10. All of these are parallel, synchronous machines with hardware interrupt and I/O bus.

Figure 1 shows a block diagram of a typical small computer. The *program counter* (PC) contains the address of the next instruction to be executed. The *memory buffer register* (MB) serves as temporary storage for information being written into and read from memory. The address of the memory cell to be accessed is placed in the *memory address register* (MA). The decoded contents of the *instruction register* (IR) controls the instruction sequencer. Other registers commonly found are an *accumulator* (AC), *general purpose registers* (GPR), an *arithmetic register* (AR) and an *index register* (IX). Most small machines make use of some subset of these registers.

Most of the logic functions are performed in the general purpose logic unit (ADR). A pulse on the hardware interrupt lead will cause the instruction sequencer to save the appropriate registers and to begin executing a different program.

ADDITIONAL HARDWARE REQUIREMENTS

This section explains the function of each portion of the block diagram for the monitor hardware shown in Figure 2.

The DEVICE SELECT modules (DS1 and DS2) are basically an array of AND gates which allow the peripheral device control signals and data signals to pass only when the proper device select code is present on the device select bus. This allows several peripheral devices to share the same I/O bus without interfering with one another. Three device codes are required, XX, $\overline{XX}$, and YY. It is desirable to have one device code ($\overline{XX}$), which is the complement of the other to verify that each bit of the device select bus can be set to both logical states.

Device codes XX and YY cause the WIRED REGISTER to be gated onto the Input Bus. The WIRED REGISTER is constructed simply by attaching alternate bits to a voltage representing a logical one and the remaining bits to logical zero. When device code YY is selected, the "DEVICE = YY" lead is enabled causing the contents of the WIRED REGISTER to be complemented before being placed on the Input Bus. Reading from both device XX and device YY causes both a 1 and a 0 to be read from each bit position. Many computers determine the status of a peripheral device by executing an instruction which causes the next instruction to be skipped if a status FF is set. By executing this instruction with device code XX the BUSY/IDLE FF will appear to be busy; if device code YY is used, the "DEVICE = YY" lead causes the FF to appear to be idle. In this way the device status testing feature may be checked.

Device code $\overline{XX}$ is used when outputting bit configurations to the monitor for comparison to the expected value. The INTERRUPT TIMER is simply a monostable FF which, after an appropriate delay, will cause a program interrupt to be sent to the computer and at the same time sets a FF, which enables the RESPONSE TIMER. The testing frequency is set by adjusting the monostable's delay time.

The RESPONSE TIMER is used to determine that the computer is taking too long to respond and may be "lost." If the RESPONSE TIMER is not reset or disabled before it "times out," an OVERTIME signal

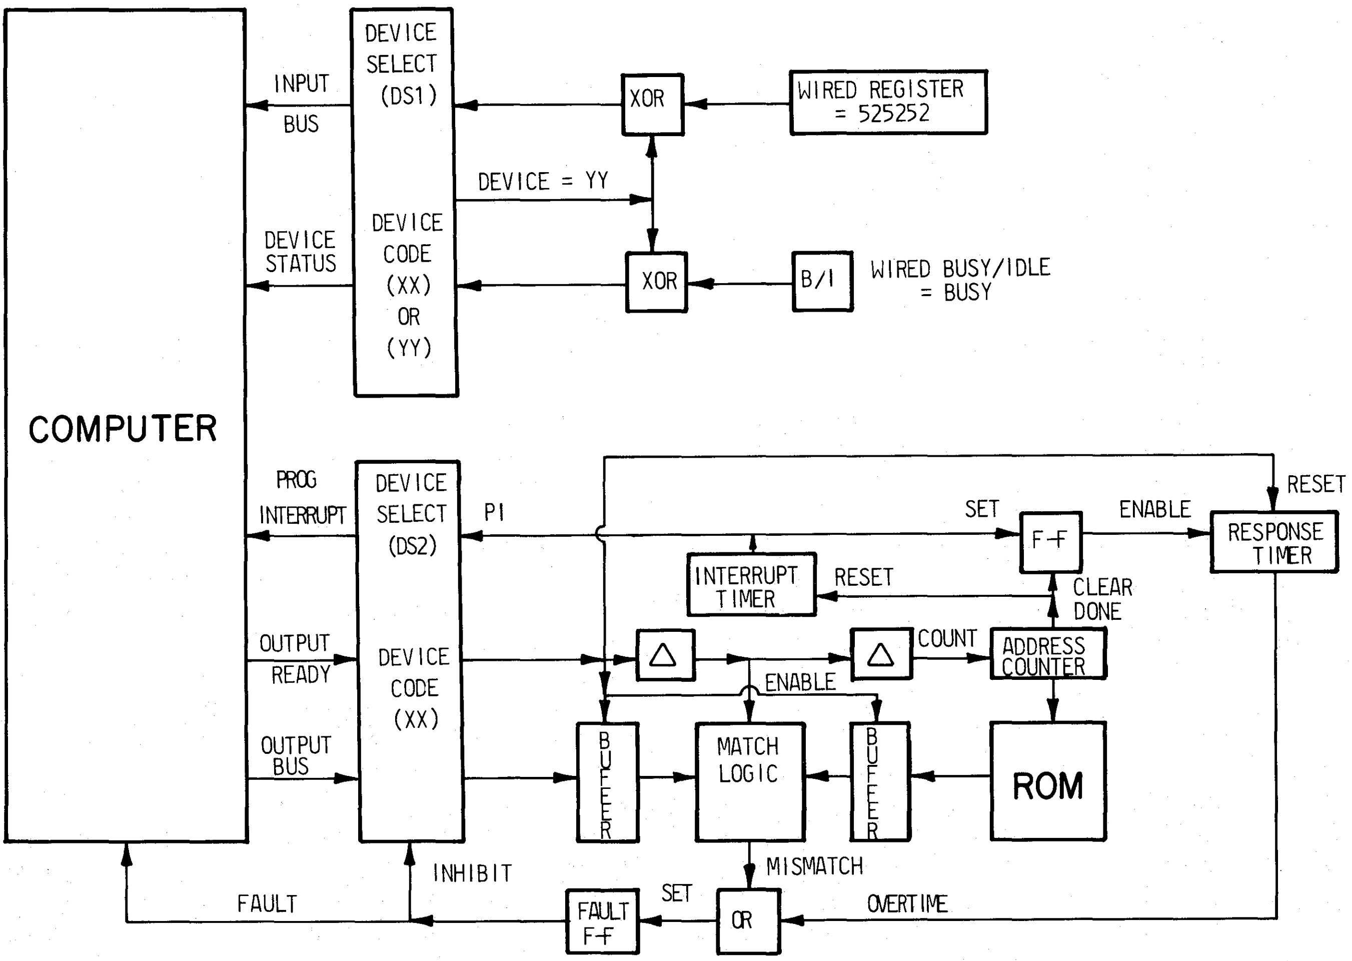

Figure 2—Block diagram for monitor hardware

is generated, indicating that a fault has been detected. A circuit to perform the RESPONSE TIMER function is shown in Figure 3.

The ADDRESS COUNTER is simply a cyclic counter designed to count modulo N, where N is the number of responses expected during a normal test. When the counter resets, a DONE signal is generated which disables the RESPONSE TIMER and resets the INTERRUPT TIMER. The ADDRESS COUNTER is incremented after each output from the computer to sequentially address the contents of the read-only memory (ROM). The ROM need not be large and may be built economically from a diode array.

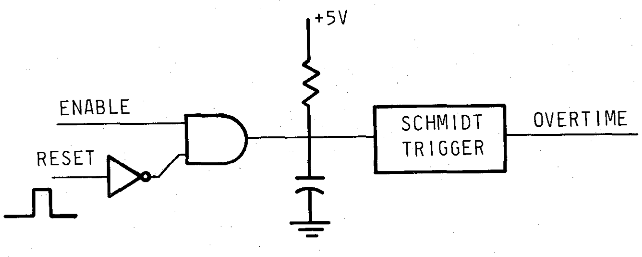

Figure 3—Response timer

The response from the computer and the expected response, read from the ROM, are both buffered and compared by the MATCH LOGIC. When enabled, the MATCH LOGIC basically OR's together each bit of the XOR of the two buffers to produce the MISMATCH signal. An OUTPUT READY signal from the computer is used to load the BUFFER, enable the MATCH LOGIC, reset the RESPONSE TIMER, and increment the ADDRESS COUNTER, all after appropriate delays.

If either a MISMATCH or an OVERTIME signal is produced, the FAULT FF is set. This inhibits any further output to the monitor, thus preserving the contents of the ADDRESS COUNTER and the two buffers as an aid for the diagnosis of the fault.

The FAULT signal may be used in whatever way seems appropriate; it may stop the computer, sound an alarm, or trigger an interrupt to call some form of self-diagnosis program, which may attempt to actually locate the fault.

All circuits may be built using conventional methods and commercially available logic gates. The total cost of the hardware components is estimated at approximately $250.

GENERAL GUIDELINES

Small computers seldom have a large amount of core memory, often as little as 4,000 words. Often, external storage is limited to paper tape, which requires manual intervention to be read. In order for a real-time fault detection scheme to be useful in these circumstances, its memory requirements should be small enough to allow it to remain resident in a very small core memory and still leave room for the system programs.

A large number of faults are severe enough to either stop execution or at least to make sequential instruction execution impossible. No additional effort need be made to detect such a fault; the resulting failure to produce the required sequence of responses will cause the fault to be detected. However, faults which affect only a single bit position of a bus or register can be among the most troublesome. This type of fault may allow execution to continue, perhaps indefinitely, without an indication the fault exists.

Certain portions of the computer are very difficult to check under the assumed restrictions. Input-Output leads, other than those used by the monitor, cannot be checked without adding more hardware for each sėt of leads. Such Input-Output leads include Direct Memory Access, Data Channel, Console Controls, and special device channels. These devices usually appear as a data bus input which cannot be controlled. It can, however, be determined that none of these inputs is stuck at a one level as this would always cause the output of the bus to be one.

The instruction control circuitry cannot be checked directly. There are no instructions which access most of the control leads. Therefore, the correct operation of a control lead can only be determined by checking conditions caused by that lead, such as the complementing of a register. A thorough check of the control circuitry, under the given constraints, would be lengthy. It can, however, be determined that most of the gating signals can be produced. This can be done by executing every instruction type and checking to see that the proper data transfers have taken place. This method would intuitively seem to be very effective and can be accomplished in a short period of time.

Because the test routine is periodically required to change the contents of memory locations outside of its own boundaries, the interrupt facility must be disabled during the execution of the test. This is necessary to insure that all locations are restored before control is released by the test routine. Since it is undesirable to lock out high-priority tasks for a long period of time, the execution time of the routine should either be very short or the routine should be segmented to allow the servicing of high-priority tasks.

There are a number of ways to cause the external monitor to recognize that a fault has occurred. One of the most reliable ways is to design the test in such a way that the computer will output an unexpected bit configuration in the event of a fault. This technique is demonstrated by the following example. The accumulator is first loaded with a bit pattern A and then caused to skip over an instruction which would place A on the I/O bus. After the skip, the AC was changed to a pattern B and output to the monitor. If the skip did not occur, pattern A would have been output and would not have matched the expected pattern B.

Another method is to cause the program to "loop" in the event of an error. The normal sequence of output bit patterns will then cease and the monitor will recognize the cessation of response as an indication of a fault. Use of these techniques reduces the read-only memory requirements for the monitor.

TESTING TECHNIQUES

This section describes several techniques, which may be used to test the various computer components.

Registers

Registers in parallel synchronous machines commonly resemble the configuration in Figure 4. Although the actual circuitry may vary, the function is very

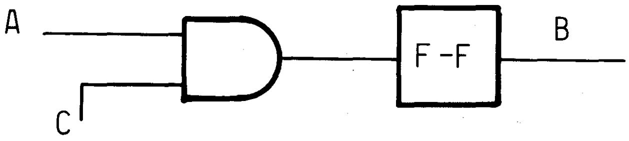

Figure 4—Flip-flop

simple and well defined. When lead C becomes enabled, the information on lead A (usually a major bus) is gated into the FF. When lead C is disabled, the FF retains the state of lead A. A variation of this type of register requires a fourth lead which clears the register prior to the enabling of lead C which then OR's the state of lead A into the FF. Verification that each bit of a register can be set to both logical states completes a functional test of the FF. A single possibility remains—a stuck at 1 fault on lead C. This fault is very severe because lead C is common to every bit of the register. Having lead C stuck at 1 would cause lead A to be fed directly into the FF and would totally incapacitate the register. In most cases the state of lead A changes many times between the setting and the reading of a register, thereby, destroying the original contents. If this does not happen automatically, an effort should be made to cause it to happen.

To check a programmable register, such as the accumulator, the register is first loaded with a bit configuration. The contents of the register are then output through the I/O bus to the external monitor. The programmable register is then loaded with the complement of the first bit configuration and its contents again output to the monitor. This procedure also checks the I/O bus drivers, and the outputs of each bus between the accumulator and the I/O bus.

Not all of the registers generally used in small machines are directly accessible under program control. In these cases a variety of techniques must be used in order to infer that the register can be set and read correctly. Five such registers were described in the introduction.

One of these registers is the arithmetic register (AR). Because the contents of the general purpose registers is commonly stored into AR so that AR may be used as the operand, many tests of the general purpose registers require the data flow to pass through AR, testing it at the same time. This commonly happens in the output instruction itself, meaning that no extra effort is required to check AR.

The second nonprogrammable register is the memory buffer (MB). This register is used to contain the data word core memory read-write operations; it must be capable of being set and cleared in order to correctly access core memory. If two complementary words can be read from memory, then the MB is operative.

The third nonprogrammable register is the instruction register (IR) which contains the OP code. This register is different from the above registers in that its contents are never gated to a point at which it could be displayed. In this case a set of instructions may be selected in such a way that together they incorporate both logical states for each bit. If it can be verified that each of these operations can be performed successfully, then it may be assumed that IR is operative.

The fourth nonprogrammable register is the memory address register (MA). This register is tested in the following manner: the contents of the sequence of addresses (0, 1, 2, 4, 8, . . . , 2^{n-1}, where n is the number of bits in MA, is saved in a test routine buffer area in real core for future restoration. Second, two complementary flags X and $\bar{X}$ are written into location 0 and read back. The flag X is left in location 0. Another flag (Y) is then written into each of the other n locations. If, after the n write operations, the contents of location 0 is still X, then the MA register is operative and the n+1 locations used for this test should be restored. To see this, assume that a bit (A) of MA is stuck at either 1 or 0. This is not to say that bit A is the only inoperative bit, but only one of possibly several. In this case, when an attempt is made to write into location 0, the flag will actually be written into another location (B). (If every faulty bit is stuck at 0, then B=0.) Later when an attempt is made to write into location 2^A, this data will also be written into location B, overwriting the original flag. In general, location B will be overwritten once for every inoperative bit in MA. When an attempt is made to read from location 0, the overwritten contents of location B will be returned, which will no longer be the flag originally placed there. It should also be noted that a fault in the address decoding circuitry or the memory itself cannot mask a fault in the MA.

The fifth nonprogrammable register, the program counter (PC), may be tested in much the same way as the MA register. The first flag to be written into location 0 is the binary configuration of a "JUMP TO A" instruction. Into the remaining n locations is written a "JUMP TO B" instruction. After the MA register has been checked, a transfer is made to location 0. This causes the PC to be loaded with a binary zero and the "JUMP TO A" instruction there to be executed. At location A, a signal is made to the monitoring unit that the transfer was successful and the contents of location 0 are changed to a "JUMP TO C" instruction. The code at location C will cause the program to loop, or output an unexpected word which will cause an error condition to arise. The test routine then proceeds to transfer to each of the locations 1, 2, 3 . . . 2^{n-1}. Each transfer should cause a return to location B, which simply continues the sequence. However, as with the MA register, if any bit of the PC is inoperative, then the "JUMP TO C" instruction will be executed and an error condition generated.

All of the above registers are found in most com-

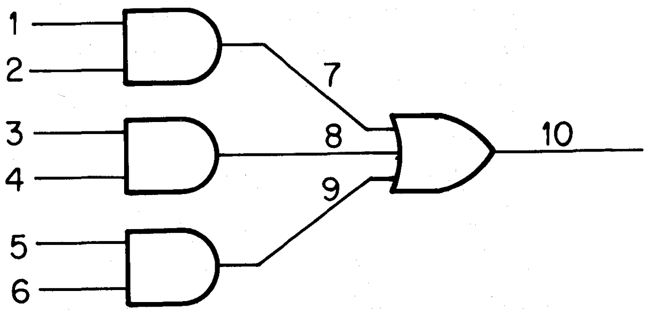

Figure 5—Bus structure

puters and the methods described are generally applicable.

In the methods for checking MA and PC, it is important to insure that addresses 0, 1, 2, . . . 2^{n-1} do not lie in critical parts of the test routine. This is simply a matter of convenience; if this restriction is undesirable, a slightly more general algorithm can be used to allow complete freedom in the location of the test routine. Since all of the n+1 locations lie in the first 2^n locations, the program could be loaded anywhere in the second half of the memory.

Data bus

A computer data bus typically consists of some variation of the circuit shown in Figure 5. Although there are many ways to implement this function, using different types of logic gates, nearly all faults will behave as though one of the leads numbered 1-10 has become frozen at one logical state. Certain varieties of logic allow the OR function to be accomplished simply by tying the outputs of gates A, B, and C together. This arrangement also satisfies the above statement. One input of each AND gate is usually common to all bit positions and functions as a gating lead for transferring data onto the bus.

A data bus may often be directly accessible to a number of peripheral devices for such features as direct memory access or a data channel. When this happens, one or more of the AND gates in Figure 5 may have inputs which cannot be controlled without interfering with certain of the peripheral devices. There will, therefore, be a few of the AND gates which will not be checked.

For the remaining AND gates, the objective is to verify that each input and output can assume either logical state. This can be done by gating both a 1 and a 0 onto the bus from every AND gate.

Control circuitry

Unlike a data bus or a register, the circuitry which controls the gating and timing for the instruction execution is neither simple in function nor standard in design.

The approach taken here is to include segments of code in the test routine which will exercise each instruction and check to see that it is performed correctly. This thoroughly tests the instruction decoder by providing it with all possible inputs. The control circuitry is the most difficult part of the computer to check because there is virtually no means of direct communication between this circuitry and the I/O bus. All tests must be made by performing an operation and verifying that the correct operations have taken place. It is possible, however, that something totally unexpected may happen in addition to normal operation of the instruction. To detect a fault such as this would require an extensive test for every instruction. There is no method known, at present, which would produce such a test using only the I/O bus with no hardware modifications to the computer. If such a method were available, it is likely that the storage requirement and execution time would limit its usefulness for a real-time environment. Fortunately, faults which occur in the control circuitry are usually quite severe and grossly affect the instruction execution. Therefore, a thorough exercising of each instruction appears to be the best approach to this problem and may be relied upon to detect the majority of such faults.

The length of the test can be reduced by studying logic diagrams in an attempt to find sections of logic used by more than one instruction. In some computers, for example, indirect addressing is handled by the same microinstruction cycle in every instruction. It would not be necessary, therefore, to test indirect addressing with each instruction.

Correct operation of certain instructions may be assumed if execution of the test routine is not possible without them. For example, it may be assumed that the JUMP instruction is operative because the first instruction executed after a hardware interrupt is a JUMP to the routine which is to handle the interrupt.

Although the approach used in this case is largely intuitive, if a little time is spent familiarizing oneself with the computer's logic and timing, the number of faults which can escape detection can be greatly reduced.

Logic function and condition logic

Most Boolean operations may be easily tested by exhaustion of their respective truth tables.

As a general rule, small computers have a ripple-carry adder. Because the circuitry is simpler, this form of adder is easier to check than one using carry-look-ahead. To check an adder, it is necessary to verify that each bit position can both generate and sink a carry. Both of these tests may be made simultaneously for all bits by adding a word of alternating ones and zeros to itself ($25252_8+25252_8$) and then adding that same word's complement to itself ($52525_8+52525_8$). It is also necessary to verify that each bit position can propagate a carry. This is accomplished by adding 1 to 77777_8. Adding $77777_8+77777_8$ verifies that every bit position can simultaneously generate and sink a carry. The remainder of the truth table may be verified by adding $00000_8+00000_8$, $77777_8+00000_8$, and $00000_8+77777_8$.

It is desirable to consult the logic drawings in order to determine how to test the overflow and conditional transfer logic. Although the implementation of this logic varies between machines, it is quite straightforward and simple to check.

Core memory

The core memory is, perhaps, the functional element which will fail most frequently. This may be attributed to the requirement for high-power circuits operating under closer tolerances than the conventional logic gates used in the rest of the computer. Many faults which occur in a core memory are the type which may be present for a long time before being discovered, such as a fault which affects only a rarely used part of memory. The ability to read and write at every address does not mean that the memory is free from faults; a faulty address decoder may read or write at two locations simultaneously.

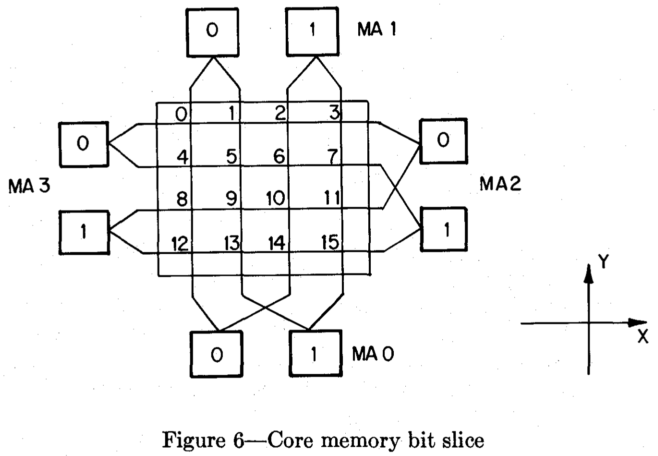

Figure 6—Core memory bit slice

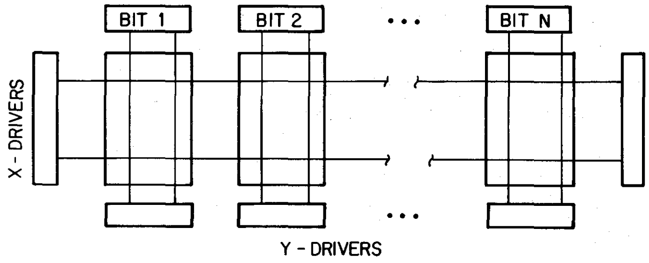

Figure 7—Memory addressing structure

Small computers commonly use a 2-1/2D arrangement for the memory address decoding.[8] This method relies on a coincidence of current on an X-axis lead and a Y-axis lead to select a core to be written or read. To do this the address bits are divided into two fields, which independently control the X and Y current drivers. In addition, each of these fields is further divided into two subfields. For example, if there are n bits in the field which selects the Y lead, then half of these bits will select one of $2^{n/2}$ current sources; the other half will select one of $2^{n/2}$ current sinks. Since every source is connected to every sink, the independent selection of one source and one sink selects one of the 2^n Y-axis leads. Different sources and sinks are used for the read and write operations.

Figure 6 depicts the addressing scheme for a 16-word memory requiring a 4-bit MA. Only a single bit position of the memory word is shown. Other bits of the same word are selected by replicating the Y-axis drivers for each bit position as shown in Figure 7.

During the write cycle, only the Y-axis drivers corresponding to bits which are to be set to 1 will be enabled. Because the read and write operations require currents in opposite directions, separate drivers are required for each of these operations. This means that a fault may affect the read operation and not the write operation and vice versa.

The test procedure for checking the address decoder is to select one of the four subfields, having length m, to be checked first. The contents of each of the 2^m locations obtained by selecting all combinations of these m bits and holding the remaining bits constant are stored in a buffer area. Each of the 2^m locations is then set to zero. Into one of the locations is written a word of all ones. Each of the remaining locations is checked to see that its contents is still zero. The original location is then checked and cleared. This process is repeated for each of the 2^m locations. Upon completion of the test, the contents of the locations are restored and the test is repeated for each of the remaining three subfields.

To justify this test, assume that one of the input leads to a read current source were stuck at 0. This would mean that at least one bit in the set of test words could not be read as a one and would be detected by the test. It is also possible that an input to a write current source could be stuck at 0. Because of a core memory's destructive read-out, the corresponding bit, or bits, could be read once and then never rewritten as a 1. Again, at least one bit of the set of test words would be stuck at 0 and the fault would be detected.

Suppose now that an input to a read current source were stuck at 1. This means that one of the 2^m addresses will select two read current sources at the same time, dividing the read current. The result will now depend upon the tolerances of the memory. The divided currents may not be sufficient to cause a core to switch. At least one test bit would then appear to be stuck at 0 and the fault would be detected. The divided currents may, however, each be sufficient to switch a core. During its execution, the test will cause a 1 to be written by using lead A. Later, when an attempt is made to read a 0 by using lead B, lead A will also be selected and a 1 will be read. Similarly, an input to a write current source may be stuck at 1. If the resulting split in the write current is insufficient to switch a core, the inability to write into certain test locations will be detected as before. If each half of the divided current is sufficient to switch a core, the writing of a 1 into some location C will also write a 1 into some location D. This extra 1 will be detected when location D is checked for a 0. Because this test is considerably longer than the previous tests, it may be desirable to partition the test. A very natural partition would be to check each group of current sources separately.

The only way to check individual cores in the memory is to read and write using every location. Although this must be a lengthy test, some time saving can be realized if the locations are checked by reading a word and writing its complement back into the same location. If the complement can be read back, the word is good. This method makes use of whatever is already in the memory location and, therefore, saves the time which would have been required to save the contents to the location and initialize the location. This test is normally not included in the test program because of the time required for its execution.

SUMMARY

This procedure has been applied to a DEC PDP-9 computer with two 8K core memory modules. The test routine requires 550 words of core memory and a maximum of 8 milliseconds per pass. The time needed to test the core memory increases with the size of the memory itself; but, by segmenting the test so that only a portion of the core is checked during each pass, it is possible to increase the memory size without increasing the amount of time required for a pass. All tests of the CPU itself are made each pass, but 12 passes are required to completely test the memory. The hardware monitor requires 58 words of read-only memory and solely determines the frequency at which the tests are made. This frequency may be adjusted according to the work load on the computer.

This technique would seem to have many applications on small machines which have previously avoided fault detection because of the cost or the need to make hardware changes to the computer.

ACKNOWLEDGMENTS

The authors would like to thank Messrs. Gary F. DePalma, G. Wayne Dietrich and J. S. Tang of Northwestern University for helping in the implementation of this fault detection scheme on the DEC PDP-9 computer.

An organization for successful project management

by DON SMITH, JR.

Computer Sciences Corporation
El Segundo, California

INTRODUCTION

Successful software development requires that the product be accepted, that schedules are met, and that costs are acceptable. The number of software development efforts that do not meet one or more of these criteria is large. Conversely, there are many examples of successful development. The total number and variety of considerations that affect the probability of success is so large as to be beyond the scope of any individual paper. There is one important element of software development that appears to have been somewhat overlooked, however, and is the subject of this paper.

This paper presents the thesis that the probability of software development success is much increased by: (1) a proper separation of responsibility within the project organization, combined with; (2) extensive formal procedures; the combination of the two providing a system of checks and balances that gives continuous, accurate visibility of project status.

A general project organization is presented here that is felt to be widely applicable, and that achieves the required set of checks and balances. The formal procedures required to enforce the organizational division are not described completely or in detail, but examples are given.

It is felt that viable commercial products will only rarely be successfully developed with project organizations that do not provide some equivalent to the checks and balances approach described here. It can be argued that superior products may be developed at less cost and more quickly by small expert groups carrying the project from inception to completion. The technical contributions possible from such an approach cannot be denied, but the need still exists to place these contributions in an environment that assures their control. It should be noted that control need not be exercised as a function that unduly limits imagination. The intent of control is to assure that considerations of product function, cost and schedule remain clearly visible, and that decisions made which significantly affect such considerations are made consciously, with the effect of such decisions having received due consideration. Concerning the time at which control should be initiated, it is felt that "control begins when the first germ of an idea for a project appears in the organization—a discernible effort which will require an expenditure of organizational resources (human effort, time, money, physical resources) and lead to an organizational objective."[1] References 2 and 3 contain related reading not totally in accord with the above view.

There are, of course, many problems of software production other than those related to project management that can prevent the end product from being successful, such as: a faulty or unknown product definition; badly estimated product life; too rapid a development speed; major design problems; poor staffing; and inappropriate marketing (see also Sections III and IV of Reference 4). Good management can in many cases, however, assist in minimizing such problems by providing early visibility of the product and its problems, and by providing an environment allowing timely remedial action.

Prior to continuing with the body of this paper, one reference is particularly recommended for project planners. This reference, by Bemer,[5] contains an extremely comprehensive and useful "Checklist for Planning Software System Production." Reference 4, also by Bemer, is further recommended reading.

MAJOR PROBLEMS IN SOFTWARE DEVELOPMENT

This section describes the problem areas that are felt to be historically most common. The problems described in this section are felt to be significantly reduced by the organization and procedures later described.

In the most general sense, the two major problem classes are:

Those that make the customer unhappy; and
Those that make the developer unhappy.

Problems in the above two classes might also be classified as follows:

Unsatisfactory product
Schedule delays
Excessive costs

The above problem classes clearly are interactive, as schedule problems lead to cost problems, an unsatisfactory product leads to remedial action (cost, schedule), etc. Thus the division is to some degree artificial, but is useful for descriptive purposes.

The above three classes of problems will now be discussed in more detail.

Unsatisfactory Product

The major causes of user dissatisfaction with the product are:

1. Too Many Bugs
2. Instability
3. Unsatisfactory Performance

1. *Too Many Bugs*

The reasons for an excessively high number of bugs are many, including: (1) over-complex initial design; (2) implementation not consistent with initial design; (3) inappropriate implementation; and (4) uncontrolled evolution. These points are elaborated upon below.

The design may be so complex that the system in fact cannot be debugged. This complexity can be introduced in a number of ways. The initial design concept may, for example, unduly require complex module interactions, extensive time-dependent characteristics, multiple and non-obvious uses of the same information by many parts of the system, etc.

Complexity can be introduced during modifications following initial design if the initial implementors, or the next generation of designers and implementors, either cannot understand the initial design, cannot make it work, or the initial design is simply unsatisfactory in some way. In such instances an approach sometimes followed is to "program around the problem", leading to further problems in all areas of system performance, including possibly the undoing of some important initial design concept unknowingly.

A further cause of program complexity is due to the excessively "sophisticated," "elegant," "clever," or "efficient" programmer. Most, if not all, systems operating today have sections that either never will work quite properly or, if they do, dare not be modified to meet new requirements, due to their initial implementation by a programmer with one of the above attributes.

Poor implementation is a very common source of bugs. The cost of finding and repairing problems caused by poor implementation is so large as to make it quite clear that proper project staffing, detail design reviews, and strictly enforced unit test requirements are of extreme importance.

A situation leading to the existence of a continually high bug rate sometimes occurs when a product undergoes an evolution process in which new features are introduced simultaneously with ongoing maintenance. In such instances, synchronization between new features and bug fixes becomes a problem. An approach sometimes encountered under these conditions is to create a "safe" local environment by minimizing dependencies upon other parts of the system, even to the extent of creating duplicate or similar local tables, functions, etc. The problems in future maintenance and modifications are obvious.

2. *Instability*

The term "stability" will be used here to characterize the degree to which a job, once entered into the system, will terminate only due to a user error, and further, the effect of the user error is minimal (e.g., execution terminated, but files created to that time are not lost). If a user's program frequently must be rerun due to problems not of his own making, or if the severity of the problem is not consistent with the severity and probability of the error, then the system may be said to be "unstable."

Instability was not a problem in the days prior to multi-programming, as only one job was generally lost, and a rerun usually was successful. In multi-programming batch systems even extreme instability could be tolerated (and was) for a while, as a rerun often worked. In time, however, more capable I/O devices such as removable disks became available, with the attendant need for extensive support software. The major stability problem then became one of file creation and retention. This problem remains in many systems.

With the advent of real-time and time-sharing systems, stability has become much more important. In such systems there are, typically, from 20 to 100 users simultaneously somewhere in the processing cycle (in core with the CPU, in core, swapped, etc.). Losing the execution state, and possibly the files, of this many programs, or of critical programs, is extremely serious.

The most significant factors affecting a system's stability are the complexity of design and implementation, and the degree of attention paid by designers and implementors to automatic system recovery. Even good automatic recovery techniques cannot overcome problems inherent in an over-complex system.

3. *Unsatisfactory Performance*

The performance of a system may be unsatisfactory to the users. The performance of most batch systems is not so bad that users consider it intolerable, though it is still a major concern. The basic algorithms for obtaining satisfactory batch throughput are basically not complex, but as batch systems attempt to service an increasingly large community of hardware and users, the simplicity possible disappears. Thus, the major operating batch systems available vary widely in design, and in classes of service performed well. Batch systems with performance problems generally are troubled with excessive overhead, complexity due to the variety of user-types intended to service, difficulties in core management, and inadequate support for large data bases.

In the time-sharing area there have been notable instances where the performance was not what was required. A number of reasons exist for performance problems in time-sharing systems, for example, the basic assumptions were over-ambitious, not well thought out, or inadequately scoped (with modeling, for example). A more frequently encountered cause of unsatisfactory performance in time-sharing systems is the attempted retrofitting of a batch system to support time-sharing users.

Schedule delays

The most frequent cause of a missed schedule is, of course, the initial creation of an unrealistic schedule. Other reasons, generally related to the first at least implicitly, include ill-defined or missing requirements, changes in baseline assumptions, the customer interface relation, plus many of the causes of product and cost problems as described elsewhere in this section.

There are frequent instances in which the product was initially ill-defined and underwent a process of definition through its development. The conditions under which the initial estimates were given often change, including such changes in the available resources (money, skill, computer time). Requirements to support new hardware previously unenvisioned are often introduced.

The type of customer interface can have a major effect upon schedule. The customer interface is defined here as that person or persons who define, interpret, and control all requirements that come from the customer. The customer's relevant technical and management experience, maturity, willingness to respond to suggested changes, understanding of problems, and readiness to assist in achieving satisfactory mechanics of living together, are quite important. In particular, it is extremely important that the customer not require that all possible "bells and whistles" be included in his product. He should be reasonable in terms of tradeoffs, where considerable design and implementation simplicity can be gained by providing somewhat less function to the user. The customer must be convinced that simplified or limited functional capabilities will often improve the eventual performance and stability, and will increase the ability to add future enhancements to the system.

Excessive costs

A major software development problem for the developer, in addition to user-related problems, is cost. Major causes of cost over-run include:

1. Schedule Delays
2. Low Initial Estimates
3. Staffing Too Rapidly
4. Staffing With Quantity, Rather Than Quality
5. Follow-on Costs
6. Type of Contract

1. *Schedule Delays*

Delayed schedules generally lead to higher cost, unless the developer had the foresight to see the schedule was unrealistic and staffed according to a reasonable schedule.

2. *Low Initial Estimates*

Some excellent techniques for estimating project schedules and costs have been presented in the literature.[6] Persons making schedule and cost estimates must previously have been closely involved with projects of similar size and complexity. They must have accurate cost and progress summaries of the previous projects. It is useful to know the original estimates for previous projects, and eventual results.

The value of PERT-type techniques in making initial estimates is limited, due to the lack of detail concerning the project available at that time. A PERT network or the equivalent should be constructed, however, even if only on a very gross scale, as a means for forcing upon the estimators a mildly rigorous framework in which to place their estimates. Of particular importance in the PERT are, of course, those things that frequently lead to schedule problems. Foremost among these are a knowledge of: (1) dependencies outside the project; (2) the period required for initial staffing, defining the organization, and other activities required to have the people know what they are supposed to be doing, why, and when; and (3) those major activities within the project which may proceed in parallel, and which must proceed serially.

Machine time estimates are almost always underestimated, on projects of all sizes, and usually by a large factor (two to four). Even when machine time estimates are made by reasonable and experienced people, they are often made invalid by the eventual uncontrolled and wasteful manner in which the computer is used. Even today we find use of "block" or "hands-on" time on large, fast machines. Unless projects develop techniques for optimal use of computer time, including the support software required to remove the need (except in rare cases) for hands-on time, problems of cost, geographically separate computer installations, and inability to maintain schedules will generally arise.

Some activities in project development can proceed quite nicely in parallel by defining the major interfaces early. For example, a compiler can often be developed in parallel with an operating system, as its interface needs are small. Similarly, applications design and coding may often overlap development of the support system.

3. *Staffing Too Rapidly*

Staffing a project is an important and complex issue. There are never as many good people available as a manager would like. A manager is aware that a certain general level of manpower will be required to do a job, and then the staffing search begins, trying to identify people who are available, have relevant experience and skills, etc. Initial estimates that a project will need a certain number of programmers should not lead to the addition of "head count" simply to meet predictions. In general, projects staff too quickly with people anxious to produce code, and not quickly enough nor with enough skill with managers and supporting staffs (e.g., integration and test activities, described later). Programmers are often brought on board in order to start doing something before they really know what to do. A good generalization is to always have the minimum number of programmers possible on a project.

4. *Staffing With Quantity, Rather Than Quality*

No matter how insensitive, trivial, simple, or straightforward a piece of code is to write, it will cost more, often much more, if a poor programmer is given the job. Sometimes the cost is hidden, perhaps for years, but once programs "work" in some sense there is a great reluctance to replace them, which tends to extend the life of some rather poor examples of the programmer's art.

In such complex areas as systems or real time software, unless there is a very large amount of review talent available, people should not be brought onto the project unless they are extremely skilled. (It can be argued that this statement should be enlarged to include all types of programming.)

Relevant experience and resumes of people cannot be considered the most important criteria for hiring. Extensive experience cannot overcome the lack of an organized approach, insight, maturity in tradeoffs, and a willingness to make very sure that a program really works correctly.

It should not be assumed that key people will be available through hiring, or transfer from other parts of the company.

5. *Follow-on Costs*

Unrealistic estimates of follow-on costs after the first release of a system are often made. Follow-on costs may include maintenance, enhancements due to oversights in the initial product (frequently stability and performance problems fall into this cateogry), user enhancements required to stay competitive, a need to support new hardware, etc. The larger a software system is the more reluctance there is to replace it. Thus the product life may be long, with a fairly continuous, and costly, development cycle.

6. *Type of Contract*

The basic types of contracts are cost-plus fee (percentage of cost, award, incentive, etc.) and fixed price. Virtually any type of contract is satisfactory if the contract administrators on both sides are both knowledgeable and reasonable. Cost-plus contracts are felt to be superior to fixed price contracts for all cases except the (relatively rare) instances in which the product, dependencies, etc., actually *can* be specified in great detail. For example, the author has observed in some detail a cost-plus contract with highly skilled technical and management interfaces, and a fixed price contract with a vague contract and inexperienced interfaces. The cost-plus contract could have been costly, but was not, due to the expertise of the contract managers. The fixed price contract in theory limited the cost, but in fact, due to extensive requirements above the scope of the contract, resulted in contract renegotiation, higher cost, schedule problems, ill will, and eventual replacement of contract managers on both sides.

There are, of course, instances of cost or product problems in cost-plus contracts, if, for example, expensive and not necessarily talented personnel are "dumped" onto the contract for profit and/or convenience. A sometimes-encountered problem in fixed price contracts is a "buy-in," followed by either minimum possible contract interpretation or change of scope. Again, experience and reasonableness on both sides is required in order to prevent the contract type from perhaps heavily contributing to cost and other problems.

OPTIMAL PROJECT ORGANIZATION

This section describes a general project organization that assists in providing a check-and-balance relation in a project that will contribute to project visibility, control, and other factors important to meeting project goals. This organization, and the corresponding procedures of which examples are given, is felt to have wide applicability, but is not, of course, an exact model of any particular project. An organization will inevitably be shaped by the job to be done, people available, company policies, etc.

This section discusses the following topics:

General Project Organization
Project Managers
Development Activities
Integration Activities
Test Activities
Procedures
Staff and General Support Activities

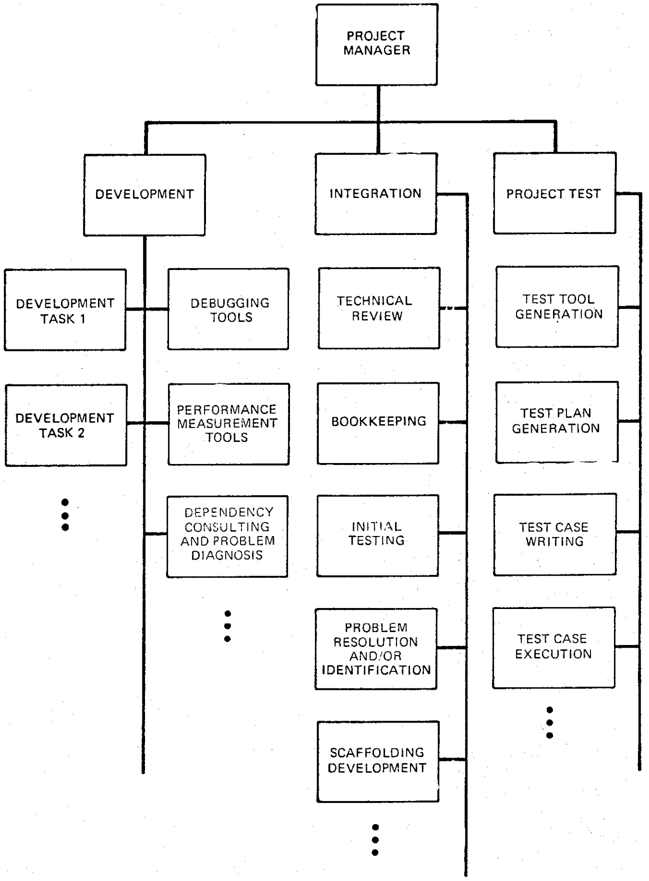

Figure 1—Project organization

General project organization

Figure 1 shows a project organization that it is felt is generally applicable for a wide range of development projects. Many of the functions shown in this figure are not, of course, required precisely as shown in particular projects, but the major functions implied, or their equivalent, are felt to be required in some form for projects on the order of five people or more.

The key element of the figure, and indeed of this paper, is the division of responsibility into separate functional groups, such as those termed here Development, Integration, and Project Test. This division is felt to be an absolute necessity. This division must occur early enough in the project life so that each functional group can adequately prepare.

The following sections describe the Development, Integration, and Project Test groups in more detail. The general responsibilities of these three groups are:

Development:	Design, write, debug and unit test new code.
Integration:	Integrate all code. Be the project "bookkeeper."
Project Test:	Determine the status of integrated code.

It is critical that people who are developing the product not be simultaneously responsible for all the bookkeeping functions, integration of new code, and confirmation that the integrated code works. The project organization must be such that all groups have strong technical people, and receive full support from the project manager. Without an appropriate division of responsibilities, and a corresponding set of procedures, both visibility of true project status and control over development are very difficult to achieve. Among the typical problems that result are: not knowing what code is really in a particular version of the system; and a requirement to accept a programmer's statement for the status of a module ("90 percent done, only a few minor things don't work").

Project managers

The three levels of project management discussed here are:

1. Project Manager
2. The Project Manager's Manager
3. First Level of Management Within the Project

One comment relative to all levels of management should be made before going into further details. Managers are assigned a responsibility, and must be allowed to make decisions within their assigned responsibility without undue requirements to justify their decisions. If a reasonable set of checks and balances exists (e.g., Review Boards), and if the managers chosen have appropriate experience and judgment, then their scope of decision making should not be frequently tampered with. Frequently no decision is worse than nearly any timely and moderately rational decision.

1. *Project Manager*

The most important single person on a project is the project manager. Therefore, choice of this person should be made with appropriate care. There are a wide variety of attributes that it is desirable to have in a project manager, and a set of attributes that if they exist in a project manager almost assuredly doom the project to failure.

The project manager must be technically strong enough to understand the important technical decisions made by those under him, to ask the right questions about those decisions, and to change them if needed. In particular, he must be able to cause the project to move toward realizable goals, and be able to say "no" to impractical ideas, and enforce it.

The project manager must have both technical and managerial maturity. All too often managers are chosen on the basis of strong technical skills plus a desire to be "promoted." Opposite extremes would be the assignment of a weak technical person to a managers role because nobody else would put up with the customer interface or personnel problems, or because the person just happened to be available.

Another characteristic that must be contained within the project manager is a desire to become *involved.* He must *manage* the project, not simply spend occasional time in reviews, believe all that is told him, and dilute his activities with marketing for new business or other company activities. It is always easier for a manager to assume that since good people are working in a certain area, and everyone is working hard, the end result will work out all right, and that he need not take the time to dig into that area in detail. On reflection, it almost always turns out that one or more areas do not develop satisfactorily, regardless of the skill of those most closely involved. Frequent reviews of design, implementation, test status, dependency status, schedule milestones, etc., by the project manager, are required.

It is not felt to be possible for a project manager to be in some sense a "pure" manager, that is, manage PERT charts, organization charts, staffing, facilities, and so forth, and allow others to make the larger technical decisions uninspected. This would rule out software project managers whose experience is only in other types of work.

2. *The Project Manager's Manager*

In addition to the project manager being of appropriate technical and supervisory capability, it is also critical that his immediate supervisor have relevant experience, a set of both common and complementary skills, and not be so sure of the project manager that an independent check of status and problems is never made. Every project manager needs someone reviewing his major decisions, a person to whom he may bring problems and receive real help, and someone to just talk to at times in order to remain objective about his project.

3. *First Level of Management Within the Project*

A superior project manager can, with appropriate organization and procedures, control up to 20–30 people satisfactorily with a set of managers reporting to him that are really "technical task leaders"—strong technical people with some supervisory capability, each supervising 3-5 people. Above the 20-30 level, however, support of full-time supervisory people within the project is required.

Development activities

Figure 1 shows a number of possible functions to be included within development. Many additional or different functions exist, of course, for any particular project. This is felt to be a reasonable example set, however. The particular activities to be described in this section are:

1. Major Development Function
2. Debugging Tools
3. Performance Measurement Tools
4. Dependency Consulting and Problem Diagnosis

Before beginning a discussion of the above, it should be mentioned that this paper does not attempt to discuss the merits of such very important development considerations as: software specification or implementation languages; types of debug tools; tradeoffs between speed, space, portability, flexibility, cost and schedule; the value of formal proofs; etc. The emphasis here is on functions that must somewhere be performed, not how they are best performed.

Two characteristics of the development process that frequently occur will first be briefly mentioned: the effect of design changes during implementation; and the occasional need to replace significant design or implementation efforts. A great deal of interpretation of the initial high level design takes place during detailed design and implementation. If not carefully controlled (via documentation and review) it is possible to develop a product substantially different from and/or inferior to that initially intended.

Occasionally it is realized that a significant mistake was made in design or implementation. The temptation always exists to "live with it," "fix it up later," or "program around it." Generally such approaches are a mistake—significant problems must be removed when discovered, or at least a plan for their removal created and begun. Too often the problems, if put off, remain in the system for a long period of time and cause far more difficulty than if remedied early.

1. *Major Development Function*

The major development function is, of course, responsibility for the overall design, detail design, debug, checkout, and internal documentation activities required for product implementation. Worth mentioning is the undesirability of fragmenting the responsibility for this effort in a manner that results in a manager with overall knowledge of the entire development not having full control over work for which he is responsible.

2. *Debugging Tools*

The creation of debugging tools is a distinct programming task, with substantial requirements to be defined, lead time needed for development, etc. In general there remains far too much dependence upon octal or hexadecimal dumps as the major aid to resolving difficult problems. Including appropriate (e.g., brief, symbolic) tools in a system initially is generally inexpensive; adding them later is quite difficult.

3. *Performance Measurement Tools*

Performance measurement tools must be included in development planning. This requirement needs planning, lead time, etc. The capture and processing of performance information is something that should go on very early in a system, but often does not. Obtaining early indication of performance problems is often critical, however, as their repair can require major surgery.

4. *Dependency Consulting and Problem Diagnosis*

Programming projects usually have significant dependencies on areas outside their direct control, for example, the hardware employed, support software, and communications facilities. Where such dependencies exist, it is best to assume that non-trivial problems will occur, and place in the project appropriate skills to isolate the problems and assist the appropriate support group in their removal. Since such problems often arise due to misunderstandings resulting from inadequate documentation, or perhaps just a complex dependency, the ready availability of consulting assistance within the project will be valuable.

Integration activities

Put briefly, this group's activities are to provide a major portion of the independent *control* and *visibility* of development activities that is required. The Integration Group lies organizationally between the Development Group and the Project Test Group. This group receives new code from Development; integrates the various pieces of new code received from Development; performs the bookkeeping tasks on detailed status of all changes that have come in; assures proper approval levels; and other similar tasks, prior to passing on a new release for testing.

The *control* over development resulting from this sort of activity is obvious—nothing goes into the system unless properly identified and approved, and extensive documentation exists should the changes need to be altered (or, in extreme cases, removed). The *visibility* provided above an approach which has Development personnel alone report on system status is a bit less obvious, but critical. Development personnel tend to be optimistic about their code, tend to report a feature as fully provided even though only part of it is done, and to otherwise exhibit human traits. Integrations' job is to be more hard-headed—something is done only if the code was turned in, with appropriate documentation (e.g., updated internals), and a repeatable test sequence (without which the change is not accepted). Thus a project manager can know *exactly* what is completed.

It is becoming more and more common in the industry for the integration function to include very strong technical people, for such purposes as: (1) providing the ability to inspect new code submitted to the system for general technical correctness; and (2) identifying integration problems well enough to fix some, and if not to provide good information to Development people. If all the the project technical strength lies in other groups, the Integration Group must always borrow technical resources from these other groups, which they give up grudgingly. An intermediate approach is to assign people from Development to each new release, thus providing additional technical muscle for integration activities.

Another important function of the Integration Group is to perform some level of initial testing on the product in order to assure that the major new functions will work together and were integrated properly. Typically a small set of regression tests is run by Integration to assure that no major regressions have occurred prior to approving a new system for more extensive testing.

In addition to the above principal activities, a number of other activities may be convenient to include in the Integration Group. An item that may come under Integration is one that is termed here "scaffolding development." In the development of a new project it is always required that some subset of the system be generated first as an anchor on which the fuller system can be developed, that some other system be used as a vehicle for creating assemblies, load elements, etc. The term "scaffolding" is used to define the set of code and procedures that is developed to substitute for missing interfaces or missing subsystems in order that a partial system can run, or that phasing from one system to another goes smoothly.

Enforcement of such standards or requirements as linkage and naming conventions and memory utilization may also be conveniently performed by Integration. Automated tools may help such activities.

Test activities

This section describes a series of testing levels, and their place in the project organization. A fundamental corollary of this section is the now (hopefully) clearly established requirement that successful projects must include: (1) early creation of test plans, procedures, and staff; and (2) one or more groups established for testing a product that are organizationally distinct from and equal to the Development Group.

A testing approach that has proved quite successful is one in which there are a number of separate and distinct test activities, with minimal overlap, each fulfilling a needed function. A possible set of testing levels, chosen for purpose of example, is the following five level set:

1. *Unit Testing* by Development programmers. These tests show that the new function(s) operate in a private environment. Development managers must review the unit test plans in detail, as a poor job at this level will be very costly later.
2. *Integration Tests,* including rerunning of some of the above unit tests, testing the ability of the system to operate without major regression such that the next testing phase can concentrate on testing new code.

3. *Project Test.* This is the major test activity and is discussed in more detail below. This group runs extensive tests on new systems to confirm that new features work.
4. *Regression Test.* In addition to testing that new features work, one must also ensure that things that used to work still do. This may be done either within the project (e.g., by Project Test), or by an organizationally separate group. The regression testing activity differs somewhat from Project Test activities in that: (1) the volume of testing is larger; (2) the features tested are generally more stable than the new features; and (3) the regression testing group has more lead time, better documentation, etc., than the group testing new features, thus need not be quite as good "detectives" to determine what the new features really are.
5. *Field Test.* Regardless of the amount of prior test, non-trivial bugs always exist in the final release. For this reason a field test should be scheduled, in which the new system is mounted in one, or a few sites, and watched for a while, prior to full release.

The Project Test Group normally performs the following functions:

1. Test Tool Generation
2. Test Plan Generation
3. Test Case Writing
4. Test Execution

1. *Test Tool Generation*

Test tool generation requires both "hooks" in the system, and programs to process and analyze the results. To minimize the requirements for support upon the Development Group, it is advisable to develop test tools that are carefully designed to capture all information that is likely to be useful, but impose minimum space and complexity requirements upon the system. These tools should not be the last functions integrated. With early data definition, the required data processing programs may be developed in parallel with the system. Typical of the test tools that are required for development of modern systems are a means to easily and repeatedly run large series of programs. For example, a common practice is to simulate a large number of users in a time-sharing environment, with input coming from precatalogued files rather than on-line users, but seen by the system in a very similar way. These "prestored" jobs may contain test programs, a sample of real user programs, or both. Information captured from these test tools should record such information as is later needed to determine such things as response times, if or not the output compares on a line-by-line basis to previous runs, and so forth.

2. *Test Plans*

Extensive study of documentation and listings plus detailed planning is required to develop a set of test plans that may be reasonably executed and analyzed. Test plans must include enough detail so test cases are not written with dependencies on functions not yet integrated. Among the many types of tests that must exist are those for testing: functional capabilities; stability; performance; fallback (the ability for a system to be replaced by an earlier release if it fails); and the ability to support various hardware variations, including degraded mode operations in which only a subset of the hardware is available.

3. *Test Case Generation*

This is a difficult effort to do well if the test programs themselves are to: (1) not produce more bugs than they find; (2) efficiently and completely implement the test specifications; and (3) be self checking to a large degree.

4. *Test Execution*

Test execution includes the actual running of the tests, creation of files used for later analysis to determine if the tests ran properly, documentation of results, getting the information back to the Development Group and consulting on procedures used, and so forth. With automated test tools this effort can be reduced very significantly, with only a few people required to test features not easily tested automatically.

Procedures

The type of procedures required to assist in providing project control and visibility may be very large. This paper does not attempt to give a detailed set of procedures. The following list, provided as an example, gives information which would be expected to be submitted by all Development programmers when their code is ready for Integration.

System level upon which the changes are based
System level intended for inclusion of the changes
Change identification
Change description
Listing of the changes
Card deck (or the equivalent)
Changed internal documentation
Changed operational documentation
Changed external documentation
Dependencies upon other changes
Modules changed
Copy of the unit test passed to confirm unit testing, and instructions for reproducing the test results in the integrated system
Approval signatures

For an example of support software to aid in implementing procedures of the above type, see the CLEAR system description of Reference 7.

A further example of a procedure usually needed is an automated planning aid of some sort. There are a number of reasons why a mechanized aid (such as PERT) is useful. These include:

1. A common basis for discussing project status is defined. Even if it is not quite everything that would be desired, everybody gets used to using it, and the shortcomings are overcome.
2. The mechanical difficulty of experimenting with changes in work required, people available, slipping dependencies, etc., is much less, as one need change merely a few data cards and rerun a program to get an initial feel for problems, tradeoffs, etc.

To meet the above objectives, the scheduling aid must have a number of attributes, including: (1) the output must be prepared by computer, not the local art department, as waiting a week to see the latest chart makes the whole thing useless; (2) the input preparation must be relatively simple; and (3) the process must be flexible enough and closely enough related to the projects' detailed activities to be a widely usable day-to-day planning tool (for example, listings should be produced that sort activities by start date, end date, person assigned, release version, etc.).

Staff and general support activities

There are a variety of activities that must exist within either the project or a supporting organization that do not always fall neatly into the Development, Integration or Project Test Groups. Those discussed here are:

1. Staffing Assistance
2. Customer Interface and Support
3. Review Board
4. Operations Support
5. Documentation
6. Status, Cost and Schedule Data Collection, Reporting

1. *Staffing Assistance*

In the early days of a project, when many people must be interviewed, resumes must be reviewed, and so forth, the project manager should not have to (and cannot) do all the recruiting for the project. It is also felt, however, that this job cannot be delegated completely to a personnel department. A good personnel department can be very valuable by performing such activities as obtaining candidate names and performing initial screening for quality and relevant experience. Technical men on the project must do all detailed screening, recruiting and staffing for the project, however. This is a difficult job to do well, as people range from uncommunicative geniuses to imposing charlatans. Nevertheless, detailed interviews combined with extensive checkups of references can assist greatly in minimizing the dead wood brought aboard. Realistically, it must be faced that more people must be hired than are needed, as some will not work out and must be discarded in short order.

2. *Customer Interface and Support*

A major element of the customer interface must, of course, be the project manager himself. This is so since he alone is responsible for the project, and therefore only he (or his manager, but hopefully not independently) can commit the project. It is often the case, however, that there is a need for frequent discussions between various people within the project and within the marketing organization, or other organizations working with the project, such that a continuous and heavy transmission of information back and forth across the project interface must exist. The project manager is generally too busy to both perform this function and manage the project, so it is wise to set up a small group, perhaps one person, reporting to the project manager, to provide a continually available interface to the customer. This may include such customer support functions as assisting in preparation of rough external documentation and/or proposals for the customer, looking in advance at conversion problems when the system becomes operational, etc.

A further important role of the customer interface may be one of providing appropriate visibility concerning progress and problems. It is fairly easy for a project manager and a customer to both be working hard and think the other one knows what each is doing, but to discover that in fact major differences of opinion occur. A good interface can reduce these problems.

3. *Review Board*

A review board should be established that includes people who are generally not assigned full time to the project, but remain cognizant of technical activities going on in the project through their continuous participation on the board. This board includes senior technical people from wherever is appropriate. The purpose of this review board is to review major decisions either already made or that must be made before going on. This helps assure that all relevant experience available is brought to bear. Items reviewed should be of both technical and administrative (e.g., cost, schedule) nature.

4. *Operations Support*

Computer operators need someone to call on for help occasionally, efficient machine room procedures need to be developed that are generally rather different in project development from those in a typical production shop, etc.

5. *Documentation*

Documentation is always a problem, both where to place it organizationally as well as who should do it. There is a very wide variety of types of documentation to be done, usually far more than is obvious at budget time. Among the major types are, of course, the internal documentation for the system (usually done in Development, with the support from elsewhere). Another obvious type is the external documentation for the user. There is also the question of documentation to support people who must run the computer center, documentation for user managers, training documentation, etc.

One of the major unsolved problems of the computer industry is the creation of appropriate documentation, at a reasonable cost. It always seems to get done eventually, but is always painful to the programming staff, and not infrequently to users.

6. *Status, Cost and Schedule Data Collection, Reporting*

Projects sometimes begin with good procedures in place for creation of status, cost and schedule collection, etc., but as time goes on less and less use is made of such procedures. A frequent cause is the lack of staff to regularly collect and report upon the data collected. This can be a substantial job, but if done properly provides management with early indications of potential trouble areas.

SUMMARY

The proper management of programming projects requires means for visibility and control. To know what is actually going on in a project, to not have critical path activities slip, to head off such difficult-to-solve problems as memory over-use and slow performance, and with all this to meet a tight schedule and budget, is a challenge met by few. The primary attributes that must be contained in a project to provide good visibility and control are:

1. Division of responsibility in a manner that gives good checks and balances (separate groups for Development, Integration and Test).
2. A large set of procedures, rigidly enforced, that supplement the above organization by forcing an automatic flow of information.
3. Managers, supervisors, and task leaders at all levels that have good technical judgment, and will "dig" to find out the true status of all work.

Commercial data processing machines in government applications

by J. D. ARON

IBM Federal Systems Division
Gaithersburg, Maryland

INTRODUCTION

When a major military weapons system is designed, it is often so far ahead of the then current commercial technology that special approaches are needed to make the system feasible. This has led to the development of many special purpose computing systems as components of large government procurements. But special purpose hardware is often too complex to be built on normal schedules; furthermore, the software to go with it must be deferred until the special machine is finished. The sequential nature of the hardware/software development cycle means that any slip in the schedule of either element directly affects the total system schedule. One obvious way to avoid cost and schedule problems due to spec:al purpose computing systems is to substitute commercially available comput ng systems for them.

There is a lag of some 3-5 years between the specification of a major government application and the detailed design of related non-government systems. Dur'ng this period, the hardware and software designs of the computing :ndustry generally incorporate the special characteristics of the government system for their standard product line. By the time the government system goes into operation, contemporary commercial systems have caught up. Thus, the convergence of government and commerc'al needs is leading to standard computing systems which meet all but a few of the needs of the special military and federal civilian applications. *In those cases where the commercial system is totally responsive to the requirements of the special system, it offers sufficient benefits to recommend it in preference to special purpose hardware.* In other cases where the commercial offerings are only partly responsive, there are still significant advantages to the use of commercial systems (modified as necessary) to be evaluated by the system manager.

BENEFITS OF USING COMMERCIAL HARDWARE

Salient benefits

The benefits of using commercial hardware depend on which elements of the system design hav e the highest priority in the mind of the user. For instance, in evaluating commercial data processing alternatives for the SAFEGUARD system, the Army l:sted five system characteristics in relative order of importance and weighted them to emphasize the ranking. Performance, including throughput and some aspects of reliability, carried 40 percent of the weight. Product Deliverability was next in importance, followed closely by Implementation Risk. Some 10 percent of the weight was assigned to Growth Potential and Cost carried a nominal 5 percent. Commercial alternatives will score very high in the last four characteristics. Will they stand up in Performance? Probably, yes. The computing performance of general purpose mach'nes has been growing by an order of magnitude every five years. There is no sign that the growth will stop.

The commercial computer approach is strongly enhanced by the availability of compatible families. This feature of the commercial market was introduced in a limited way in 1962. Taking advantage of this, for instance, the USAF Command Post Project 473L was able to install an IBM 1401 computer very early in the system design stage to test out concepts related to disk storage and display consoles. Later, as the workload on this facility grew, the 1401 was replaced by the larger 1410 without substantially altering the system. Through the emulation capabilities of the third generation S/360, some of the original 473L programs could still be used after the 1410 reached the limit of its utility. Most manufacturers now offer commercial families of compatible machines. The same degree of compatibility is seldom offered in the special purpose computer market for simple economic reasons: neither the buyer nor the vendor has a cost justification for developing any features other than those directly applicable to the special application. Consequently, there is less growth capability in special purpose machines procured for military systems than there is in the standard commercial product line of a given manufacturer.

Referring again to 473L, the use of the 1401 as an interim test bed illustrates a common aspect of the system development process. In order to make progress on the overall system it is important to overlap many activities. Programming, as an example, will proceed while the hardware is still being built. In 473L it was necessary to create a simulator of the Librascope L-3055 computer, specially procured for the project. The simulator ran on a commercial 709 located in the programming facility. By using the simulator, the programmers were shielded from delivery delays in the L-3055.

The rigid product test protocols observed by most manufacturers further increase the confidence that commercial machines will perform according to their advertised parameters. The risk, as has occurred on special procurements, that a computer will be delivered with some of its instruction set still undefined and perhaps not included in the circuitry is negligible with commerical machines.

If the performance and reliability of commercial machines are sufficient to justify their use to the systems engineers who design the military and federal civilian systems, then the software support available with the machines should throw the decision well over in favor of the commercial product. *Software, which includes development aids as well as the deliverable computer programs, has become the most difficult aspect of large systems to plan and control.* Project management is generally unfamiliar with the nature of software and lacks the experience to estimate and schedule the programming effort accurately. However, since a data processing system is a package of hardware and software, in which the software is the only feature directly accessible to the user, the system cannot be completed until the software has satisfactorily passed its tests. It is specifically in the area of software that commercial machines have a marked advantage over special purpose implementations.

Vendor software, available with the first delivery of machines, normally includes a basic operating system which controls the hardware function and facilitates the preparation and execution of user programs. In addition, the vendor supplies a variety of language processors: basic assembly language for manipulating the hardware instruction set, higher level languages such as FORTRAN, Algol, COBOL, JOVIAL, and PL/1 for application programs, and simulation languages such GPSS and SIMSCRIPT for building models. The higher level languages are easier to use than the basic assembly language and speed up the development effort. The languages have the added benefit that they are easy to learn and can be transferred from one machine to another with relative ease.

The advantages of higher level languages are so self-evident that some have been written to run on special purpose processors. But the resources applied by the general purpose machine manufacturer to come up with a comprehensive efficient high language processor are too extensive to be duplicated on each special processor. The result is most often a limited subset of the full language and an inefficient compiler.

This last point, when extended to cover additional areas of vendor support and product enhancement, emphasizes one more significant benefit of commercial machines: *Commercial systems are usually less expensive because they achieve economies of scale inaccessible to special products.*

Characteristics of applications of interest

There are three general classes of government applications which can be identified according to the stringency of their unique requirements:

Class I—Problems such as inventory management, management information systems, finance and accounting, etc., which are performed daily or less often in an office environment.

Class II—Problems such as assisting commanders in operational situations or controlling weapons and space missions. An office environment with special security, reliability, and availability provisions is required in fixed installations. Installations in aircraft or ships may call for special equipment.

Class III—Problems such as air navigation, weapons guidance, or space vehicle maneuver control in an environment in which temperatures and other physical parameters can vary widely and where the computing element may have to be shaped so as to fit into a small space. Reliability must be very high and maintenance may be impractical once the mission has started.

Class I problems are normally handled by commercial hardware. Class II problems are dominated by the environmental constraints and are normally handled by special hardware*. Class II problems, which are the primary subject of this paper, present the opportunity for tradeoffs between special and standard hardware. The typical tradeoff to be made is whether to place a specially designed machine in an uncontrolled field environment or to create a spec'ally designed controlled environment in which to place a commercial machine. The commercial machine approach is most appropriate for fixed installations at headquarters locations and for transportable facilities in vehicular vans and airlift pods. The decision can swing either way for ship and submar:ne installations. The airborne case will almost always call for special hardware to meet space and weight constraints.

The SAFEGUARD advanced ballistic missile defense system falls in the second class. So do Air Traffic Control and the ground support for the Apollo manned space flight system. In each case there is a need for large capacity storage, fast computation, versatile input/output devices, communication with other systems, high availability, and the flexibility to respond to changing workload requirements.

Performance

No effective measure of computer performance has been developed that applies to more than one situation; therefore, it is common to describe performance requirements by the arbitrary value of the instruction execution time. The lack of other throughput requirements is usually due to the inability of the system designers to anticipate the effect on throughput of interactions among the programs in the job stream. At best, the designers can lay down specifications for system throughput based on the real time requirements of one critical activity. Most of the complex systems of interest to the government involve many related activities; e.g., the relations between radar data and aircraft tracks and between aircraft tracks and flight plans and between aircraft tracks and traffic control procedures. The relationships cannot be unravelled so that the system design requires all of the computing to be done on a single computer configuration† where all the related information is available at the same time. While it may be useful to categorize machines based on a single parameter, selection of a machine for a particular application should be based on a more thorough analysis of its capability to handle the specifics of the job. The selection of computer hardware should be one of the last things done in the design phase. Premature selection will force the designers to distort the rest of the system to conform to the computer. Problem definition, workload sizing, allowable computing overlaps, deferrable computations, absolute real-time deadlines, I/O rates, and other job descriptors should be determined first. Then a balanced computer configuration can be selected (using a gross model for timing and storage evaluation) which will do the job. If this policy is followed, the lead time for computer delivery will be compressed.

There are very few performance requirements that cannot be handled by off-the-shelf hardware. The performance criteria in which commercial machines exceed the capabilities of most special purpose machines include:

1. Range of speeds available for a family of central processors;
2. Range of memory capacity for a given processor or family of processors;
3. Number and diversity of input/output devices available.
   - card handling equipment
   - printers
   - typewriters and teletypewriter terminals
   - displays and plotters
   - communications adapters
   - tapes
   - disk units
   - drum units
   - on-line sensors and output controllers
   - other computers
4. number of computer programs available
   - to support the machine operations
   - to support programmers
   - to solve problems
   - to support terminal users
   - to support system analysts

A characteristic of a commercial product line is the way in which the above facilities are coordinated so that a large number of possible configurations of the system can be used efficiently. In the typical special processor whatever support is provided in the way of balanced performance or software support is optimized around the original problem statement and may be somewhat clumsy when used for a variation of the problem or for a different problem.

* Some Class III problems require so many identical computers that economies of scale can be realized.

† Which may contain multiple CPUs.

The areas in which commercial and special machines can be roughly the same include:

1. Ability to multiprogram (time-share more than one program at a time);
2. Ability to multiprocess (run one problem on more than one computer to share the load);
3. Ability to handle real-time inputs;
4. Ability to connect redundant system elements through cross-channel switches;
5. Ability to interface with special processors of a different type;
6. Ability to nterface with special input/output devices.

The fact that commercial market requirements have grown to include these features makes the standard products highly competitive with special machines. However, there are performance limitations in many commercial machines which can be avoided in special machines at the expense of balanced machine operation. The areas in which special purpose processors can be superior include:

1. Instantaneous speed of input/output (bits per second per channel);
2. Maximum capacity of I/O channels (bits per second for all channels taken together);
3. Interference between memory cycles and I/O cycles;
4. Ability to do parallel processing (run many copies of the same program at once);
5. Do self-diagnosis and error correction.

With few exceptions, the special purpose processors used in military and federal civilian applications were built by the same people who build the commercial products. Therefore, there is no technical reason why the same capabilities could not be offered by them in their standard product line. Their decision not to make such products available is an economic decision.

Software and compatibility

As mentioned earlier, the computer programs required to construct and operate a complex system are beginning to dominate the project. Not only are the costs, as a proportion of project cost, increasing but the schedule impact of software development is being felt in later operational dates. The larger the programming task is, the more severe the impact is. In order to shorten the overall development schedule two steps are recommended:

1. Use existing tested software where applicable.
2. Build and test programs in parallel with other elements of the project.

These steps are facilitated by the use of commercial machines because the vendor can supply a library of tested support programs. Commercial test machines compatible with the proposed operational computer can also be obtained. The library of software for commercial machines extends beyond basic operating systems, languages, and utilities. Information handling systems which assist the user build and maintain files as well as query them are offered in versions which stress speed of retrieval and versions which provide great file handling flexibility at slower speeds. Management control support programs can be obtained which process project activity network data. Mathematical and statistical routines, output display formatters and report generators, flowchart programs, and various aids to the programmer are also found in vendor libraries.*

The process of programming consists of designing the logical set of steps to solve a problem and then coding and testing the steps. Both logical design and coding are subject to error; the errors, or "bugs" are detected by running program segments with test data. As the programmer finds and corrects the bugs he then repeats the process of design, code and test until his unit of programming is correct. Later his unit will be integrated with the programs written by others and the group of programs will be tested against the system specification. Without exception, additional errors will be detected at this point. However, it is not clear whether the new error is due to a faulty program unit, a faulty test case, a machine error, an operator's mistake, or a faulty system spec. Therefore, the analysis of the error involves a great deal of trial and error and a lot of machine time. It is very important that this process be carried out on a machine which acts exactly the way the final operational system will act if all the errors are to be found. Thus, the machine used by the programmers for debugging their program units should ideally be compatible with the machine in the operational system. Programmers need large blocks of uninterrupted computer time. Rather than sharing an engineering prototype, programmers want their own machine that will let them get started on productive work at the earliest possible time.

* Modern libraries include programs from many sources; some are available at no charge, others are sold, leased, or licensed.

Carrying this concept one step further, many programming managers are examining methods for increasing programmer productivity by giving the programmer better access to a computer and by giving him better tools at the computer. The access problem is addressed by installing a time-sharing system which allows the programmer to do his work at a terminal, cutting out the middlemen in the computer facility.* The tools question is addressed by providing programs to maintain the programmer's library and history files. With these tools, the programmer can create test data files, program files, and command files so that he can invoke a set of commands to execute a set of programs against specified test data. He can do this without handling any of the input data more than once, saving himself a lot of paperwork and a lot of running back and forth to the machine room. When the machine he is using is compatible with the final operational machine, it is a simple matter to transfer the set of completed work to the operational system to signify that he is done. When the final machine is different, there is an extensive requirement for translation, reprogramming, and retesting before the program can be accepted for the final system. In other words, *the compatibility of the support machine with the final machine shortens the time and lowers the cost of producing a final version of the programming system.*

The benefits of the compatibility concept carry over to the operational system in some instances. Several government systems have been specified in such a way as to have all programming done at a central point. In TACFIRE, an Army artillery fire control system, the programming was to be done in the U.S. and shipped to tactical installations at field locations around the world. The programs, written in PL/1, would be debugged and tested on a commercial machine in the U.S. using a compiler modified so as to create output programs in the language of the field machines. Under these conditions, it must be assumed that no changes of any type were to be made to the programs in the field. Such a system is feasible but is more difficult to manage than one in which the ability to make a change in the field exists. Compatibility between the base machine and the field machines would provide that option in systems similar to TACFIRE.

A considerable advantage of commercial machines for the fast startup of a project and for the installation of the initial capability lies in the ease of training the project staff to use the equipment. The likelihood that trained personnel can be hired to use commercial machines is high and getting higher as schools add data processing courses to their curricula. The likelihood that trained people exist for a special purpose machine is nil. Furthermore, the nature of the training for a commercial machine is identical to that offered by the vendor or any number of independent computer training schools. The training program for a special purpose processor is almost always unique and may be unsuitable for teaching institutions. The corollary of the training problem is that many people are willing to work on a general purpose machine whereas they are reluctant to accept employment to work on a unique machine. Their reasons are tied to their future career plans. Employment history shows that a computer engineer or programmer has more opportunities for advancement when he is in the main stream of the industry that when he is associated with a special purpose one-of-a-kind system.

Hardware and compatibility

There are several other factors affecting the specifications of military and federal civilian systems. Some are spurious; for instance, it is not unknown for a buyer to specify an advanced componentry because it is new—not because it is essential. This was common during the transition from vacuum tubes to transistors. Although such a spec may have been necessary to achieve a performance objective, in some situations it simply increased the risk of on-time delivery. Other specs are more significant because they reduce the system cost and reduce the complexity of the system both functionally and operationally. An example is the specification of a standard interface for connecting input/output devices to the computer. At the many Air Force and NASA ranges, for instance, there was a proliferation of special sensors to track rockets and aircraft and to process communications from space vehicles and from remote tracking stations. Acquired at different times for different purposes, the sensors had a wide variety of interfaces. Consequently, when it became evident that unified range operations would improve the support provided to all range users, a whole new set of "black boxes" had to be acquired to connect the sensors into the common network. In this respect, commercial machines are ahead of the government. Standard interfaces that allow off-the-shelf equipment of one manufacturer to interface with that of another manufacturer are the norm. Vendor specifications of their standard interface in terms of wiring diagrams and voltage levels are readily available so

* For simple debugging, the time-sharing system may look like a subset of the operational machine. The use of "virtual machines" can eliminate this restriction if required.

that it is reasonably easy to procure peripheral devices that meet the standard. This facilitates the use of other vendors' devices and permits the attachment of special purpose sensor and control devices to the central computer. The result is a capacity for horizontal growth.

Manufacturers provide for vertical growth by designing a compatible family which includes central computers of various speeds. Thus, the IBM S/360 line provides for compatible processors (each capable of reading the same programs and handling the same input/output records) that can handle anywhere from 5.33 bits per microsecond to 2370.37 bits per microsecond. While the bits per microsecond do not relate directly to performance, they do give a feel for the very wide range of capability found in a compatible family. Additional vertical growth can be obtained by increasing the amount of storage available on the central computer. This contributes to throughput by reducing the amount of traffic between the central computer and the auxiliary storage devices. Here, too, the range is enormous running from a few thousand characters to several million characters of storage in the same family. An analysis of the combined computational and information handling capability of a line such as the S/360 shows a ratio of overall performance of 36×10^6 between the very large S/360-195 and the very small S/360-20. More realistically, there is a range of two orders of magnitude in the performance of the Model 195 versus the Model 65 which would be a typical development support machine for the large processor.

The existence of compatible families of commercial machines permits the installation of a small machine for which complete software support will be available in more or less the same form as the support for a larger version of the machine so that the scaffolding developed around the small machine is directly transferrable to its successor. Thus, maximum use can be made of commercial components early in the schedule without compromising the flexibility of the system design.

Reliability and serviceability

Under the topic of reliability and serviceability are included considerations of availability (is the machine ready when requested?), reliability (does the machine function correctly?), maintainability (how long does it take to service and repair?), and modifiability (how easy is it to add a feature to correct a recurrent problem?). In engineering terms, these characteristics are often provided by redundant facilities. In some machines, the redundancy is built into each box by repeating circuits twice or three times. More commonly, the system as a whole is redundant with more than one processor connected through cross-channel switches to multiple copies of the input/output devices. When one element fails or deteriorates, it is removed from the system for maintenance and the rest of the system continues to operate. The level of redundancy is established so that the remaining equipment can handle the entire application (fail-safe) or some subset of the application (fail-soft). In addition, the software is designed to permit frequent checkpoints which copy the status of the machine so that, if a subsequent error occurs, the program can back up to the checkpoint and restart with correct data. The time required for automatic restart is small compared to the repair time of the machine and, in fact, the operator may not even notice that an interruption occurred. The ability to do these things was developed on special purpose machines but is now generally available on all major commercial machines.

The reliability which is demanded of individual units of equipment may exceed the design limits of commercial hardware. This degree of reliability, however, may be somewhat unrealistic. Enemy action, failure of sensors, or natural catastrophe might cause a system failure quite independent of the condition of the individual system elements. For instance, suppose an air traffic control system were based on data from satellite-borne sensors passed to the ground through a communications ground station. In principle, one ground station would suffice for the system. In practice, one ground station is inadequate because it could be put out of action by an earthquake, fire, aircraft accident, broken transmission line, etc. At least two ground stations are needed to make the system reliable. The additional ground stations could share the system workload or could act as backup for the prime station. In each station there could be a duplex or multiprocessor computer to increase its availability. Now the system as a whole is more likely to work properly than if there were only one station regardless of the reliability of the individual units in the single ground station. Thus, although commercial machines fail to meet the initial hardware specs of many special applications, the need for these restrictive reliability standards can be called into question in those applications where system reliability results from good system design.

Component technology in commercial hardware equals or exceeds the performance called for in contemporary special hardware. The large volume of the commercial vendors had led to the development of mass production techniques for componentry which have a high yield at very low cost. The comparable process technology for special components would require the same initial development expense without the equivalent product base against which to amortize the cost. A related benefit of mass production is that the lifetime in the field for a given family of components is quite high. This makes it economically feasible for a manufacturer to continue to produce spare parts for that component family long after new production of the machine is terminated.

The fact that commercial hardware does use production quantity components leads to a very high degree of standardization with the system. The number of different parts used is generally held down to facilitate the logistics of resupplying the field maintenance staff. A great deal of effort goes into making the system simple to maintain: extensive diagnostic aids are provided, pluggable replacement assemblies of optimum cost (trading off repair versus throwaway) are designed, multiple sourcing for parts is planned, training material is designed to be explicit yet easy to learn and understand, machines are assembled for easy access to components, etc. Commercial machines are built, wherever possible, to use standard power sources and to place a minimum burden on the user for special office conditions or construction. The commercial system development cycle includes the preparation of training programs for maintenance people as well as engineers and programmers. In most cases, a pool of experienced maintenance people exists at the time of delivery of the first field machine. Similarly, a large and adequate stock of spare parts and replacement units is placed on the shelf to meet the needs of the users. The byproducts of mass production are not obtained in special purpose computers. Here, reliability is obtained by more careful parts inspection, by designing for larger margins of safety, and by continuing operation while minor repairs are in progress. The degree of reliability achieved approaches that desired as close as the buyer's budget permits. The net result is that, in areas of service and reliability, the commercial standard is very high and, although not higher than what the government buyer wants, it is often a good deal higher than what he ends up buying.

Flexibility

The use of standards to improve the general purpose product could restrict the flexibility of commercial systems. Fortunately, this has not occurred. The standards normally apply to components and interfaces in such a way that system modification is quite easy. This can be observed in applications where one aspect of the problem must be processed at a much faster rate than other aspects. As an example, a communications satellite may store data received as it travels around the globe and then spew it out all at once when it passes over a receiving station near its home base. The data must be accepted when the satellite is overhead because there will never be another opportunity to pick up the message. In this case, commercial machines can still be applied as, indeed, they are. A special input buffer is required to collect and hold the satellite output; the buffer is a very high speed recorder. Then, at computer speed, the buffer transfers the data to the computer. In some instances, such as at missile ranges where the data stream is to be sampled before it is analyzed, the buffer may do a limited amount of data screening, editing, and summarizing before transferring the stream to the computer. This combination of an "intelligent channel" with a computer is a special case of the commercial machines' ability to interface with special I/O devices. When the input stream exceeds the computer capacity for extended periods of time, it is necessary to replace the computer with a higher speed processor. In practice, this requirement occurs with both commercial and special processors; however, the replacement is often more practical with commercial machines from compatible families.

In those problems that call for a parallel processor, several options are available. Very few problems are so well structured that, at all times, they can be subdivided into exactly the same number of identical computations. Thus, a machine like the Illiac which provides 64 parallel processors may be fully utilized only when a 64 part problem is being processed. Most problems involve some serial processes in addition to the parallel processes. For instance, in a system which analyzes seismic data to detect earthquake events, the process may start with some housekeeping to set up the input record format and allocate some memory locations to the results of the analysis. Then, by applying a transform algorithm to the input data the results can be computed and stored in the allocated space. The frequency with which the computer is asked to compute the transform may be small in the light of other jobs to be done in the facility. Therefore, instead of buying a parallel computer, the project manager will consider augmenting a standard commercial machine with a low cost Fast Fourier Analyzer box that attaches to an input channel of his computer. The speed of the FFA is only used for FFA problems; the rest of the time it is ignored.

LIMITATION OF COMMERCIAL HARDWARE

The advantages listed above are not without limits. Several limiting features of commercial machines have been mentioned but bear repeating. Others related to commercial business practice are also relevant.

Environment

A typical office environment implies a room with air conditioning and good janitorial services, plenty of enclosed storage space, space for maintenance people, etc. Such facilities are often available for military systems even when the room is inside a bombproof shelter. When the computer is in a properly shielded environment, a special effort to "harden" the computer against shock, vibration, fungus, vermin, dirt, electromagnetic and nuclear radiation, etc., is redundant. On the other hand, some machines are meant to be used on board ships, in jeeps, in aircraft, in remote locations without normal stateside services, etc. In these cases, the hardware itself may be designed to be protected against the hostile environment. The hardening takes the form of specially built components which, in general, cost more than those used in commercial products; therefore they are not found in off-the-shelf equipment except for the machines aimed at the process control market (steel mills, paper mills, refineries, etc).

It has been demonstrated many times that commercial hardware can be installed in military vehicles so that it can be transported without damage and can be operated in the vehicle given an appropriate enclosure. Transportability requirements are not uniform, however, and the degree of transportability varies from machine to machine. The most powerful machines tend to exceed the floor area of one van. Certain general trends have improved the ability of the industry to build transportable machines: smaller boxes that are easier to place in a vehicle, more liberal temperature ranges, etc. These features are evident in the reduction of setup time for a commercial machine. In the 1950s a week was allowed to assemble a large computer and check out the problems that may have occurred in the move via padded van from the factory. In 1970, a day or two is all that is required with very few problems introduced by the transport. When the same machine is to be placed in a van—as has been done in the Army CS-3 system—some additional precautions are required. Most of them are mechanical. Stiffening of the cabinets and the movable panels in the machines may be required to reduce the effects of shock and vibration. The whole machine may be mounted on shock absorbers to shield it from the environment. And a short checkout cycle may be added to the set-up procedure after the van comes to a stop and the machine is turned on. In general, the commercial machine is not operated while the transport is moving (except on board ship).

The input/output devices for the commercial market present a more severe problem in transportable systems. They are primarily mechanical devices with sensitive alignment and close tolerances between high speed moving parts. They do not stand up as well as the electronic computer. It is normal for the project manager to substitute militarized I/O devices for the commercial products in transportable installations. Specially designed disk and tapes have been built for this purpose and, by virtue of the standard interface concept, can be attached to a variety of computers. A transportable system can consist of all off-the-shelf hardware or a combination of standard processors and special peripheral devices. Thus, it is not essential to assume that all elements of a military system must be hardened. If a commercial machine is the best one for the application, it can often be installed in such a way as to be protected from the environment.

When it comes to the third class of applications where the environment is so hostile that special hardening is required, the commercial machines are no longer feasible. Machines in Class III are usually very small both physically and functionally. They are built to fit into odd-shaped spaces. They weigh very little. Their word sizes and instruction sets are smaller than those offered in commercial machines. Their input and output devices may bear no resemblance at all to the cards, tapes, and disks found in larger information handling systems. As an example, the computer in a space vehicle may be used only to calculate orbital rendezvous parameters or descent speeds and angles. Its inputs may be from instruments in the cockpit of the capsule; instruments used nowhere else except in this particular space mission. Its size may be that of a home tape recorder to permit it to fit in the astronaut's console. Its memory may be only large enough for a single computation; a new computation may require reloading of the memory by radio from an earth station. The computations it performs may be so well worked out in advance that the magnitudes of all the numbers in the computations are known; therefore, there is no need for floating point instructions in the repertoire of the computer. The programs are probably written and optimized in machine language so as to take as little memory as possible; therefore, no high level language compiler or massive operating system is called for. All these features tend to make the general purpose capabilities of commercial hardware and software unnecessary for the space computer. In fact, the bulk represented by the standard features of commercial hardware is undesirable in the space computer. On the other hand, it is essential that the space computer work when it is needed. This leads to a high degree of redundancy in the design of the system in order to increase the reliability, availability, and fail-safe characteristics of the system. Since, in the example of the space capsule, there is no practical way to maintain or repair the computer, it is possible to design the computer to be discarded on failure and replaced by a spare. Obviously, the priorities for a system of this type are quite different from those set for commercial computers. These *priorities make specialization an asset in the third class of application where it is a penalty in the other two classes.*

On the other hand, some applications in Class II call for the same environment as Class III even though they require the functional capabilities of Class II machines and programs. Examples are surface and undersea naval applications, airborne applications or airborne back-up for ground based systems, and long duration manned space laboratory missions. Some of the applicable specifications might be:

1. Dimensions — 26″ × 48″ × 66″ for passage through watertight hatches
2. Weight—45# per box for 2-man lift
3. Temperature and Humidity—operate in shelters with interior temperature 60°-90°F, relative humidity 15-95 percent, operate for limited periods at −65° - +125°F, non-operating exposure to −80° - +160°F.
4. Other—withstand salt, fog, rain, sand and dust, sunshine, fungus, high altitude, 5g vibration, 30g shock, vermin.

It is not cost effective to design normal commercial hardware to withstand these extreme conditions. However, it is possible to build hardened machines to specs that are compatible with commercial machines. This will permit the benefits of commercial support in the development process to be realized. It may also facilitate communication between hardened systems and normal systems; i.e., a ground based command center and its airborne alternate.

Commercial practice

The project manager who is convinced that commercial data processing is appropriate for his project may find that there are some obstacles to his getting what he needs. The practice in the industry is to withhold information on advanced developments until the machines are fully tested and are ready for public announcement. Prior to this time, the existence of a suitable machine may be unknown to the project manager. His best move in these circumstances is to make his needs known through an industry briefing. Then, by agreeing to protect the proprietary rights of the vendors, he can obtain the advanced information for use in his decision process.

There is a tendency for government project managers to schedule the system so that they get to install the very first machine of a new product line. Although the vendor does a very thorough job of factory test, the first one or two machines off the production line are still liable to have bugs in them. The project manager would be better off to downgrade the glamour of the first installation and place more weight on the stability of the later machines in the production line.

A commercial machine is suitable for a government system when it meets all the requirements of the government system. However, the commercial machine was designed for a broader market than the single government application. It contains many features in addition to those needed by the project. There are two disadvantages and one advantage to this. The cost of the unnecessary features is included in the price of the machine. The cost is not restricted to the acquisition price of the machine. The added features also take up space and use up time in the operational system. This disadvantage is offset by the fact that the commercial machine is usually much less expensive than the special purpose alternative. In some critically timed real-time systems, the added features must be removed. This problem ties in to the second disadvantage. The more features a machine has, the more complex it is and the more things that can go wrong with it. The effects of complexity are controlled by good system development procedures but their impact on operations and maintenance cannot be ignored. The advantage of the added features found on commercial machines is that the programmers can usually find ways to use the features to improve the system software.

There are other features that are generally useful in government systems which are seldom found in commercial machines. The average business data processing application does not call for them. An example is the ability to remove a unit of the computer for service without interrupting the computer operation. The ability to reconfigure around a failed unit has been provided with some commercial systems but they are designed to stop while the unit is removed and then restart with some manual intervention to describe the new configuration. In systems with enough redundant elements to permit continuous operation there is no reason to stop the computer to remove a unit; however, special modifications may be needed to prevent the computer from automatically stopping under these conditions. The modifications essentially place a switch in the hardware that isolates the failed unit electronically the same way a switch in the software permits the logical rearrangement of boxes.

When the project manager recognizes the need for a modification to the commercial machine there is generally no great problem in designing and installing the change. However, the industry business practice may increase the cost impact of that change. The normal maintenance of commercial hardware and software has been designed to give maximum service at minimum cost. This is achieved by standardizing the training and diagnostic aids given the service personnel. A corollary of this approach is that the serviceman is not well equipped to understand user modifications to the hardware or software; therefore, his service commitment may be modified or even voided by certain types of modifications. The protection against loss of service is simple; the project manager and the service supplier should mutually agree to a service agreement which spells out the extent of the service commitment and alerts the manager in advance of the exposure he has. The reverse of this situation may have similar impact. The vendor of commercial hardware normally makes engineering changes to the machines over a period of years. The purpose of the changes is to correct minor problems, facilitate service, reduce failure rates, etc. The changes are transparent to the user except in cases where the user has modified the hardware. The project manager must be prepared to trade off the benefits attributed to the engineering change against the value of his modification.

CHARACTERISTICS OF THE DEVELOPMENT PROCESS

The systems included in the second class above are dominated by large real-time information handling systems—SAGE, Air Traffic Control, SAFEGUARD, TACFIRE, Naval Tactical Data System, Marine Tactical Data System, Apollo, Orbiting Astronomical Observatory, National Military Command System, Intelligence Data Handling System, etc. *The consequence of size is complexity.* There are so many interactions among the elements of a large system that no one man has the ability to comprehend and manage the total entity. As a consequence, the system is organized into subsystems and smaller components to limit the span of control of each manager to a scope that he can handle. The step by step delineation of system components changes the focus of attention from the system itself to the parts of the system. As a result, the structural interactions which define the system may not get enough attention to ensure their integrity.

Project control

The concept of "change" is basic to system development. It is unrealistic for a system manager to assume that the objectives established at the outset of a project will be unaffected by changes in the environment or in the detailed plans for implementing a given function. Rather than be crippled by an inflexible plan, the manager establishes procedures which permit the formal modification of his baseline specification by changes which are agreed to by all affected parties. Such a set of procedures protects the system against arbitrary changes but permits necessary changes. In order to be effective, the change control process must be able to determine the interactions of each proposed change with the rest of the system.

The government calls the control procedure "configuration management" and provides vendors with guidelines for describing the work breakdown and keeping track of the base specification. For a large system, it takes about ten years to reach the operational phase of the cycle. Lots of things change during that period which can upset earlier commitments. Brigadier General W. R. Reed, U.S. Army, suggested how serious the problem can be when, after eight years of a study and design effort, it was realized that changes had occurred in computer technology that had a profound impact on the environment being studied. In fact, he estimated that computers improved by a factor of ten every 3.8* years. Such an order of magnitude improvement required a new definition of the environment in which the computers were to be used. Gen. Reed was talking about the Army tactical fire control system, TACFIRE, which in eight years had been obsoleted twice before it ever reached the acquisition stage until 1968 by which time its specs were again being overtaken by new technology. The guideline implied by this situation is that computer specs should not be frozen early in the system definition stage since they will probably have to be redone later.

Postponing the actual computer decision does not impede the progress of the system. The data processing subsystem can be described in terms of the functional and performance characteristics desired. These characteristics can then be incorporated into a model of the subsystem which can be exercised to evaluate the design concept and predict the performance of the actual hardware when it is selected according to the

* As compared to my estimate of 5 years. The rate of computer improvements is hard to determine but remarks by Lowell D. Amdahl, president of COMPATA, Inc., at the June 1970 meeting of the IEEE computer group indicated that Gen. Reed's figures have not changed substantially since 1962.

approved design. The model is a computer program which can be run on a standard commercial machine. (This technique, used with great success in the Apollo program, has added value when the computer used to exercise the model is compatible with the computer ultimately procured for the system. When this is the case, parts of the model may be reusable in the ultimate system.)

The model is a design aid and may be thrown away after the total system goes into operation. Preferably it is retained as the basis for continuing improvement of the operational systems. Nevertheless, it is never more than a part of the scaffolding required to support the system builders. Other parts of the scaffolding for a data processing subsystem are test programs and data generators; input/output simulators; computer services for running engineering problems and debugging programs; compilers, sorts, and other programs to prepare system programs for execution; controlled libraries to separate work in process from released work; project control administration and analysis (as in PERT); and many other activities both technical and managerial. *The optimum environment—from the standpoint of project control, training, cost, and testing—is one in which the same computer family is used for all functions of control, support, and ultimate operations.* The advantage of sticking with one computer family throughout the life of the project is that predictable results can be achieved on schedule without the distractions posed by a new, incompatible machine.

System development guidelines

Various guidelines are generally accepted as constructive when dealing with large systems. One such guideline attempts to strengthen the system structure without tying the hands of the component developers. It calls for the design to be done from the top down. That means that the structure of each level of the system is designed before the details of the next lower level are developed. Top down design is an effective device for identifying and controlling the interfaces within the system. In addition, this approach minimizes the constraints on the component designers because it provides them with a set of functional and performance objectives for their area of responsibility without telling them how to build their specific "black box". Since each element of the system is simply a "black box" to the level above it, a different black box with the same external characteristics can be substituted for the original element without making any other changes to the system. This is one reason why it is feasible to use a simulated environment during the development of a system; simulated black boxes are used until the real thing is available. Such design flexibility is essential during the design stages of the system specifications.

Phased implementation

Aware of the need for adapting to changes in the system design, the system requirements, and the system environment, experienced system managers lay out a phasing plan which will reach the final system in useful steps. They start with an initial operating capability (IOC) to get a minimal capability for meeting operational requirements and to provide an environment in which to test out the design concepts for the operational system. Only by installing an IOC can the designers evaluate their ideas against realistic man-machine tests and modify the final system to overcome the weaknesses observed in the IOC. The existence of the IOC often leads to more pervasive changes to the system design as well. Considering the long lead time for most large systems, the original requirements statement is often out of date when the IOC is installed. Top management does not realize this until they try to use the IOC. Then they observe that some of the things they asked for are not appropriate to the problems they face today. In addition, for the first time they have an opportunity to observe how the data processing system can contribute to their decision making functions. This leads them over a period of time to restate the functions assigned to the computer so as to take advantage of its speed and flexibility. Invariably, their new definitions of the computer workload place more work on the machine and less on the user. Therefore, it is normal for the final operational system to represent an upward growth from the IOC.

Recognizing that the IOC is a test vehicle, not the ultimate system, it should be installed at the least expense but in a form that is easily modified. The best way to minimize the cost of the IOC is to acquire a commercial computer. In this situation, the original design and development costs have been borne by the vendor and are distributed equitably among all the users of that computer. A special purpose machine in the IOC passes all the design and development costs as well as the manufacturing cost along to the single buyer.

The decision to select off-the-shelf hardware for a government system affects the balance of the system plan. The timing of the decision to use commercial data processing equipment should be made in the system definition phase of the development cycle. It should occur after the overall system design and all of the subsystem functions have been defined and before the subsystem component specifications are complete. Having decided to use commercial technology, the actual selection of a machine should be deferred until the start of the acquisition phase to take advantage of the latest available technology. As stated earlier, the system specifications can be written around function and performance objectives rather that detailed characteristics of the data processor so that the delayed procurement does not slow up the design process. By selecting a machine that is part of a compatible family of computers, the manager can allow for future growth requirements. To achieve the benefits stated earlier, the manager must verify that the compatible family includes basic software packages, that the maximum capacity machine in the family is large enough to permit substantial vertical growth, and that the family has a published standard interface.

SUMMARY AND CONCLUSION

Most of the performance and reliability specifications for military and federal civilian applications can be handled by one or more machines available off-the-shelf. With minor modifications to their functional capability, addition of special I/O boxes, and installation in suitable enclosures, the commercial machines can generally fit all the requirements of ground-based application areas. In fact, because of the family characteristics of many commercial machines, they outperform the typical special purpose machine with respect to growth capability and cost effectiveness. The delivery schedules for commercial machines are substantially more reliable than those for specially engineered equipment. Although the first machine delivery off the production line in commercial practice may vary from schedule by several months, subsequent deliveries are sufficiently certain to permit vendors to accept penalty clauses for late delivery as a normal business practice. By comparison, special machines have been as much as three years late with delays of one year from the projected schedule occurring with some frequency. The reason for the delays is seldom poor workmanship on the part of the builder. Most of the time it is due to the fact that changes to the machine specs occur during the machine development cycle which cause rework and rescheduling. The commercial machines have been fully specified before they are announced and before delivery commitments are accepted; therefore, the specs are not subject to change in the same way. The price of commercial machines is more stable than the price of the typical cost-plus special machine; again, because of the different impact of product changes. More important to the integrity of the application, commercial machines have already passed stringent product tests before they are announced for sale. The project manager can have very high confidence that a machine that meets his requirements on paper will perform properly in fact. He cannot have the same level of confidence in a special purpose machine since he must commit himself to its design specs without any assurance that the machine so specified can be built and, if buildable, will perform exactly as planned. His ability to predict these things at procurement time simply falls far short of his ability to predict—and measure—the same things on off-the-shelf systems. At the same time, he is able to compare his requirements to the offerings of several competitive vendors in the commercial market in order to select the least expensive system for his project.

Risk reduction is a key advantage in the eyes of the project manager. In addition, the advantages in the development process are significant. The fact that a test cell can be established for the engineers and a separate support machine can be set up for the software team contributes to shortening the system schedule. The testing itself becomes less risky. Because the computer and its vendor software have been extensively tested before shipment, the application programmers can simplify their test detective work by assuming that the commercial data processing subsystem are error-free; therefore, errors must lie in the application programs or test cases. The assumption will not always be valid but the order it imposes on the error analysis procedure will speed up the process. In particular, the assumption that the various programs in the system have been fully debugged directs the attention of the test team to the interactions among the components where it belongs and away from the internal workings of each program unit.

Since systems are built and used by people, a major effort in any system development involves the training of the development team and the operational and maintenance teams. The earlier the training can start the better as long as the material taught is truly representative of the final operational system. When using commercial machines, the knowledge that the machine and its software are well defined permits training in this area to begin immediately after the procurement decision. Effective training can be procured from a variety of sources without the need for structuring a permanent educational office in the project. Moreover, the computer time needed for the trainees can be obtained on the vendor's machine (which, by definition, will be compatible with the project machine) without interfering with the test activities on the project machines.

The project manager concerned with meeting a set of operational objectives at minimum cost on a firm schedule must minimize the risk associated with each element of his system. By specifying commercial data processing subsystems he can satisfy his functional and performance needs in the large class of command and control applications as he has traditionally done in administrative applications. He will accomplish this with less cost, equal or higher performance in both the development cycle and in the operational installations, simpler logistics, and with much less risk of slippage or overrun. A general guideline to follow, contrary to past practice, would be that *commercial data processing should be used in all cases except those in which there is a specific obstacle to prevent them from doing the job.*

Programming language efficiency in real-time software systems

by J. O. HENRIKSEN

R. E. MERWIN

SAFEGUARD System Office of U. S. Army
Arlington, Virginia

INTRODUCTION

Early in the development cycle of a real-time software system, the designer must select one or more programming languages to be used in writing the system. As shown in Figure 1, there is available today a continuum of programming languages ranging from "high-level" languages like PL/I to "low-level" traditional assembly languages.

At the present time, high-level languages are widely used in conventional scientific and commerical software production, while low-level languages are widely used in the development of real-time systems. The wide acceptance of high-level languages in conventional applications may be attributed to favorable cost-performance tradeoff. Given an application whose data and program structures can in a reasonable straightforward manner be represented in a high-level language, use of the high-level language will result in conservation of human resources at the expense of machine resources. Real-time systems represent a class of applications where machine performance becomes a critical resource. In this case, factors other than fiscal cost of the machine resource become dominant. As a consequence, the program and data structure of a real-time system must be hardware motivated and any programming language used to implement such systems *must* allow the programmer to fully exploit the characteristics of the hardware. Since the design of program and data structure is hardware-motivated, artificial software restrictions, in the form of language limitations, are unacceptable. Such considerations have given rise to a new type of programming language, called "systems implementation language." The systems implementation language in effect attempts to represent a *range* on the continuum of programming languages. It permits the programmer to readily access and exploit hardware features, but allows him to perform the bulk of his coding by utilizing a less cumbersome higher level language. There are several attempts to analyze programming languages described in the literature.[1,2,3] In the sections which follow, an investigation is described in which representative programs from a phased-array radar real-time software system are coded in selected programming languages. Performance measures are described, results tabulated, and conclusions are drawn on the basis of these results. This investigation was carried out under the sponsorship of the SAFEGUARD System Office of the U.S. Army by Brown University,[4] the System Development Corporation,[5] University of Michigan,[6] and the Westinghouse Corporation.[7]

MODUS OPERANDI

Three existing programs developed to control the phased array radar used in the SAFEGUARD Anti-Ballistic Missile System test program on Kwajalein Atoll were selected as typical examples of real-time software. A functional description including flow charts and data sets was prepared for each of these programs based upon the actual assembly language code for the equivalent function produced for the SAFEGUARD data processor. From the supplied functional descriptions, the study participants constructed programs in various languages and ran standard sets of test data

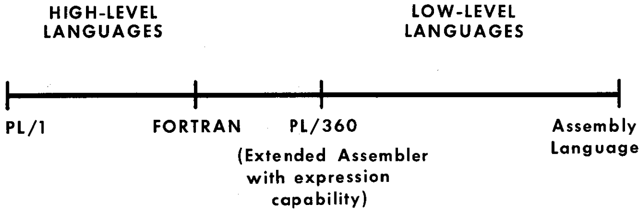

Figure 1—Continuum of programming languages

for performance measurements. Five languages; PL/1, FORTRAN-IV-H, JOVIAL, Brown University's Language for System Development (LSD), and IBM 360 basic assembly language were compared in performance runs on IBM 360-67 hardware. FORTRAN-V and SLEUTH assembly language were compared on the UNIVAC-1108. Of the languages compared, PL/I, FORTRAN-IV, and V are selected as representative high-level languages, JOVIAL as a precursor of systems implementation languages, LSD as systems implementation language currently being developed, and IBM 360 basic assembly language as a baseline for performance measurement.

ALGORITHM DESCRIPTIONS

GETTASK

The first algorithm modelled, GETTASK, is a task dispatcher for a single task list multi-processor. In the system studies, tasks are related in PERT-like networks such as the one shown in Figure 2.

In such a network, the completion of Task #1 allows the simultaneous execution (if 3 processors are available) of Tasks 2, 3, and 4. In general, a given task may have any number of predecessor tasks which must be completed prior to its running, and a task may have an arbitrary number of successors. In the case where more than one task is eligible to be run at the same time, a priority scheme is used to assign a task to a processor.

The implementation of such a precedence network is achieved by use of absolute enablement bits (AEBs) and conditional enablement bits (CEBs). Associated with each task is a CEB word, an AEB, and a successor list. Each element in a successor list contains a pointer to another task's CEB word and a mask to be logically ORed with the CEB word. In the example above, the successor list for Task #1 would contain pointers to Tasks #2, #3, and #4. Each CEB in a CEB word corresponds to a unique precedence condition. For example, the CEB word for Task #5 in the above network would have one bit to be set upon completion of Task #2 and another upon completion of Task #3. Each time the logical OR is performed, a check is made to see if all CEBs are set to 1, and if so, the AEB for the corresponding task is set to 1, indicating that the task is ready for dispatching. The system is general enough to allow enablement of tasks as a function of time or system conditions by allowing certain dedicated bits to be set only by the operating system.

EXLIGEN

The second algorithm modelled, EXLIGEN, is a portion of a radar control program execution list generator which converts requests for radar transmissions, according to time and type, into a fast access execution list format for later processing. Scheduling of transmissions is done on a cyclic basis: a request made in cycle n is handled by the scheduler in cycle n+1 and actually transmitted in cycle n+2. A master "menu" of allowable transmissions is available to several subsystems within the radar control program, and it is possible that these subsystems can make conflicting transmission requests. The list generation algorithm is carried out in two passes: in pass 1, a scan is made of all requests in order of increasing time, and requests are consolidated according to request type; and in pass 2, a list is constructed and ordered by priority of request type with certain requests of the same type consolidated into single list entries.

UPDATE

The third algorithm modelled, UPDATE, is a portion of a Kalman filter algorithm used to filter radar return data. On the basis of signal-to-noise ratio in the radar returns, weights are calculated to be applied to the current radar observations, and using these weights, a

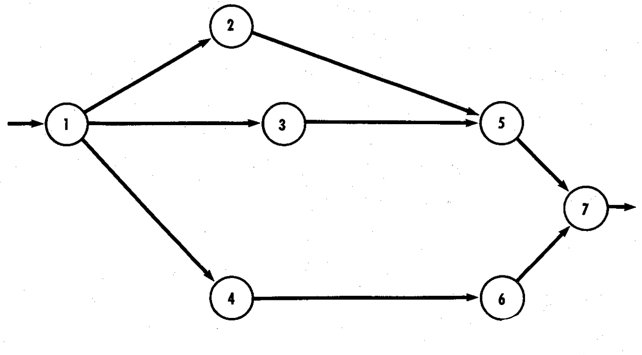

Figure 2—Task precedence lattice

state vector for an object in track is updated. The algorithm is completely described by recursively applied equations, which are amenable to solution in any FORTRAN-like language.

SUMMARY OF RESULTS

The results of the individual comparative studies submitted by the four participants are shown below. The four performance cirteria chosen were, number of source statements, number of object instructions, number of storage words required to contain the programs and data, and program running times. Comparative number of source statements reflect ease of expression in the two languages, i.e., a program that requires more source statements in one language than another is less naturally expressed in this language. Comparative numbers of object instructions are a partial measure of translator efficiency but do not reveal the impact of run-time routines called by the translator. Comparative object code storage requirements of language translators reflecting storage efficiency represents usage of a critical machine resource in most real-time applications. Specific comments on these criteria are included in the discussion of each study results.

The University of Michigan

The Michigan study was carried out on an IBM 360/MOD67-2 computer with 1.5M bytes of storage and compared FORTRAN, PL/I, and IBM 360 basic assembly language. In addition to coding the three algorithms with a "strict" interpretation of the original data structure, Michigan investigators carried out a redesign of the data structures used in GETTASK and EXLIGEN. The revised implementations, using redesigned data structures, were functionally equivalent to the original descriptions but exhibit enhanced translator performance.

Results, as presented in Table I, show a marked superiority of assembly language programs on the IBM 360. On the average for all cases tested, FORTRAN programs ran 2.7 times as long, and PL/I programs 7.4 times as long, as the corresponding assembly language programs. Results similar to this were noted in a benchmark study [8] which compared assembly language and FORTRAN on several large current systems. While the PL/I language offers a great deal of generality in the range of problems and data structures it can handle, it is at the expense of performance. Because of the wide range of the language,

producing an optimizing compiler is difficult, and the language has not had a long enough history to reach the state of development of compilers for other languages. One of the big disadvantages of FORTRAN and even PL/I is that the languages do not have syntactic forms which correspond directly to powerful hardware capabilities, i.e., the hardware is too highly masked by the use of these languages. For FORTRAN, the narrow range of syntactic forms appears to be the biggest weakness. On the whole, for the problems studied, FORTRAN appeared to produce reasonably efficient code for the statements allowed in the language, but the range of available statements was clearly restrictive to the programmer. The best performance of FORTRAN and PL/I was on the algebraic UPDATE program, which reflects that UPDATE was the most naturally expressed (in these languages) of the three problems.

The improvements in performance obtained by redesign of the data structures are interesting to note. For all languages, data structure redesign yielded performance enhancement, but the improvements obtained were substantially greater for FORTRAN and PL/I. This simply illustrates the fact that performance in high-level languages suffers as program and data organizations become more and more removed from basic structures in the languages. Since program and data organization in real-time systems are often dictated by hardware organization and data formats, applicability of high-level languages may be relatively low.

SDC

The SDC Study was performed principally on an IBM 360/MOD67 and additionally on the UNIVAC 1108 and CDC 3800 using the JOVIAL language. The goals of this study were to exhibit performance for another language on IBM 360 equipment and to explore the ease of transferability of software between dissimilar machines. The JOVIAL language exhibits a great deal of flexibility in definitional capabilities for data structures. It represents a substantial improvement over FORTRAN in this respect, but is not quite as wide ranging as PL/I. The JOVIAL language also allows a programmer to insert assembly language instructions into a program in order to utilize the hardware features he may desire. JOVIAL does not have (in

the IBM 360 version) optimization features which are as extensive as those of FORTRAN-IV-H, but produces "reasonable" code, certainly much better than that of PL/I. Performance of IBM 360 JOVIAL is given in Table II. The numbers shown may be meaningfully compared with the University of Michigan numbers for the strict data structures. As one might expect, JOVIAL performed better than FORTRAN-IV-H, much better than PL/I, and worse than IBM 360 basic assembly language in the GETTASK and EXLIGEN problems. In the UPDATE problem, however, the optimizing features of FORTRAN-IV-H enabled it to outperform JOVIAL.

The algorithms were executed on the UNIVAC 1108 and CDC 3800 by simply changing the data definition statements to account for different word sizes. Additionally, driver programs had to be altered because of differences in system input-output and timer routines. The significant fact is that with the exception of "direct" assembly language statements in GETTASK, no executable statements in the programs required change. The framework for carrying out such a transfer to a different machine is relatively easily used, as illustrated by the fact that the CDC 3800 conversion was done as a minimal effort by a programmer unfamiliar with the original IBM 360 JOVIAL version.

Brown University

The LSD language is being developed by Brown University as a systems programming language for the IBM 360. LSD is syntactically similar to PL/I, but not nearly as broad in scope. It is specifically tied to the organization of the IBM 360 hardware, for example, the 16 general purpose registers of the IBM 360 can be directly referenced and manipulated in LSD statements. The design philosophy of LSD can be summarized by saying that it attempts to make the hardware readily accessible to the programmer while retaining the ease of usage of a high-level language. In order to produce optimal code, the programmer *must* be thoroughly familiar with IBM 360 hardware, as only the simplest forms of optimization are performed by the compiler.

The Brown University investigators used University of Michigan implementations of the three programs as a starting point. PL/I statements were then transliterated into LSD statements by means of an automatic transliteration program. Results for compilation of the resultant LSD source code are shown in Table III under the column labeled LSD-I. The data generated for EXLIGEN by LSD could not be verified and should be regarded as tentatine. Next, the investigators carried out an optimization of the LSD code at the source

level for the UPDATE program, taking advantages of facilities not provided by PL/I. The results are shown in column labelled LSD-II. University of Michigan FORTRAN-IV and PL/I results are included for purpose of comparison. Timings shown for Brown University results have been adjusted upward by 10 percent from the measured values on an IBM 360/MOD67I-1 in order to make them directly comparable to the timings obtained on the University of Michigan IBM 360/MOD67-2 (1.5M Bytes Storage).

Westinghouse

The Westinghouse study was performed on the UNIVAC 1108 and compared with the SLEUTH assembly language with FORTRAN V, UNIVAC's highly-touted optimizing FORTRAN compiler. Two programmers were employed, one coding only in FORTRAN and the other only in SLEUTH. They designed, together with the project supervisor, compatible data structures so that a single driver program could drive either the FORTRAN V or SLEUTH versions of a particular algorithm. The data structures were amenable to problem solution on the UNIVAC 1108 and were not the same as data structures originally developed for the SAFEGUARD data processor.

On the whole, the performance of FORTRAN V as shown in Table IV was of surprisingly high quality. The design of compatible data structures for SLEUTH and FORTRAN V appears to have been slightly slanted toward FORTRAN, i.e., to force the SLEUTH programmer to use a data structure that can also be used by FORTRAN (especially in the areas of manipulating data pointers) is somewhat of a handicap. For the UPDATE algorithm, which was purely algebraic in nature, relatively good performance was expected from FORTRAN. The algorithm was a relatively small piece of code and was simple enough to be easily handled by a compiler, i.e., assembly code "tricks" could not be employed to any significant advantage. In actual performance, the FORTRAN version ran significantly better than the SLEUTH version. If the SLEUTH version were to be recoded using the FORTRAN version as a guide, it is probable that it could be made to perform better than the FORTRAN version. The significant fact is that in the time frame allotted to this study, FORTRAN actually produced a better program, reflecting that in certain cases a cleverly written compiler can actually surpass human performance.

CONCLUSIONS

The following conclusions relative to the performance in terms of efficient object code production and CPU running times for programming languages, i.e., high-level or assembly, are drawn from the results summarized above.

(a) If CPU running time and storage utilization are the primary criteria for evaluation, assembly language coding is distinctly superior to high-level languages available today.

(b) System's Implementation Languages, which appear to offer the advantages of high-level languages with respect to reducing software development costs, also produce object code with efficiency approaching that of assembly languages. This performance improvement, largely achieved by allowing programmers to take advantage of system hardware features, implies a machine dependence of such languages and loss of transferability of programs written in these languages from one computer architecture to another.

(c) Careful design of program data structures can greatly improve the performance of present-day higher-level languages in production of efficient object code.

(d) The production costs associated with high-level languages are lower, up to a threshold at which specific desired manipulations cannot easily be made in the language.

(e) Transferability is easily achieved in high-level languages, provided that direct usage of machine dependent characteristics is carefully controlled.

(f) Data structures designed for a particular machine architecture must be modified if any kind of efficiency is desired in transferral to another machine architecture.

(g) The "ideal" high-level language must allow flexibility in data definition capabilities as JOVIAL does and FORTRAN IV does not, but be realistic in scope, as PL/I is not.

ACKNOWLEDGMENTS

The programming language efficiency study was carried out by four groups under the overall guidance of the authors. The study directors were Prof. B. Arden, University of Michigan; Mr. P. Waszkiewicz, Westinghouse; Mr. R. Knight, SDC and Prof. A. Van Dam, Brown University. The coding was done by Mr. J. Hamilton, University of Michigan; Messrs. G. H. Rouillard and R. L. Specht, Westinghouse; Mr. R. Brunstrum, SDC and Messrs. R. D. Bergeron, J. D. Gannon and J. V. Guttag, Brown University.

A review of recursive filtering algorithms

by BERNARD FRIEDLAND

The Singer Company
Little Falls, New Jersey

INTRODUCTION

The recursive filtering theory introduced scarcely a decade ago by Kalman[1,2] and Kalman and Bucy[3] has been widely hailed as a major development in data processing, perhaps as important as the work of Weiner[4] on linear filtering.

The introduction of Kalman's filtering theory could not have come at a more propitious time. The theory was expressed in the vector-matrix notation which had only recently been introduced to control engineers, and problems to which the theory was applicable were known to many investigators. Perhaps the most important reason for the almost immediate reception of the theory is that it is expressed essentially in the form of a computer program—in other words, it is naturally suited to implementation on a high-speed digital computer. Digital-computer implementation of earlier filtering and smoothing algorithms, on the other hand, did not seem to be very promising.

The fundamental result of Kalman's first papers can be stated fairly concisely: consider the discrete-time dynamic process evolving according to the "transition equation"

$$x_{n+1} = \Phi_n x_n + \Gamma_n u_n \tag{1.1}$$

where

- x_n is the "state vector" of the process at the nth instant of observation
- u_n is a vector of random excitations
- Φ_n is the (known) "transition matrix"
- Γ_n is a known matrix

Suppose that noisy observations y_n of the state are made in accordance with

$$y_n = H_n x_n + v_n \tag{1.2}$$

and, further, that u_n and v_n are gaussian, independent of each other and of u_k and v_k for all $k \neq n$. The *optimum estimate* $\hat{x}_n$ of x_n, given $y_n, y_{n-1}, \ldots$ can be expressed by means of the recursion equations

$$\hat{x}_n = \tilde{x}_n + K_n(y_n - H\tilde{x}_n) \tag{1.3}$$

$$\tilde{x}_n = \Phi_{n-1}\hat{x}_{n-1} \tag{1.4}$$

where

$$K_n = \tilde{P}_n H_n'(H_n \tilde{P}_n H_n' + R_n)^{-1} \tag{1.5}$$

$$\tilde{P}_n = \Phi_{n-1}\hat{P}_{n-1}\Phi_{n-1}' + \Gamma_{n-1}Q_{n-1}\Gamma_{n-1}' \tag{1.6}$$

$$\hat{P}_n = (I - K_n H_n)\tilde{P}_n \tag{1.7}$$

in which (′) denotes matrix transposition,

Q_n is the covariance matrix of the excitation noise u_n, i.e.,

$$Q_n = E[u_n u_n']$$

and

R_n is the covariance matrix of the observation noise.

The recursive nature of the Kalman filtering algorithm and its immediate translation into a computer program is illustrated in the flow chart of Figure 1a.

The reader may have noticed that the sense in which the estimate, computed by the algorithm defined by (1.3)-(1.6), is optimum has not yet been defined. This omission is intentional, because, quite remarkably, the estimate is optimum in every reasonable sense: it is the least-squares estimate, the minimum-variance estimate, and a maximum-likelihood estimate. It is also the conditional mean given the observation data, i.e.,

$$\hat{x}_n = E[x_n \mid y_n, y_{n-1}, \ldots]$$

The other quantities in (1.3)-(1.7) also have statistical

significance, namely:

$\tilde{x}_n = E[x_n \mid y_{n-1}, y_{n-2}, \ldots]$, conditional mean of x_n, prior to observation y_n

$\hat{P}_n = E[(x_n - \hat{x}_n)(x_n - \hat{x}_n)']$, conditional a posteriori covariance matrix

$\tilde{P}_n = E[(x_n - \tilde{x}_n)(x_n - \tilde{x}_n)']$, conditional a priori covariance matrix

It is noted that the covariance matrices $\hat{P}_n$ and $\tilde{P}_n$ and hence the gain matrices K_n are independent of the observation data. Hence the latter can be computed off-line and stored for on-line implementation of (1.3) as indicated in the flow chart of Figure 1b. When u_n and v_n are correlated, Kalman's recursive filtering algorithm is somewhat more complicated and uses the covariance matrix $C_n = E[u_n v_n']$. The more general algorithm is given in References 1 and 2.

Figure 1b

Although recursive filtering is informally called "Kalman filtering," there is considerable dispute among the cognoscenti over who really deserves to be credited with the actual discovery. It would appear that the essentials of the theory were "in the wind" for several years prior to the appearance of Kalman's original paper and hence may have been discovered independently and published internally by several investigators just prior to the presentation of Kalman's paper at the 1959 Joint Automatic Control Conference. Earliest actual publication in a technical journal is claimed by Swerling,[5] and it is generally agreed that this is the earliest appearance of this theory.

DEVELOPMENT OF THE THEORY

The appearance of a new analytical technique of general utility is likely to engender a large number and variety of other studies. Recursive filtering is no exception: hundreds of papers and several textbooks have been written on this subject. Theoretical papers which have appeared since the original work of Kalman and Bucy treat with one or more of the following subjects.

- Alternative developments of the basic results and relationships with other subjects.
- Extensions to nonlinear and/or nongaussian processes.
- Subsidiary analysis of (usually messy) details.

Alternate developments of the theory

The fact that the estimate produced by the recursive filtering algorithm is optimum in many ways suggests also that there are many ways in which the same result can be derived. This is the case precisely: there seems to be as many different ways of deriving the results as there are users thereof; one ventures to say that every user has derived the results for himself at one time or another.

Kalman's original derivation makes use of a theorem on orthogonal projections for gaussian random variables and in the opinion of many investigators was unduly complicated. In the years that followed, derivations appeared which did not require all the mathematical apparatus used by Kalman.

The essential features of the recursive filtering algorithm can be developed without recourse to statistical concepts: the standard method of least squares and some ordinary matrix algebra are all that are needed to establish the basic relations. This development follows the line of reasoning suggested by Swerling[5] and is well-known to workers in the field. Because the derivation is fairly simple and will be useful for further discussion, we will present it here.

Suppose that the random excitations u_n on the process (1.1) are absent and it is required to determine the initial state vector x_0 on the basis of observation vectors $y_0, y_1, \ldots, y_n$. Using (1.1) and (1.2) it is seen that

$$\begin{aligned} y_n &= H_n\Phi_{n-1}\ldots\Phi_1 x_0 + v_n \\ &= H_n F_{n-1} x_0 + v_n \\ y_{n-1} &= H_{n-1}\Phi_{n-2}\ldots\Phi_2 x_0 + v_{n-1} \\ &= H_{n-1}F_{n-2}x_0 + v_{n-1} \\ &\vdots \\ y_0 &= H_0 x_0 + v_0 \end{aligned} \tag{2.1}$$

where $F_n = \Phi_n \ldots \Phi_1$. These equations can be concatenated into the single matrix equation

$$Y_n = M_n x_0 + V_n \tag{2.2}$$

where

$$Y_n = \begin{bmatrix} y_n \\ \vdots \\ y_0 \end{bmatrix} \quad M_n = \begin{bmatrix} H_n F_{n-1} \\ \vdots \\ H_0 \end{bmatrix} \quad V_n = \begin{bmatrix} v_n \\ \vdots \\ v_0 \end{bmatrix}$$

Suppose that for n sufficiently large, there is enough data to determine x_0. Then (2.2) will have a unique solution if there were no measurement errors. If there are more equations in (2.2) than components in the initial state, then (2.2) can be solved by means of weighted least squares. It is well-known that to minimize the quadratic form

$$Q = (Y_n - \bar{Y}_n)'W_n(Y_n - \bar{Y}_n) = V_n'W_nV_n$$

where Y_n is the observed sequence, $\bar{Y}_n$ is the sequence which would be observed in the absence of errors, and W_n is a (positive-definite, but otherwise arbitrary) weighting matrix, the optimum solution to (2.2) is

$$x_0^{(n)} = (M_n'W_nM_n)^{-1}M_n'W_nY_n \tag{2.3}$$

The superscript (n) on x_0 indicates that this is the initial state estimated on the basis of n measurements, and (2.3) is the standard, nonrecursive least squares formula. If the number of observations is large, the matrix M_n is correspondingly large: hence a fairly extensive calculation may be required to evaluate (2.3). Moreover, the calculation must be repeated each time a new observation or group of observations is to be included. Wouldn't it be convenient if the result of calculating the $(n-1)$st estimate $x_0^{(n-1)}$ could be used to simplify the calculation of $x_0^{(n)}$? To do this, the matrices M_n and W_n are partitioned as follows:

$$W_n=\left[\begin{array}{c|c} R_n^{-1} & 0 \\ \hline 0 & W_{n-1} \end{array}\right] \qquad M_n=\left[\begin{array}{c} H_nF_{n-1} \\ \hline M_{n-1} \end{array}\right] \tag{2.4}$$

(Note that this implies that the weighting matrix W_n consists of diagonal blocks. R_n^{-1} represents the new matrix in W_n that was not in W_{n-1}.) Using the submatrices in (2.4) it is found that (2.3) becomes

$$(F_{n-1}'H_n'R_n^{-1}H_nF_{n-1}+M_{n-1}'W_{n-1}M_{n-1})x_0^{(n)}$$
$$=F_{n-1}'H_n'R_n^{-1}y_n+M_{n-1}'W_{n-1}Y_{n-1} \tag{2.5}$$

where

$$Y_{n-1}=\begin{bmatrix} y_{n-1} \\ \vdots \\ y_0 \end{bmatrix}$$

Note, however, that if $x_0^{(n-1)}$ were computed by least squares, it would satisfy

$$Y_{n-1}=M_{n-1}x_0^{(n-1)}$$

Accordingly (2.5) becomes

$$(F_{n-1}'H_n'R_n^{-1}H_nF_{n-1}+M_{n-1}'W_{n-1}M_{n-1})x_0^{(n)}$$
$$=F_{n-1}'H_n'R_n^{-1}y_n+M_{n-1}'W_{n-1}M_{n-1}x_0^{(n-1)} \tag{2.6}$$

Note that (2.6) is already in recursive form: $x_0^{(n)}$ is expressed in terms of $x_0^{(n-1)}$ and the new observation y_n. To put the result of (2.6) in the form given earlier, we define a matrix $\tilde{P}_n$ by

$$F_{n-1}'\tilde{P}_n^{-1}F_{n-1}=M_{n-1}'W_{n-1}M_{n-1} \tag{2.7}$$

then (2.6) becomes

$$F_{n-1}x_0^{(n)}$$
$$=(\tilde{P}_n^{-1}+H_n'R_n^{-1}H_n)^{-1}(\tilde{P}_nF_{n-1}x_0^{(n-1)}+H_n'R_n^{-1}y_n) \tag{2.8}$$

after multiplication by the inverse of F_{n-1}' (which exists since F_n is the product of nonsingular transition matrices). It is also reasonable to define

$\tilde{x}_n=F_{n-1}x_0^{(n-1)}$, estimate of x_n using $x_0^{(n-1)}$

$\hat{x}_n=F_{n-1}x_0^{(n)}$, estimate of x_n using $x_0^{(n)}$

then (2.8) becomes

$$\hat{x}_n=({}_n\tilde{P}^{-1}+H_n'R_n^{-1}H_n)^{-1}[\tilde{P}_n^{-1}\tilde{x}_n+H_n'R_n^{-1}y_n] \tag{2.9}$$

Finally, we make use of a well-known matrix identity

$$(P^{-1}+H'R^{-1}H)^{-1}=P-PH'(HPH'+R)^{-1}HP \tag{2.10}$$

for arbitrary nonsingular matrices P and R. This reduces (2.9) to

$$\hat{x}_n=\tilde{x}_n+K_n(y_n-H_n\tilde{x}_n)$$

with

$$K_n=\tilde{P}_nH_n'(H_n\tilde{P}_nH_n'+R_n)^{-1}$$

which is the same as (1.3) and (1.5). Also, using (2.7) and (2.4)

$$F_n'\tilde{P}_{n+1}^{-1}F_n=M_n'W_nM_n$$
$$=F_{n-1}'H_n'R_n^{-1}H_nF_{n-1}+F_{n-1}'P_n^{-1}F_{n-1}$$
$$=F_{n-1}'[H_n'R_n^{-1}H_n+\tilde{P}_n^{-1}]F_{n-1} \tag{2.11}$$

But, $F_n=\Phi_nF_{n-1}$. Hence (2.11) becomes

$$\Phi_n'\tilde{P}_{n+1}^{-1}\Phi_n=\tilde{P}_n^{-1}+H_n'R_n^{-1}H_n \tag{2.12}$$

Let

$$\hat{P}_n^{-1}=\Phi_n'\tilde{P}_{n+1}^{-1}\Phi_n \tag{2.13}$$

Then, on using (2.10), (2.12) becomes

$$\hat{P}_n=(I-K_nH_n)\tilde{P}_n \tag{2.14}$$

Also, (2.13) becomes

$$\tilde{P}_{n+1}=\Phi_n\hat{P}_n\Phi_n' \tag{2.15}$$

It is seen that (2.14) is the same as (1.7) and (2.15) is the same as (1.6) with $Q_{n-1}\equiv 0$, which is equivalent to the absence of random excitation.

The derivation presented above emphasizes that recursive filtering is equivalent to weighted least squares when there is no random excitation on the process. The theoretical equivalence of the two methods, however, does not mean that there is nothing new in the recursive filtering algorithm. For even though the two methods are theoretically equivalent, they are computationally quite different. In particular, the standard least squares algorithm (2.3) entails inversion of a matrix whose dimensions are equal to the number of components in the state vector; the recursive algorithm, on the other hand, requires inversion of a matrix no larger than the number of simultaneous observations, i.e., the dimension of the observation vector. Since the latter, in most practical cases, is much smaller than the former, the recursive filtering algorithm generally permits computations to proceed with smaller matrices. This feature, however, is not the most significant. More significant is the numerical problem which arises when the number of observations is large. In this case the matrix $M_n'W_nM_n$, which is to be inverted for the least squares estimate, has long, skinny matrices M_n' and M_n as its outer factors. Hence a single element in $M_n'W_nM_n$ could be the sum of a large number of products. If the individual products are comparable in magnitude and could have different signs, it is evident that the accumulated round-off error could be enough to make the elements of the resulting matrix a set of random numbers. All following calculations would then be meaningless. Since the recursive calculation never entails dealing directly with large matrices, computational problems are considerably forestalled—but not entirely eliminated.

One might think that the equivalence of the solution to a statistical problem—finding the conditional mean of a random process—is equivalent to the solution of nonstatistical problem is a fortuitous circumstance. This, however, is not the case. It turns out that this equivalence applies in a more general context as discussed in the recent, excellent book by Jazwinski.[6]

The equivalence of the conditional mean, the minimum variance estimate, and the maximum likelihood estimate, has led to a variety of derivations based on statistical concepts, in addition to the orthogonal projection theorem used by Kalman. For example, the results of the first section can be derived by use of Bayes' Theorem and/or by finding the expression for the probability density function for x_n, given $y_n, \ldots y_0$.

Continuous-time processes

The problem originally considered by Kalman concerned a discrete-time dynamic process (1.1) with discrete-time ("sampled-data") observations. The extension to a continuous-time process without random excitation, and with sampled observations, is immediate. Suppose the process is governed by

$$\dot{x}=A(t)x \tag{2.16}$$

with observations taken at discrete-times

$$y_n=y(t_n)=H(t_n)x(t_n)+v_n$$

The solution to (2.16) can be expressed by

$$x(t_{n+1})=\Phi(t_{n+1},t_n)x(t_n)$$

where $\Phi(t_{n+1}, t_n)$ is the transition matrix, which is the solution at time t_{n+1} to the matrix differential equation

$$\dot{\Phi}=A(t)\Phi \tag{2.17}$$

with $\Phi(t_n)=I$, the identity matrix. Obviously this transition matrix is used in place of Φ_n, and the earlier discrete-time results are directly applicable.

The transition matrix Φ_n is needed in two places: to update the state estimate via (1.4) and to update the covariance matrix via (1.6). It is worth noting, however, that the transition matrix is not needed to update the state estimate. Instead the differential equation (2.16) can be integrated over the interval $[t_n, t_{n+1}]$ with $x(t_n)=\hat{x}_n$ to obtain $x(t_{n+1})=\tilde{x}_{n+1})$. This additional computation may be justified when it is believed that the evaluation of the transition matrix may be inaccurate, because inaccuracies in the transition matrix in updating the covariance matrix (1.5) are far less serious than errors in the transition matrix used to evaluate the estimate of the state. The former type of error will result in using a somewhat erroneous gain matrix K_n, but the latter will result in a direct error in the estimate of the state.

When random excitation is present on the dynamics, a variety of theoretical problems arise the treatment of which entails sophisticated mathematical concepts. Jazwinski's book[6] contains a very well written account of the relevant mathematical techniques. The major difficulty arises because the continuous time analog of the random excitation v_n is white noise which has very disagreeable mathematical properties. Consider the effect of adding white noise to the process (2.16), i.e.,

$$\dot{x}=A(t)x+B(t)\xi \tag{2.18}$$

with ξ being white noise having a known spectral density matrix. If ξ were nonrandom, the solution to (2.18) would be

$$x(t_{n+1})=\Phi(t_{n+1},t_n)x(t_n)+\int_{t_n}^{t_{n+1}}\Phi(t_{n+1},t)B(t)\xi(t)\,dt \tag{2.19}$$

Since $\xi(t)$ is white noise, however, the integral in (2.19) must be interpreted in a stochastic sense. In accordance with standard theory, the integral

$$v_n=\int_{t_n}^{t_{n+1}}\Phi(t_{n+1},t)B(t)\xi(t)\,dt$$

is a random variable, uncorrelated with v_k, $k\neq n$ having zero mean and covariance matrix:

$$Q_n=\int_{t_n}^{t_{n+1}}\Phi(t_{n+1},t)B(t)\Sigma(t)B'(t)\Phi'(t_{n+1},t)\,dt \tag{2.20}$$

where $\Sigma(t)$ is the spectral density matrix of the white noise $\xi(t)$, i.e., $E[\xi(t)\xi'(\tau)]=\Sigma(t)\delta(t-\tau)$. Hence, except for the possible difficulty in evaluating (2.20), the discrete-time theory is applicable to (2.19).

When the observations are continuous, however, i.e.,

$$y(t)=H(t)x(t)+\eta(t) \tag{2.21}$$

with $\eta(t)$ being white noise, the discrete-time algorithm is not directly applicable. A heuristic deviation of the continuous-time equations of Kalman filter is possible by use of a limiting process as described by Kalman.[2] For small intervals of time, the solution to (2.18) can be approximated by

$$x(t_{n+1})=[I+A(t_n)\Delta t_n]x(t_n)+B(t_n)v_n \tag{2.22}$$

where

$$\Delta t=t_{n+1}-t_n$$

v_n is a random variable of zero mean and variance $\Sigma(t_n)\Delta t_n$, owing to the integration of white noise for an interval Δt_n.

Owing to the white noise on the observations it is not possible to sample the output $y(t)$ at discrete times; instead, it is necessary to smooth the output during the intervals. Simple averaging is easiest to treat. For this type of smoothing

$$y_n=\frac{1}{\Delta t}\int_{t_{n-1}}^{t_n} y(t)\,dt \doteq y(t_n)+w_n=H(t_n)x(t_n)+w_n \tag{2.23}$$

where

$$w_n=\frac{1}{\Delta t}\int_{t_{n-1}}^{t_n}\eta(t)\,dt$$

The integral in w_n is a random variable of zero mean and variance $N\Delta t$ where N is the spectral density matrix of the white noise η. Accordingly

w_n is a random variable of zero mean and variance

$$(1/\Delta t)^2 N\Delta t=N/\Delta t$$

Using (2.22) and (2.23) as the characterization of an approximate discrete-time system, and applying the discrete-time filtering algorithm, gives

$$\hat{x}(t_{n+1})=[I+A(t_n)\Delta t]\{\hat{x}(t_n)+\hat{P}_nH'(t_n)R_n^{-1}[y_n-H(t_n)\hat{x}(t_n)]\}$$

Substituting $R_n=N/\Delta t$ into this equation and rearranging terms gives

$$\frac{\hat{x}(t_{n+1})-\hat{x}(t_n)}{\Delta t}=[A(t_n)\hat{x}(t_n)+\hat{P}_nH'(t_n)N^{-1}(y_n-H(t_n)\hat{x}(t_n)]+O(\Delta t)$$

Hence, as $\Delta t\to 0$, we obtain

$$\dot{\hat{x}}=A(t)\hat{x}+K(y-H(t)\hat{x}) \tag{2.24}$$

with

$$K=\hat{P}_nH'(t)N^{-1}$$

Also, the variance equations (1.6)-(1.7), which can be written in the form

$$\hat{P}_{n+1}^{-1}=(\Phi_n\hat{P}_n\Phi_n'+\Gamma_nQ_n\Gamma_n)^{-1}+H_{n+1}'R_{n+1}H_{n+1}$$

become

$$\hat{P}_{n+1}^{-1}=\{\hat{P}_n+[A(t_n)P_n+P_nA'(t_n)+B(t_n)\Sigma(t_n)B'(t_n)]\Delta t+O(\overline{\Delta t}^2)\}^{-1}+H'(t_n)N^{-1}H(t_n)\Delta t$$

Upon rearranging terms and omitting terms of $O(\overline{\Delta t}^2)$ we obtain

$$\frac{\hat{P}_{n+1}-\hat{P}_n}{\Delta t}=A(t_n)P_n+P_nA'(t_n)+B(t_n)\Sigma(t_n)B'(t_n)-P_nH'(t_n)N^{-1}H(t_n)P_n$$

Finally, passing to the limit as $\Delta t\to 0$, we get

$$\dot{\hat{P}}=A(t)\hat{P}+\hat{P}A'(t)+B(t)\Sigma(t)B'(t)-\hat{P}H'(t)N^{-1}H(t)\hat{P} \tag{2.25}$$

Thus the optimum state estimate evolves in accordance with the differential equation of the original process, but forced by the term $K(y-H\hat{x})$. The covariance matrix P evolves in accordance with the matrix Riccati equation (2.25).

Rigorous treatment of the continuous-time process entails rather sophisticated concepts of stochastic processes. The original treatment by Kalman and Bucy[3] is entirely rigorous, but is confined to linear systems. More general formulations which, in principle, are capable of generalization to nonlinear processes, have been developed by Stratonovich,[7] Kushner,[8,9] Bucy,[10] and Kailath and Frost,[11,12] and by others.

EXTENSION OF THE THEORY

Like most theories, the theory of recursive filtering is applicable exactly in almost no practical situation: few processes are linear, almost no random noise is gaussian (although what it is if not gaussian is another problem), and frequently the actual process model is not known. All these problems have received attention in the decade since the appearance of the Kalman-Bucy papers, and are still receiving attention at the present time. A comprehensive survey of the various extensions which have been published is an overwhelming assignment—a comprehensive bibliography could easily contain a thousand items. There are, however, several trends in the investigations being pursued which can be outlined in broad perspective.

Nonlinear discrete-time processes

A general discrete-time process could be represented by the difference equation

$$x_{n+1}=f(x_n, u_n) \tag{3.1}$$

a general observation may be expressed by

$$y_n=h(x_n, v_n) \tag{3.2}$$

where, in most u_n and v_n are random variables about which very little is known. The usual way of handling a nonlinear problem is to linearize it along a nominal solution. In the present case, suppose a nominal sequence $\bar{x}_0, \bar{x}_1, \ldots, \bar{x}_n$ were known, and, moreover, it is known *a priori* that the random quantities u_n and v_n are "small enough" to insure that the differences

$$e_n=x_n-\bar{x}_n \tag{3.3}$$

are small. Then (3.1) and (3.2) become

$$\begin{aligned} x_{n+1} &\doteq f(\bar{x}_n)+\bar{\Phi}_n(x_n-\bar{x}_n)+\bar{\Gamma}_n u_n \\ y_n &= h(\bar{x}_n)+\bar{H}_n(x_n-\bar{x}_n)+\bar{Z}_n v_n \end{aligned} \tag{3.4}$$

but

$$\bar{x}_{n+1}=f(\bar{x}_n)$$

$$y_n=h(\bar{x}_n)= \text{nominal observation}$$

where

$$\bar{\Phi}_n=\left[\frac{\partial f(x_n, 0)}{\partial x_n}\right]_{x_n=\bar{x}_n}$$

$$\bar{\Gamma}_n=\left[\frac{\partial f(x_n, 0)}{\partial u_n}\right]_{x_n=\bar{x}_n}$$

$$\bar{H}_n=\left[\frac{\partial h(x_n, 0)}{\partial x_n}\right]_{x_n=\bar{x}_n}$$

$$\bar{Z}_n=\left[\frac{\partial h(x_n, 0)}{\partial x_n}\right]_{x_n=\bar{x}_n}$$

or

$$e_{n+1}=\bar{\Phi}_n e_n+\bar{\Gamma}_n u_n+O(e_n^2) \tag{3.5}$$

$$y_n-\bar{y}_n=\bar{H}_n e_n+\bar{Z}_n v_n+O(e_n^2) \tag{3.6}$$

Since (3.5) and (3.6), after omitting the terms of $O(e_n^2)$ constitute a linear system, the linear theory of the previous section is applicable, and the deviations from the nominal trajectory are given by

$$\tilde{e}_{n+1}=\bar{\Phi}_n\hat{e}_n \tag{3.7}$$

$$\hat{e}_n=\tilde{e}_n+K_n(y_n-H_n\tilde{e}_n) \tag{3.8}$$

or in terms of the total state

$$\begin{aligned} \tilde{x}_{n+1} &= f(\bar{x}_n)+\bar{\Phi}_n\hat{e}_n \\ &= f(\hat{x}_n)-\hat{\Phi}_n(\hat{x}_n-\bar{x}_n)+\bar{\Phi}_n(\hat{x}_n-\bar{x}_n) \end{aligned} \tag{3.9}$$

$$\hat{\Phi}_n=\left[\frac{\partial f(x_n, 0)}{\partial x_n}\right]_{x_n=\hat{x}_n}$$

Note that except for the difference between $\bar{\Phi}_n$ and $\hat{\Phi}_n$ (3.9) can be written

$$\tilde{x}_{n+1}=f(\hat{x}_n) \tag{3.10}$$

Moreover, in many situations the estimated solutions $\hat{x}_n$ is more accurate than any *a priori* nominal solution $\bar{x}_n\neq\hat{x}_n$; in fact, there may be no reasonable way of determining $\bar{x}_n$ other than by making it identical to the $\hat{x}_n$, i.e., by *defining* the nominal solution as the running estimate. In this case (3.9) and (3.10) are identical. The same reasoning gives

$$\hat{x}_n=\tilde{x}_n+K_n[y_n-h(\tilde{x}_n)] \tag{3.11}$$

The recursive algorithm (3.10) and (3.11) with the gain matrix computed from (1.5) and (1.6) with

$$\Phi_n=\hat{\Phi}_n, \qquad H_n=\hat{H}_n$$

is the so-called "extended" Kalman filter, as it is now termed. These equations were used as early as 1962 by Smith.[13] The following features of the extended Kalman filter are worth emphasizing. See Figure 2.

- No nominal trajectory is required
- Covariance matrices $\tilde{P}_n$, $\hat{P}_n$, and gain matrix K_n must be computed on-line
- Statistical optimality is only approximate.

Although no nominal trajectory is required, it *is* necessary to compute the covariance matrix on-line and this computation occupies the bulk of the computation requirements. It is not insignificant that strict optimality cannot be assured for the extended Kalman filter; as a matter of fact, it often happens that the estimate given by (3.10) and (3.11) actually *diverges* from the true trajectory as the number of observations processed increases. This "divergence problem," to be discussed subsequently, could result because the terms of $O(e_n^2)$, so casually omitted in developing the filtering equations, in fact, may not be negligible. can introduce a statistical bias into the results; the effect, paradoxically, is most serious when the random noise represented by $\bar{\Gamma}_n u_n$ and $\bar{Z}_n v_n$ in (3.5) and (3.6), respectively, is small relative to the nonlinear terms. When the random terms are large they tend to swamp the nonlinear terms; i.e., those of $O(e_n^2)$; when they are small the nonlinear terms may be predominate. Since the nonlinear terms add to the random terms, one is tempted to increase the covariance matrices of the latter in a heuristic attempt to account for nonlinearity. This approach is often quite successful, but could be dangerous because the nonlinear terms are not random, but are related to the linear terms in a systematic way.

The limitations of the linearized Kalman filtering equation (3.7) and (3.8) or the extended Kalman filter (3.10) and (3.11) have led to a number of investigations, some still continuing, of more accurate extensions of the basic theory or of alternate approaches. These investigations appear to have been motivated by two considerations: the desire to achieve performance closer to the optimum, and the need to avoid problems which arise in applying the linearized or extended algorithm.

The desire to avoid the "divergence" attributable to omission of nonlinear terms is a practical motivation which may be handled in various ways, not necessarily related to achieving "better" (i.e., closer to optimum) performance. In the presence of nonlinearities and/or nongaussian random variables, the very definition of the optimum estimate is a problem: in the linear, gaussian case the conditional mean is also the minimum variance estimate and the maximum likelihood (Bayes) estimate. In the linear, but nongaussian case, the minimum variance estimate (which is what is obtained by applying the Kalman-filtering algorithm) is not always the conditional mean, and neither may be the maximum likelihood estimate. In the nonlinear case, moreover, none of the estimates can be expressed by an exact recursion algorithm; errors are introduced by use of truncated approximations the effects of which are very difficult to assess. As a practical matter performance of nonlinear filters can be assessed only by Monte-Carlo stimulation: a "fix" which works well in one application may be useless or even worse than the basic extended algorithm in another.

Improved estimation algorithms can generally be classified in two categories: higher order, explicit algorithms and iterative algorithms. In the former, the updated estimate $\hat{x}_{n+1}$ is obtained from $\hat{x}_n$ by an explicit computation which entails no iteration and no check of accuracy; in the iterative techniques, the updated estimate $\hat{x}_{n+1}$ is an implicit function of $\hat{x}_n$ which is solved for iteratively.

Iterative techniques

Iterative techniques for treatment of nonlinear problems may be visualized as generalizations of the ancient Newton-Raphson technique for solving nonlinear equations. Suppose, for example, that we have a single observation y from which it is possible to determine the state x through the solution of the system of equations represented by

$$y = h(x) \tag{3.12}$$

If this is true, the Jacobian matrix

$$H(x) = \left[\frac{\partial h}{\partial x}\right]$$

is nonsingular in the vicinity of the solution to (3.12). The standard Newton-Raphson iteration algorithm for solving (3.12) is

$$\hat{x} = \tilde{x} + [H(\tilde{x})]^{-1}[y - h(\tilde{x})] \tag{3.13}$$

where

$\tilde{x}$ is a prior estimate of the solution

$\hat{x}$ is a revised estimate

When $\hat{x}$ differs significantly from $\tilde{x}$, $\tilde{x}$ is replaced by $\hat{x}$ and the iteration is continued until $|| \hat{x} - \tilde{x} ||$ is sufficiently small in accordance with some criterion established by the user.

Comparison of (3.13) with the observation update equation (3.11) of extended Kalman filtering reveals a very striking similarity. In Kalman filtering the gain matrix

$$K_n = \tilde{P}_n H_n'(H_n \tilde{P}_n H_n' + R_n)^{-1}, \quad H_n = H(\tilde{x}_n)$$

multiplies the residual $y - h(\tilde{x})$ while in the Newton-Raphson algorithm the residual is multiplied by H_n^{-1}. If the observation noise is absent, and H_n^{-1} exists, however, the Kalman filter gain becomes

$$K_n = \tilde{P}_n H_n'(H_n')^{-1} \tilde{P}_n^{-1} H_n^{-1} = H_n^{-1}$$

In other words the Kalman filter gain is the same as the Newton-Raphson weighting matrix when the latter exists and the noise is negligible. The Kalman gain matrix may thus be regarded as a generalized version of the Newton-Raphson gain which reduces to the latter in the case when noise is absent and H_n^{-1} exists. When H_n^{-1} does not exist, i.e., when the number of observations is insufficient to permit determination of the state, but noise is absent, then the Kalman gain matrix $K_n = \tilde{P}_n H_n'(H_n \tilde{P}_n H_n')^{-1}$ is a "generalized inverse" of H_n in the sense that $H_n K_n = I$, regardless of the value of $\tilde{P}_n$.

Although the Kalman filter uses a more general gain matrix, it does not perform the iterations of the Newton-Raphson technique. In the linear case, of course, the iterations are not necessary. In the nonlinear case, however, one would expect that the initial estimate $\tilde{x}$ of the state could be improved upon by iteration unless the uncertainty in the observation has an effect equal to the effect of the nonlinearity. Thus, in an application entailing highly accurate, but nonlinear, sensors, one could expect significant benefit from use of the iterations; conversely, when the sensor noise is large relative to the nonlinearity, little improvement due to the iteration is to be expected.

Assuming that iterations are to be employed, what is a suitable convergence criterion? If (3.12) is solved exactly—to the precision available to the computer—then all past history of the process is ignored. If no iterations are used, then nonlinear effects are disregarded. A reasonable convergence criterion would be to iterate until the contribution of the error to the residual vector $y - h(\tilde{x})$ is just about as large as the nonlinear effect. The (approximate) covariance matrix of the residual is $H_n \tilde{P}_n H_n' + R_n$. Since, in the absense of nonlinear effects, most of the residuals can be expected to be less than their corresponding theoretical standard deviation, i.e.,

$$[y_i - h_i(\tilde{x})]^2 < [H_n \tilde{P}_n H_n' + R_n]_{ii}^2 = \sigma_i^2 \tag{3.14}$$

it would be reasonable to continue iteration until (3.14) is satisfied. The addition of the Newton-Raphson iteration cycle to account for nonlinear observations entails a negligible complication of the basic algorithm, as the flow-chart of Figure 3 shows. The operating time, of course, will be increased in proportion to the average number of iterations necessary to pass the convergence test. Whether this additional running time is justified depends on the improvement achieved. Moreover, in an application in which the computer is dedicated to the Kalman filtering algorithm, there may be time available for the iteration so that the additional cost could be inconsequential.

The ideas inherent in the Newton-Raphson iteration technique may be extended to the case in which the state cannot be determined from a single observation, but requires a series of observations and knowledge of the process dynamics. The general equations may be derived, using considerations of least-squares by combining the analysis of the second section and of this section. The inherent statistical parameters can be brought into the problem formulation explicitly. Typical developments are to be found in Cox,[14] and Friedland and Bernstein.[15]

Explicit techniques

The general advantage of iterative techniques is their relative simplicity; the potential disadvantages include uncertain convergence, and possible inefficiency in terms of running time. As an alternative to iterative techniques for nonlinear estimation, it is possible to consider explicit algorithms, i.e., those in which a fixed number of calculations are performed at each step.

The most obvious approach is based on the recognition that the extended Kalman filtering algorithm can be interpreted as the low-order terms in series expansions. Inclusion of additional terms could justifiably be expected to produce better results. Return again to the simplest case in which a single observation suffices to determine the state, i.e., $y=h(x)$ where $h(\cdot)$ is an invertible nonlinear function. In this case we could write, for arbitrary x

$$x=\varphi(y)$$

where $\varphi(x)$ is the inverse function of $h(\cdot)$. Assuming the existence of the required derivatives, one could write

$$x=\varphi(\tilde{y})+\left[\frac{\partial\varphi}{\partial\tilde{y}}\right](y-\tilde{y})+\frac{1}{2}\left[\frac{\partial^2\varphi}{\tilde{y}^2}\right](y-\tilde{y})^2+\cdots \quad (3.15)$$

where, in the multivariable case

$$\left[\frac{\partial\varphi}{\partial y}\right]=\left[\frac{\partial\varphi_i}{\partial y_j}\right], \quad \text{a matrix}$$

$$\left[\frac{\partial^2\varphi}{\partial y^2}\right]=\left[\frac{\partial^2\varphi_i}{\partial y_jy_k}\right], \text{ a third rank tensor.}$$

If

$$\tilde{y}=h(\tilde{x}), \qquad \tilde{x}=\varphi(\tilde{y})$$

Then (3.15) becomes

$$x=\tilde{x}+\left[\frac{\partial\varphi}{\partial y}\right][y-h(\tilde{x})]+\frac{1}{2}\left[\frac{\partial^2\varphi}{\partial y^2}\right][y-h(\tilde{x})]^2+\cdots \quad (3.16)$$

Moreover

$$\left[\frac{\partial\varphi}{\partial\tilde{y}}\right]=\left[\frac{\partial h}{\partial\tilde{x}}\right]^{-1}$$

Hence it is seen that the Newton-Raphson iteration formula (3.13) comprises the first two terms of a series. Also, the Kalman algorithm can be viewed as a statistical generalization of the Newton-Raphson formula. It is thus reasonable to expect that an explicit nonlinear filtering algorithm could be obtained as a generalization of (3.16), i.e.,

$$\hat{x}_n=\tilde{x}_n+K_n^{(2)}[y-h(\tilde{x}_n)]+K_n^{(3)}[y-h(\tilde{x}_n)]^2+\cdots \quad (3.17)$$

where $K_n^{(i)}$ denotes a tensor of rank i and the expression $K^{(i)}r^{i-1}$ denotes tensor multiplication, i.e., contraction to a vector. The use of an explicit formula of the form (3.17) raises several theoretical and practical questions.

The major theoretical question is the definition of an optimum estimate. Whereas in the linear, gaussian case all estimates are equivalent and thus lead to the same algorithm; this is not the case in the nonlinear case. As a consequence the weighting tensors $K_n^{(i)}$ in (3.17) depend on how the estimate is defined. It would be comforting to know that the differences between the weighting tensors for different estimates are insignificant. Unfortunately, this is not the case: even the sign of the second order term may depend on the definition employed.

The practical question is concerned with the computational requirements of explicit methods. It is clear that both storage and time requirements become very large to compute even the second-order terms in a system with a large-dimension state vector. To justify the additional computer requirements, it is necessary to show that use of higher-order terms really provide significant benefit in terms of performance. The reader interested in further pursuing higher order methods, as well as iterative methods, will find an excellent discussion and additional references in Chapters 8 and 9 of Jazwinski's book.[6]

The Kalman filtering technique for linear processes has a theoretical basis in the fact that equations for the propagation of the conditional mean $\hat{x}$ and conditional variance $\hat{P}$ are relatively simple and, moreover, serve to completely characterize the conditional probability distribution of the random state vector x given the observation data $y(t)$. In the nonlinear, nongaussian case, the conditional mean and covariance do not serve completely to characterize the conditional probability density function, and any finite number of moments can only yield an approximation to the actual probability density function. Since the conditional density function is all one needs to determine everything one would want to know about the variable, Bucy reasoned that there may be better methods of learning how the density function propagates than by propagating all its moments. In particular, he and Senne[16] developed a method which is completely different from the series methods. This method is based representing the density function by its actual numerical values at points in a high-dimensional grid and developing a method of representing the motion of this density function in space. Owing to the large number of points needed to represent a high-dimensional density function, only the points at which the density function is "concentrated" are determined and propagated. Although the method seems quite complicated, Bucy and Senne claim it is competitive with series-expansion methods and, in cases they have examined, has given better results than other methods.

Nonlinear continuous-time processes

Very few real processes start out with discrete-time models. In most cases a continuous-time model (in the form of differential equations) is the starting point. When there is no random excitation on the process, and observations are made at discrete instants of time, there is little difficulty in applying the discrete-time (extended-linear) theory. Suppose for example that the process is governed by

$$\dot{x} = \alpha(x) \tag{3.18}$$

The solution of (3.18):

$$x(t_n) = x(t_{n-1}) + \int_{t_{n-1}}^{t_n} \alpha[x(\lambda)]\, d\lambda \tag{3.19}$$

defines the function $f(x_n)$ in (3.1). Thus the time-update (3.10) is computed by numerical integration of (3.18) over the intervals between observations. The initial condition for starting the integration is $\hat{x}_{n-1} = \hat{x}(t_{n-1})$ and the result, just prior to the next observation at t_n is $\bar{x}(t_n)$. The update for the nth observation is then computed through use of (3.11).

In order to update the covariance matrix, in accordance with (1.6), it is necessary to have the differential transition matrix. Since an analytic expression for the nonlinear function f is not generally available, it is not possible to calculate $\Phi = [\partial f/\partial x]$ analytically. Owing to the definition of f as the solution of a system of ordinary differential equations, however, it is possible to compute the transition matrix by numerical integration of the matrix differential equation

$$\dot{\Phi} = \left[\frac{\partial \alpha}{\partial x}\right] \Phi \tag{3.20}$$

with the initial condition $\Phi(t_{n-1}) = I$, where $[\partial\alpha/\partial x]$ is the Jacobian matrix of $\alpha(x)$ evaluated along the solution to (3.18). Thus $x(t_n)$ and Φ_n are evaluated concurrently by numerical integration of a system of $n(n+1)$ differential equations. The process differential equations must be integrated to an accuracy consistent with the observation errors; in other words, the numerical errors in obtaining $\bar{x}_n = \bar{x}(t_n)$ from $\hat{x}(t_{n-1})$ must be of a lower order than the correction $K_n[y_n - h(\bar{x}_n)]$. The computation of the transition matrix, however, requires accuracy only consistent with the accuracy to which the statistical parameters are known. In practice this usually means that the numerical integration algorithm used for (3.20) can be less sophisticated than that used to integrate (3.18). For example, while a fourth-order Runge-Kutta algorithm might be needed to integrate (3.18), it could well happen that a simple, first-order Euler algorithm

$$\Phi_n = I + \left[\frac{\partial\alpha}{\partial x}\right] (t_n - t_{n-1})$$

would provide sufficient accuracy for the state transition matrix.

Nonlinear dynamics with random excitation create problems on the frontiers of investigation in the mathematical theory of stochastic processes. The very meaning of differential equations with white noise excitation is open to serious question: almost nothing is known about how to interpret a general differential equation of the form $\dot{x} = \alpha(x, \xi)$ with ξ being white noise; the meaning of the more restrictive equation

$$\dot{x} = \alpha(x) + B(x)\xi$$

in which the white noise ξ is additive, is open to two interpretations, depending upon whether one uses the mathematically-favored "Itô calculus" or the "Stratonovich calculus" unless the matrix B does not depend on x. A lucid discussion of the two interpretations is given by Jazwinski.[6] Since white noise is a mathematical abstraction which cannot exist in nature, the different interpretations are of more interest to mathematicians than to engineers and physicists. Moreover, unless a very precise analysis of the physical behavior of the dynamic process is made, it is usually impossible to establish the precise nature of the random excitation. For this reason it would seem reasonable to account for all the random effects in a typical process by a model of the form

$$x_{n+1} = f(x_n) + \Gamma_n u_n$$

where Γ_n and u_n are selected empirically to account for the cumulative random errors caused by all random excitation during the intervals between the observations.

Parameter estimation

In various applications there may be a number of parameters to be estimated in addition to the dynamic state variables. Suppose the parameters are designated as b_i $(i = 1, \ldots, m)$ and arranged in a vector

$$b = \begin{bmatrix} b_1 \\ \vdots \\ b_m \end{bmatrix}$$

Then the discrete-time dynamics can be represented as

$$x_{n+1} = f(x_n, b, u_n) \qquad (3.21)$$

Likewise the observations can be expressed as

$$y_n = h(x_n, b, v_n) \qquad (3.22)$$

These equations are general enough to include as special cases observation bias and constant (unknown) forcing terms. Each observation bias is represented by a parameter b_i which appears only in the observation equation. Each constant forcing term appears only in the dynamic equations unless it contributes to a direct measurement.

There is a standard trick for handling parameter estimation, namely to treat b as a part of an enlarged state vector of $k+m$ components.

$$z_n = \left[\frac{x_n}{b_n}\right]$$

Since b is a constant it evolves in accordance with the equation

$$b_{n+1} = b_n$$

The initial condition $\hat{b}_0$ for the estimate is taken as the expected value before any observations, usually zero. The standard extended linear algorithm (or any other nonlinear extension) is applied to estimate z_n; the resulting estimate contains the estimate $\hat{x}_n$ in the presence of (initially) unknown parameters are well as an estimate $\hat{b}_n$ of the unknown parameters. The method works effectively and, in fact, often is the key to the success of the Kalman filtering algorithm in practical applications which abound in uncertain parameters. In the sense that the filter by estimating the uncertain parameters adapts to their presence, the technique may be and, in fact, has been termed "adaptive."

One of the problems with this method of parameter estimation is that the dimension of the big vector z_n can be quite large and, as a result the calculations, may require the manipulation of large matrices. In addition to requiring considerable storage, the usual numerical difficulties associated with large-matrix calculations may be present. In an attempt to avoid such numerical difficulties, Friedland[17] developed a computation technique, which is mathematically equivalent to dealing with the large vector z_n and the associated covariance matrices, but in which the estimation of the parameter vector b_n is decoupled from the estimation of the state vector. In particular, the algorithm consists of computing the estimate $\bar{x}_n$ of the state as if the parameter vector b were equal to its expected value prior to any observations, say zero, and the corresponding residual vectors $\bar{r}_n = y_n - h(\bar{x}_n)$. These residuals are used as the input to a "parameter estimator" which produces the optimum estimate $\hat{b}_n$ of the parameter b. The estimate $\hat{b}_n$ is then multiplied by a matrix V_n to yield the corrected estimate:

$$\hat{x}_n = \bar{x}_n + V_n\hat{b}_n \tag{3.23}$$

In applying this method, there are usually parameters which cannot be estimated, i.e., $\hat{b}_n$ changes negligibly from its value prior to any observations. It is clear from (3.23) that such parameters need not be included in the state vector z_n or in the parameter vector b_n. It is cautioned, however, that the covariance matrix, say, $\bar{P}_n$ which accompanies the computation of $\bar{x}_n$ does *not* realistically represent the accuracy of the estimated state. When uncertain parameters are present, the actual covariance matrix of the state is given by

$$\hat{P}_n = \bar{P}_n + V_nM_nV_n' \tag{3.24}$$

where V_n is the matrix in (3.23) and M_n is the covariance matrix of the parameter vector, i.e.,

$$M_n = E[\hat{b}_n\hat{b}_n'] \tag{3.25}$$

When the uncertainty is large it is quite possible that $V_nM_nV_n'$ is of the same order of magnitude as $\bar{P}_n$ or perhaps even larger.

THE "DIVERGENCE" PROBLEM

Almost as soon as Kalman's recursive filtering algorithm was announced there were a number of investigators ready to apply it to their specific problem. It was quickly discovered that a practical difficulty of the method is that the estimate of the state may tend to diverge from the true state and, in fact, may tend to be ridiculous. Kalman showed that the filtering algorithm is stable, i.e., erroneous covariance matrices for the dynamic noise and the observation noise will not cause the estimate to diverge from the true state. Consequently, the divergence could not be attributed to an inherent instability of the algorithm. Other explanations for the divergence problem had to be found. It became evident that the divergence problem cannot be attributed to a single source. Sometimes it may be due to difficulty in propagating the estimate of the state, in accordance with (3.10) and (3.11); sometimes in propagating the covariance matrix in accordance with (1.6) and (1.7); sometimes both.

Modeling errors

Errors in propagating the estimate of the state may result because of numerical errors in integrating the dynamic equations $\dot{x} = f(x)$, or because the dynamic equations do not really represent the true behavior of the process. The state of the art in numerical integration having been very advanced by the time the recursive filtering algorithm was introduced, the effect of numerical errors could reasonably be discarded. The possibility that the differential equations being integrated, however, do not accurately represent the true physical behavior of the process, however, is not so easily dismissed. The true behavior of the process may not be sufficiently well understood to be modeled accurately, or else an accurate dynamic model may be impractically complicated. The consequence of these "modeling errors" could very well be the divergence of the estimated state from the true state. Possible cures for the modeling errors which have been applied with success in various applications include:

- Representation of the modeling errors by "pseudo-noise"
- Bounding of the covariance matrix
- Use of finite—or fading-memory filtering
- Selective improvement of modeling.

The performance of the Kalman filter is achieved through the correlation of the state of the process at a given time to the state at earlier times. This correlation is established through the dynamics of the process. It follows that if the dynamic model is incorrect, the correlations assumed to be developed may be unreliable, and their use could be dangerous. Any noise present in the process excitation retards the development of this correlation, and it is thus reasonable to represent uncertainty in the model as having the same effect as would be produced by noise. The covariance matrix of this "pseudo-noise" is selected so that the standard deviation in the latter is about equal to the level of uncertainty in the dynamic model.

A technique related to the use of pseudo-noise is *a priori* covariance matrix bounding. The rationale for this technique is that, on physical grounds, we would regard it as impossible to achieve better than a specified accuracy in estimating some of the state variables. If the covariance matrix indicates that higher accuracy is being achieved, the matrix is increased to the *a priori* lower limit. Thus, instead of adding the covariance matrix $\Gamma_nQ_n\Gamma_n'$ corresponding to a known dynamic noise level at each step, this matrix is adjusted so that $\tilde{P}_{n+1} = \Phi_n\hat{P}_n\Phi_n' + \Gamma_nQ_n\Gamma_n'$ does not decrease below a specified lower limit. Similarly, the observation-updated covariance matrix $\hat{P}_n = \tilde{P}_n - \tilde{P}_nH_n'(H_n\tilde{P}_nH_n' + R_n)^{-1}H_n\tilde{P}_n$ can be kept from falling below a specified limit.

Another point of view on modeling uncertainties is represented by the idea that the validity of the dynamic model may be of limited duration. For example, there may be certain long-term trends which the model does not accurately treat, but near-term behavior may be modeled quite accurately. If this is the case, it would follow that data that are older than the interval over which the model is valid ought be discarded. In other words, the "memory" of the filter should be limited to the interval of validity of the model. The Kalman filtering algorithm, however, has infinite memory, in the sense that that the estimate at any instant of time depends on every observation datum ever processed. To be sure, the importance of each datum to the total estimate diminishes as more data are processed, but there is no way of entirely eliminating dependence on data older than a given time. Moreover, in a process with unstable dynamics, the importance of early data may be emphasized disproportionately. To avoid the dependence on all past data, the use of "finite memory" filters has been proposed by various investigators. The general idea is that the estimate $\hat{x}_n$ of the state x_n would be based on a finite amount of past data. For example, the optimum estimate could be defined by

$$\hat{x}_n = [x_n \mid y_n, y_{n-1}, \ldots, y_{n-N+1}] \tag{4.1}$$

i.e., the conditional mean given the most recent N observations: each time a new observation is made, the oldest observation is deleted. One method of obtaining a finite-memory estimate is to use a non-recursive algorithm. For example, assuming no dynamic noise, and following the development in the second section, the least-squares estimate of x_n given $y_n, \ldots y_{n-N+1}$, for a linear process, is given by

$$\hat{x}_n = \Phi_{n-1}\Phi_{n-2} \ldots \Phi_{n-N+1} x_{n-N+1}^{(n)} = F_{n,N} x_{n-N+1}^{(n)}$$

where

$$x_{n-N+1}^{(n)} = (M_{n,N}' W_{n,N} M_{n,N})^{-1} M_n' W_{n,N} Y_{n,N} \tag{4.2}$$

and

$$M_{n,N} = \begin{bmatrix} H_n\Phi_{n-1} & \cdots & \Phi_{n-N+1} \\ H_{n-1}\Phi_{n-2} & \cdots & \Phi_{n-N+1} \\ & \vdots & \\ H_{n-N+2} & \Phi_{n-N+1} & \\ H_{n-N+1} & & \end{bmatrix} \quad Y_{n,N} = \begin{bmatrix} y_n \\ y_{n-1} \\ \vdots \\ y_{n-N+1} \end{bmatrix}$$

Representation of (4.2) in recursive form appears to be difficult. Jazwinski[6] has a discussion of the implementation of algorithms for processing a finite amount of past data.

Instead of dropping all dependence on data older than a given number of samples, various investigators have suggested that a gradual diminution of importance of the data be assumed as the age of the data is increased. This can be accomplished by assuming that the noise covariance matrix increases from its "nominal" value in proportion to the number of samples elapsed. The computational advantage of the assumption of gradual diminution of data importance is that the data processing can usually be represented by a recursive algorithm. For example, Tarn and Zaborszky,[18] have shown that if the effective covariance matrix is taken as $s^l R_n (s > 1)$ where l is the number of elapsed samples the implementation is achieved by simply multiplying the term $\Phi_{n-1}\hat{P}_{n-1}\Phi_{n-1}'$ in (1.6) by s. Improvement by as much as a factor of 3 has been demonstrated in simulation[18] using a scale factor s in the vicinity of 1.1. The particular simplicity of this "cure" would appear to make it worth considering in instances of suspected divergence.

Perhaps the best treatment of modeling errors is to use a superior model. As already noted, this may not be always possible either because a better model may not be available, or because a better model, although available, may be too complicated. Very little can be done in the former case; in the latter case, however, it might be possible to use the recursive filtering method to reduce the complexity of the model to achieve a suitable balance between performance and complexity. The most complete model is formulated, and, in a series of simulation runs, the model is simplified until further simplifications are found to result in significant degradation in performance.

Covariance matrix computational errors

In a linear process the covariance matrices $\tilde{P}_n$ and $\hat{P}_n$ are independent of the estimates $\tilde{x}_n$ and $\hat{x}_n$, and can thus be computed in advance and stored in the computer, although storage problems may make if preferable to compute these "on-line" as the filter operates. In the extended Kalman filter, however, the covariance matrices depend on the actual estimates, and the real-time computation is unavoidable. The real-time computation of the covariance matrix may result in numerical errors which, if not corrected, could cause unsatisfactory filter performance. The basic difficulty is the tendency of the covariance matrix to lose its positive-definite character. It is emphasized that this is strictly a *numerical* problem, unrelated to any modeling errors which may (or may not) also be present. In other words, even if the transition matrix Φ_n and the observation sensitivity matrix H_n are not correct, errors in these matrices in themselves cannot cause the covariance matrix to become indefinite. This fact is easy to prove. Suppose $\tilde{P}_n$ is positive-definite. Then its inverse $\tilde{P}_n^{-1}$ exists, and is positive-definite. Consequently,

$$\hat{P}_n^{-1} = \tilde{P}_n^{-1} + H_n' R_n^{-1} H_n \tag{4.3}$$

is positive-definite since $H_n' R_n^{-1} H_n$ is (at least) positive semi-definite, and the sum of a positive definite matrix and a positive semi-definite matrix is positive definite. Thus $\hat{P}_n = (\hat{P}_n^{-1})^{-1}$ exists and is positive definite. Now the transition matrix of a dynamic process is nonsingular, so $\Phi_n \hat{P}_n \Phi_n'$ is also positive definite and hence

$$\tilde{P}_{n+1} = \Phi_n \hat{P}_n \Phi_n' + \Gamma_n Q_n \Gamma_n'$$

is positive definite for any positive semi-definite Q_n.

This reasoning makes it clear that if $\tilde{P}_0$ is positive definite then all subsequent values $\tilde{P}_n$ and $\hat{P}_n$ $(n=0, 1, 2, \ldots)$ are *theoretically* positive-definite. Theoretical positive-definiteness, unfortunately does not assure freedom from numerical difficulties. In particular, the matrix $\hat{P}_n^{-1}$ and its inverse $\hat{P}_n$ are very frequently ill-conditioned matrices, in the sense that they may have numerically large elements but a relatively small determinant. In particular, suppose that at some step $\tilde{P}_n^{-1}$ is very small (i.e., $\tilde{P}_n$ is very large) but that $H_n' R_n^{-1} H_n$ is large, i.e., R_n is small—this corresponds to the case in which the sensors are very accurate. Suppose also that not all the state variables are measured; then $H_n' R_n^{-1} H_n$ will be a singular (positive-semidefinite) matrix and the sum

$$\hat{P}_n^{-1} = \tilde{P}_n^{-1} + H_n' R_n^{-1} H_n$$

will be ill-conditioned. The computation of its inverse may be expected to be fraught with error.

One obvious possible solution to the problem of ill-conditioned covariance matrices is to increase the precision of computation. When double-precision hardware is available, the only significant cost is in storage, and thus double-precision calculations may be a feasible cure. In instances when double-precision hardware is not available, or when numerical difficulties traceable to ill-conditioned matrices persist even when double-precision arithmetic is used, it is necessary to seek alternative methods. Various *ad hoc* "fixes" have been used with success. One method is to add fixed small positive numbers to the diagonal elements of the covariance matrices as they are computed, on the theory that if a matrix is nearly singular, the addition of a small positive diagonal matrix makes it less so. Another method, entailing more calculation, is to test the covariance matrix for positive-definiteness, and, if at any stage, the matrix becomes indefinite, to add a small positive definite matrix just large enough to make the result slightly positive-definite. Since the covariance matrix is theoretically symmetrical, some users employ a "symmetrization" operation in which P_n is replaced by $(P_n + P_n')/2$, which is, of course, a symmetric matrix. The advantage of symmetrization is not certain, however, because the real parts of the eigenvalues of a matrix are unchanged by this operation, and, as a result, indefiniteness is not affected by symmetrization. On the other hand, numerical difficulties which might be obvious upon inspection of the unsymmetrized covariance matrix could be masked by the symmetrization operation.

A systematic method of possibly overcoming the ill-conditioning problem is to use the inverse of the covariance matrix (which some investigators have called the "information matrix"). In particular, let

$$\tilde{\mathfrak{b}}_n = \tilde{P}_n^{-1}, \qquad \hat{\mathfrak{b}}_n = \hat{P}_n^{-1}$$

Then, using (4.3)

$$\hat{\mathfrak{b}}_n = \tilde{\mathfrak{b}}_n + H_n R_n^{-1} H_n' \tag{4.4}$$

and using (2.9), which implies $K_n = \hat{P}_n H_n' R_n^{-1}$, we obtain

$$K_n = \hat{\mathfrak{b}}_n^{-1} H_n' R_n^{-1} \tag{4.5}$$

The inverse R_n^{-1} of the observation noise covariance matrix can be given as input data instead of R_n. Thus the information matrix $\hat{\mathfrak{b}}_n$ is obviously no worse conditioned than $\tilde{\mathfrak{b}}_n$ and its inversion to obtain the gain matrix K_n from (4.5) should cause no difficulty. Moreover, any error which arises in the computation of K_n is not propagated to later steps in the filter operation. In the absence of dynamic excitation noise $(Q_n \equiv 0)$, the time update of the information matrix is given by

$$\tilde{\mathfrak{b}}_{n+1} = \tilde{P}_{n+1}^{-1} = \Psi_n \hat{\mathfrak{b}}_n \Psi_n' \tag{4.6}$$

where

$$\Psi_n = \Phi_n^{-1\prime}$$

Because Ψ_n' is the inverse of a *transition matrix*, it can be computed by numerical integration of the *adjoint* differential equation

$$\dot{\Psi} = -\left[\frac{\partial \alpha}{\partial x}\right]' \Psi$$

and entails no matrix inversion. Thus, when there is no process excitation present, the computational requirements of this method are comparable to the method of covariance matrices; the major difference is that now it is necessary to invert an $n \times n$ matrix $\hat{\mathfrak{b}}_n$ to obtain the gain matrix instead of an $r \times r$ matrix $(H_n \tilde{P}_n H_n' + R_n)$. Since r, the dimension of the observation vector is usually much smaller than n, the additional computer time needed to realize the calculations using (4.4) through (4.6) may be rather considerable.

When random excitation is present in the dynamics, i.e., $\Gamma_n \neq 0$ in (1.1), then (4.6) is not valid; instead, the correct relationship is

$$\tilde{b}_{n+1} = \Psi_n[\hat{b}_n^{-1} + \Psi_n'\Gamma_n Q_n \Gamma_n' \Psi_n]^{-1}\Psi_n' \qquad (4.7)$$

and entails an additional matrix inversion. In most cases, however, the additive noise as represented by $\Gamma_n Q_n \Gamma_n'$ would be expected to be quite small, and the inverse of the bracketed matrix in (4.7) can be approximated by $\hat{b}_n - \hat{b}_n \Psi_n' \Gamma_n Q_n \Gamma_n' \Psi_n \hat{b}_n$. Thus (4.7) would be approximated by

$$\tilde{b}_{n+1} \doteq \Psi \hat{b}_n \Psi_n' - \Psi_n \hat{b}_n \Psi_n' \Gamma_n Q_n \Gamma_n \Psi_n \hat{b}_n \Psi_n' \qquad (4.8)$$

The computation of the additional term in (4.8) not present in (4.7) entails two additional matrix multiplications, which may not prove significantly better to evaluation of (4.7).

It is worth pointing out that the matrices to be inverted in all aspects of Kalman filtering are symmetric and (theoretically) positive-definite. Use of inversion algorithms that are specific for such matrices might be desirable. In particular, the Gauss-Seidel iterative method for inverting $\hat{b}_n^{-1} + \Psi_n' \Gamma_n Q_n \Gamma_n' \Psi_n$, with $\hat{b}_n$ used to start the iteration, would very likely converge in one or two iterations.

Another method for dealing with the ill-conditioned matrices that arise in the recursive least-squares algorithm, has been termed the "square-root method." The method is based on representing each covariance matrix as the product of a lower triangular matrix and its transpose, i.e.,

$$P_n = S_n S_n', \qquad \hat{P}_n = \hat{S}_n \hat{S}_n' \qquad (4.9)$$

where S is a matrix in which $S_{ij} = 0$ for $j > i$. When P and S are scalars $S = \sqrt{P}$, hence the name of the method. (In a strict sense a lower triangular matrix S satisfying (4.9) is *not* the square root of P. A true matrix square root, say W, satisfies $W^2 = P$, and when P is symmetric, W is also symmetric and thus cannot be lower triangular.)

A survey of the background and current status of the square-root method is contained in a recent paper by Kaminski, Bryson and Schmidt.[19] In the absence of process noise, the square root algorithm may be expressed by the formulas

$$K_n = \tilde{S}_n F_n G_n'^{-1} G_n^{-1} \qquad (4.10)$$

where

$$F_n = \tilde{S}_n' H_n' \qquad (4.11)$$

and

$$G_n G_n' = R_n + F_n' F_n \qquad (4.12)$$

i.e., G_n is the (unique) lower triangular factor of $R_n + F_n F_n'$ and G_n' is the corresponding upper triangular factor. The updating of the "square root" matrix is done using

$$\hat{S}_n = \tilde{S}_n - \tilde{S}_n F_n G_n^{-1\prime}(G_n' + V_n)^{-1} F_n' \qquad (4.13)$$

$$\tilde{S}_{n+1} = \Phi_n \hat{S}_n$$

where

$$V_n V_n' = R_n$$

Only triangular matrices are inverted in (4.10) and (4.13) which is a considerable advantage. The major computational chore is in the factorization of the matrix $R_n + F_n F_n'$. This factorization problem is somewhat analogous to the spectral factorization problem which arises in Wiener filtering (see Friedland[20] for a discussion of this connection as well as for independent development of the Cholesky-Banachiewicz algorithm[19] for accomplishing the factorization).

When process noise is present, a more complicated algorithm is needed, but the basic ideas are the same.

The large consumer of computer capacity is the triangularization operation implicit in (4.12). The efficiency of the square-root method thus depends on the algorithm used to find G_n. The authors of Reference 19 have made an extensive study of suitable algorithms and conclude that Householder's algorithm is adaptable to this problem. A count of operations made in Reference 19 shows that the square-root algorithm may typically require only as much as 30 percent of additional computer time over that required by the conventional (Kalman-Bucy) algorithm and even less time than use of the information-matrix algorithm. The numerical advantage of the square-root method is claimed to be equivalent to doubling the precision of calculations: ". . . a single precision square-root filter would provide the accuracy equivalent of a double precision conventional filter in ill-conditioned problems."[19]

CONCLUDING REMARKS

No survey of the first decade of Kalman filtering would be complete without a discussion of applications which were investigated almost as soon as the theory appeared. (Since the Swerling paper,[5] which predates Kalman's paper by a year, deals with an application, it would be reasonable to assert that applications were investigated even before Kalman's theory appeared.)

Coming at the time of the rapid expansion of the country's aerospace program, it is understandable that the majority of applications were in the aerospace field. G. Smith's very timely paper[13] aroused considerable interest when it was presented and perhaps was to a very large measure responsible for the rapid assimilation of the method by aerospace engineers. The application of the method to orbit and trajectory determination described in the book[21] of a notable expert, R. Battin, helped to establish the importance of the theory. Since the earliest papers, which demonstrated feasibility of the method largely through simulations, the number of applications which have been studied is overwhelming. Hundreds of papers demonstrating potential performance have been presented at technical meetings and have been published in the journals of technical societies. Moreover, the published studies represent only a small fraction of those actually performed. Many others are documented in company internal technical reports or in final reports of limited circulation (many also classified) prepared under government contract. The recursive filtering algorithm is so simple that almost anyone can develop a simulation program. Many organizations evidently have done so.

Application of the Kalman filtering technique to processing of real-world data has naturally been more limited than application studies conducted through simulation. Nevertheless, the number and importance of real-world applications of this technique is most impressive. Those who have listened to the broadcasts of Apollo flight conversations must have heard reference to "state-vector updates"—clearly the language of Kalman filtering. And also the substance. A review of the extensive use of Kalman filtering in the Apollo program by Battin and Levine is contained in a compendium[22] of theory and applications papers that were presented at a 1970 AGARD meeting. Another important application of Kalman filtering has been to aided-inertial navigation. The Kalman filter, in this application, is used to optimally mix data from an inertial platform which has very low inherent short-term errors, but which can build up substantial secular drifts, and non-inertial (e.g., radio ranging, LORAN, doppler) navigation aids which have opposite characteristics, namely that they are relatively drift-free but typically quite noisy. The Kalman filtering algorithm is implemented using an airborne digital computer on the C5-A military transport. A description of the system is given in Reference 22. Inertial navigation applications have advanced to the point that implementation of the Kalman filtering algorithm is now a significant design consideration, in particular, with regard to the design of airborne digital computers to be used in such systems.

Kalman filtering applications appears to be significantly less widespread outside of the aerospace field. Perhaps one reason for this is that dynamic models which play a large role in Kalman filtering are not well established for processes if interest, especially in very large-scale systems (e.g., urban dynamics, ecological systems, etc.). The existence of an analytically-defined dynamic model would appear to be a minimum prerequisite for application of the recursive filtering algorithm, unless methods can be found for using the algorithms in the absence of such models. In the field of industrial processes, Kalman filtering applications have been reported in conjunction with direct digital control. An early, and by now rather celebrated, application in the Swedish paper-making industry was presented by Åström.[23] Other applications in the paper industry, the cement industry, the metallurgical industry, the electric power industry, have been reported or proposed.

The recursive filtering technique developed by Kalman and Bucy would appear to be mature and vigorous despite its youth. The easy theoretical problems seem to have been solved, and the reasons why the difficult problems are difficult have been discovered; approximate methods have been developed to facilitate engineering applications and to develop insights; applications in diverse fields have been studied and often implemented; the basic results are teachable and are included in many curricula in systems engineering. Like many engineering analysis techniques of the past, some of the glamor of Kalman filtering is likely to wear off. What remains, however, will continue to be useful for many years to come.

On computational methods for dynamic and static optimization*

by D. H. JACOBSON

Harvard University
Cambridge, Massachusetts

INTRODUCTION

In the 1960s the joint impact of fast digital computers and the space age stimulated the ingenuity of a number of researchers in optimization and prompted them to invent new and/or better (faster, more elegant) methods for solving, numerically, optimization problems of different types. Two areas that received much attention were trajectory optimization and parameter optimization. That is, the computational problems of determining optimal trajectories (generally, functions of time) and optimal parameter values by minimizing (maximizing) appropriate performance criteria.

Many of the (very successful) algorithms developed were heuristic in that they were good ideas translated skillfully, albeit non-rigorously in the mathematical sense, into algorithms and computer programs. More recently, more effort has been assigned to the theoretical problems of convergence and rate of convergence of algorithms. But, and this is an important point, new powerful algorithms rarely arise out of purely abstract treatments while on the other hand good heuristic methods seldom manifest themselves unless their inventors have at least some deep, albeit informal, understanding of theories of convergence which would enable them to propose an algorithm which is "unlikely not to converge." Thus, good heuristics and theory of algorithms should complement one another in the invention and development of numerical methods.

Certain trajectory optimization algorithms that manifested themselves, as powerful numerical methods for solving real aerospace problems are described in References 1 and 5. The reader should acquaint himself with these because, though some of the methods are dated, insight into the development of computational methods in optimization can be gained and, moreover, certain of the second-variational algorithms remain as attractive methods.

Our work in trajectory optimization (or, more generally, computation of optimal controls) has been concerned with the development of a class of algorithms and a methodology of computation based on Dynamic Programming. The approach which is called Differential Dynamic Programming (DDP) arose as a consequence of an early stimulating paper[6] and is quite extensively described in Reference 7. While no theorems of convergence are given in Reference 7, conditions and proofs for continued descent are provided, and the algorithms have successfully solved a number of substantial numerical problems. Thus, there is still room for theoretical extensions in the form of convergence proofs and rate of convergence studies, though these will be nontrivial. Mayne's[8] recent approach to DDP may prove to be useful in these theoretical problems.

In parameter optimization which, basically, involves choosing the values of n variables to minimize a scalar function, the most famous and widely used methods are given in References 9 and 10. These methods are based on quadratic modelling of the function to be minimized and hence are quasi-Newton in type. Interestingly Fletcher and Powell's algorithm appeared in 1963, and has been very popular, but it was not until 1971 that a proof of convergence was offered by Powell.[11]

Our interest in the function minimization problem led us to propose a new class of algorithms which is based upon the concept of an homogeneous function.[12] Our algorithm[12] is but one possible example of the use of the homogeneous model and it is likely that others will be forthcoming. The algorithm is roughly at the stage that Fletcher and Powell's was circa 1964 in that computational experience suggests that it is attractive, while convergence and rate of convergence studies are yet to come.

A recent book which is appealing in its novelty of approach to the theoretical questions of convergence

* This research is supported by the Joint Services Electronics Program on Contract N00014-67-A-0298-0006.

and rate of convergence is Polak's.[13] Here, general theorems on convergence are presented and applied to known and new algorithms. Though this general theorem approach is appealing and useful it is not a panacea; indeed, some effort appears to be needed to twist the algorithm described in Reference 12 into the framework and verification of a number of required conditions seems to be nontrivial.[14]

With this background and philosophy noted, we continue with subsequent sections of this paper which describe briefly the notions of DDP for control optimization, and homogeneous modelling for function optimization. These are two approaches which seem to be attractive and which, as outlined above, offer potential for future research.

OPTIMAL CONTROL COMPUTATION

Problem formulation

We are concerned with the problem of finding a control function $u(\cdot)$ which minimizes

$$V(x_0, u(\cdot), t_0) = \int_{t_0}^{t_f} L(x, u, t)\, dt + F[x(t_f)] \quad (1)$$

subject to the dynamic system constraints

$$\dot{x} = f(x, u, t); \quad x(t_0) = x_0 \quad (2)$$

and the terminal and control constraints

$$\psi(x(t_f)) = 0 \quad (3)$$

$$g(u(t)) \leq 0 \quad (4)$$

Here, $L: R^n \times R^m \times R^1 \rightarrow R^1$, $F: R^n \rightarrow R^1$, $f: R^n \times R^m \times R^1 \rightarrow R^n$, $\psi: R^n \rightarrow R^s$, $g: R^m \rightarrow R^q$, and all these functions are assumed to be three times continuously differentiable in each argument. The initial and final times t_0, t_f are assumed to be given.

In general, one is unable to find the absolute minimum of V (some sort of global search technique would be required) unless V is a convex functional of $u(\cdot)$ which would exclude the possibility of there existing a number of local minima having different V values. Typically what one can find is a stationary point of V or, at best, a local minimum of V.

It is known that a necessary condition (Pontryagin's Principle) for $V(x_0, u(\cdot), t_0)$ to have a relative minimum with respect to $u(\cdot)$ at $u(\cdot) = u^0(\cdot)$ is that there exist multipliers $\rho_0 \in R_+^1$, $\nu \in R^s$, $\lambda(\cdot)$ absolutely continuous, not all zero, such that

$$-\dot{\lambda} = H_x; \quad \lambda(t_f) = \rho_0 F_x[x(t_f)] + \nu^T \psi_x[x(t_f)] \quad (5)$$

where

$$H(x, u, \lambda, t) = \rho_0 L(x, u, t) + \lambda^T f(x, u, t) \quad (6)$$

and

$$u^0(t) = \arg \min_{u(t) \epsilon U} H(x, u, \lambda, t) \quad (7)$$

where

$$U \equiv \{u(t) : g(u(t)) \leq 0\} \quad (8)$$

Usually one assumes that the problem is normal (i.e., that the conditions can be satisfied with $\rho_0 \neq 0$) so that ρ_0 can be set equal to unity.

Thus, at the very least, one is interested in determining a control function which satisfies the above necessary condition.

Certain algorithms [2], [3] are based directly on second-order expansions of the above optimality conditions, but we prefer to use the notion of DDP which is intuitively more appealing and gives rise to algorithms which are significantly different from those arising from expansions of conditions (5)-(7). Of course, with hindsight, it is possible to derive these algorithms by expanding (5)-(7) but it is the Dynamic Programming formulation which gave rise to these in the first place (see Reference 15 for some discussion of this).

For the purpose of this presentation we shall assume $g(\cdot) = 0$ (i.e., no control constraints) and at the outset we shall assume $\psi(\cdot) = 0$ (no terminal constraints) though we shall allow $\psi(\cdot) \neq 0$ later in the paper (see Reference 7 for DDP algorithms that handle control constraints).

We define the optimal value function $V^0(x, t)$ by

$$V^0(x, t) \overset{\Delta}{=} \min_{u(\tau), t \leq \tau \leq t_f} \int_t^{t_f} L(x, u, t)\, dt + F(x(t_f)) \quad (9)$$

On assuming that $V^0(x, t)$ is twice continuously differentiable with respect to x, t one can obtain the following (Bellman) partial differential equation for $V^0(x, t)$:

$$-(\partial V^0/\partial t)(x, t) = \min_u [L(x, u, t) + \{V_x^0(x, t)\}^T f(x, u, t)] \quad (10)$$

$$\overset{\Delta}{=} \min_u H(x, u, V_x^0, t) \quad (11)$$

where

$$V^0[x(t_f), t_f] = F[x(t_f)] \quad (12)$$

The solution of this partial differential equation is straightforward in the case of quadratic L, F and linear f (V^0 turns out to be a quadratic function of x) but, in general, it can be solved only numerically. As

$V^0: R^n \times R^1 \to R^1$, storage and computer time requirements become unmanageable for $n \geq 3$. This is in contrast to Differential Dynamic Programming which allows us to compute the optimal control $u^0(\cdot)$ for quite large n but does not yield the global solution of Bellman's equation (in many cases knowledge of this solution would be of doubtful value; often, all one wants is $u^0(t)$, $t \in [t_0, t_f]$).

Differential dynamic programming

Here we shall indicate the approach of DDP and refer the reader to Reference 7 for details of the algorithm. Basically, one guesses a nominal control function $\bar{u}(\cdot)$ which yields a nominal cost $V[x_0, \bar{u}(\cdot), t_0]$ and a nominal state variable trajectory $\bar{x}(\cdot)$. Estimates of $V_x^0[\bar{x}(t), t]$, $V_{xx}^0[\bar{x}(t), t]$ are obtained and this "local information concerning V^0" is used to yield an improved control function $u_1(\cdot) = \bar{u}(\cdot) + \delta u(\cdot)$ where $\delta u(\cdot)$ is such that

$$V(x_0, u_1(\cdot), t_0) < V(x_0, \bar{u}(\cdot), t_0) \tag{13}$$

The DDP algorithm is then used iteratively until a stopping criterion is satisfied; e.g.,

$$\int_{t_0}^{t_f} H_u{}^T H_u \, dt \leq \epsilon \tag{14}$$

Fixed end-point problem

Here we allow terminal constraints

$$\psi[x(t_f)] = 0 \tag{15}$$

In order to solve this problem we make the assumption that

$$V[x_0, u(\cdot), b, t_0] \overset{\Delta}{=} V[x_0, u(\cdot), t_0] + b^T \psi[x(t_f)] \tag{16}$$

has a minimum w.r.t. $u(\cdot)$ for all $b \in R^s$. Note that a well-known sufficient condition for this to be true is that $L(x, u, t)$ be strictly convex in $[x, u]^T$, F be convex in $x(t_f)$, f be linear in x, u, and ψ be linear in $x(t_f)$.

If the above assumption and certain other conditions [7] are satisfied then the optimal solution is given by

$$\max_{b \in R^s} V^0(x_0, b, t_0) \tag{17}$$

where

$$V^0(x_0, b, t_0) \overset{\Delta}{=} \min_{u(\cdot)} \int_{t_0}^{t_f} L(x, u, t) \, dt + F[x(t_f)] + b^T \psi[x(t_f)] \tag{18}$$

DDP extends easily to this situation by computing estimates of $V_b^0(x_0, \bar{b}, t_0)$, $V_{bb}^0(x_0, \bar{b}, t_0)$ to enable the nominal value of $\bar{b}$ to be improved iteratively.[7]

DDP algorithms for solving problems with control variable constraints are presented in Reference 7 but the important case of control problems with state variable inequality constraints has not been solved; i.e., the case where the trajectory must satisfy

$$S(x(t), t) \leq 0, \quad \forall t \in [t_0, t_f], \quad S: R^n \times R^1 \to R^1 \tag{19}$$

Certain optimality conditions for this problem [16], obtained recently, could stimulate activity in this important area of research.

FUNCTION MINIMIZATION

In the previous section we outlined the DDP approach for computing minima of functionals (dynamic optimization) and suggested a problem (state constrained) for future research. Here we wish to outline a new approach to the minimization of functions and to again suggest research directions.

Problem formulation

$$\underset{x}{\text{Minimize}}\, C(x), \quad C: R^n \to R^1 \tag{20}$$

Here C is assumed to be twice continuously differentiable and to have a unique stationary point, which is its minimum, at $x = x^*$ (in the case of functions having multi-minima and/or stationary points, available algorithms will generally find "the nearest one").

Available methods

Apart from the classical steepest descent and Newton methods, the two most widely used methods are probably the conjugate gradient method[9] and Fletcher and Powell's method.[10] These methods have the attractive feature of converging in n steps to the minimum if $C(x)$ is a quadratic function,

$$C(x) = \tfrac{1}{2}(x - x^*)^T Q (x - x^*) + \bar{\omega} \tag{21}$$

When applied to non-quadratics (computed examples show that) these methods are impressive in their speed of convergence provided that the non-quadratic looks quadratic in the neighborhood of the minimum [i.e., provided $C_{xx}(x^*) > 0$]. There is a host of other methods based on quadratic models (Quasi-Newton methods) and each has its advantages and disadvantages when compared with References 9 and 10; see, for example

Reference 17. The important point is that researchers in this field have exploited and continue to exploit, admittedly cleverly, the quadratic model. Thus, the homogeneous model, described below, seems to be a departure from conventional approaches (though a certain method that arises from the homogeneous model is closely related to Newton's method).

Homogeneous function as a model for minimization algorithms

The continuously differentiable function $C(x)$ is said to be homogeneous of degree γ if

$$C(x) = \gamma^{-1}(x-x^*)^T(\partial C/\partial x)(x) + \bar{\omega} \qquad (22)$$

Clearly a quadratic function is homogeneous of degree 2. An example of a non-quadratic homogeneous function is

$$C(x) = [\tfrac{1}{2}(x-x^*)^T Q(x-x^*)]^p, \quad p>1, Q>0 \qquad (23)$$

Since $C_{xx}(x^*)=0$ convergence of conjugate gradient methods is particularly poor for this type of function [12].

Multiplying (22) by γ yields

$$\gamma C(x) = (x-x^*)^T(\partial C/\partial x)(x) + \omega, \quad \gamma\bar{\omega} \overset{\Delta}{=} \omega \qquad (24)$$

Now, the attractiveness of this model is apparent; namely, the unknowns x^*, γ, ω appear *linearly* and can be solved for, given $n+2$ linearly independent vectors

$$[C(x_i), (\partial C/\partial x)(x_i), -1], \quad i=1, \ldots n+2 \qquad (25)$$

Our new algorithm, for general functions, described in Reference 12 is one possible procedure for iteratively updating the estimates of x^*, γ, ω as new data points become available. Numerical experience indicates that the algorithm is at worst competitive with Fletcher and Powell's and, in a number of representative examples, is almost twice as fast in terms of number of evaluations of the pair $[C(x), (\partial C/\partial x)(x)]$.

Though the class of homogeneous functions is larger than, and includes, quadratic functions, a suitable modification of Newton's method will find the minimum, x^*, in one step. Differentiating (24) with respect to x yields

$$[(\partial^2 C/\partial x^2)(x)](x-x^*) = (\gamma-1)(\partial C/\partial x)(x) \qquad (26)$$

whence, if the required inverse exists and is positive definite,

$$x^* = x - (\gamma-1)[(\partial^2 C/\partial x^2)(x)]^{-1}(\partial C/\partial x)(x) \qquad (27)$$

Note that this is a Newton step modified by the scale factor $(\gamma-1)$. Thus Newton's method, which minimizes a quadratic in one step, minimizes a homogeneous function if a step length of $(\gamma-1)$ is used. This appears to be unknown in the function minimization literature though analogous behavior, in the problem of locating a repeated root of an equation, was recognized in 1870 by Schröder. Unfortunately, methods which generate estimates of the second derivative matrix (inverse) from past data, for example Fletcher and Powell, do not preserve this valuable property; this is another motivation for estimating x^*, γ, ω directly from (24), as is done in Reference 12.

CONCLUSION

In this paper our intent is to place in perspective certain approaches to the development of optimization techniques, and to suggest certain research directions.

Two areas of recent activity, namely dynamic and static optimization via DDP and homogeneous modelling, are introduced. DDP and homogeneous modelling are two novel approaches to optimization which could be exploited further.

Piecewise linear approximations of fewest line segments

by D. G. WILSON

Virginia Commonwealth University
Richmond, Virginia

INTRODUCTION

Schwerdtfeger[4,5] has considered the problem of interpolation and curve fitting over a given partition by a sum of continuous sectionally linear functions. He showed how to construct an orthogonal system of these functions over a given partition and how to use this system to obtain an approximation of a given function which is best in the least square sense.

Stone,[6] Bellman,[1] and Gluss[2] have analyzed various aspects of the problem of obtaining a piecewise linear approximation, not necessarily continuous, with a given number of line segments which is best in the least square sense.

More recently, Phillips[3] has given an algorithm for obtaining a continuous piecewise linear approximation to a function whose second derivative is of one sign. This algorithm gives an approximation which is of fewest segments among those with a given deviation. The output from this algorithm is a partition of the given interval and the parameters of a straight line over each subinterval of the partition.

We consider the problem of approximating a continuous sectionally linear function by another piecewise linear function, which may or may not be continuous, satisfying:

(a) the approximation is within a given deviation, which need not be constant, of the given function and
(b) the approximation is extremal in the sense that there is no other piecewise linear approximation which is within the same or lesser deviation and which has fewer line segments.

We give an algorithm which solves the problem as stated and a modification which gives a continuous piecewise linear, approximation which is within a given deviation of the given function and which is extremal among such approximations in the sense given above.

We thus solve the problem of fitting data known only at discrete abscissa values within a variable tolerance. Our algorithms can also be used to approximate continuous functions. However, in this case a partition of the interval of interest must be chosen first, the values of the function at these points computed, and an initial continuous piecewise linear approximation obtained by linear interpolation. It is evident that our algorithms cannot give a "good" fit if this initial approximation is not "good." It is also evident how to make this initial approximation "good." But it is not at all obvious how to make it how "good." We have not solved this problem in general. Perhaps a combination of Phillip's algorithm and ours could be used to solve the problem for continuous functions whose domains are separable into intervals over which the second derivative is of one sign.

In the second section we give a precise statement of the problem we have solved. Section three contains the basic algorithm and the modification. Section four contains the proofs which validate the algorithm. Section five contains some sample results. Section six acknowledges the assistance of others. A listing of a FORTRAN program which implements our algorithms is appended.

STATEMENT OF THE PROBLEM

Let P denote a partition of the finite interval $[a, b]$.

$$P = \{x_0, x_1, \ldots, x_n\},\ x_0 = a,\ x_n = b,\ i > j \Rightarrow x_i > x_j.$$

Let $f(x)$ be a continuous function defined on $[a, b]$ which is linear on each subinterval $[x_{i-1}, x_i] i = 1, \ldots, n$. Let $\delta(x)$ be the continuous sectionally linear extension to $[a, b]$, obtained by linear interpolation, of $\delta(x) = \delta_j$ when $x = x_j \in P$, where $\delta_j > 0$, $j = 0, \ldots, n$, are the permissible deviations at the points of P.

Then the problem is, given $u_0 = a$, determine m, p_i, q_i, and u_i, $i = 1, \ldots, m$ such that $F(x)$ given by:

$$F(x) = p_i x + q_i$$

when $x \in [u_{i-1}, u_i)$ for $i = 1, \ldots, m$ and

$$F(u_m) = p_m x + q_m,$$

satisfies $|f(x) - F(x)| \leq \delta(x)$ for $x \in [a, b]$ and m, the number of linear segments of F, is a minimum.

THE ALGORITHM

We consider each $f(x_i)$ as the center of a vertical line segment of length $2\delta_i$ over the corresponding x_i. We denote by $L_t(x)$ and $L_b(x)$ the continuous piecewise linear functions $f + \delta$ and $f - \delta$ respectively.

Briefly our algorithm successively determines the longest "line of sight" into the two dimensional "tunnel" bounded by L_b and L_t. The process terminates since there are only a finite number of data points.

We index the approximating line segments by a parameter k initially set to 1. We define a parameter $\lambda(k)$ taking values $+1$ and -1 which indicates whether the previous line segment, the $(k-1)$th, terminated on L_t, $\lambda(k) = +1$, or on L_b, $\lambda(k) = -1$. It is evident that any line segment which at each point x of its domain, is within $\delta(x)$ of $f(x)$ must either extend to $x = b$ or terminate either on L_t or on L_b. Initially we arbitrarily take $\lambda(1) = +1$.

We are interested in the maximum and minimum permissible slopes for an approximating line segment through a given point. Accordingly we define:

$$S_k(x, y) = [L_t(y) - f(x) - \lambda(k)\delta(x)]/(y - x), \quad (2.1)$$

$$s_k(x, y) = [L_b(y) - f(x) - \lambda(k)\delta(x)]/(y - x), \quad (2.2)$$

$$\Sigma_k(x, y, A) = \inf_{x < z \leq y}\{S_k(x, z), A\},$$

and

$$\sigma_k(x, y, B) = \sup_{x < z \leq y}\{s_k(x, z), B\}.$$

$\Sigma_k(x, y, A)$ is the minimum of the maximum permissible slopes of approximating segments over $[x, y]$ through $(x, f(x) + \lambda(k)\delta(x))$ which are not greater than some given slope A. Similarly $\sigma_k(x, y, B)$ is the maximum of the minimum permissible slopes of approximating segments over $[x, y]$ through $(x, f(x) + \lambda(k)\delta(x))$ which are not less than some given slope B.

If $\Sigma_k(x, y, A) \geq \sigma_k(x, y, B)$, then an approximating segment can be drawn through $(x, f(x) + \lambda(k)\delta(x))$ which extends at least from x to y. We are naturally interested in the largest y for which this is true. We define

$$Y_k(x, A, B) = \sup\{y \mid y \leq b, \Sigma_k(x, y, A) \geq \sigma_k(x, y, B)\},$$

$$H_k(x, A, B) = \max\{i \mid x_i \in P, x_i \leq Y_k(x, A, B)\}.$$

$Y_k(x, A, B)$ is the right endpoint of the domain of the longest approximating segment through $(x, f(x) + \lambda(k)\delta(x))$ with slope between B and A. The value of $Y_k(x, A, B)$ may not be in P, but this value can be determined since f is a continuous piecewise linear function. We will return to this point.

Before giving the algorithm we define three more quantities of interest. Let

$$X_k(x, A, B) = \begin{cases} \max[x, \{x_i \mid x_i \in P, x_i < Y_k(x, A, B), \\ S_k(x, x_i) = \Sigma_k(x, x_i, A)\}] \quad \text{if} \quad \lambda(k) = +1 \\ \max[x, \{x_i \in P, x_i < Y_k(x, A, B), \\ s_k(x, x_i) = \sigma_k(x, x_i, B)\}] \quad \text{if} \quad \lambda(k) = -1, \end{cases}$$

(the sets defined in braces in the previous expression may be empty),

$$P_k(w, x, y, z) = \begin{cases} \min\{\min[s_k(y, x_i) \mid x_i \in P, w \leq x_i < y], \\ \min[S_k(y, x_i) \mid x_i \in P, y < x_i \leq z]\} \\ \text{if} \quad \lambda(k) = +1, \\ s_k(x, y) \quad \text{if} \quad \lambda(k) = -1, \end{cases}$$

$$Q_k(w, x, y, z) = \begin{cases} S_k(x, y) \quad \text{if} \quad \lambda(k) = +1, \\ \max\{\max[S_k(y, x_i) \mid x_i \in P, w \leq x_i < y], \\ \max[x_k(y, x_i) \mid x_i \in P, y < x_i \leq x]\} \\ \text{if} \quad \lambda(k) = -1. \end{cases}$$

$X_k(x, A, B)$ determines a "pivot point" in our two dimensional tunnel to the right of x. This will be taken as a new "eyepoint" for determining a new "line of sight" extending farther to the right. P_k and Q_k determine respectively a maximum and a minimum slope for a new segment through the pivot point. These will determine the parameters A and B for subsequent evaluations of σ_k, Σ_k, Y_k, X_k. This is another point to which we shall return.

We are now ready to give our algorithm:

Initialization:

Set: $z_0 = z^* = u_0 = a$, $\lambda(1) = +1$, $j = 1$, $k = 1$,

$$A_0 = [f(x_1) + \delta(x_1) - f(x_0) - \delta(x_0)]/(x_1 - x_0),$$

$$B_0 = [f(x_1) - \delta(x_1) - f(x_0) - \delta(x_0)]/(x_1 - x_0).$$

Set an indicator if the approximation is to be continuous.

Iteration:

1. Compute: $y_j = Y_k(z_{j-1}, A_{j-1}, B_{j-1})$,

   $h = H_k(z_{j-1}, A_{j-1}, B_{j-1}) + 1$,

   $z_j = X_k(z_{j-1}, A_{j-1}, B_{j-1})$.
2. If $y_j = b$, then go to Termination step 4.
3. If $\lambda(k) = +1$ and $S_k(z_{j-1}, x_h) < \sigma_k(z_{j-1}, x_h, B_{j-1})$, or if $\lambda(k) = -1$ and $s_k(z_{j-1}, x_h) > \Sigma_k(z_{j-1}, x_h, A_{j-1})$, then go to Termination step 1.
4. If $z_j = z_{j-1}$, then go to Termination step 2.
5. Compute: $A_j = P_k(z^*, z_{j-1}\ z_j, y_j)$,

   $B_j = Q_k(z^*, z_{j-1}, z_j, y_j)$.
6. Increment j by $+1$ and go to Iteration step 1.

Termination:

1. If $\lambda(k) = +1$, then set $p_k = S_k(z_j, y_j)$. If $\lambda(k) = -1$, then set $p_k = s_k(z_j, y_j)$. Set $q_k = f(z_j) + \lambda(k)\delta(z_j) - p_k z_j$. Set $\lambda(k+1) = \lambda(k)$. Go to Termination step 3.
2. If $\lambda(k) = -1$, then set $p_k = s_k(z_j, y_j)$. If $\lambda(k) = +1$, then set $p_k = S_k(z_j, y_j)$. Set $q_k = f(z_j) + \lambda(k)\delta(z) - p_k z_j$. Set $\lambda(k+1) = -\lambda(k)$.
3. Set: $u_k = y_j$,

   $z_0 = y_j$,

   $A_0 = S_k(z_0, x_h)$,

   $B_0 = s_k(z_0, x_h)$.

   If the approximation is to be continuous, then set $z^* = z_j$, otherwise set $z^* = y_j$. If the approximation is to be continuous and $k > 1$, then recompute u_{k-1}, the abscissa value at the intersection of the current and previous segments. Set: $j = 1$, increment k by $+1$ and go to Iteration step 1.
4. Set: $p_k = \{\Sigma_k(z_{j-1}, b, A_{j-1}) + \sigma_k(z_{j-1}, b, B_{j-1})\}/2$,

   $q_k = f(z_{j-1}) + \lambda(k)\delta(z_{j-1}) - p_k z_{j-1}$,

   $u_k = b$.

   If the approximation is to be continuous and $k > 1$, then recompute u_{k-1}, the abscissa value at the intersection of the current and previous segments. End.

VALIDATION

In this section we show that $Y_k(x, A, B)$ can be computed, that the algorithm just given does generate a piecewise linear approximation which is extremal in the sense already defined and finally that the modification to be implemented for a continuous approximation does generate an extremal continuous piecewise linear approximation as asserted.

Lemma 1:

For a fixed x the functions $S_k(x, y)$ and $s_k(x, y)$ are continuous piecewise linear functions of $(y-x)^{-1}$ for $y \in (x, b]$, and the partition of the functions into segments linear in $(y-x)^{-1}$ is exactly P.

Proof:

The functions are rational and hence continuous on $(x, b]$. Let x_i and x_{i+1} be successive points of $P \cap [x, b]$. That S_k and s_k are linear in $(y-x)^{-1}$ for $y \in (x_i, x_{i+1}]$ follows from substituting

$$L_\mu(y) = L_\mu(x_i) + [L_\mu(x_{i+1}) - L_\mu(x_i)](y - x_i)/(x_{i+1} - x_i)$$

for $\mu = t$ into the definition of S_k equation (2.1) and for $\mu = b$ into the definition of s_k equation 2.2. Writing $(y - x_i) = (y - x) + (x - x_i)$ and dividing out $(y-x)$ gives an expression linear in $(y-x)^{-1}$.

Corollary 1:

For a fixed $x \in [a, b]$, if x_i and x_{i+1} are successive points of $P \cap [x, b]$, then $S_k(x, y)$ and $s_k(x, y)$ are monotone functions of y for $y \in (x_i, x_{i+1}]$.

Corollary 2:

For fixed $x \in [a, b]$, $S_k(x, y)$ and $s_k(x, y)$ take their minimum and maximum values respectively at points y' and y'' which belong to $P \cap (x, b]$.

Lemma 2:

For a fixed $x \in [a, b]$, A and B, if x_i and x_{i+1} are successive points of $P \cap (x, b]$ with $\Sigma_k(x, x_i, A) \geq \sigma_k(x, x_i, B)$ and $\Sigma_k(x, x_{i+1}, A) < \sigma_k(x, x_{i+1}, B)$, then either $s_k(x, x_{i+1}) > \Sigma_k(x, x_i, A)$ or $S_k(x, x_{i+1}) < \sigma_k(x, x_i, B)$ and not both.

Proof:

We show first that under the hypothesis not both inequalities may hold. Since $S_k(x, x_{i+1}) \geq s_k(x, x_{i+1})$, both inequalities would imply $\sigma_k(x, x_i, B) > \Sigma_k(x, x_i, A)$ which contradicts the hypothesis.

We now show that under the hypothesis not both inequalities may fail. From the definition of Σ_k and σ_k, and lemma 1: If $s_k(x, x_{i+1}) \leq \Sigma_k(x, x_i, A)$ and $\sigma_k(x, x_i, B) \leq \Sigma_k(x, x_i, A)$, then $\sigma_k(x, x_{i+1}, B) \leq \Sigma_k(x, x_i, A)$; similarly if $S_k(x, x_{i+1}) \geq \sigma_k(x, x_i, B)$ and $\Sigma_k(x, x_i, A) \geq \sigma_k(x, x_i, B)$, then $\Sigma_k(x, x_{i+1}\ A) \geq \sigma_k(x\ x_i, B)$. Thus, if the hypothesis held but both inequalities failed we would have: $\Sigma_k(x, x_i, A) \geq \sigma_k(x, x_{i+1}, B) > \Sigma_k(x, x_{i+1}, A) \geq \sigma_k(x, x_i, B)$. But this implies $s_k(x, x_{i+1}) > S_k(x, x_{i+1})$ which is impossible.

Lemma 3:

For a fixed $x\in[a, b]$, A and B, let x_i and x_{i+1} be successive points of $P\cap(x, b]$ with $\Sigma_k(x, x_i, A)\geq \sigma_k(x, x_i, B)$ and $\sigma_k(x, x_{i+1}, B)>\Sigma_k(x, x_{i+1}, A)$. If $s_k(x, x_{i+1})>\Sigma_k(x, x_i, A)$, then $Y_k(x, A, B)$ is the z value for which

$$L_b(z)=(z-x)\Sigma_k(x, x_i, A)+f(x)+\lambda(k)\delta(x);$$

while if $S_k(x, x_{i+1})<\sigma_k(x, x_i, B)$, then $Y_k(x, A, B)$ is the z value for which

$$L_t(z)=(z-x)\sigma_k(x, x_i, B)+f(x)+\lambda(k)\delta(x).$$

Proof:

Lemma 2 shows that one of these formulae can be selected. The formulae follow from the definitions of S_k and s_k, Equations (2.1) and (2.2) and the observations that if $s_k(x, x_{i+1})>\Sigma_k(x, x_i, A)$, then $s_k(x, z)$ is an increasing function of z for $z\in(x_i, x_{i+1}]$ and we are interested in the z for which $s_k(x, z)=\Sigma_k(x, x_i, A)$, while if $S_k(x, x_{i+1})<\sigma_k(x, x_i, B)$, then $S_k(x, z)$ is a decreasing function of z for $z\in(x_i, x_{i+1}]$ and we are interested in the z for which $S_k(x, z)=\sigma_k(x, x_i, B)$.

This lemma shows constructively that $Y_k(x, A, B)$ can be computed. This is the only function we have defined about which there was potential doubt.

It is evident that our algorithm generates a piecewise linear approximation which is within δ of f. We now show that this approximation is extremal.

For convenience we identify the last z_j associated with the kth segment as e_k, the abscissa value of the eyepoint of this segment. This value is available at the termination step of each segment. Note that

$$f(e_k)+\lambda(k)\delta(e_k)=e_kp_k+q_k.$$

Since each segment, except possibly the right most, terminates on either L_t or L_b we have shown that each approximating segment, again except possibly the right most, has at least two points on the boundary of our two dimensional tunnel. The extremal property of our approximation follows from each approximating segment, except possibly the right most, having at least three points on the boundary which alternate between the boundary lines.

We will prove this assertion in the next two lemmas. The first of these merely establishes a useful geometric fact.

Lemma 4:

Let $a\leq x<y<z$, and let R stand for any of: $>$, $<$, $\geq$, $\leq$, or $=$. If $\lambda(k)=+1$ and $S_k(x, y)Rs_k(x, z)$, then $S_k(x, y)Rs_k(y, z)$. If $\lambda(k)=-1$ and $s_k(x, y)RS_k(x, z)$, then $s_k(x, y)RS_k(y, z)$.

Proof:

If $\lambda(k)=+1$, then the hypotheses imply:

$$[L_t(y)-L_t(x)](z-x)R[L_b(z)-L_t(x)](y-x).$$

In this relation we substitute $(z-y+y-x)$ for $(z-x)$ on the left and $[L_b(z)-L_t(y)+L_t(y)-L_t(x)]$ for $[L_b(z)-L_t(x)]$ on the right. The result is:

$$[L_t(y)-L_t(x)](z-y)R[L_b(z)-L_t(y)](y-x).$$

The conclusion, $S_k(x, y)Rs_k(y, z)$, follows from dividing this relation by $(z-y)(y-x)>0$.

The argument is similar in the case $\lambda(k)=-1$.

Lemma 5:

If the kth approximating segment is not the right most and terminates on L_μ, where $\mu=b$ or t, then there exist $x'\in[u_{k-1}, u_k)$ and $x''\in(x', u_k)$ such that $L_\mu(x')=x'p_k+\lambda(k)\delta(x')$ and $L_v(x'')=x''p_k+\lambda(k)\delta(x'')$ where if $\mu=b$, then $v=t$ and vice versa.

Proof:

The idea of the proof is simple although the notation is complicated. The outline of the proof is as follows. If the kth segment is not the right most, then the slope of this segment is both the maximum of the minimum permissible slopes for approximating segments through, $(e_k, L_\mu(e_k))$ which intersect the vertical segment over u_{k-1}, and the minimum of the maximum permissible slopes for approximating segments through this eyepoint which intersect this vertical segment. Furthermore each of these slopes is determined by a point on the boundary. One of these points is the terminal point of the segment, the other is the point whose existence this lemma asserts.

There are four possible cases determined by: $L_t(u_k)=u_kp_k+q_k$ with $\lambda(k)=\pm1$, and $L_b(u_k)=u_kp_k+q_k$ with $\lambda(k)=\pm1$. We shall consider the two cases with $\lambda(k)=+1$. The other two are similar to these.

We consider first $\lambda(k)=+1$ and $L_t(u_k)=u_kp_k+q_k$. Then $L_t(e_k)=e_kp_k+q_k$, $x'=e_k$ and we need to find $x''\in(x', u_k)$. If $e_k=u_{k-1}$, then the slope of the line through $(u_{k-1}, L_t(u_{k-1}))$ and $(u_{k+1}, L_t(u_{k+1}))$ is the minimum permissible slope of an approximating segment over $[u_{k-1}, u_k]$. By lemma 3 and corollary 2 of lemma 1 this minimum slope is the slope of a line from $(u_{k-1}, L_t(u_{k-1}))$ through $(x_i, L_b(x_i))$ for some $x_i\in P\cap(u_{k-1}, u_k]$. Furthermore, this x_i is not u_k since $L_t(u_k)=u_kp_k+q_k$. In this case x'' is this x_i.

If $e_k\neq u_{k-1}$, then to determine u_k, p_k and q_k more than one pass through the iteration phase of our algorithm was required. Let e_{k^*} and y_{k^*} be respectively z_{j-2} and y_{j-1}, where $e_k=z_j$ from the determination of u_k, p_k and

q_k and let $x_{k*}=\min\{x \mid x\in P, x\geq y_{k*}\}$. Then

$$p_k=\Sigma_k(e_k, u_k, A)=\sigma_k(e_k, u_k, B),$$

where

$$A=P_k(u_{k-1}, e_{k*}, e_k, y_{k*}),$$

and

$$B=Q_k(u_{k-1}, e_{k*}, e_k, y_{k*}).$$

If there were no $x''\in(e_k, u_k)$ such that $L_b(x'')=x''p_k+q_k$, then p_k would equal B and $s_k(e_k, x_i)$ would be less than B for each $x_i\in P\cap(e_k, u_k]$. But this is impossible. For the algorithm which gives the value of y_j insures that $S_k(e_{k*}, e_k)\leq s_k(e_{k*}, x_{k*})$; and lemma 4 then implies $S_k(e_{k*}, e_k)\leq s_k(e_k, x_{k*})$. Finally, since $\lambda=+1$, we have $B=S_k(e_{k*}, e_k)$. Hence $s_k(e_k, x_{k*})\geq B$, and the existence of an x'' is established.

We suppose now that $\lambda(k)=+1$ and $L_b(u_k)=u_kp_k+q_k$. Then $L_t(e_k)=e_kp_k+q_k$ and we will show that there exists $x'\in[u_{k-1}, e_k)$ such that $L_b(x')=x'p_k+q_k$. This follows from $s_k(e_k, u_k)=P_k(u_{k-1}, e_{k*}, e_k, y_{k*})$. For $s_k(e_k, u_k)=\sigma_k(e_k, u_k, B)=\Sigma_k(e_k, u_k, A)$, and if this is not A, namely $P_k(u_{k-1}, e_{k*}, e_k, y_{k*})$, then there exists some $x_i\in P\cap(e_k, u_k)$ such that $S_k(e_k, x_i)<A$. But this contradicts the definition of e_k as the last z_j from the iteration phase in the determination of u_k, p_k and q_k.

Corollary 1:

There is no approximating linear segment whose domain includes u_{k-1} which extends farther to the right than u_k.

Proof:

Such a segment would have to cross our kth approximating segment twice.

Corollary 2:

Our approximation is extremal in the sense stated.

Proof:

Any other linear approximation of fewer line segments must have at least one segment whose domain begins to the left of and ends to the right of the domain of one of our approximating segments.

Lemma 6:

The modification of our algorithm for a continuous approximation does give a continuous piecewise linear approximation which is extremal in the sense we have defined.

Proof:

The modification is to one of the argument values where P_k and Q_k are to be evaluated. The result is to insure that for $k>1$ the kth segment extended to the left intersects the $(k-1)$th segment between the x'' and u_k of lemma 5. That this approximation is extremal follows from the observation made in the proof of corollary 2 of lemma 5.

SAMPLE RESULTS

The appended FORTRAN program, with a suitable driver, was run a number of times. An input parameter determined if the approximation was to be continuous and whether or not the deviation was to vary. If the deviation was not to vary it was taken as the first input tolerance.

One set of test data was the following:

```
  INPUT DATA, NUMBER OF POINTS=20

      X            Y         TOLERANCE

   1.0000       0.7175        0.1250
   2.0000       0.6250        0.0625
   3.0000       0.6250        0.0625
   4.0000       0.6250        0.1250
   5.0000       0.6563        0.1250
   6.0000       0.7500        0.2500
   7.0000       0.6563        0.1250
   8.0000       0.6406        0.0313
   9.0000       0.7500        0.0312
  10.0000       0.5000        0.0156
  11.0000       0.7500        0.1250
  12.0000       0.6250        0.0625
  13.0000       0.6250        0.0625
  14.0000       0.6250        0.1250
  15.0000       0.6563        0.1250
  16.0000       0.7500        0.2500
  17.0000       0.6563        0.1250
  18.0000       0.6406        0.0313
  19.0000       0.7500        0.0312
  20.0000       1.0000        0.0156
```

The results, when the deviation was taken as constant, namely 0.125, were:

```

  0.2329  -3.6572  18.6084  20.0000 0.6759 1.0000
```

when the approximation was required to be continuous.

These results show that it may not require any additional segments to have the approximation be continuous for a given set of tolerances.

Another set of test data was:

```
  INPUT DATA, NUMBER OF POINTS=13

     X            Y        TOLERANCE

   0.0          5.0000       0.2000
   1.0000       4.0000       0.1000
   2.0000       3.1000       0.3000
   3.0000       3.1000       0.0100
   4.0000       3.1000       0.0030
   5.0000       4.0000       0.2000
   6.0000       5.0000       0.3000
   7.0000       6.0000       0.5000
   8.0000       6.0000       0.2000
   9.0000       6.0000       0.1000
  10.0000       4.0000       0.7500
  11.0000       2.5000       1.0000
  12.0000       1.0000       0.2000
```

The results were:

```
5 LINE SEGMENTS WERE REQUIRED TO
    FIT THESE DATA EQUATION OF
    APPROXIMATION  IS  Y=PX+Q
         FOR U.LT.X.LT.V

    P         Q        U        V     Y(U)   Y(V)

 -0.7500   4.8000   0.0      2.5333 4.8000 2.9000

  0.8333  -0.0333   4.0000   7.4800 3.3000 6.2000
 -0.2632   8.1684   7.4800   9.0360 6.2000 5.7905
 -1.6500  20.7000   9.0360  12.0000 5.7905 0.9000
```

when the approximation was required to be continuous and the deviation was taken as 0.2; and:

```
5 LINE SEGMENTS WERE REQUIRED TO
    FIT THESE DATA EQUATION OF
    APPROXIMATION  IS  Y=PX+Q
         FOR U.LT.X.LT.V

    P         Q        U        V     Y(U)   Y(V)

 -0.7000   4.8000   0.0      2.4530 4.8000 3.0829
  0.0130   3.0510   2.4530   4.0000 3.0829 3.1030
  0.7990  -0.0930   4.0000   7.9099 3.1030 6.2270
 -0.3000   8.6000   7.9099   9.1905 6.2270 5.8429
 -1.7237  21.6847   9.1905  12.0000 5.8428 1.0000
```

when the approximation was required to be continuous and the deviation was permitted to vary.

The program will accept any non-negative tolerance including zero. If all tolerances are zero the program gives the parameters for linear interpolation.

ACKNOWLEDGMENTS

This problem was originally given to me by Mr. Fred Stahl of the John D. Kettelle Corporation. I am indebted to Dr. W. A. Thedford of Virginia Commonwealth University for a suggestion which led to the modification for a continuous approximation.

Mr. W. T. Lipscomb III, a student at V.C.U., programmed a preliminary version of the algorithm and in numerous discussions contributed some of the descriptive terminology. His name appears as a coauthor of the appended listing.

Sincere appreciation goes to my wife Gwendolyn who typed this manuscript.

Experimental results on a new computer method for generating optimal policy variables in (s, S) inventory control problem

by P. E. VALISALO, B. D. SIVAZLIAN and J. F. MAILLOT

University of Florida
Gainesville, Florida

INTRODUCTION

The problem of developing a computable solution to the optimal periodic review stationary (s, S) inventory control problem has not received the same level of attention as the theoretical works first initiated in 1951 by the well-known paper of Arrow, Harris, Marschak.[1]

Even for some of the simplest situations, perhaps closest to practice, involving a fixed set-up cost, and a linear holding and shortage cost, the solution to the mathematical problem of determining the optimal values of s and S to minimize the total expected cost per period, requires the formal solution of an integral equation of the Volterra type and an optimization problem of a fairly complex objective function involving the decision variables s and S.

Explicit theoretical solutions for s and S can be obtained as computable formulas for some very simple demand distributions as for example the negative exponential distribution. Approximations to the optimal solutions were proposed by Roberts[2] in 1962. In 1965, Veinott and Wagner[6] developed an algorithmic procedure applicable to instances when the demand distribution is described by a discrete random variable; the study fails to discuss the computational efficiency of the algorithm and its usability in practice particularly in relation to the large number of input variables (at least five) which are necessary to compute a single pair of optimal values of (s, S). In practice, this facet of the computational problem cannot be ignored since inventory control involves usually several thousand of commodities, each commodity necessitating frequent updating of the set of input variables due to changes in economic or other conditions. In 1968, Sivazlian[3] derived a set of equations to compute the optimal values of s and $Q=S-s$ and developed conceptual approaches to solve these equations on the digital computer and on the analog computer. The feasibility of using analog computers was demonstrated in a set of experiments published in 1970 by Sivazlian and Valisalo.[5] By using dimensional analysis and using numerical inversion techniques for Laplace transforms, Sivazlian[4] generated a set of graphs for the case of gamma distribution demand with integer order, to obtain the optimal values of s and Q for all possible values of input variables. The computational feasibility of the problem was also discussed.

Although both analog and digital computer techniques proved successful, certain computational deficiencies were encountered in both methods. In using analog computers, experimental errors were generated when increasing the number of integrators. Further the derivation of results for complex demand distributions was limited by the capability of the analog computer system. In using digital computation, the discretization of the problem and the numerical method utilized could generate solution instability.

These two deficiencies were ultimately resolved by combining the conceptual basis of analog computation with the capacity and speed of digital computers by using the Continuous Simulation and Modeling Programming (C.S.M.P.) on the IBM 360/65 digital computer. The C.S.M.P. is a simulation language which works on block diagrams as an analog computer does but which utilizes a digital program. The present paper presents preliminary results obtained using this computation technique and discusses some inherent merits of this method.

THEORETICAL CONSIDERATIONS

A brief discussion of the theoretical results as obtained by Sivazlian[3] is necessary.

Consider the periodic review inventory control problem of a single commodity system where the demand per period for the commodity is described by a continuous random variable $\xi(0<\xi<\infty)$ with probability density function $\phi(\xi)$ identically and independently distributed from period to period. Assume that the following cost components affect the operation of the system: a fixed order cost K, a holding cost and a shortage cost. Complete backlogging is allowed and delivery of orders is immediate. Let $L(x)$ be the expected holding and shortage cost over one period when the stock level at the beginning of the period following a decision is x. An $(\mathcal{S}, S)$ policy is in effect, that is, whenever the stock level at the beginning of a period lies between $\mathcal{S}$ and S, no order is placed, and whenever the stock level falls below $\mathcal{S}$, it is brought up to S. It can be shown[3,4] that for $\mathcal{S}\geq 0$ the values of $\mathcal{S}$ and $Q=S-\mathcal{S}$ which minimize the total expected cost per period for the stationary inventory system are solutions to the system of equations

$$m(\mathcal{S}, Q)=0 \tag{1}$$

and

$$\int_0^Q m(\mathcal{S}, x)\, dx=K \tag{2}$$

where $m(\mathcal{S}, x)$ satisfies the Volterra integral equation

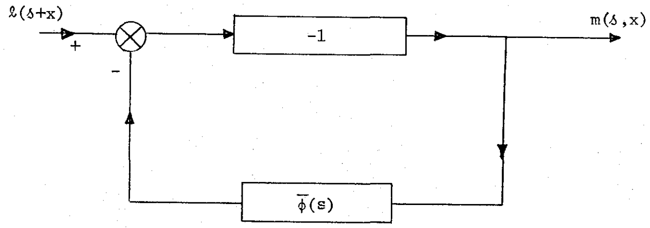

Figure 1—Feedback system simulating the equation

$$m(\mathcal{S}, x) = -l(\mathcal{S} + x) + \int_0^x m(\mathcal{S}, x-u)\, \phi\,(u)\, du$$

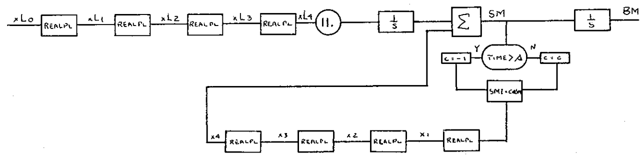

Figure 2—Flow chart for the digital simulation when h = 1, p = 10, n = 4 and a = .40

$$m(\mathcal{S},\, x) = -L'(\mathcal{S}+x) + \int_0^x m(\mathcal{S},\, x-\xi)\phi(\xi)\, d\xi \qquad (3)$$

Let

$$l(x) = L'(x)$$

$$\bar{l}(s,\, \mathcal{S}) = \mathcal{L}\{l(\mathcal{S}+x)\}$$

$$\bar{\phi}(s) = \mathcal{L}\{\phi(x)\}$$

$$\bar{m}(s,\, \mathcal{S}) = \mathcal{L}\{m(\mathcal{S},\, x)\}$$

Then, from taking the Laplace transforms on both sides of (3) and solving for $\bar{m}(\mathcal{S}, s)$ we obtain

$$\bar{m}(\mathcal{S},\, s) = \frac{-\bar{l}(\mathcal{S},\, s)}{1-\bar{\phi}(s)}$$

Thus, the integral equation (3) can be solved using the feedback system of Figure 1.

The optimal values $\mathcal{S}$ and Q can be determined by observing that the output function $m(\mathcal{S}, x)$ must satisfy equations (1) and (2). The interesting practical case which was investigated was the following:

Assume proportional holding and shortage costs, measured at end of period, then

$$L(x) = h\int_0^x (x-u)\phi(u)\, du + p\int_x^\infty (u-x)\phi(u)\, du \qquad (4)$$

In inventory terminology, h is the unit holding cost and p is the unit shortage cost. Differentiating (4) with respect to x, we obtain the following expression for $l(x)$:

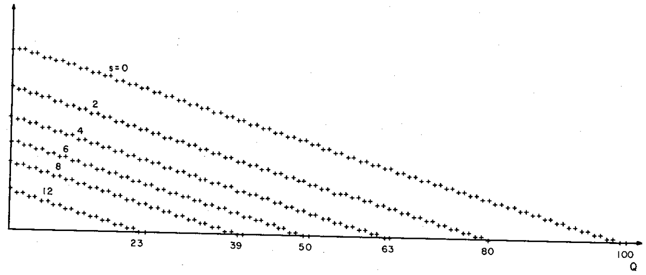

Figure 4—C.S.M.P. results for m(S, x) when n = 1, a = .1 and increments of .01

$$l(x) = (h+p)\int_0^x \phi(u)\, du - p \qquad (5)$$

We shall restrict our attention to the case when $\phi(\cdot)$ is a gamma density function of integer order n, i.e.,

$$\phi(\xi) = \frac{(a\xi)^{n-1}}{(n-1)!}ae^{-a\xi}a>0, \quad n=1, 2, \ldots \qquad (6)$$

Note then that in the s domain

$$\bar{\phi}(s) = a^n/(s+a)^n \quad n=1, 2, \ldots \qquad (7)$$

THE CONTINUOUS SYSTEM MODELING PROGRAM AND EXPERIMENTAL RESULTS

For illustrative purpose the numerical values of $h=1$, $p=10$ and $a=.10n$ were used. The selection of this particular value of a yields an expected demand of 10 units per period irrespective of the order of the gamma distribution. In Reference 5 a parallel connection was used to generate the gamma distribution. In contradistinction, a series connection is used in this paper involving a cascade of n filters of $a/(s+a)$. Thus, the

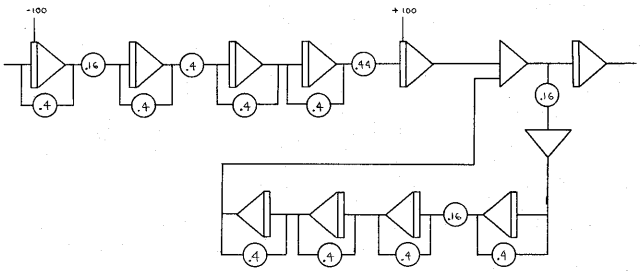

Figure 3—Analog equivalent of Figure 2

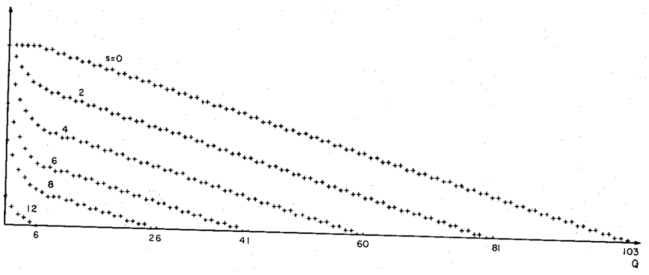

Figure 5—C.S.M.P. results for m(S, x) when n = 4, a = 4 and increments of .01

entire problem was to be redesigned in such a way that the number of feedback loops as used in the original analog circuitry[5] was eliminated; instead, a serial first order loop approach was implemented. Figure 2 illustrates the flow chart of the digital simulation when $n=4$, while Figure 3 is the analog equivalent of Figure 2. Referring to Figure 2, when time is less than $\mathcal{S}$, $c=0$ and the feedback loop is idle. When time is greater than $\mathcal{S}$, then $c=-1$ thus initiating the feedback loop. At the same time, the last integrator marked $1/s$ is turned on on operate mode. The logic part has been left out in Figure 3 for the sake of simplicity and because it has well been defined in Reference 5. The C.S.M.P. program for $n=1$ to $n=19$ (Table I) was so designed as to print out the Q and K values when the function $m(\mathcal{S}, x)$ reaches zero.

DISCUSSION

A significant marked improvement results for the output function $m(\mathcal{S}, x)$; this is illustrated in Figures 4, 5 and 6 for values of $n=1$, 4 and 19 respectively. The fact that the function $m(\mathcal{S}, x)$ can be generated for a gamma distribution of an order as high as $n=19$ is significant, particularly in the context of previous work.

Tables II and III report respectively some of the numerical results for $n=1$ and $n=4$ obtained from analog computation and digital computation using C.S.M.P. Increments of 1.00, .10 and .01 were used for comparison purposes.

It may be noticed that the order of magnitude of n depends on the size of the analog installation,[5] whereas the digital does not seem to have any limitations on the value of n at all. It is evident that the advantage of the analog system is not present in the discretized problem particularly when an immediate visual or graphical picture is desired for $m(\mathcal{S}, x)$.

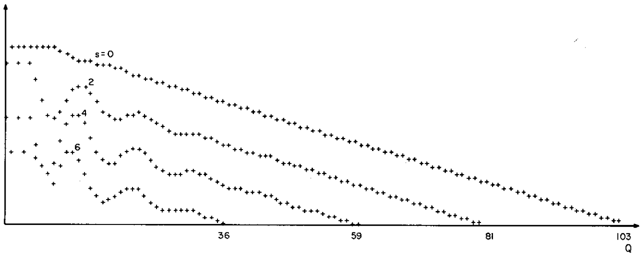

Figure 6—C.S.M.P. results for $m(\mathcal{S}, x)$ when $n = 19$, $a = 1.9$ and increments of .01

Bounds on multiprocessing anomalies and related packing algorithms

by R. L. GRAHAM

Bell Telephone Laboratories, Inc.
Murray Hill, New Jersey

INTRODUCTION

It has been known for some time that certain rather general models of multiprocessing systems frequently exhibit behavior which could be termed "anomalous," e.g., an *increase* in the number of processors of the system can cause an *increase* in the time used to complete a job.[42,36,20] In order to fully realize the potential benefits afforded by parallel processing, it becomes important to understand the underlying causes of this behavior and the extent to which the resulting system performance may be degraded.

In this paper we survey a number of theoretical results obtained during the past few years in connection with this topic. We also discuss many of the algorithms designed either to optimize or at least to improve the performance of the multiprocessor system under consideration.

The performance of a system or an algorithm can be measured in several rather different ways.[5] Two of the most common involve examining the *expected* behavior and the *worst-case* behavior of the object under consideration. Although knowledge of expected behavior is generally more useful in typical day-to-day applications, theoretical results in this direction require assumptions concerning the underlying probability distributions of the parameters involved and historically have been extremely resistant to attack.

On the other hand, there are many situations for which worst-case behavior is the appropriate measure (in addition to the fact that worst-case behavior does bound expected behavior). This type of analysis is currently a very active area of research, and theoretical insight into the worst-case behavior of a number of algorithms from various disciplines is now beginning to emerge (e.g., see References 7, 14, 15, 19, 20, 21, 26, 27, 29, 32, 33, 44, 47, and especially Reference 41.) It is this latter measure of performance which will be used on the models and algorithms of this paper. Since it is essential to have on hand the worst examples one can think of before conjecturing and (hopefully) proving bounds on worst-case behavior, numerous such examples will be given throughout the text.

Before concluding this section, it seems appropriate to make a few remarks concerning the general area of these topics. Recent years have seen the emergence of a vital and important new discipline, often called "analysis of algorithms." As its broad objective, it seeks to obtain a deeper understanding of the nature of algorithms. These investigations range, for example, from the detailed analysis of the behavior of a specific sorting routine, on one hand, to the recent negative solution[†] to Hilbert's Tenth Problem by Matijasevič[37] and Julia Robinson,[43] on the other. It is within this general framework that the present discussion should be viewed.

A GENERAL MULTIPROCESSING SYSTEM

Let us suppose we have n (abstract) identical processors P_i, $i=1, \ldots, n$, and we are given a set of tasks $\mathcal{T}=\{T_1, \ldots, T_r\}$ which is to be processed by the P_i. We are also given a partial order[††] $<$ on $\mathcal{T}$ and a function $\mu:\mathcal{T}\rightarrow(0, \infty)$. Once a processor P_i begins to execute a task T_j, it works without interruption until the completion of that task,[†††] requiring altogether $\mu(T_j)$ units of time. It is also required that the partial order be respected in the following sense: If $T_i<T_j$ then T_j cannot be started until T_i has been completed. Finally, we are given a sequence $L=(T_{i_1}, \ldots, T_{i_r})$, called the

[†] Which roughly speaking shows that there is no universal algorithm for deciding whether a diophantine equation has solutions or not.

[††] See Reference 31 for terminology.

[†††] This is known as *nonpreemptive* scheduling as opposed to *preemptive* scheduling in which the execution of a task may be interrupted.[5]

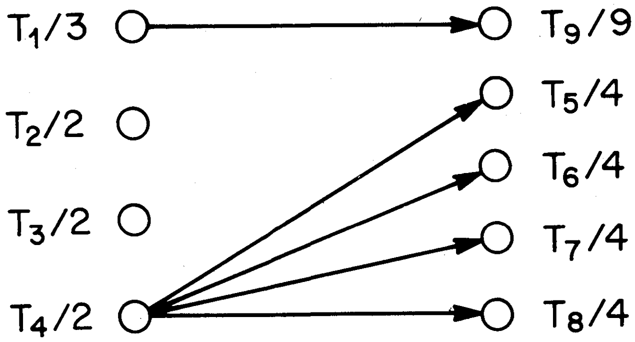

Figure 1—A simple graph G

(*priority*) *list* (or schedule) consisting of some permutation of all the tasks $\mathcal{T}$. The P_i execute the T_j as follows: Initially, at time 0, all the processors (instantaneously) scan the list L from the beginning, searching for tasks T_i which are "ready" to be executed, i.e., which have no predecessors under $<$. The first ready task T_j in L which P_i finds immediately begins to be executed by P_i; P_i continues to execute T_j for the $\mu(T_j)$ units of time required to complete T_j. In general, at any time a processor P_i completes a task, it immediately scans L for the first available ready task to execute. If there are currently no such tasks, then P_i becomes idle. We shall also say in this case that P_i is executing an *empty task* which we denote by φ (or φ_i). P_i remains idle until some other P_k completes a task, at which time P_i (and, of course, P_k) immediately scans L for ready tasks which may now exist because of the completion of T_j. If two (or more) processors both attempt to start executing a task, it will be our convention to assign the task to the processor with the smaller index. The least time at which all tasks of T have been completed will be denoted by ω.

We consider an example which illustrates the working of the preceding multiprocessing system and various anomalies associated with it. We indicate the partial order $<$ on T and the function μ by a *directed graph*[†] $G(<, \mu)$. In $G(<, \mu)$ the vertices correspond to the T_i and a directed edge from T_i to T_j denotes $T_i < T_j$. The vertex T_j of $G(<, \mu)$ will usually be labeled with the symbols $T_j/\mu(T_j)$. The activity of each P_i is conveniently represented by a *timing diagram D* (also known as a Gantt chart.[2] D consists of n horizontal half-lines (labeled by the P_i) in which each line is a time axis starting from time 0 and is subdivided into segments labeled according to the corresponding activity of the P_i. In Figure 1 we show a simple graph G.

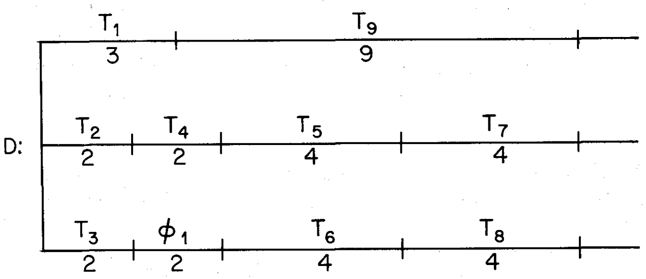

Figure 2—The timing diagram D for G

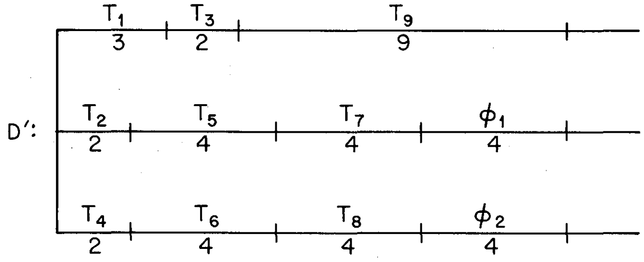

Figure 3—The timing diagram D′ when L′ is used

In Figure 2, we give the corresponding timing diagram D assuming that the list $L = (T_1, T_2, \ldots, T_9)$ is used with three processors. The finishing time is $\omega = 12$.

Note that on D we have labeled the intervals above by the task and below by the length of time needed to execute the task.

It is evident from the definition of ω that it is a function of L, μ, $<$ and n. Let us vary each of these four parameters in the example and see the resulting effect this variation has on ω.

(i) Replace L by $L' = (T_1, T_2, T_4, T_5, T_6, T_3, T_9, T_7, T_8)$, leaving μ, $<$ and n unchanged (Figure 3). For the new list L', $\omega' = \omega'(L', \mu, <, n) = 14$.

(ii) Change $<$ to $<'$ by removing $T_4 < T_5$ and $T_4 < T_6$.

For the new partial order $<'$, $\omega' = \omega'(L, \mu, <', n) = 16$ (Figure 4).

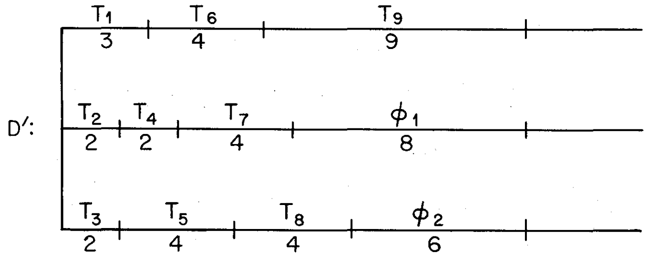

Figure 4—The timing diagram D′ when <′ is used

[†] For terminology in graph theory, see Reference 23.

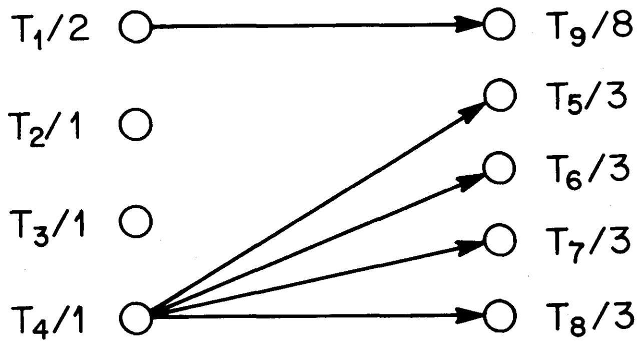

Figure 5—The new graph G using μ'

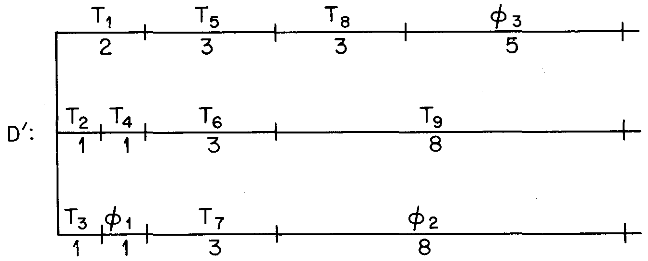

Figure 6—The timing diagram D′ when μ' is used

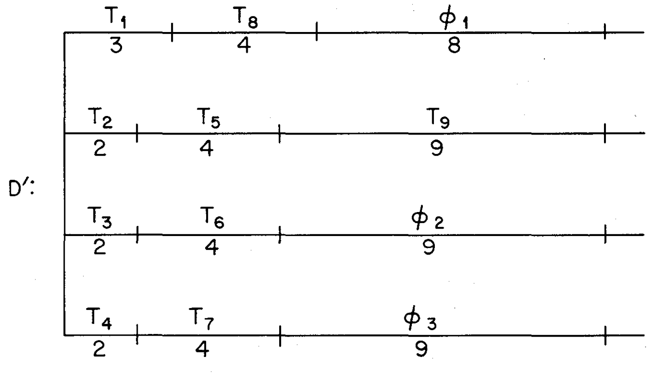

Figure 7—The timing diagram D′ when 4 processors are used

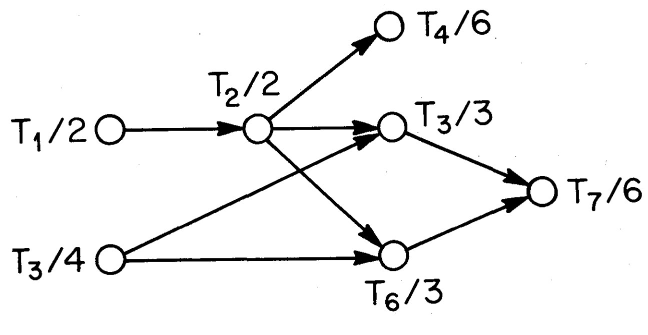

Figure 8—Another simple graph

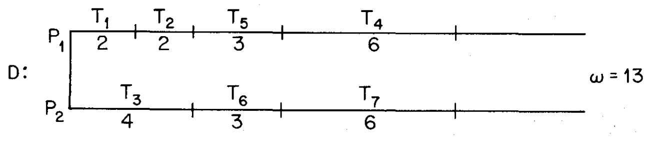

Figure 9—The timing diagram D using the list L

(iii) Decrease μ to μ' by defining $\mu'(T_i) = \mu(T_i) - 1$ for all i. In this case $G(<, \mu)$ is shown in Figure 5.

The corresponding timing diagram D' is shown in Figure 6 where we see $\omega' = \omega'(L, \mu', <, n) = 13$.

(iv) Increase n from three to four (Figure 7). In this case $\omega' = 15$!

Note that in (iii) by using the list $L'' = (T_1, T_2, T_3, T_4, T_9, T_5, T_6, T_7, T_8)$ we can reduce the finishing time to 10 which is less than the 12 of the original unshortened problem. This does not always have to occur though, as the example given in Figure 8 shows.

When the (optimal) list $L = (T_1, T_2, T_3, T_5, T_6, T_4, T_7)$ is used, $\omega = 13$ (Figure 9).

If all execution times are decreased by one unit then *all* lists generate the same finishing time $\omega' = 14$. A typical D' is shown in Figure 10.

A GENERAL BOUND

The examples in the preceding section show that contrary to what might generally be expected, *relaxing* $<$, *decreasing* μ or *increasing* n can all cause ω to *increase*. It is natural to inquire into the extent to which these changes can affect the finishing time ω. The right measure turns out to be the ratio of the possible finishing times, and a bound is given in the following result.

Theorem.[19,20]

Suppose we are given a set of tasks $\mathcal{T}$, which we wish to execute twice. The first time we use a time function μ, a partial order $<$, a list L and a multiprocessing system composed of n processors. The second time we

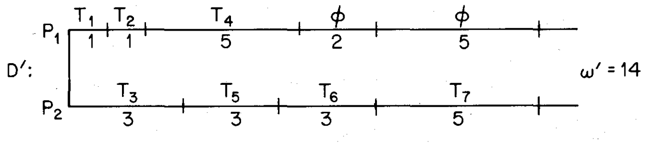

Figure 10—A timing diagram D using shortened times

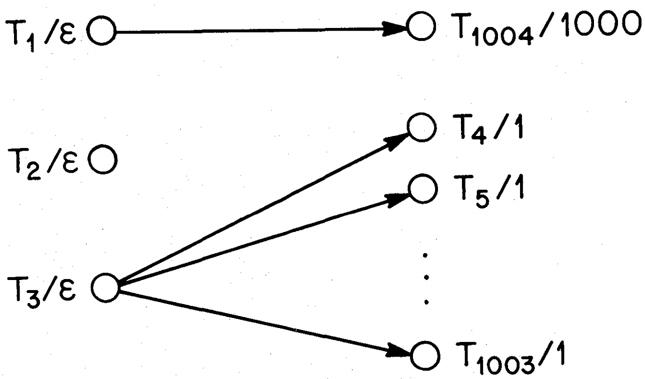

Figure 11—A graph G

use a time function $\mu' \le \mu$, a partial order[†] $<' \subseteq <$, a list L' and a multiprocessing system composed of n' processors. Let ω and ω' denote the respective finishing times. Then

$$\omega'/\omega \le 1+(n-)1/n'. \tag{1}$$

Furthermore, this bound is best possible in the sense that the right-hand side cannot be replaced by any smaller function of n and n'.

For $n = n'$, the bound becomes

$$\omega'/\omega \le 2-1/n \tag{2}$$

In fact, examples[††] can be given[19] which show that the bound in (2) can be achieved (to within an arbitrary $\epsilon > 0$) by varying any *one* of the three parameters L, μ and $<$. Note that (2) implies that using the worst possible list instead of the best possible list still only results in an increase in ω of at most a factor of $2-1/n$.

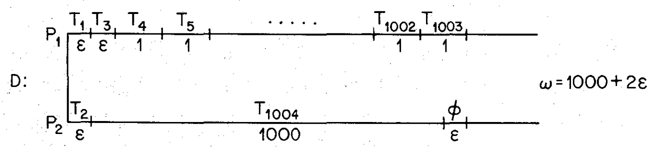

Figure 12—2 processors are used to execute the tasks of G

When $n = 1$, (1) implies $\omega'/\omega \le 1$ which agrees with the obvious fact that the aforementioned changes in L, μ, $<$ and n can never cause increase in the running time when compared to that for single processor. On the other hand, when $n > 1$ then even a large increase in the number of processors (but with a fixed list L) can cause ω to increase as the example given in Figure 11 shows (where $0 < \epsilon < 1$).

If the tasks of G are executed by two processors using the list $L = (T_1, T_2, T_3, \ldots, T_{1004})$ then $\omega = 1000 + 2\epsilon$ (Figure 12).

If the tasks of G are executed by 1000 processors using the same list L then $\omega' = 1001 + \epsilon$ (Figure 13). However, it is always true that the use of a suitable list will prevent ω from increasing because of an increase in n (e.g., in this case, take $L = (T_{1004}, T_1, T_2, \ldots, T_{1003})$).

We mention here that even if inserted idleness and preemption[†] are allowed in the first run, it can be shown that ω/ω' is still bounded above by $2-1/n$.[3,18]

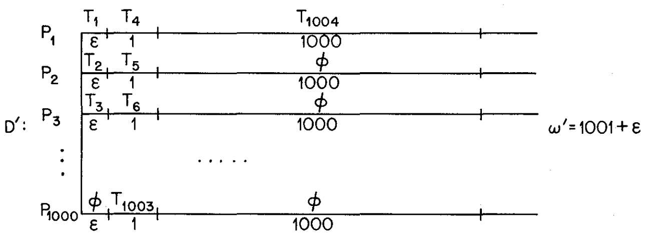

Figure 13—1000 processors are used to execute the tasks of G

SOME SPECIAL BOUNDS

We next consider results arising from attempts at finding lists which keep the ratio of ω/ω_0 close to one. Since for any given problem, there are just finitely many possible lists then one might be tempted to say: "Examine them all and select the optimum." Not much insight is needed, however, to realize that due to the explosive growth of functions such as $n!$, this is not a realistic solution. What one is looking for instead is an algorithm which will guarantee that ω/ω_0 is reasonably close to one provided we are willing to expend an appropriate amount of energy applying the algorithm. Unfortunately, no general results of this type presently exist. There is a special case, however, in which steps in this direction have been taken. This is the case in which $<$ is empty, i.e., there are no precedence constraints between the tasks. We shall restrict ourselves to this case for the remainder of this section.

Suppose, for some (arbitrary) k, the k tasks with the largest values of μ have been selected[†] and somehow

[†] Since a partial order on $\mathfrak{T}$ is a subset of $\mathfrak{T} \times \mathfrak{T}$, $<' \subseteq <$ has the obvious meaning.

[††] Recent examples of M. T. Kaufman (personal communication) show that in many cases the bounds of (1) and (2) can be achieved even when $\mu(T) = 1$ for all T.

[†] i.e., holding a processor idle when it could be busy and interrupting the execution of a task before completion.

[†] Recent results of Blum, Floyd, Pratt, Rivest and Tarjan[41] allow this to be done in no more than $6r$ binary comparisons where r denotes the number of tasks.

arranged in a list L_k which is optimal with respect to this set of k tasks (i.e., for no other list can this set of k tasks finish earlier). Form the list $L^{(k)}$ by adjoining the remaining tasks arbitrarily but so that they follow all the tasks of L_k. Let $\omega(k)$ denote the finishing time using this list with a system of n processors. If ω_0 denotes the global optimum, i.e., the minimum possible finishing time over all possible lists then the following result holds.

Theorem.[20]

$$\frac{\omega(k)}{\omega_0} \leq 1+\frac{1-1/n}{1+[k/n]} \tag{3}$$

For $k \equiv 0 (\text{mod } n)$ this bound is best possible.

For the case of $k \equiv 0 (\text{mod } n)$ the following example establishes the optimality of the bound from below.

For $1 \leq i \leq k+1+n(n-1)$, define $\mu(T_i)$ by

$$\mu(T_i)=\begin{cases} n & \text{for } 1 \leq i \leq k+1, \\ 1 & \text{for } k+2 \leq i \leq k+1+n(n-1). \end{cases}$$

For this set of tasks and the list $L(k)=(T_1, \ldots, T_k, T_{k+2}, \ldots, T_{k+1+n(n-1)}, T_{k+1})$ we have $\omega(k)=k+2n-1$.

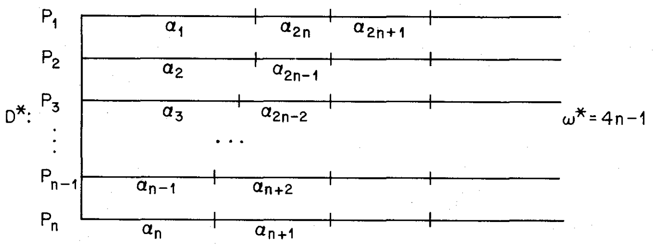

Figure 14—The timing diagram D* using the decreasing list L*

Since $\omega_0=k+n$, and $k \equiv 0 (\text{mod } n)$ then

$$\frac{\omega(k)}{\omega_0}=1+\frac{1-1/n}{1+[k/n]}$$

as asserted.

For $k=0$, (3) reduces to (2) while for $k=n$ we have

$$\omega(n)/\omega_0 \leq 3/2-1/2n. \tag{4}$$

The required optimal assignment of the largest n tasks to the n processors is immediate—just assign each of these tasks to a different processor. For $k=2n$, (3) reduces to

$$\omega(2n)/\omega_0 \leq 4/3-1/3n, \tag{5}$$

a bound which will soon be encountered again.

An important property of (3) is that the right-hand side tends to 1 as k gets larger compared to n. Thus, in order for $\omega(k)$ to be assured of being within 10 percent of the minimum value ω_0, for example, it suffices to optimally schedule the largest $9n$ tasks.

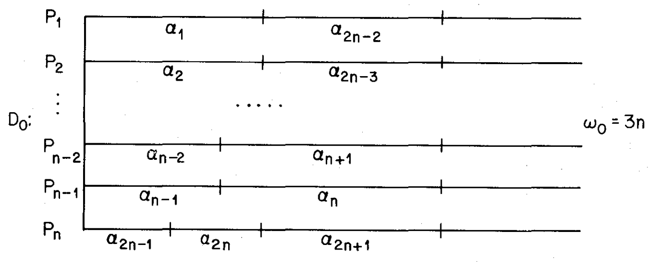

Figure 15—The timing diagram D₀ using an optimal list

Another heuristic technique for approximating the optimal finishing time ω_0 is to use the "decreasing" list† $L^*=(T_{i_1}, T_{i_2}, \ldots)$ where $\mu(T_{i_1}) \geq \mu(T_{i_2}) \geq \ldots$. The corresponding finishing time ω^* satisfies the following inequality.

Theorem.[20]

$$\omega^*/\omega_0 \leq 4/3-1/3n. \tag{6}$$

This bound is best possible.

For $n=2$, (6) yields a bound of 7/6 which is exactly the ratio obtained from the canonical example with five tasks having execution times of 3, 3, 2, 2 and 2. More generally, the following example shows that (6) is exact. $\mathfrak{T}$ consists of $r=2n+1$ independent tasks T_k with $\mu(T_k)=\alpha_k=2n-[(k+1)/2]$ for $1 \leq k \leq 2n$ and $\mu(T_{2n+1})=\alpha_{2n+1}=n$ (where $[x]$ denotes the greatest integer not exceeding x). Thus

$$(\alpha_1, \alpha_2, \ldots, \alpha_{2n+1})$$
$$=(2n-1, 2n-1, 2n-2, 2n-2, \ldots, n+1, n+1, n, n, n)$$

In Figure 14, $\mathfrak{T}$ is executed using the decreasing list $L^*=(T_1, T_2, \ldots, T_{2n+1})$.

In Figure 15, $\mathfrak{T}$ is executed using an optimal list.

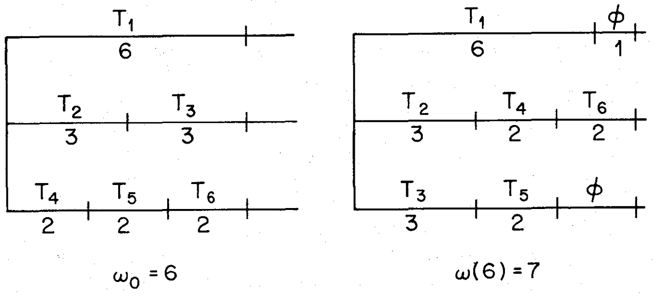

Figure 16—Example illustrating difference between L* and L(2n)

† Such a list can be formed in essentially no more than $r \log r/\log 2$ binary comparisons.[33]

It is interesting to observe that although the right-hand sides of (5) and (6) are the same, arranging the tasks by decreasing execution time does not necessarily guarantee that the largest $2n$ tasks will be executed optimally by L^*. An example showing this (due to J. H. Spencer (personal communication)) is given in Figure 16. The execution times of the tasks are (6, 3, 3, 2, 2, 2) and three processors are used.

The following result shows that if none of the execution times is large compared to the sum of all the execution times then ω^* cannot be too far from ω_0.

Theorem.[18]

If $<$ is empty and

$$\max \mu(T) / \sum_{T} \mu(T) \leq \beta$$

then

$$\omega^*/\omega_0 \leq 1+n\beta. \tag{7}$$

Another approach is to start with a timing diagram resulting from some arbitrary list and then make *pairwise interchanges* between tasks executed by pairs of processors which decrease the finishing time, until this can no longer be done. If ω' denotes the final finishing time resulting from this operation then it can be shown[18] that

$$\omega'/\omega_0 \leq 2-2/(n+1) \tag{8}$$

and, furthermore, this bound cannot be improved.

SOME ALGORITHMS FOR OPTIMAL LISTS

There seems little doubt that even for the case when $<$ is empty, $\mu(T)$ is an integer, and $n=2$, any algorithm which determines an optimal list for any set of tasks must be essentially enumerative† in its computational efficiency. This problem can be rephrased as follows:

Given a sequence $S=(s_1, \ldots, s_r)$ of positive integers find a choice of $\epsilon_i = \pm 1$ such that

$$\left| \sum_{k=1}^{r} \epsilon_k s_k \right|$$

is minimized.

Thus any hope for efficient algorithms which produce optimal schedules for more general multiprocessing problems seems remote indeed. There are several special cases, however, for which such algorithms exist.

For the case when $\mu(T)=1$ for all tasks T and $<$ is a forest,† Hu[28] has shown that the following algorithm generates an optimal list L_0.

(i) Define the level $\lambda(T)$ of any terminal†† task T to be 1.
(ii) If T' is an immediate successor of T, define $\lambda(T)$ to be $\lambda(T')+1$.
(iii) Form the list $L_0=(T_{i_1}, T_{i_2}, \ldots, T_{i_r})$ in order of decreasing λ values, i.e., $\lambda(T_{i_1}) \geq \lambda(T_{i_2}) \geq \cdots \geq \lambda(T_{i_r})$.

Theorem.[28]

L_0 is an optimal list when $\mu(T)=1$ for all T and $<$ is a tree.

The only other case for which an efficient algorithm is currently known is when $\mu(T)=1$ for all T, $n=2$ and $<$ is arbitrary. In fact, two quite distinct algorithms have been given. One of these, due to Fujii, Kasami and Ninomiya[11,12] is based on a matching algorithm for bipartite graphs of Edmonds[8] and appears to be of order $O(r^3)$. The other, due to Coffman and Graham,[3] uses the following labeling technique:

Assuming there are r tasks, each task T will be assigned a unique label $\alpha(T) \epsilon \{1, 2, \ldots, r\}$.

(i) Choose an arbitrary terminal task T_0 and define $\alpha(T_0)=1$.
(ii) Assume the values $1, 2, \ldots, k-1$ have been assigned for some $k \leq r$. For each unlabeled task T having all its immediate successors already labeled, form the decreasing sequence $M(T)=(m_1, m_2, \ldots, m_5)$ of the labels of T's immediate successors. These $M(T)$ are lexicographically† ordered. Choose a *minimal* $M(T')$ in this order and define $\alpha(T')=k$.
(iii) Form the list $L^*=(T_{i_1}, T_{i_2}, \ldots, T_{i_r})$ according to decreasing α values, i.e., $\alpha(T_{i_1}) > \alpha(T_{i_2}) > \cdots > \alpha(T_{i_r})$.

Theorem.[3]

L^* is an optimal list when $\mu(T)=1$ for all T and $n=2$.

† More precisely, the number of steps it may require cannot be bounded by a fixed polynomial in the number of bits of information needed to specify the input data.

† This means that every task T has at most one immediate successor T′, i.e., T < T′ and for no T″ is T < T″ < T′. Actually, by adding a dummy task T_0 preceded by all other tasks, < can be made into a *tree*, without loss of generality.

†† i.e., a task with no successor.

† i.e., dictionary order, so that (5, 4, 3) precedes (6, 2) and (5, 4, 3, 2).

This algorithm has been shown to be of order $O(r^2)$ and so, in a sense, is best possible since the partial order $<$ can also have this order of number of elements.

The increase in complexity of this algorithm over Hu's algorithm seems to be due to the greatly increased structure an *arbitrary* partial order may have when compared to that of a tree. Even relatively simple partial orders can defeat many other algorithms which might be thought to be optimal for this case. The example in Figure 17 illustrates this.

An optimal list for this example is $L^* = (T_{10}, T_9, \ldots, T_1)$ where we assume $\mu(T_i) = 1$ for all i. Any algorithm which allows T_{10} not to be executed first is not optimal, as, for example, executing tasks on the basis of the longest chain to a terminal task (i.e., according to levels), or executing tasks on the basis of the largest number of successors.

For $n > 2$ and $\mu(T) = 1$ for all T, the algorithm no longer produces optimal lists as the example in Figure 18 shows.

It would be interesting to know the worst-case behavior of the lists produced by this algorithm for general n.

The current state of affairs here seems to be similar to that of the job-shop scheduling problem[5,30] for which optimal schedules can be efficiently generated when $n = 2$, while for $n > 2$ no satisfactory algorithms are known.

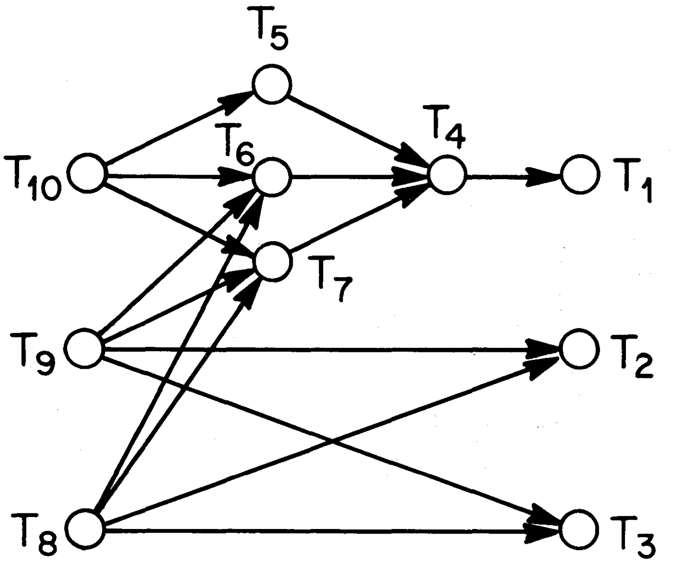

Figure 17—A useful graph for counterexamples

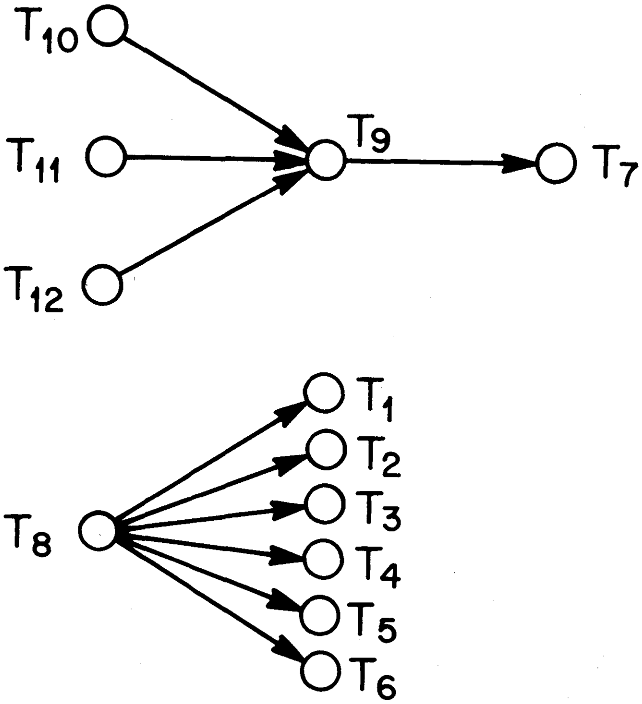

Figure 18—A counterexample to optimality when $n = 3$

A DUAL PROBLEM

Up to this point, we have generally regarded the number of processors as fixed and asked for the list L which (approximately) minimizes the finishing time ω. We now invert this question as follows: For a fixed deadline ω^*, we ask for a list L which when used will (approximately) minimize the number of processors needed to execute all tasks by the time ω^*. Of course, the two questions are essentially equivalent, and so no efficient algorithms are known for the general case.† Nevertheless, a number of recent results are now available for several special cases and these will be the subject of this section.

We first make a few remarks concerning the general case. It is not hard to see that if λ^* denotes the length of the longest chain†† in the partially-ordered set of tasks $\mathfrak{J}$, then we must have $\omega^* \geq \lambda^*$. Otherwise, no number of processors could execute all tasks of $\mathfrak{J}$ in ω^* time units. On the other hand, if sufficiently many processors are available then all tasks of $\mathfrak{J}$ can be executed in time λ^*. In fact, if m^* denotes the maximal number of mutually *incomparable*† tasks of $\mathfrak{J}$, then it is never necessary to have more than m^* processors in the system since clearly no more than m^* can be in operation at any one time.

† Both of these questions are raised in Reference 10.

†† i.e., a sequence $T_{i_1} < T_{i_2} < \cdots < T_{i_m}$ with $\sum_k \mu(T_{i_k})$ maximal.

† T_i and T_j are incomparable if neither $T_i < T_j$ nor $T_j < T_i$ hold.

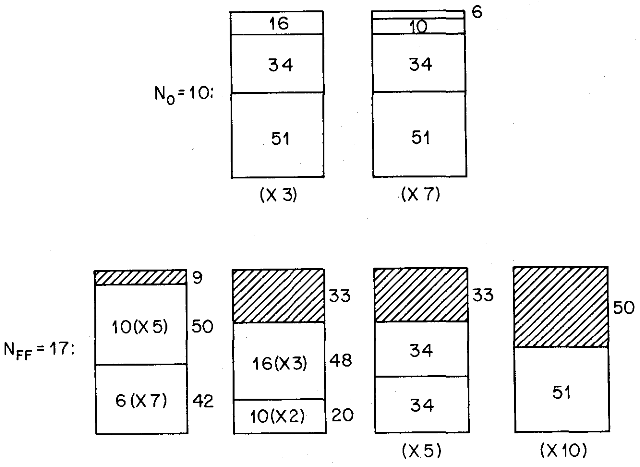

Figure 19—An example with N_{FF}/N_0 = 17/10

For the case in which $\mu(T)=1$ for all tasks T, lower bounds for both problems are provided by results of Hu.[28] In this case, if $\lambda(T)$ denotes the *level* of a task T as defined in the preceding section, let m denote the *maximum* level of any task in $\mathfrak{J}$ and for $0 \leq k \leq m$, let $\Lambda(k)$ denote the number of tasks having level strictly greater than k.

Theorem.[28]

If n processors can execute $\mathfrak{J}$ with finishing time ω then

$$\omega \geq \max_{0 \leq k \leq m} (k+\Lambda(k)/n). \qquad (9)$$

For other early results dealing with these and related problems, the reader may consult References 1, 5, 13, 24, 38, 42, 45, and 46.

For the remainder of this section, we restrict ourselves to the special case in which there are no precedence constraints on the tasks. In this case the second problem becomes a special case of the one-dimensional cutting stock problem[15,17] as well as a special case of the assembly-line balancing problem.[5]

We can also think of the problem in the following terms. We are given a set of objects ${}_i$O with O_i having weight $\alpha_i=\mu(T_i)$, $1 \leq i \leq r$. We have at our disposal an unlimited supply of boxes B_j, each with a maximum capacity of ω^* units of weight. It is required to assign all the objects to the minimum number N_0 of boxes subject to the constraint that the total weight assigned to any box can be no more than ω^*. In this form, this question takes the form of a typical loading or packing problem.[9] Integer linear programming algorithms have been given[9,16,17,25] for obtaining optimal solutions for this problem, but the amount of computation necessary soon becomes excessive as the size of the problem grows.

Several heuristic algorithms have been suggested[9,15,40] for approximating N_0. One of these, which we call the "first-fit" algorithm, is defined as follows: For a given list $L=(\alpha_{i_2}, \alpha_{i_2}, \ldots, \alpha_{i_r})$, the α_{i_k} are successively assigned in order of increasing k, each to the box B_j of lowest index into which it can validly be placed. The number of boxes thus required will be denoted by $N_{FF}(L)$, or just N_{FF}, when the dependence on L is suppressed.

If L is chosen so that $\alpha_{i_1} \geq \alpha_{i_2} \geq \cdots \geq \alpha_{i_r}$ then the first-fit algorithm using this list is called the "first-fit decreasing" algorithm and the corresponding $N_{FF}(L)$ is denoted by N_{FFD}.

Instead of first-fit, one might instead assign the next α_k in a list L to the box in which the resulting unused capacity is minimal. This is called the "best-fit" algorithm and N_{BF} will denote the number of boxes required in this case. The corresponding definitions of "best-fit decreasing" and N_{BFD} are analogous to first-fit decreasing and N_{FFD} and are omitted.

One of the first questions which arises concerning these algorithms is the extent by which they can ever deviate from N_0. Only for N_{FF} is the behavior accurately known.

Theorem.[47,15]

For any $\epsilon > 0$, if N_0 is sufficiently large then

$$N_{FF}/N_0 < 17/10+\epsilon. \qquad (10)$$

The 17/10 in (10) is best possible. An example for which $N_{FF}/N_0=17/10$ is given in Figure 19 (where

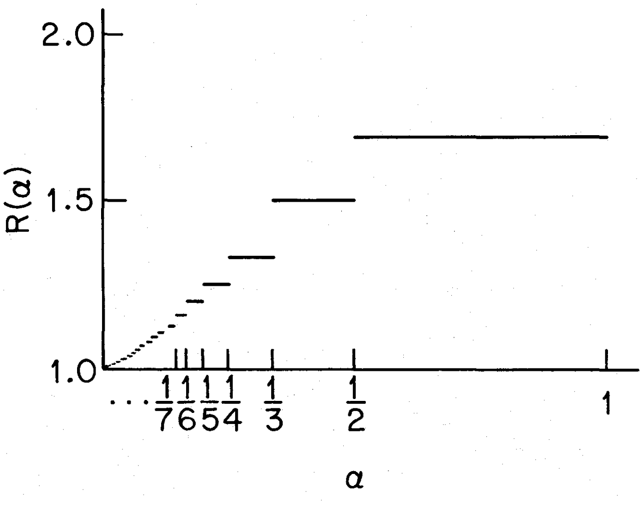

Figure 20—The function R(α)

$\omega^* = 101$). The multiplicity of types of boxes and objects are given in parentheses.

For any $\epsilon > 0$ examples can be given with $N_{FF}/N_0 \geq 17/10 - \epsilon$ and N_0 arbitrarily large. It appears, however, that for N_0 sufficiently large, N_{FF}/N_0 is strictly less than 17/10.

In order to achieve a ratio N_{FF}/N_0 close to 17/10 it is necessary[15] to have some of the α_i exceed $\omega^*/2$. Conversely, if all α_i are small compared to ω^* then N_{FF}/N_0 must be relatively close to one. This is stated precisely in the following result.

Theorem.[15]

Suppose $\max \alpha_i/\omega^* \leq \alpha$. Then for any $\epsilon > 0$, if N_0 is sufficiently large then

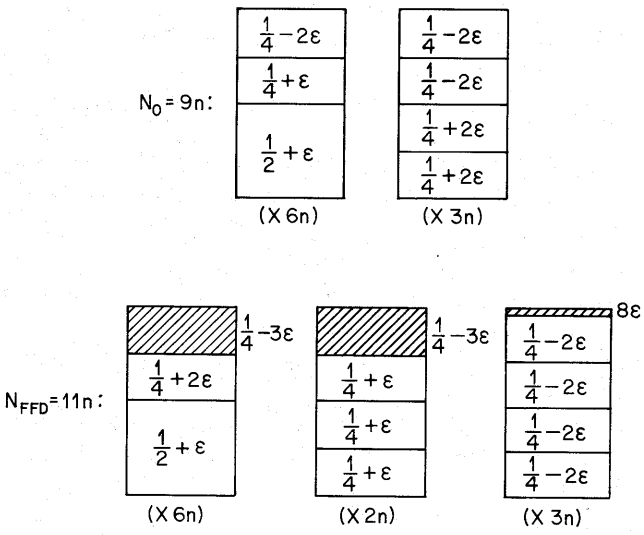
$$N_{FF}/N_0 - \epsilon \leq \begin{cases} 17/10 \text{ for } \alpha > \frac{1}{2}, \\ 1 + \lfloor \alpha^{-1} \rfloor^{-1} \text{ for } 0 < \alpha \leq \frac{1}{2}. \end{cases} \qquad (11)$$

The right-hand side of (11) cannot be replaced by any smaller function of α.

We denote the right-hand side of (11) by $R(\alpha)$ and illustrate it in Figure 20.

It is conjectured[15] that the worst-case behavior of N_{BF}/N_0 is the same as that of N_{FF}/N_0 but this has not yet been established. It is known that $R(\alpha)$ is also a lower bound for N_{BF}/N_0 when $\max \alpha_i \leq \alpha\omega^*$.

As one might suspect, N_{FFD}/N_0 cannot differ from 1 by as much as N_{FF}/N_0 can. This is shown in the following result.



$N_0 = 9n$:

Figure 22—An example with $N_{FFD}/N_{BFD} = 11/10$ and N_0 large

Theorem.[15]

For any $\epsilon > 0$, if N_0 is sufficiently large then

$$N_{FFD}/N_0 < 5/4 + \epsilon. \qquad (12)$$

The example in Figure 21 shows that

$$N_{FFD}/N_0 \geq 11/9 \qquad (13)$$

is possible for N_0 arbitrarily large. It is conjectured that the 5/4 in (12) can be replaced by 11/9; this has been established[15] for some restricted classes of α_i.

The preceding remarks also apply, *mutatis mutandis*, to the ratio N_{BFD}/N_0. This is implied by the following somewhat surprising result.

Theorem.[15]

If $\max \alpha_i/\omega^* \geq 1/5$ then $N_{FFD} = N_{BFD}$.

The quantity 1/5 above cannot be replaced by any smaller number as the example in Figure 22 shows.

This example raises the whole question concerning the extent by which the numbers N_{FF}, N_{BF}, N_{FFD} and N_{BFD} may differ among themselves (assuming that N_0 is large). The example in Figure 22 shows that $N_{FFD}/N_{BFD} \geq 11/10$ is possible for arbitrarily large N_0. On the other hand, the example of Figure 23 shows that $N_{BFD}/N_{FFD} \geq 13/12$ is possible for arbitrarily large N_0. These two examples represent the worst behavior of N_{FFD}/N_{BFD} and N_{BFD}/N_{FFD} currently known.

Another algorithm which has been proposed[40] proceeds by first selecting from all the α_i a subset which packs B_1 as well as possible, then selecting from the

(X n)

Figure 23—An example with $N_{BFD}/N_{FFD} = 13/12$ and N_0 large

remaining α_i a subset which packs B_2 as well as possible, etc. Although more computation would usually be required for this algorithm than for the first-fit decreasing algorithm it might be hoped that the number $\bar{N}$ of boxes required is reasonably close to N_0. This does *not* have to be the case, however, since examples exist for any $\epsilon > 0$ for which N_0 is arbitrarily large and

$$\bar{N}/N_0 > \sum_{n=1}^{\infty} 1/(2^n-1) - \epsilon. \qquad (14)$$

The quantity

$$\sum_{n=1}^{\infty} 1/(2^n-1) = 1.606695\ldots$$

in (14) is conjectured[15] to be best possible.

Some of the difficulty in proving many of the preceding results and conjectures seems to stem from the fact that a *decrease* in the values of the α_i may result in an *increase* in the number of boxes required. For example, if the weights (760, 395, 395, 379, 379, 241, 200, 105, 105, 40) are packed into boxes of capacity 1000 using the first-fit decreasing algorithm then we find $N_{FFD}=3$ which is optimal. However, if all the weights are decreased by one, so that now the weights (759, 394, 394, 378, 378, 240, 199, 104, 104, 39) are packed into boxes of capacity 1000 using the first-fit decreasing algorithm, we have $N_{FFD}=4$ which is clearly not optimal. In fact, the following example shows that N_{FF} can *increase* when some of the α_i are *deleted.* In Figure 24 the list $L = (7, 9, 7, 1, 6, 2, 4, 3)$ is used with the first-fit algorithm to pack boxes of capacity 13, resulting in $N_{FF}(L) = 3$.

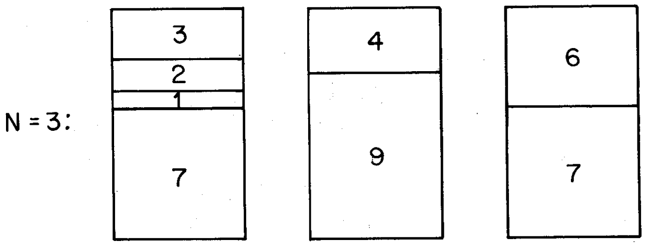

Figure 24—An optimal packing using L

If the number 1 is deleted from L, to form the list $L' = (7, 9, 7, 6, 2, 4, 3)$, then we see in Figure 25 that $N_{FF}(L') = 4$.

DYNAMIC TASK SELECTION

As an alternative to having a fixed list L prior to execution time which determines the order in which tasks should be attempted, one might employ an algorithm which determines the scheduling of the tasks in a dynamic way, making decisions dependent on the intermediate results of the execution. Unfortunately, no efficient algorithms of this type are known which can prevent the worst possible worst-case behavior.

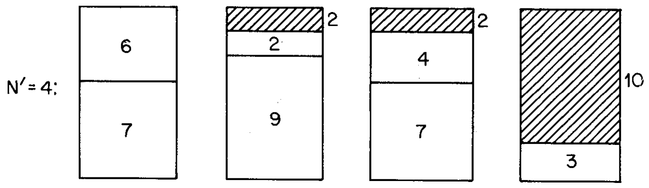

Figure 25—A nonoptimal packing using the deleted list L′

Perhaps the most natural candidate is the "critical-path" algorithm,[5] which always selects as the next task to be executed, that available task which belongs to the longest[†] chain of currently unexecuted tasks. This type of analysis forms the basis for many of the project planning techniques which have been developed such as PERT, CPM, etc.[39] Its worst-case behavior can be bad as possible as the example in Figure 26 shows (where $0 < \epsilon < 1$).

If ω_{CP} denotes the finishing time for three processors when the critical path algorithm is used on the example in Figure 26, we have $\omega_{CP} = 2n - 1 - 2\epsilon$. However, the

[†] Where, as mentioned before, the length of a chain $T_{i1} < \cdots < T_{im}$ is $\sum_k \mu(T_{ik})$.

optimal solution has $\omega_0 = n$, giving a ratio of

$$\omega_{CP}/\omega_0 = 2-1+2\epsilon/n \tag{15}$$

Since ϵ may be chosen arbitrarily close to 0, then ω_{CP}/ω_0 may be arbitrarily close to the previous bound of $2-1/n$.

This example also applies to the algorithm which selects as the next task to be executed, that available task for which the sum of the execution times of all its successors is maximal.

It may be true that the critical path algorithm may not have such extreme worst-case behavior when all the $\mu(T_i)$ are nearly equal, although not too much in this direction can be hoped for as the example in Figure 27 shows.
In this example, where n processors are used and all $\mu(T_i)=1$, $\omega_{CP}=2n$ is possible depending on how some of the ties are broken. Since $\omega_0 = n+1$ then we obtain a ratio

$$\omega_{CP}/\omega_0 = 2-2/(n+1) \tag{16}$$

which may be the maximum value possible in this case.

CONCLUDING REMARKS

As the reader will have gathered from the preceding discussion, there are certainly more questions than answers available at this point in time. We take this opportunity to comment on several of these questions, indicating what seem to the author to be fruitful directions for further research.

1. What efficient algorithms exist for preventing worst-case behavior in the general multiprocessor problem from approaching the $2-1/n$ bound? It certainly seems that just as in the case when there are no precedence constraints between tasks, it should be possible to show in some quantitative sense, that if one is willing to use more complex algorithms, one can be guaranteed of getting closer to the optimum.

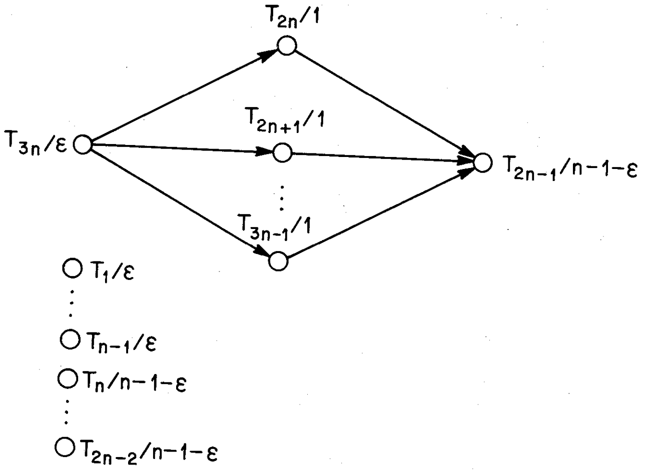

Figure 26—Example which causes worst possible critical path algorithm behavior

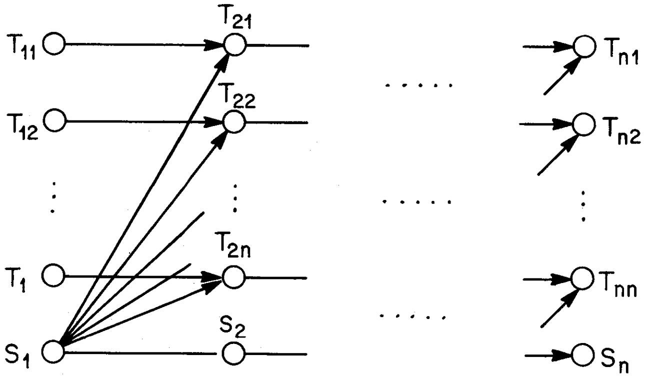

Figure 27—Example which can cause bad critical path algorithm behavior

2. There seems to be little possibility that an efficient† algorithm exists for the determination of optimal schedules for the general multiprocessor problem. Recent work of S. Cook[6] and R. M. Karp (personal communication) helps to clarify some of these issues. They show that a large class of combinatorial problems (one of which is a special case of this problem) are equivalent in this respect, i.e., either they all have efficient algorithms or none do. However, up to now everyone has been singularly unsuccessful in proving the nonexistence of such algorithms. The time seems ripe to remedy this unsatisfactory situation.

3. In the other direction, it seems likely that efficient algorithms should exist for other special cases. For example, good candidates would appear to be the cases $n=3$, $\mu(T)=1$ for all T and $n=2$, $\mu(T)=1$ or 2 for all T.

4. In reference to the dual (cutting stock) problem of an earlier section, a number of interesting open questions remain, in addition to those already mentioned. For example, one could allow boxes of different capacities and study the behavior of $N_{FF}(L)/N_{FF}(L')$ for a fixed set of weights, as a function of the lists L and L', the ordering of the boxes, the distribution of the capacities and weights, etc.[9] It would also be of interest to examine two-dimensional analogues of these problems in view of the applicability of the results (e.g., see References 16 and 17).

5. Much of the motivation for studying worst-case behavior is derived from the possible insight the results

† In the sense of Edmonds.[8]

may provide for the typical or expected behavior of the system. Very little has been rigorously established in this direction so far although some empirical results are available. For example, in simulation studies involving fairly large task sets, from two to nine processors, and unit task execution times, Manacher[36] reports that in roughly four-fifths of his runs, optimal lists fail to remain optimal when the task execution times are (randomly) slightly perturbed. In other studies, Krone[34] has investigated the typical behavior of several algorithms applied to tasks with no precedence constraints. In particular, he compared the finishing times ω^* and ω' obtained by using the "decreasing" list L^* and by using stabilized pairwise interchanges, respectively. He found that usually $\omega' < \omega^*$ when execution times had a large variance (in spite of the fact that their worst-case behavior is reversed). On the other hand, when the execution times were more nearly equal, ω^* was very good and, in fact, frequently optimal.

In view of the remarkable progress which has occurred in this and other branches of computer science during the past decade, there is little doubt in my mind that the answers to these and many other related questions will be uncovered in the not-too-distant future.

Computation of recursive programs—Theory vs practice

by ZOHAR MANNA

Stanford University
Stanford, California

This note is actually an informal exposition of a part of a recent paper by Manna, Ness and Vuillemin.[1] We have two main purposes in this note. First, we present some known results about computation of recursive programs, emphasizing some differences between the theoretical and practical approaches. Second, we introduce the computational induction method for proving properties of recursive programs. It turns out that most known methods for proving properties of programs are very closely related to the computational induction method. We illustrate this point by showing how Floyd's inductive assertions method for proving properties of "flowchart programs" can be expressed in terms of computational induction on recursive programs.

The reader should be aware that some of the results presented in this note hold only under certain restrictions which are ignored in this informal presentation.

RECURSIVE PROGRAMS

To simplify our discussion, we shall restrict ourselves to a particularly simple language, chosen because of its similarity to familiar languages such as ALGOL or LISP. A program in our language, called a *recursive program,* is of the form

$$F(\bar{x}) \Leftarrow \tau[F](\bar{x}),$$

where $\tau[F](\bar{x})$ is a composition of known functions and the function variable F, applied to the individual variables $\bar{x}=(x_1, x_2, \ldots, x_n)$. The following, for example, is a recursive program over the integers

$$P_0\colon\quad F(x_1, x_2) \Leftarrow \textit{if } x_1=x_2 \textit{ then } x_2+1 \textit{ else } F(x_1, F(x_1-1, x_2+1)).$$

We allow our known functions to be partial, i.e., they may be *undefined* for some arguments. This is quite natural, since our known functions represent the result of some computation, and a computation process may in general give results for some arguments and run indefinitely for others. We include as limiting cases of partial functions, the partial functions defined for all arguments (called total functions) as well as the partial function undefined for all arguments.

Let us consider now the following partial functions:

$f_1(x_1, x_2)$: x_1+1

$f_2(x_1, x_2)$: *if* $x_1 \geq x_2$ *then* x_1+1 *else* x_2-1, and

$f_3(x_1, x_2)$: *if* $(x_1 \geq x_2) \wedge (x_1-x_2 \text{ even})$ *then* x_1+1
else undefined.

These three functions have an interesting common property: For each i $(1 \leq i \leq 3)$, when we replace all occurrences of F in the program P_0 by f_i, the lefthand side and the righthand side of the $\Leftarrow$ yield identical partial functions, namely,
$f_i(x_1, x_2) \equiv \textit{if } x_1=x_2 \textit{ then } x_2+1 \textit{ else } f_i(x_1, f_i(x_1-1, x_2+1))$.
It is straightforward to see that the equality holds for $f_1(x_1, x_2)$, for example, since in this case we get

$$x_1+1 \equiv \textit{if } x_1=x_2 \textit{ then } x_2+1 \textit{ else } x_1+1,$$

which is clearly true. One can similarly verify that f_2 and f_3 have the same property. We therefore say that the functions f_1, f_2 and f_3 are *fixpoints* of the recursive program P_0.

Among the three functions, f_3 has one important special property: for any (x_1, x_2) such that $f_3(x_1, x_2)$ is defined, i.e., $(x_1 \geq x_2) \wedge (x_1-x_2 \text{ even})$, both $f_1(x_1, x_2)$ and $f_2(x_1, x_2)$ are also defined and have the same value as $f_3(x_1, x_2)$. For short, we say that f_3 is "less defined" than f_1 and f_2 and denote this by $f_3 \subseteq f_1$ and $f_3 \subseteq f_2$. It can be shown that f_3 has this property not only with respect to f_1 and f_2 but with respect to all fixpoints of the recursive program P_0. Moreover, $f_3(x_1, x_2)$ is the *only* function having this property; f_3 is therefore said to be the *least (defined) fixpoint of* P_0.

One of the most important results related to this topic is due to Kleene,[2] who showed that *every recursive program P has a unique least fixpoint (denoted by f_P).*

In discussing our recursive programs, the key problem is: *What is the partial function f defined by a recursive program P?* There are two viewpoints.

(a) *Fixpoint approach*: Let it be the unique least fixpoint f_P.
(b) *Computational approach*: Let it be the computed function f_C for some given computation rule C (such as "call by name" or "call by value").

Now we come to a very interesting point. All the theory of proving properties of recursive programs is actually based on the assumption that the function defined by a recursive program is exactly the least fixpoint f_P. That is, the fixpoint approach is adopted. Unfortunately, many commonly used programming languages imply computation rules for evaluating such recursive programs (such as "call by value!!") which do not necessarily lead to the least fixpoint.

Let us consider, for example, the following recursive program over the integers

$$P_1: \quad F(x_1, x_2) \Leftarrow \mathit{if}\ x_1=0\ \mathit{then}\ 1\ \mathit{else}\ F(x_1-1, F(x_1-x_2, x_2)).$$

The least fixpoint f_{P_1} can be shown to be

$$f_{P_1}(x_1, x_2): \quad \mathit{if}\ x_1 \geq 0\ \mathit{then}\ 1\ \mathit{else\ undefined}.$$

However, the computed function f_C, where C is "call by value," turns out to be

$$f_C(x_1, x_2): \quad \mathit{if}\ x_1=0 \vee [x_1>0 \wedge x_2>0 \wedge (x_2 \text{ divides } x_1)]\ \mathit{then}\ 1\ \mathit{else\ undefined}.$$

Thus, f_C is properly less defined than f_{P_1}, e.g., $f_C(1, 0)$ is undefined while $f_{P_1}(1, 0)=1$.*

There are two ways to view this problem: either (a) theoreticians are wasting their time by developing methods for proving properties of programs which "do not exist" in practice. They should concentrate their efforts in developing direct methods for proving properties of programs as they are actually executed; or (b) existing computer systems should be modified, since they are computing recursive programs in a way which prevents their user from benefiting from the results of the theory of computation. Language designers and implementors should look for efficient computation rules which always lead to the least fixpoint. "Call by name," for example, is such a computation rule, but unfortunately it often leads to very inefficient computations. An efficient computation rule which always leads to the least fixpoint can be obtained by modifying "call by value" so that the evaluation of the arguments of the function variable F are delayed as long as possible.[4]

One way to cope with the problem would be to develop translation techniques, so that for every given recursive program P and computation rule C, we can construct a recursive program P' such that the computed function of P is identical to the least fixpoint of P'. The verification techniques can then be applied to P'. This is probably the way many verification systems are going to work in the future. The main reason for adopting this approach is the existence of a very powerful method, the computational induction method, for proving properties of the least fixpoint of recursive programs. Most known methods for proving properties of programs can be expressed in terms of the computational induction method, as illustrated later. The computational induction method has two important advantages over the other methods: First, it is very convenient for machine implementation;[5] and second, termination and equivalence proofs can be handled in exactly the same way as correctness proofs.

THE COMPUTATIONAL INDUCTION METHOD

We now describe the *computational induction* method for proving properties of recursive programs. The idea is essentially to prove properties of the least fixpoint f_P of a given recursive program P by induction on the level of recursion.

Let us consider, for example, the recursive program

$$P_2: \quad F(x) \Leftarrow \mathit{if}\ x=0\ \mathit{then}\ 1\ \mathit{else}\ x \cdot F(x-1),$$

over the natural numbers. The least fixpoint function $f_{P_2}(x)$ of this recursive program is the factorial function $x!$.

Let us denote now by $f^i(x)$ the partial function indicating the "information" we have after the ith level of recursion. That is,

$f^0(x)$ is *undefined* (for all x);

$f^1(x)$ is $\mathit{if}\ x=0\ \mathit{then}\ 1\ \mathit{else}\ x \cdot f^0(x-1)$, i.e.,

$$\mathit{if}\ x=0\ \mathit{then}\ 1\ \mathit{else\ undefined};$$

$f^2(x)$ is $\mathit{if}\ x=0\ \mathit{then}\ 1\ \mathit{else}\ x \cdot f^1(x-1)$, i.e.,

$\mathit{if}\ x=0\ \mathit{then}\ 1\ \mathit{else}\ x \cdot (\text{if } x-1=0\ \mathit{then}\ 1\ \mathit{else\ undefined})$, or in short,

$\mathit{if}\ x=0 \vee x=1\ \mathit{then}\ 1\ \mathit{else\ undefined};$

etc.

* It can actually be shown, in general, that for every recursive program P and any computation rule C, if f_C and f_P are not identical, then f_C must be less defined than f_P (Cadiou [3]).

In general, for every i, $i\geq 1$,

$$f^i(x) \text{ is } \textit{if } x=0 \textit{ then } 1 \textit{ else } x\cdot f^{i-1}(x-1),$$

which is

$$\textit{if } x<i \textit{ then } x! \textit{ else undefined.}$$

This sequence of functions has a limit which is exactly the least fixpoint of the recursive program; that is,

$$\lim_i f^i(x) \equiv x!$$

The important point is that this is actually the case for any recursive program P. That is, if P is a recursive program of the form

$$F(\bar{x}) \Leftarrow \tau[F](\bar{x}),$$

and $f^i(\bar{x})$ is defined by

$$f^0(\bar{x}) \text{ is } \textit{undefined} \text{ (for all } \bar{x}),$$

and

$$f^i(\bar{x}) \text{ is } \tau[f^{i-1}](\bar{x}) \text{ for } i\geq 1,^*$$

then

$$\lim_i f^i(\bar{x}) \equiv f_P(\bar{x}).$$

This suggests an induction rule for proving properties of f_P. To show that some property φ holds for f_P, i.e., $\varphi(f_P)$, we show that $\varphi(f^i)$ holds for all $i\geq 0$, and therefore we may conclude that $\varphi(\lim_i f^i)$, i.e., $\varphi(f_P)$, holds.

There are two ways to state this rule. Both are essentially equally powerful. These are actually the rules for simple and complete induction on the level of recursion.

(a) *simple induction*
if $\varphi(f^0)$ *holds and* $\forall i[\varphi(f^i)\Rightarrow\varphi(f^{i+1})]$ *holds, then* $\varphi(f_P)$ *holds.*

(b) *complete induction*
if $\forall i\{[(\forall j \textit{ s.t. } j<i)\varphi(f^j)]\Rightarrow\varphi(f^i)\}$ *holds,*** *then* $\varphi(f_P)$ *holds.*

The simple induction rule is essentially the "μ-rule" suggested by deBakker and Scott,[6] while the complete induction rule is the "truncation induction rule" of Morris.[7]

Example: Consider the two recursive programs[7]

$$P_3:\quad F(x,y)\Leftarrow \textit{if } p(x) \textit{ then } y \textit{ else } h(F(k(x),y)),$$

and

$$P_4:\quad G(x,y)\Leftarrow \textit{if } p(x) \textit{ then } y \textit{ else } G(k(x),h(y)).$$

For our purpose there is no need to specify the domain of the programs or the meaning of p, h and k. We would like to prove, using the two forms of induction, that

$$f_{P_3}(x,y)\equiv g_{P_4}(x,y) \text{ for all } x \text{ and } y.$$

Proof by simple induction

If we restrict ourselves to simple induction, it is much more convenient to prove a stronger result than the desired one. This often simplifies proofs by induction by allowing a stronger induction assumption, even though we have to prove a stronger result. So, we actually show that

$$\varphi(f_{P_3},g_{P_4}):\quad \forall x\forall y\{[f_{P_3}(x,y)\equiv g_{P_4}(x,y)] \wedge [g_{P_4}(x,h(y))\equiv h(g_{P_4}(x,y))]\}$$

holds. We proceed in two steps:

(a) $\varphi(f^0,g^0)$, i.e., $\forall x\forall y\{[f^0(x,y)\equiv g^0(x,y)] \wedge [g^0(x,h(y))\equiv h(g^0(x,y))]\}$.

$$\forall x\forall y\{[\textit{undefined}\equiv\textit{undefined}] \wedge [\textit{undefined}\equiv\textit{undefined}]\}.$$

(b) $\forall i[\varphi(f^i,g^i)\Rightarrow\varphi(f^{i+1},g^{i+1})]$.

We assume

$$\forall x\forall y\{[f^i(x,y)\equiv g^i(x,y)] \wedge [g^i(x,h(y))\equiv h(g^i(x,y))]\},$$

and prove

$$\forall x\forall y\{[f^{i+1}(x,y)\equiv g^{i+1}(x,y)] \wedge [g^{i+1}(x,h(y))\equiv h(g^{i+1}(x,y))]\}.$$

$$\begin{aligned} f^{i+1}(x,y) &\equiv \textit{if } p(x) \textit{ then } y \textit{ else } h(f^i(k(x),y))\\ &\equiv \textit{if } p(x) \textit{ then } y \textit{ else } h(g^i(k(x),y))\\ &\equiv \textit{if } p(x) \textit{ then } y \textit{ else } g^i(k(x),h(y))\\ &\equiv g^{i+1}(x,y).\end{aligned}$$

$$\begin{aligned} g^{i+1}(x,h(y)) &\equiv \textit{if } p(x) \textit{ then } h(y) \textit{ else } g^i(k(x),h^2(y))\\ &\equiv \textit{if } p(x) \textit{ then } h(y) \textit{ else } h(g^i(k(x),h(y)))\\ &\equiv h(\textit{if } p(x) \textit{ then } y \textit{ else } g^i(k(x),h(y)))\\ &\equiv h(g^{i+1}(x,y)).\end{aligned}$$

Proof by complete induction

Using complete induction we can prove the desired result directly; that is, we prove that

$$\varphi(f_{P_3},g_{P_4}):\quad \forall x\forall y[f_{P_3}(x,y)\equiv g_{P_4}(x,y)]$$

* Where J[f^{i-1}] is the result of replacing f^{i-1} for all occurrences of F in J[F]

** Note that this indicates implicitly the need to prove $\varphi(f^0)$ separately, since for $i = 0$ there is no j s.t. $j < i$.

holds. This is done by showing first that $\varphi(f^0, g^0)$ and $\varphi(f^1, g^1)$ hold, and then that $\varphi(f^i, g^i)$ holds for all $i \geq 2$. (We treat the cases for $i=0$ and $i=1$ separately, since to prove $\varphi(f^i, g^i)$ we use the induction hypothesis for both $i-1$ and $i-2$.)

(a) $\varphi(f^0, g^0)$, i.e., $\forall x \forall y [f^0(x, y) \equiv g^0(x, y)]$.

$$\forall x \forall y [\mathit{undefined} \equiv \mathit{undefined}].$$

(b) $\varphi(f^1, g^1)$, i.e., $\forall x \forall y [f^1(x, y) \equiv g^1(x, y)]$.

$$\begin{aligned} f^1(x, y) &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ h(f^0(k(x), y)) \\ &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else\ undefined} \\ &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ g^0(k(x), h(y)) \\ &\equiv g^1(x, y). \end{aligned}$$

(c) $(\forall i \geq 2)[\varphi(f^{i-2}, g^{i-2}) \wedge \varphi(f^{i-1}, g^{i-1}) \Rightarrow \varphi(f^i, g^i)]$
We assume

$$\forall x \forall y [f^{i-2}(x, y) \equiv g^{i-2}(x, y)]$$

and

$$\forall x \forall y [f^{i-1}(x, y) \equiv g^{i-1}(x, y)],$$

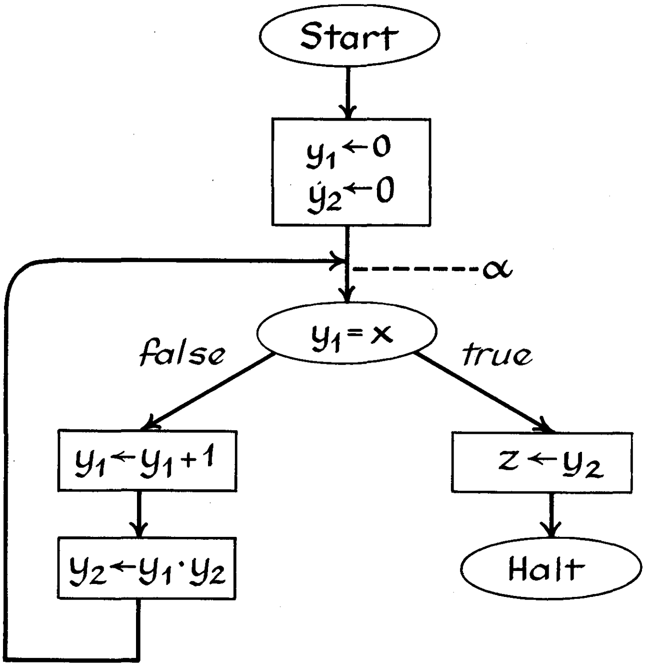
and deduce

$$\forall x \forall y [f^i(x, y) \equiv g^i(x, y)].$$

$$\begin{aligned} f^i(x, y) &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ h(f^{i-1}(k(x), y)) \\ &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ h(g^{i-1}(k(x), y)) \\ &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ h(\mathit{if}\ p(k(x))\ \mathit{then}\ y \\ &\qquad\qquad \mathit{else}\ g^{i-2}(k^2(x), h(y))) \\ &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ (\mathit{if}\ p(k(x))\ \mathit{then}\ h(y) \\ &\qquad\qquad \mathit{else}\ h(g^{i-2}(k^2(x), h(y)))) \\ &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ (\mathit{if}\ p(k(x))\ \mathit{then}\ h(y) \\ &\qquad\qquad \mathit{else}\ h(f^{i-2}(k^2(x), h(y)))) \\ &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ f^{i-1}(k(x), h(y)) \\ &\equiv \mathit{if}\ p(x)\ \mathit{then}\ y\ \mathit{else}\ g^{i-1}(k(x), h(y)) \\ &\equiv g^i(x, y). \end{aligned}$$

THE INDUCTIVE ASSERTIONS METHOD

The most widely used method for proving properties of "flowchart programs" is presently the *inductive assertions method*, suggested by Floyd[8] and Naur.[9] It can be shown that for any proof by inductive assertions, there is a naturally corresponding computational induction proof. We shall illustrate the inductive assertion method and its relation to computational induction on the following simple flowchart program:



We wish first to use the inductive assertions method to show that the above flowchart program over the natural numbers computes the factorial function, i.e., $z = x!$, *whenever it terminates*. To do this, we associate a predicate $Q(x, y_1, y_2)$, called an "inductive assertion," with the point labelled α in the program, and show that Q must be true for the values of the variables x, y_1, y_2 whenever execution of the program reaches point α. Thus, we must show (a) that the assertion holds when point α is first reached after starting execution, (i.e., that $Q(x, 0, 1)$ holds) and (b) that it remains true when one goes around the loop from α to α (i.e., that $y_1 \neq x \wedge Q(x, y_1, y_2)$ implies $Q(x, y_1+1, (y_1+1) \cdot y_2)$). To prove the desired result we finally show (c) that $z = x!$ follows from the assertion $Q(x, y_1, y_2)$ when the program terminates (i.e., that $y_1 = x \wedge Q(x, y_1, y_2)$ implies $y_2 = x!$).

We take $Q(x, y_1, y_2)$ *to be* $y_2 = y_1!$. Then:

(a) $Q(x, 0, 1)$ is $1 = 0!$.
(b) We assume $y_1 \neq x$ and $Q(x, y_1, y_2)$, i.e., $y_2 = y_1!$. Then $Q(x, y_1+1, (y_1+1) \cdot y_2)$ is $(y_1+1) \cdot y_2 = (y_1+1)!$, i.e., $(y_1+1) \cdot y_1! = (y_1+1)!$.
(c) We assume $y_1 = x$ and $Q(x, y_1, y_2)$, i.e., $y_2 = y_1!$, then $y_2 = y_1! = x!$ as desired.

To show the relation between this method and computational induction, we must first translate the flowchart program into a recursive program. Following the technique of McCarthy,[10] we find that the above flowchart program is $f_{P_5}(x, 0, 1)$, i.e., the least fixpoint of the recursive program P_5 (with $y_1=0$ and $y_2=1$) where

$$P_5: \quad F(x, y_1, y_2) \Leftarrow \textit{if } y_1=x \textit{ then } y_2 \quad \textit{else } F(x, y_1+1, (y_1+1)\cdot y_2).$$

We shall prove by (simple) computational induction that $f_{P_5}(x, 0, 1) \subseteq x!$, i.e., the value of $f_{P_5}(x, 0, 1)$ is $x!$ whenever $f_{P_5}(x, 0, 1)$ is defined, which is precisely what the above proof by inductive assertions showed.

We take $\varphi(F)$ to be the following predicate:

$$(\forall x, y_1, y_2)\{Q(x, y_1, y_2) \Rightarrow [F(x, y_1, y_2) \subseteq x!]\},$$

where $Q(x, y_1, y_2)$ is $y_2=y_1!$, the induction assertion used before. Obviously $\varphi(f^0)$ holds. To show that $\varphi(f^i)$ implies $\varphi(f^{i+1})$ for $i \geq 0$, we consider two cases: either $y_1=x$, in which case the proof follows directly from (c) above, or $y_1 \neq x$, which follows directly from (b).

By computational induction we therefore have $\varphi(f_P)$, i.e., $Q(x, y_1, y_2) \Rightarrow [f_P(x, y_1, y_2) \subseteq x!]$ for all x, y_1, y_2. But since $Q(x, 0, 1)$ is known from (a) to hold, we conclude that $f_P(x, 0, 1) \subseteq x!$, as desired.

Mathematical concepts in programming language semantics

by DANA SCOTT

Princeton University
Princeton, New Jersey

INTRODUCTION

In mathematics after some centuries of development the semantical situation is very clean. This may not be surprising, as the subject attracts people who enjoy clarity, generality, and neatness. On the one hand we have our concepts of mathematical *objects* (numbers, relations, functions, sets), and on the other we have various formal means of *expression.* The mathematical expressions are generated for the most part in a very regular manner, and every effort is made to supply all expressions with denotations. (This is not always so easy to do. The theory of distributions, for example, provided a non-obvious construction of denotations for expressions of an operational calculus. The derivative operator was well serviced, but one still cannot multiply two distributions.)

The point of such activity is that the formal rules of the calculus of expressions allow solutions of problems to be found and give us ways of checking correctness of proposed solutions. It is by no means the case that mathematical inspiration is thus reduced to automatic algebra, but the possibility of formal manipulation is a great help. Not only can we record useful lemmas, but a precise language is essential for teaching and communication.

It is of course possible to pick formalisms out of thin air and to ask people to accept their usefulness on mystical grounds. (The operational calculus was developed a little that way.) There is no denying that clever guesswork can be very successful, but ultimately it is fair to ask the mystic just what he is talking about. A way to counter that question is to show how the concepts being symbolized in the new language are explained in terms of familiar notions. To do this we can try either to correlate directly denotations definable in familiar terms with the expressions of the new language or to show how to translate the new expressions out of every context in which they might occur leaving only what is familiar remaining. If you can do it the first way, you can do it the second way, obviously; the converse is not obvious though. A contextual translation scheme may be very sensitive to the context: a transformation appropriate for one occurrence of an expression may not work elsewhere.

The *negative integers* can be used as a good example here. The rules of algebra are such that all minus signs can be eliminated from an equation by multiplying out the formal polynomials and then using transposition. (Different rules are used for different contexts, note.) If it is the question of an *algebraic law* with variables, we use this trick: Suppose we wish to assert that the equation $f(x)=g(x)$ holds for all x at both positive and negative values. Of course $f(x)=g(x)$ holds for all non-negative x. But so does $f(-x)=g(-x)$. In other words *one* equation has been equivalently translated into *two,* in which the variable can be restricted to the more familiar range. Now Descartes may have been willing to do algebra this way, but we would no longer consider it reasonable. We have developed our theory of numbers so as to include both positive and negative quantities, and we have gone on to imaginary and complex numbers with great gains in understanding. In the new algebra, expressions are directly meaningful and no translations are required. Nevertheless we prove that the new algebra is *consistent* by constructing a model out of familiar stuff. Complex numbers were fairly easy to handle; quaternions were harder. You all know examples and know that mathematicians are busy every day finding other weird structures. Whether the results deserve other than a mother's love is another question.

What does this discussion have to do with programming languages? Very much I feel. Programming languages have introduced a new dimension into the problem of semantics. In the first place there has been an explosion in the size and complexity of the expressions that must be considered. In view of the complications, every effort is made to allow the writer of the program to keep tiresome details *implicit*: some controls can be written in, but generally it is the *compiler* that will take care of the boring parts. Now many, many compilers have been written—even students can do it these days. A compiler can be viewed as a *translator* from the source language (unfamiliar) into machine language (familiar). Why cannot we say, then, that the semantical problems of programming language are solved? The answer is, I believe, that every compiler (if it is meant for a real machine) is a compromise. There must be as many compilers as there are machines, each reflecting limitations and peculiarities of the given machine. Should not the ideal of language definition be machine independent?

Certainly the introduction of *abstract* machines does not settle this difficulty of a multiplicity of translation schemes. After all even for an abstract machine the compiler writer must choose specific ways of keeping track of the order or depth of nesting of computation initiations. There may be different ways of doing this, all of which lead to the same results. The variety of approaches even on an abstract machine may make it quite impossible to define in any meaningful way just what is a single computation *step*. Therefore, the idea of the *state of the computation* is not apparently at all well determined by the source language alone. When a specific compiler is fixed, however, we may very well want to investigate how it handles computation steps. But the question remains: do they have anything to do with the semantical definition of the original language? I think not.

Before pursuing the question of the proper level at which semantics enters, we should take note of a second dimension-expanding consequence of programming language study. Mathematical concepts generally have a rather *static* quality. True, mathematicians study flows on manifolds and many-body problems, but it seems to me that often the interest centers on global qualities or asymptotic behavior. What is peculiar in programming language—especially from a linguistic point of view—is that exactly the same symbols may possess a quite different import in different segments of a program. This is most apparent in the way variables (identifiers) are used. I need give no examples here; all of you understand why variables are not employed in the *assignment statement* in a "mathematical" way. The dynamic character of command execution requires a quite different treatment of variables, and this dynamic urge permeates the whole semantic analysis. The principal virtue of the programming language is that the compounding of the various operations need only be indicated in a rather schematic way, since the calculation is meant to be automatic in any case. But the calculation is not meant as a game or a joke. It is something that needs precision, so we must be able to "follow" what happens in some rather definite sense. What we are discussing is how definite this has to be in order to have a good semantical definition of a language.

Some years ago, Christopher Strachey began a project of trying to expose the semantics of a programming language as a series of mutually recursive functional equations.[1] The particular complex of equations would be "syntax directed" in the sense that each clause of the recursive syntactical specification of the language would have a corresponding equation. The equations taken together would define the meaning of a program, because made to correspond to a program text would be a recursively defined function. This function was intended as a state-transformation function: the function that takes an initial state to the final state that results from executing the program. In many instances the notion of "state" used here could be taken to be "state of the memory" or some abstraction from that idea to make the definition machine independent.

The formalism Strachey used to state his equations was a modified version of the λ-calculus. There was an inherent difficulty in this approach: The λ-calculus at the time was just another symbolic calculus.[2] The criteria for equivalence of expressions were rather weak, and it was not clear in which directions they should be expanded. The advantage of the λ-calculus was that it was "clean," especially in its handling of variables, which was done along the usual "mathematical" lines.[3,4] Thus it was felt that some progress had been made in explaining the unfamiliar in terms of the familiar. Still, the project was not quite complete.

One objection to the λ-calculus the present author had was that it possessed no *mathematical* semantics. It was another kind of operational calculus. True, the calculus had been proved *consistent*, but the consistency proof did not seem to give clear hints as to how to extend usefully the principles of equivalence of expressions.[5] This uncertainty was particularly unsettling in view of the many *inconsistent* extensions that had been proposed. The main difficulty rested on the thoroughly *type-free* style of functional application and abstraction used in the λ-calculus, where, for example, a function could be applied to *itself* as an argument.[6] And it was just this type-free character of the system that Strachey wanted to exploit.

During the fall of 1969 the author resided in Oxford in order to learn more about Strachey's ideas on programming languages. After long, and sometimes rather heated, discussions on the role of mathematics in semantics, it slowly began to dawn on the author that there might be an "objective" interpretation of the λ-calculus. As explained elsewhere,[7,8] it was possible finally to combine ideas and techniques from many sources into a coherent theory of models for the λ-calculus. The key step was to find the right idea of an abstract *domain* (which turned out to be a kind of topological space) so that an appropriate notion of a *function space* would be a domain of the same kind. From that point it was only a matter of time until the question of whether a domain might exist that could be isomorphically identified with its own function space would arise. Fortunately the author was able to see how to effect the required mathematical construction, and a new approach to functional calculi was opened up.

This sounds most abstract and impractical, but the spaces constructed are actually no worse then the real numbers. The "irrational" elements can be explained as limits of infinite sequences in ways that are quite reminiscent of classical analysis.[9] And what is more important *proofs* about the properties of the elements can be given inductively by "successive approximation" in a simple and natural way. Furthermore it is possible to discuss the effectiveness and computability of various elements and processes so as to tie in the abstractions with actual computation.

In this paper it will not be possible to discuss the mathematical details, though a few words will be inserted here and there to resolve puzzles about whether the method is reasonable.[10] Instead it will be shown how the theory of these abstract domains can be applied to typical semantical problems, thus supplying the mathematical foundation needed for Strachey's equational approach. It is not claimed that the project for a mathematical semantics is at all completely finished, but the ideas have been found to be so flexible that we have gained full confidence that we can do serious model building incorporating features whenever the need for them is realized.[11]

LOCATIONS AND STORES

There are many levels of storage from core to disk to tape to card hopper to the mind of the user sitting at a console. Some of these are more addressible than others (and more reliable). Some require special handling, especially as regards allocation of space in preparation for future acts of storage. In the present discussion we shall not treat these subtleties, even though they are very important for good compiler operation. We shall simplify the presentation for the sake of illustration by making these assumptions:

- There are but two facets to storage: *internal* and *external*.
- The internal storage is addressed by elements of a homogeneous collection of *locations*.
- The *contents* stored at each location always may be read out (nondestructively), and at any time new contents may be read in *updating* (destroying) the old contents.
- The current *state* of the store allows a distinction between the *area* of active locations (with contents) and passive or free locations (without contents).
- At any time a *new* location may be selected from those free and placed in the active area.
- At any time a location may be *lost* or retired to the free list.
- One part of the external store allows *reading* in of fresh information (input).
- The other part of the external store allows *writing* of computed information (output).
- External reading and writing are *independent* operations: what is written cannot be read back unless it has been separately stored internally.

The statements of these rather natural assumptions have been given first in fairly precise yet intuitive language. The point of the present paper is to show how to "mathematize" such assumptions in terms of a model that can be incorporated into a full semantical definition. (No *formal language* has been discussed at this point, however.) To carry out the mathematical modelling, we postulate first the existence of several *domains* that will be interrelated by the model:

The basic domains

L = locations

V = stored values

S = states of the store

T = truth values

Possibly it would have been better to say "storable values" since not every element of V is actually stored. Just what these quantities are supposed to be will be left open until the next section. One has a variety of choices depending on the kind of language that is to be interpreted.

These domains alone do not specify the model because they have not yet been supplied with any structure. This can be effected by listing the operations and transformations that may be applied to the domains in various combinations:

The store operators

$$\begin{aligned} \textit{Contents}&: \mathrm{L}\to[\mathrm{S}\to\mathrm{V}] \\ \textit{Update}&: \mathrm{L}\times\mathrm{V}\to[\mathrm{S}\to\mathrm{S}] \\ \textit{Area}&: \mathrm{L}\to[\mathrm{S}\to\mathrm{T}] \\ \textit{New}&: \mathrm{S}\to\mathrm{L} \\ \textit{Lose}&: \mathrm{L}\to[\mathrm{S}\to\mathrm{S}] \\ \textit{Read}&: \mathrm{S}\to\mathrm{V}\times\mathrm{S} \\ \textit{Write}&: \mathrm{V}\to[\mathrm{S}\to\mathrm{S}] \end{aligned}$$

Given any two domains D_0 and D_1, we write $[D_0\to D_1]$ for the space of all (admissible) functions from D_0 into D_1. (At this stage we do not need to worry just which functions are admissible.) We write $f: D_0\to D_1$ to indicate that f is just such a function. What we have listed above are the functions that correspond to our intuitive ideas about the structure of the store. In order to explain how this works, the following variables will be used (with or without sub- and superscripts) restricted to the indicated domains:

$$\alpha{:}\mathrm{L},\quad \beta{:}\mathrm{V},\quad \sigma{:}\mathrm{S},\quad \tau{:}\mathrm{T}$$

Suppose, then, α is a particular location and σ is the current state of the store. The function value *Contents*$(\alpha)(\sigma)$ is to be the V-value stored by σ at α. Conversely, let β be a *given* V-value. The *pair* (α, β) in L×V provides the desired information for updating the store. Therefore, when we write

$$\textit{Update}(\alpha, \beta)(\sigma) = \sigma'$$

we want σ', the transformed store, to be just like σ except in having β stored now in location α. Similarly *Area*$(\alpha)(\sigma)$ is *true* or *false* according as α is in the active area of σ. The function *Lose*(σ) transforms σ into the store σ'' which is just like σ except that α has been freed. Exactly what *Read* and *Write* do depends on the activities of the mad scientist at the console. Supposing, however, that he does not ruin the equipment, whenever *Read*(σ) is activated *something* will happen. This transformation can be recorded as a pair (β', σ'), where β' is a storable value, and σ' has the same internal state as σ did, but the external condition is made all eager and ready for the next input. In a similar way, the function *Write*(β') may be regarded as only affecting the external portion of the store.

The functional notation of mathematics has the gloss of precision. But so far the gloss is the only aspect introduced, since note that the above explanations of what the functions are supposed to do are just as informal as the original assumptions given in ordinary language. What must be avoided in this kind of work is the Fairthorne *Hovercraft effect* described[12] as an "approach in which we use extremely sophisticated techniques and mathematical devices to skim at very high speed and great expense over the subject of concern without ever touching it."

Now in mathematical model building the way to touch ground is to find out how to formulate with precision the *postulates* that correspond to the intuitive assumptions. *Notational* precision is not enough—if there is no way of proving useful theorems. So far our postulates have been rather weak: nothing more than simply noting the functional characters (or logical *types*) of certain operators. The next step is to say exactly how these operators are connected.

What I wish to claim is that each of the intuitive assumptions previously informally indicated can be expressed rigorously by an *equation.* For example, after updating the store at a location, the contents of the location will be found to be what is expected and the location will be found to be active. This statement makes two equations as follows:[r]

$$\textit{Contents}(\alpha)(\textit{Update}(\alpha, \beta)(\sigma)) = \beta$$

$$\textit{Area}(\alpha)(\textit{Update}(\alpha, \beta)(\sigma)) = \textit{true}$$

These equations are meant to hold for *all* α, β, σ. What about locations α' different from α? If $\alpha'\neq\alpha$, we expect that:

$$\textit{Contents}(\alpha')(\textit{Update}(\alpha, \beta)(\sigma)) = \textit{Contents}(\alpha')(\sigma)$$

Similarly in the case of *Area.* If we introduce the *equality relation* on L:

$$\textit{Eq}: \mathrm{L}\times\mathrm{L}\to\mathrm{T}$$

and *conditional expressions,* these four equations can be reduced to two in the obvious way.

In writing these equations, one puzzle is what to write in the cases where the functions are possibly *undefined.* A solution is to introduce a *special value* to correspond to this case. The symbol for this value adopted here is $\perp$. We write $f(x) = \perp$ to indicate that the function x is undefined at x. (Other symbols in use are Ω, ω, $*$, and UU.) This convention is useful in the main equation relating *Contents* to *Area*:

$$\begin{aligned} \textit{Contents}(\alpha)(\sigma) = \textit{if } & \textit{Area}(\alpha)(\sigma) \\ & \textit{then Contents}(\alpha)(\sigma) \\ & \textit{else } \perp \end{aligned}$$

There is not enough room here to formulate all the necessary equations; thus, my claim must remain just that.[13] But it does not seem to me that the claim is too implausible. Note, however, that these postulates on the character of the store would not completely specify everything. The exact nature of V is left open at this stage of the model building. Concerning L, all we would know is that there are infinitely many locations, because new ones can be produced indefinitely. Actually that is probably enough to know about L until one gets into problems of allocation. The input/output phase has also been left a little vague, but that is not necessarily bad either. If we can prove any theorems at all, it is better to prove them from fewer assumptions. *Some* assumptions are needed, nevertheless; and it requires experimentation to find just the right balance. Part of the thesis of this paper is that the mathematical style advocated allows for this experimentation to take place in a convenient way.

A LANGUAGE

There were no surprises in the discussion of storage in the previous section, and there are no surprises planned for this section either. All we shall do here is to indulge in some very modest language design. Any real innovation is saved for the section on semantics. And this is how it should be, otherwise we would not be giving solutions to natural problems. It is quite possible, though, that after the semantical approach has been appreciated language design practice will be altered. Strachey has argued for this,[14] but the effects remain to be seen. In any case we hope to develop a semantical style within which the consequences of different design choices can be studied.

To start with our language will be divided into the usual syntactical categories:

The syntactical domains

$$\text{Id} = \text{identifiers}$$

$$\text{Num} = \text{numerals}$$

$$\text{Op} = \text{(binary numerical) operations}$$

$$\text{Cmd} = \text{commands}$$

$$\text{Exp} = \text{expressions}$$

A feature of our method is that we treat these domains on a par with the basic and semantical domains. They are different, since they are constructed for syntactical purposes; but they are domains nevertheless. The following variables are used in restricted senses:

$$\xi{:}\text{Id}, \quad \nu{:}\text{Num}, \quad \omega{:}\text{Op}, \quad \gamma{:}\text{Cmd}, \quad \epsilon{:}\text{Exp}$$

The syntax for Id, Num, and Op will not be given since it is standard. The remaining two categories are defined as follows:

Commands

$$\gamma ::= \epsilon_0 := \epsilon_1 \mid \text{write } \epsilon \mid !\epsilon \mid \epsilon \rightarrow \gamma_0, \gamma_1 \mid$$

$$\text{dummy} \mid \gamma_0 ; \gamma_1 \mid \text{while } \epsilon \text{ do } \gamma \mid$$

$$\text{let } \xi \equiv \epsilon \text{ in } \gamma \mid \text{let } \xi = \epsilon \text{ in } \gamma \mid \text{letrec } \xi \text{ be } \epsilon \text{ in } \gamma \mid$$

$$(\gamma)$$

Expressions

$$\epsilon ::= \xi \mid \perp \mid \text{read} \mid \gamma \text{ result is } \epsilon \mid \epsilon_0 \rightarrow \epsilon_1, \epsilon_2 \mid$$

$$\epsilon{:}\text{T} \mid \text{true} \mid \text{false} \mid \epsilon_0 = \epsilon_1 \mid$$

$$\epsilon{:}\text{N} \mid \nu \mid \epsilon_0 \omega \epsilon_1 \mid$$

$$\epsilon{:}\text{C} \mid {:}\gamma \mid$$

$$\epsilon{:}\text{P} \mid \lambda\xi . \epsilon \mid \epsilon_0 \epsilon_1 \mid$$

$$\epsilon{:}\text{R} \mid \downarrow \epsilon \mid \uparrow \epsilon \mid$$

$$(\epsilon)$$

Some comments are necessary: (i) There is an unpleasant *conflict* in this syntax between the use of words versus the use of symbols. The trouble is that there are not enough symbols—especially on keyboards—otherwise all constructs could be symbolized. But then one has to remember what the symbols are for, so it is better to use words—especially English words. But it takes so long to write out all those words. The situation is hopeless. (ii) There is an unpleasant *ambiguity* in this syntax. The same string could be parsed in several different ways. Necessarily, then, the meaning of a command or an expression will have to depend on the *parse.* But we will pretend in writing equations that everything can be determined from the string alone. If that worries you, please write in the parentheses (you are allowed to by the last clause of the definition). But no one can stand to write in all those parentheses. The situation is hopeless. But for the semantical theory it does not really matter.[15]

The style of language definition was chosen to give a *few* hints as to the meanings. But I hope there are some constructs that seem quite mysterious on a first reading.

Some explanation is in order. Take commands first. The first clause gives us *assignment statements.* Everyone knows what they mean—except what does it mean to have a *compound* expression on the left? Well, never mind. The next command is obviously intended to invoke *output.* That was easy. For the next clause it would have been better to write do ϵ. In this language commands can be set up and (their closures) stored away for later execution. This command means that ϵ should be evaluated out; and if the value is a command closure, then it should be *done.* If not, what then? Never mind. Next we have the *conditional* command (Boolean-valued expressions are possible). To execute dummy, *do nothing*—except waste time. The semicolon provides the means for sequencing, or *composition,* of commands. Next we have the while statement. Its effect is well-known. Finally there are three kinds of initialization of parameters in blocks. But which is which?

An odd fact about many programming languages is that identifiers are used for many different purposes even though they form just one syntactical category. The context is expected to give the clue as to use. It is not such a bad idea. When one starts to write a program, the number of identifiers to be used is probably not known. To have to divide them up into various subcategories would complicate the language a great deal, and restrict the ways they could be chosen, by tiresome rules. They have only a local significance in any case, so some rough, informal conventions of programming style are sufficient to assure readability of programs.

The three types of initialization in this language illustrate three quite different uses of identifiers. In the first, we begin by evaluating ϵ. It will turn out to be either an L-value or a V-value. Whatever it is, we associate the *same* value with ξ and go on to execute γ under this assignment (keeping assignments to other identifiers the same as before, of course). In the second, we evaluate ϵ. If the value is a V-value, we are happy. If the value is an L-value, we find the contents of the current state of the store in that location—a V-value. In either case we now have a V-value. Next we find a *new* L-value outside the active area of the store and attach it to ξ. Finally we update this location with the computed V-value. Thus prepared, we can now execute γ. (The only reason for being so complicated is that in γ we would like to be able to use ξ on the left of assignment statements.) The first two cases are not so very different, but the third presents a fresh aspect.

At the time of making a *recursive* definition, we want to associate the "import" of ϵ with ξ, but we do *not* want to evaluate ϵ. Also ϵ may contain ξ (a free occurrence of the identifier), and we want ξ to mean the same as we just said. Having made this tie-up without actually evaluating anything, we begin to execute γ. Every time we find a (free) ξ, in effect, we want to *replace* it be ϵ and continue the evaluation. That is to say, ϵ will be evaluated only when it is called for by an occurrence of ξ. Since ϵ contains ξ, this may happen repeatedly. This sequence of events is quite unlike the non-recursive initializations where the ξ's in ϵ are not at the same as the ξ's in γ.

Turning now to expressions, the explanations can be rather short. The read expression invokes input and has a V-value. The result is combination allows for the command γ to be executed before ϵ is evaluated. Next we see the *conditional* expression. The ϵ:X expressions are all Boolean-valued and are *tests* on the nature of the value of ϵ. In lines two and three of the definition we have obvious *Boolean-valued* or *numerical-valued* expressions. In line four we have to do with (closures of) *commands,* and :γ forms just such a closure making a command into an expression. Line five has to do with *procedures.* First we find λ-*abstraction* (functional abstraction) which forms a (closure of) a procedure from an expression with respect to a formal parameter. Next we have *application* of a procedure to an argument. Line six, finally, has to do with *references.* We can *make* a reference (to the value of ϵ), or we can *look up* a reference. References bring in the problem of *sharing,* but we will not treat it in this paper. Nor shall we discuss *arrays.* Note too that *labels* and *jumps* have not been included.

The explanations just given have not been very full; but the programming concepts mentioned are familiar, and most of us would now have a fairly good idea of what a program written in this language would do. Such intuitive understanding is not rigorous semantics, however, and as everyone knows sticky points can arise. Just as we could turn the intuitive assumptions about the store into precise equations, so must we formalize our semantical understanding, as will be outlined in the next section.

THE SEMANTICS

The plan of the semantical definition is that every command and every expression shall denote something. It is the construction of the domains in which the values lie that requires the mathematics. We have spoken already about the basic domains L, V, S, and T. Of these L and T can be given independently in advance, but V and S can only be formed in conjunction with the over-all semantical project. To do this we have to look at the kinds of expressions there are to be found in the language and to provide appropriate domains. The uses of the identifiers also have to be taken into account. This analysis suggests these domains in addition to the four already isolated:

The semantical domains

N = numerical values

E = expression values

W = dynamic values

D = denoted values

C = command values

P = procedure values

R = reference values

The denoted values accumulate all the possible values that might be attached to an identifier. A scheme of such attachments is called an *environment*. Mathematically it is just a function from identifiers to denoted values. All our evaluations will have to take place within (or relative to) such an environment. The following variable is restricted to environments:

$$\rho\colon \mathrm{Id} \to \mathrm{D}$$

Environments can change, but the meanings of the numerals and the numerical operations are fixed. The way to fix them is to define in the standard way these two functions:

$$\mathit{Numval}\colon \mathrm{Num} \to \mathrm{N}$$

$$\mathit{Opval}\colon \mathrm{Op} \to [\mathrm{N} \times \mathrm{N} \to \mathrm{N}]$$

Explicit definitions need not be given here.

Ultimately a command means a store transformation. In mathematics expressions have "static" expression values, but in programming it turns out that commands can be invoked in evaluating a command. Thus an expression has an *effect* as well as a value. We also have to remember that expressions are sometimes used for their L-values and sometimes for their V-values. All of this can be summarized in several semantical functions which have these logical types:

The semantical functions

$$\mathcal{C}\colon \mathrm{Cmd} \to [[\mathrm{Id} \to \mathrm{D}] \to [\mathrm{S} \to \mathrm{S}]]$$

$$\mathcal{E}\colon \mathrm{Exp} \to [[\mathrm{Id} \to \mathrm{D}] \to [\mathrm{S} \to \mathrm{E} \times \mathrm{S}]]$$

$$\mathcal{L}\colon \mathrm{Exp} \to [[\mathrm{Id} \to \mathrm{D}] \to [\mathrm{S} \to \mathrm{L} \times \mathrm{S}]]$$

$$\mathcal{V}\colon \mathrm{Exp} \to [[\mathrm{Id} \to \mathrm{D}] \to [\mathrm{S} \to \mathrm{V} \times \mathrm{S}]]$$

To understand how these functional types are arrived at, consider a command γ. Given an environment ρ and a state of the store σ, we can write the equation

$$\mathcal{C}(\gamma)(\rho)(\sigma) = \sigma'$$

to indicate that σ' will be the state achieved after execution of γ. Similarly for expressions the equation

$$\mathcal{E}(\epsilon)(\rho)(\sigma) = (\eta, \sigma')$$

indicates that η is the value found for ϵ, while σ' is the state achieved after the act of evaluation.

An immediate question is why the ρ and σ are separated as arguments. The answer is that they enter into the evaluations in different ways. For one thing, they change at quite different rates with ρ staying fixed much longer than σ. For another, we will be tempted to copy ρ, but we will generally never feel free to ask for a copy of the *whole* store—there just is no room for that. Possibly in simulating a small machine on a large machine we could conceive of programming the copying of the store, but this is not yet a standard concept. In a way ρ enters at a more conscious level, while σ flows along as the unconscious. Much of the action on σ is meant to be automatic, though there is communication between the levels. Besides these reasons, it is often the case that we want to discuss $\mathcal{C}(\gamma)(\rho)$ without reference to a particular σ; thus it is convenient to be able to drop it off as the last (deepest) argument.

For stylistic reasons and as an aid to the eye, we shall use *emphatic brackets* with the semantical functions:

$$\mathcal{E}[\![\epsilon]\!](\rho)(\sigma)$$

These are helpful because the expressions tend to get along and to pile up their own parentheses. Before we can discuss the semantical equations, however, we must return to the definitions of the various domains.

The domains L, T and N are given. The rest are constructed. The constructions can be summarized as follows:

The domain equations

$$\mathrm{V} = \mathrm{T} + \mathrm{N} + \mathrm{C} + \mathrm{P} + \mathrm{R}$$

$$\mathrm{E} = \mathrm{V} + \mathrm{L}$$

$$\mathrm{W} = \mathrm{S} \to \mathrm{E} \times \mathrm{S}$$

$$\mathrm{D} = \mathrm{E} + \mathrm{W}$$

$$\mathrm{C} = \mathrm{S} \to \mathrm{S}$$

$$\mathrm{P} = \mathrm{E} \to \mathrm{W}$$

$$\mathrm{R} = \mathrm{L}$$

We shall not need variables over all of these domains. The following restricted variables are used:

$$\eta{:}\mathrm{E},\quad \delta{:}\mathrm{W},\quad \theta{:}\mathrm{C}$$

One domain is missing from the list: namely, S. The construction of S is a bit complicated and needs more discussion of L than we have time for here. Roughly

$$\mathrm{S}=\mathrm{A}\times[\mathrm{L}\to\mathrm{V}]\times\mathrm{I/O},$$

where the A-coordinate represents the area; the middle coordinate, the contents-function; and the last, the input/output features. But this is a little too rough, though we must leave it at that.[16]

What is essential to note here is the highly recursive character of these domain equations; in particular, V involves S and S involves V. The involvement comes about through the use of function domains such as [S→S] and [L→V]. Since V-values are storable values, something seems wrong here. We said earlier that we would not store (i.e., copy) stores, yet we are asking to store a store *function* $\theta{:}\mathrm{S}\to\mathrm{S}$. There is actually no conflict here. Functions involve their arguments in a *potential*, not actual, manner. In implementing such a language, functions would be stored as finite *descriptions* (i.e., texts of definitions) not as infinitary abstract objects. From the point of view of mathematical conception, however, we want to imagine in theory that it is the functions that are stored. If we did not want to do this, we should explicitly program the syntax of function definition and the necessary interpretive operations. In any case, storing a function is done without storing the store.

Granting the reasonableness of the connections between V and S, it is still fair to ask whether such domains exist. This is where the real mathematics enters. The idea mentioned in the Introduction of constructing λ-calculus models can be employed to construct these more involved domains. It requires a combination of lattice theory and topology to achieve the proper kind of function theory.[17] On set-theoretical grounds it is clear that when we write [S→S] we cannot mean to take *arbitrary* functions, otherwise the cardinality of S (and of V) would become unbounded. The point is that the functions defined by programs are of a very special sort. Looked at in the right way they are *continuous* functions, and there are many fewer continuous functions than there are arbitrary functions. And this turned out to be the secret: by restricting the function spaces to the continuous functions, the required domains can indeed be constructed. Expensive as this device is, the Hovercraft effect is avoided by showing that such a theory of domains fits in very well with the theory of computable functions (recursive functions) and that all the functions required by the semantics of the language are indeed computable. In particular the theory provides a basis for justifying the existence of functions defined by involved recursions (like the semantical functions) and for proving properties of such functions.[18,19]

It should be stressed that the semantical domains make no explicit reference to the syntax of the language. True, we gave the language first, and then cooked up the domains to match. It could have easily been the other way round. Take V for example. There were five main sections to the definition of an expression corresponding to five sorts of values an expression could have. (Strictly speaking this is not true. The expressions $\epsilon_0\epsilon_1$ and $\uparrow\epsilon$ could have arbitrary values. It might have been more logical to put these clauses on the first line of the definition.) Therefore in the construction of V, we had to provide for five sorts of elements, T, N, C, P, and R. The summation operation (+) on domains has to be defined as a *disjoint union* (and a little care is needed with the topology of the resulting space). If we had wanted, we could have included other sorts of summands. They would not have been reflected in the language, however. It is an interesting question whether the language reflects enough of the structure of the domain V, but one that we cannot pause to consider here. The point is that language design and domain construction are parallel activities, each can (and should) affect the other.

Finally it remains to illustrate some of the equations needed to define the semantical functions:

Some semantical equations

$$\mathcal{C}[\epsilon_0{:}=\epsilon_1](\rho)=\mathit{Update}{*}\mathit{Pair}(\mathcal{L}[\epsilon_0](\rho))(\mathcal{V}[\epsilon_1](\rho))$$

$$\mathcal{C}[\mathrm{write}\ \epsilon](\rho)=\mathit{Write}{*}\mathcal{E}[\epsilon](\rho)$$

$$\mathcal{C}[\gamma_0;\gamma_1](\rho)=\mathcal{C}[\gamma_1](\rho)\circ\mathcal{C}[\gamma_0](\rho)$$

$$\mathcal{C}[!\epsilon](\rho)=\mathit{Do}{*}\mathcal{E}[\epsilon](\rho)$$

$$\mathcal{C}[\mathrm{let}\ \xi\equiv\epsilon\ \mathrm{in}\ \gamma](\rho)=(\lambda\eta\cdot\mathcal{C}[\gamma](\rho[\eta/\xi]))*\xi[\epsilon](\rho)$$

$$\mathcal{C}[\mathrm{letrec}\ \xi\ \mathrm{be}\ \epsilon\ \mathrm{in}\ \gamma](\rho)$$

$$=\mathcal{C}[\gamma](\rho[\mathit{Fixpoint}(\lambda\delta\cdot\mathcal{E}[\epsilon](\rho[\delta/\xi]))/\xi])$$

For the $\mathcal{C}$-function there should be 11 equations in all; and for the $\mathcal{E}$-function, 21 equations. Then the semantical definition would be complete. Note how the equations are mutually recursive functional equations: the $\mathcal{C}$- and $\mathcal{E}$-functions occur on both sides of the equations in functional contexts. Note too that there is much unexplained notation.

In order to be able to combine functions, we need at least two kinds of composition; because some functions are of type [S→S], and some are of type [S→X×S]. We can see how this works in one example. Let:

$$f = \mathcal{L}[\epsilon_0](\rho) : \mathrm{S} \to \mathrm{L} \times \mathrm{S}$$

$$g = \mathcal{V}[\epsilon_1](\rho) : \mathrm{S} \to \mathrm{V} \times \mathrm{S}$$

We want:

$$\mathit{Pair}(f)(g) : \mathrm{S} \to [\mathrm{L} \times \mathrm{V}] \times \mathrm{S}.$$

Suppose σ is a given state. Then $f(\sigma) = (\alpha, \sigma')$. Carrying over σ' to the next step, $g(\sigma') = (\beta, \sigma'')$. So we can define:

$$\mathit{Pair}(f)(g)(\sigma) = ((\alpha, \beta), \sigma'').$$

(The reason for doing it this way is to get the effect of two separate evaluations, because there were two expressions ϵ_0 and ϵ_1 needing evaluation.) Then by definition:

$$(\mathit{Update} * \mathit{Pair}(f)(g))(\sigma) = \mathit{Update}(\alpha, \beta)(\sigma'')$$

This shows how $*$ is a form of functional composition. In the third equation we wrote $\circ$, since this was just the ordinary composition of two [S→S] functions.

The notation $\rho[\eta/\xi]$ means that the original environment ρ has been altered to assign the value η to the argument ξ. (Remember that the arguments of environments are the formal identifiers as syntactic objects.) The import of the fifth equation then is to evaluate ϵ first, pass on the value to the environment, and then execute the command starting in the state achieved after evaluation of ϵ. Note that ϵ is evaluated in the original environment.

The *Fixpoint* function in the last equation is applied to a function F: W→W. All our domains are constructed so that functions defined by expressions always have fixed points—*if* they have the same domain of definition and range of values, of course. The domains are lattices as well as topological spaces, so we can speak of the *least* solution to the equation:

$$\delta_0 = F(\delta_0).$$

This $\delta_0 = \mathit{Fixpoint}(F)$. Fixed points of functional equations solve recursions. So in the letrec command, we first set up the solution δ_0, and then execute the command in the environment $\rho[\delta_0/\xi]$. This explains our *mathematical* concept of recursion.[20] Note that there are no stacks, no pointers, no bookkeeping. None of those devices of implementation are relevant to the concept. That is why this is a mathematical semantics.

CONCLUSION

The presentation in this paper has been but a sketch. For a complete semantics even of this small language, many more details would be required. But it is hoped that enough of the project has been exposed to convince the reader that it is possible to carry out such a plan. And it is not even too painful to do so: not so many mathematical constructs are required, and the equations need not be so very complicated. Of course, judgment of the worth of doing so should be withheld until the semantical equations for a really serious language are fully written out.

Applications of language theory to compiler design

by J. D. ULLMAN

Princeton University
Princeton, New Jersey

INTRODUCTION

There are certain aspects of language theory that have had, or can have, significant impact on the design and implementation of compilers. These areas are, principally, the subjects of context free grammars and syntax directed translations. It is perhaps to be expected that the deep and interesting theorems of language theory do not usually find application. Rather, it is the definitions of formal constructs and their elementary properties that find use.

In this paper, we will discuss some of the ways in which the language theorist can help the compiler designer. First, we will discuss classes of context free grammars that have fast parsing algorithms and discuss briefly what these algorithms are. Then we shall discuss schemes for specifying the translations which must be performed by the compiler.

CONTEXT FREE GRAMMARS

Let us proceed to the principal formalism of use to compiler writers, the context free grammar.

Definition: A *context free grammar* (CFG) is a four-tuple (N, Σ, P, S), where N and Σ are finite, disjoint sets of *nonterminals* and *terminals*, respectively; S in N, is the *start symbol*, and P is a finite list of *productions* of the form $A \rightarrow \alpha$, where A is in N and α in $(N \cup \Sigma)^*$.†

Example: A good example grammar, which will be subsequently referred to as G_0, is $(\{E, T, F\}, \{a, (,), +, *\}, P, E)$, where P consists of the following productions.

(1) $E \rightarrow E+T$
(2) $E \rightarrow T$
(3) $T \rightarrow T*F$
(4) $T \rightarrow F$
(5) $F \rightarrow (E)$
(6) $F \rightarrow a$

G_0 defines arithmetic expressions over operators $+$ and $*$, with no structured variables, and with a representing any identifier.

The way in which a CFG serves to define strings of terminal symbols is as follows.

Definition: Let $G = (N, \Sigma, P, S)$ be a CFG. We define the relation $\underset{G}{\Rightarrow}$ on $(N \cup \Sigma)^*$, by: if α and β are any strings in $(N \cup \Sigma)^*$, and $A \rightarrow \gamma$ is a production, then $\alpha A \beta \underset{G}{\Rightarrow} \alpha\gamma\beta$. If α is in Σ^*, then $\alpha A \beta \underset{Glm}{\Rightarrow} \alpha\gamma\beta$ and if β is in Σ^*, then $\alpha A \beta \underset{Grm}{\Rightarrow} \alpha\gamma\beta$; *lm* and *rm* stand for *leftmost* and *rightmost*, respectively. The *transitive closure* of any relation R, denoted R^+, is defined by:

(1) if aRb, then aR^+b;
(2) if aR^+b, and bR^+c, then aR^+c;
(3) aR^+b only if it so follows from (1) and (2).

The *reflexive-transitive closure* of relation R, denoted R^*, is defined by aR^*b if and only if $a=b$ or aR^*b. Thus, we can use $\alpha \overset{*}{\underset{G}{\Rightarrow}} \beta$, for example, to express the notion that α can become β by some (possibly null) sequence of replacements of left sides of productions by their right sides.

We will, whenever no ambiguity results, drop the subscript G from the nine relations $\underset{G}{\Rightarrow}$, $\underset{Glm}{\Rightarrow}$, $\underset{Grm}{\Rightarrow}$, and their transitive, and reflexive-transitive closures.

We say $L(G)$, the language *defined by* G, is $\{w \mid w$ is in Σ^* and $S \overset{*}{\Rightarrow} w\}$. $L(G)$ is said to be a *context-free language* (CFL).

Convention: Unless we state otherwise, the following convention regarding symbols of a context free grammar holds.

(1) $A, B, C, \ldots$ are nonterminals.
(2) $\ldots, X, Y, Z$ are either terminals or nonterminals.
(3) $a, b, c, \ldots$ are terminals.
(4) $u, \ldots, z$ are terminal strings.

† If X is any alphabet, then X^* denotes the set of finite length strings of symbols in X, including e, the string of length 0.

(5) $\alpha, \beta, \gamma, \ldots$ are strings of terminals and/or nonterminals.
(6) S is the start symbol; except in G_0, where E is the start symbol.
(7) e denotes the empty string.

We may, using this convention, specify a CFG merely by listing its productions. Moreover, we use the shorthand $A \rightarrow \alpha_1 \mid \cdots \mid \alpha_n$ to stand for the productions $A \rightarrow \alpha_1, A \rightarrow \alpha_2, \ldots, A \rightarrow \alpha_n$.

Definition: Let $G=(N, \Sigma, P, S)$ be a CFG. If $\alpha_1 \Rightarrow \alpha_2 \Rightarrow \cdots \Rightarrow \alpha_n$, then we say there is a *derivation* of α_n from α_1. If $\alpha_i \underset{lm}{\Rightarrow} \alpha_{i+1}$, $1 \leq i < n$, we call this a *leftmost derivation*, and if $\alpha_i \underset{rm}{\Rightarrow} \alpha_{i+1}$, $1 \leq i < n$, it is a *rightmost derivation*. Most often, we are interested in the case where $\alpha_1 = S$. If $S \overset{*}{\Rightarrow} \alpha$, then α is a *sentential form*. If $S \overset{*}{\underset{lm}{\Rightarrow}} \alpha$, it is a *left sentential form*, and if $S \overset{*}{\underset{rm}{\Rightarrow}} \alpha$, it is a *right sentential form*.

Example: Let us consider G_0, and the string $a*a+a$ in $L(G_0)$. It has the following derivations, among others.

(1) $E \Rightarrow E+T \Rightarrow T+T \Rightarrow T+F$
$\Rightarrow T*F+F \Rightarrow T*a+F \Rightarrow F*a+F$
$\Rightarrow F*a+a \Rightarrow a*a+a$
(2) $E \Rightarrow E+T \Rightarrow T+T \Rightarrow T*F+T$
$\Rightarrow F*F+T \Rightarrow a*F+T \Rightarrow a*a+T$
$\Rightarrow a*a+F \Rightarrow a*a+a$
(3) $E \Rightarrow E+T \Rightarrow E+F \Rightarrow E+a \Rightarrow T+a$
$\Rightarrow T*F+a \Rightarrow T*a+a \Rightarrow F*a+a \Rightarrow a*a+a$

Derivation (1) is neither rightmost nor leftmost. (2) is leftmost and (3) is rightmost. $F*a+F$ is a sentential form of G_0, but happens not to be a left or right sentential form. $a*a+a$ is both a left and right sentential form, and is in $L(G_0)$.

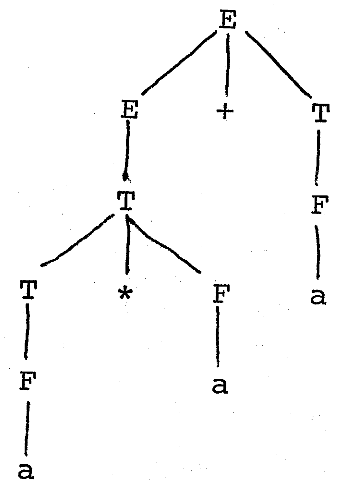
Given a derivation of w from S we can construct a *parse tree* for w as follows. Let $S=\alpha_1 \Rightarrow \alpha_2 \ldots \Rightarrow \alpha_n = w$.

(1) Begin with a single node labeled S. This node is a trivial tree, and is said to be the tree for α_1. In general the tree for α_i will have a leaf *corresponding to* each symbol of α_i. Initially, the lone symbol S of α_1 corresponds to the lone node.
(2) Suppose we have constructed the tree for α_i, $i<n$. Let α_{i+1} be constructed by replacing some instance of A in α_i by β. To this instance of A there corresponds a leaf. Make descendants of that leaf for each symbol of β, ordered from the left. If β is the empty string, then we create a single descendant, labeled e.

The construction of a tree defined above is called *top down*. We can also construct the same tree *bottom up*, as follows.

(1) Begin with an isolated node corresponding to each symbol of α_n. As this algorithm proceeds, we will have a collection of trees corresponding to each step of the derivation. At the end, there will be one tree for the first sentential form α_1 (i.e., S).
(2) Suppose we have a collection of trees for α_i, $1<i \leq n$, where to each symbol of α_i there corresponds a root of one of the trees. If α_i is constructed from α_{i-1} by replacing A by β, create a new node, labeled A, whose direct descendants are the roots of the trees for the symbols of β. The order of symbols in β reflects the order of the descendants. If, however, $\beta=e$, create one descendant for the node labeled A, and label the descendant e.

Example: The unique parse tree for $a*a+a$ in G_0 is shown below. Note that the leaves of the tree read $a*a+a$, from the left.



It is easy to show that the top down and bottom up methods of tree construction yield the same tree when applied to one derivation.

An important property of a CFG is that it be *unambiguous*, that is, no word in its language has more than one parse tree. Because of the way syntax directed translation algorithms work on parse trees, an ambiguous programming language is very likely to provide surprising machine code when (at least some of) its programs are compiled. It is easy to show that the condition of unambiguity is tantamount to saying that each word in the language has a unique leftmost derivation and a unique rightmost derivation.

EARLEY'S ALGORITHM

There is one outstanding method of recognizing the words of an aribtrary CFL and building parse trees, although many others have been proposed. This is the method of Earley.[1] Descriptions of other general methods can be found in References 2 and 3. Earley's method works as follows.

(1) Let $G=(N, \Sigma, P, S)$ and let $a_1 \ldots a_n$ be the word we wish to recognize or parse. We construct lists $I_0, I_1, \ldots, I_n$, of *items*; an item is of the form $[A \rightarrow \alpha \cdot \beta, i]$, where $A \rightarrow \alpha\beta$ is a production and i an integer.

(2) Construct I_0 as follows.
 (i) Add $[S \rightarrow \cdot \alpha, 0]$ to I_0, for each $S \rightarrow \alpha$ in P.
 (ii) If $[A \rightarrow \cdot \mathrm{B}\alpha, 0]$ is on I_0, add $[B \rightarrow \cdot \beta, 0]$ to I_0, if it is not already there, for each $B \rightarrow \beta$ in P.

(3) Suppose we have constructed I_{i-1}. Construct I_i as follows.
 (i) For all $[A \rightarrow \alpha \cdot a_i\beta, j]$ on I_{i-1}, add $[A \rightarrow \alpha a_i \cdot \beta, j]$ to I_i. Recall that a_i is the ith input position.
 (ii) If $[A \rightarrow \alpha \cdot, j]$ is on list I_i, add $[B \rightarrow \beta A \cdot \gamma, k]$ to I_i, if $[B \rightarrow \beta \cdot A\gamma, k]$ is on I_j.
 (iii) If $[A \rightarrow \alpha \cdot B\beta, j]$ is on I_i, add $[B \rightarrow \cdot \gamma, i]$ to I_i for all $B \rightarrow \gamma$ in P.

We can show that item $[A \rightarrow \alpha \cdot \beta, j]$ is placed on I_i if and only if there is a leftmost derivation

$$S \overset{*}{\underset{lm}{\Rightarrow}} a_1 \ldots a_j A\gamma \underset{lm}{\Rightarrow} a_1 \ldots a_j\alpha\beta\gamma \overset{*}{\underset{lm}{\Rightarrow}} a_1 \ldots a_i\beta\gamma.$$

As a special case of the above, $a_1 \ldots a_n$ is in $L(G)$ if and only if $[S \rightarrow \alpha \cdot, 0]$ is on I_n for some α. Thus, it is easy to see how Earley's algorithm can be used to recognize the words of a language. Moreover, once the lists have been constructed, it is possible to build the parse tree of the word. We shall not explore this further here, but the intuitive idea behind the tree construction algorithm is to let the item $[S \rightarrow \alpha \cdot, 0]$ on I_n represent the root, then look for those *complete* (dot at the right end) items which lead to its being placed on I_n. Make these items correspond to the descendants of the root, and proceed top down, finding "causes" for each item corresponding to a node.

Example: The lists for G_0, with input $a*a$ are shown below.

I_0	I_1	I_2	I_3
$E \rightarrow \cdot E+T, 0$	$F \rightarrow a \cdot, 0$	$T \rightarrow T* \cdot F, 0$	$F \rightarrow a \cdot, 2$
$E \rightarrow \cdot T, 0$	$T \rightarrow F \cdot, 0$	$F \rightarrow \cdot (E), 2$	$T \rightarrow T*F \cdot, 0$
$T \rightarrow \cdot T*F, 0$	$E \rightarrow T \cdot, 0$	$F \rightarrow \cdot a, 2$	$E \rightarrow T \cdot, 0$
$T \rightarrow \cdot F, 0$	$T \rightarrow T \cdot *F, 0$		$T \rightarrow T \cdot *F, 0$
$F \rightarrow \cdot (E), 0$			
$F \rightarrow \cdot a, 0$			

List I_3 is constructed as follows. $[F \rightarrow a \cdot, 2]$ is added by rule (3i), because $[F \rightarrow \cdot a, 2]$ is on I_2. $[T \rightarrow T*F \cdot, 0]$ is added to I_3 by rule (3ii), because $[T \rightarrow T* \cdot F, 0]$ is on I_2 and $[F \rightarrow a \cdot, 2]$ is on I_3. $[E \rightarrow T \cdot, 0]$ and $[T \rightarrow T \cdot *F, 0]$ are added because $[E \rightarrow \cdot T, 0]$ and $[T \rightarrow \cdot T*F, 0]$ are on I_0, and $[T \rightarrow T*F \cdot, 0]$ is on I_3. Since $[E \rightarrow T \cdot, 0]$ is on I_3, $a*a$ is in $L(G_0)$.

Earley's algorithm can be implemented in $O(n^2)$ steps of a random access computer if the underlying grammar is unambiguous, and in $O(n^3)$ steps for an arbitrary grammar. Moreover, on many grammars of practical interest, Earley's algorithm operates in $O(n)$ steps. It is the fastest known general parsing algorithm.

LL GRAMMARS

We will now begin the study of several subclasses of the context free grammars. None of the three classes we consider is capable of generating all the context free languages. However, confronted with a context free language that is associated with a real programming language, it is highly likely that grammars in the classes to be discussed do exist.

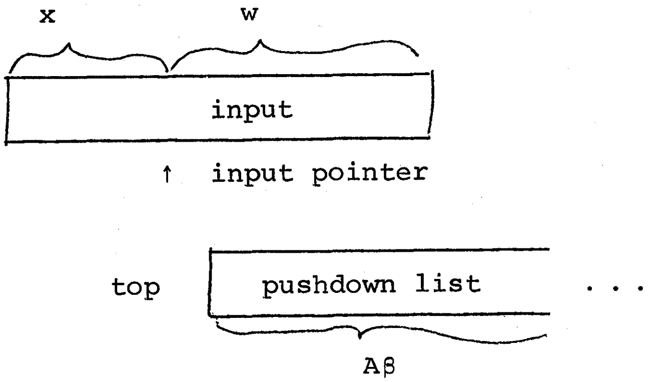
Our first subclass of grammars, called $LL(k)$, for *l*eft to right scan, producing a *l*eftmost derivation, with k symbol lookahead, was first examined in Reference 4. The $LL(l)$ case was developed independently in Reference 5. Development of the theory can be found in References 6 and 7. The general idea can be summarized as follows.

Let $G=(N, \Sigma, P, S)$ be a CFG, and let w be in Σ^*. We may attempt to find a leftmost derivation for w by starting with S and trying to proceed to successive left sentential forms. Suppose we have obtained

$$S=\alpha_1 \underset{lm}{\Rightarrow} \alpha_2 \underset{lm}{\Rightarrow} \cdots \underset{lm}{\Rightarrow} \alpha_i,$$

where $\alpha_i = xA\beta$, and x is a prefix of w. If there are several productions with A on the left, we must select the proper one. It is desirable that we be able to do so using only information which we have accumulated so far during the parse (which we represent by saying that we "know what β is") and the k symbols of w beyond prefix x, for some small k. If we can always make this decision correctly, we say G is $LL(k)$.

If a grammar is $LL(k)$, we can parse it deterministically in a simple fashion. One pushdown list, which holds the portion of a left sentential form to the right of the prefix of terminals ($A\beta$ in the case of α_i, above) is used. (There is also some other information on the list, but we shall not discuss this here. A discussion can be found in in Reference 3.) The input w is scanned left to right, and if α_i has been reached, the input pointer will have scanned over prefix x, and is ready to read the first k symbols of w. The arrangement is shown below.



If production $A \rightarrow \gamma$ is chosen to expand A, the pushdown list is made to hold $\gamma\beta$. Then, any terminals on top of the pushdown list are compared with the input immediately to the right of the input pointer, and the next left sentential form will be properly represented. The process of expanding the topmost nonterminal on the pushdown list then repeats. Note that while expanding nonterminals, we could construct a parse tree top down if we wished.

It should be noted that the pushdown list may carry information other than grammar symbols, in order to summarize at the top of the list, the important information about what is in the list (β in our example). However, this information is not essential, if the grammar is modified properly. We now give the formal definition of an $LL(k)$ grammar.

Definition: If α is a string, let $|\alpha|$ denote the length of α. Let $\alpha{:}k$ denote the first k symbols of α, or all of α if $|\alpha| < k$. Let $G = (N, \Sigma, P, S)$ be a CFG. We say G is $LL(k)$ if whenever we have the following two derivations

(1) $S \underset{lm}{\overset{*}{\Rightarrow}} xA\alpha \underset{lm}{\overset{*}{\Rightarrow}} x\beta\alpha \underset{lm}{\overset{*}{\Rightarrow}} xy$

(2) $S \underset{lm}{\overset{*}{\Rightarrow}} xA\alpha \underset{lm}{\overset{*}{\Rightarrow}} x\gamma\alpha \underset{lm}{\overset{*}{\Rightarrow}} xz$

and $y{:}k = z{:}k$. Then we may conclude that $\beta = \gamma$.

Stated less formally, suppose we are parsing w, and have so far reached left sentential form $xA\alpha$. We have, as indicated in the informal parsing procedure which introduced the section, not scanned w more than k symbols beyond x. Thus, either xy or xz could be w, as far as we know. Suppose $A \rightarrow \beta$ and $\alpha \rightarrow \gamma$ are two productions. Then the $LL(k)$ definition assures us that independent of w, but depending on x, α and the first symbols of w beyond x (which are $y{:}k$, or equivalently, $z{:}k$), we may uniquely select the proper production with which to replace A.

Example: Consider the grammar

$$S \rightarrow aBB \mid b$$

$$B \rightarrow bSS \mid a$$

This grammar is $LL(l)$. For suppose we have two derivations (1) and (2), as in the $LL(k)$ definition. If $y{:}1 = z{:}1 = a$, and A is S, then clearly aBB is both β and γ. If A is B, the $\beta = \gamma = a$. If $y{:}1 = z{:}1 = b$, then $\beta = \gamma = b$ if A is S, and $\beta = \gamma = bSS$ if A is B.

LR GRAMMARS

Just as the $LL(k)$ grammars are a natural class of grammars for which parse trees can be built deterministically, top down, via leftmost derivations, there is a natural class of grammars, called $LR(k)$, for *l*eft to right scan, producing *r*ightmost derivations with k symbol lookahead, for which parse trees can be constructed deterministically bottom up via rightmost derivations. This class of grammars was defined in Reference 8, and the theory, including optimization of LR parsers has been discussed in References 9-13.

Definition: Let

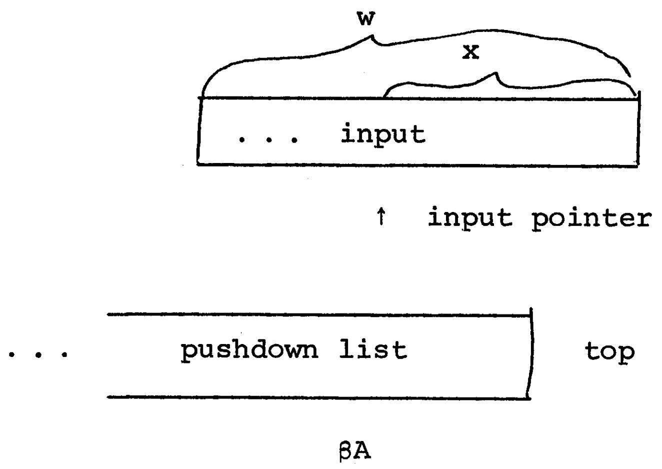
$$S \underset{rm}{\Rightarrow} \alpha Ax \underset{rm}{\Rightarrow} \alpha\beta x.$$

Then β, in the position shown, is said to be a *handle* of right sentential form $\alpha\beta x$. The handle of a right sentential form need not be uniquely defined, but will be, if the grammar is unambiguous.

Given grammar $G = (N, \Sigma, P, S)$ and w in Σ^*, we could attempt to find a rightmost derivation of w, starting with w and working backwards toward S. Suppose we have found

$$S \underset{rm}{\overset{*}{\Rightarrow}} \alpha_i \underset{rm}{\Rightarrow} \alpha_{i+1} \underset{rm}{\Rightarrow} \dots \underset{rm}{\Rightarrow} \alpha_m = w.$$

In order to find the right sentential form previous to α_i, we must find its handle and replace the handle by the left side of the production used to create the handle. If we can do so, we can recognize and parse using a pushdown list as shown.



Suppose α_i is βAx. Then βA will appear on the pushdown list, with A at the top. (As with *LL* grammars, there will be some extra information on the list helping us to make parsing decisions. See References 3 and 8.) x will be a suffix of the input, unscanned to this point. (In the case $i=m$, i.e., $\alpha_i=w$, the pushdown list would be empty, with the input pointer at the left end.) The handle of βAx cannot appear wholly within β, by the definition of a rightmost derivation. Thus, either it is a suffix of βA, or its right end is somewhere within x.

Using the extra information on the pushdown list and the k symbols to the right of the input pointer, the $LR(k)$ parser concludes either

(1) that the handle is not yet on the pushdown list, and an input symbol must be shifted from the input to the pushdown list (i.e., the input pointer moves right, and the symbol which it leaves is placed on top of the pushdown list, or

(2) that the handle is now on top of the pushdown list. In this case, the extra information tells us what production was used at the step which created α_i, and we can *reduce* α_i to α_{i-1} by replacing the handle by the appropriate nonterminal.

Whether (1) or (2) applies, the $LR(k)$ parser repeats the decision whether to shift or reduce. Since we cannot shift indefinitely, we must eventually reduce. If the grammar is $LR(k)$, the correct decision will be made at each step, and we will trace out a rightmost derivation in reverse order. Note that we can build the parse tree bottom up as we do the reductions. We will now give the formal $LR(k)$ definition.

Definition: Let $G=(N, \Sigma, P, S)$ be a CFG, and let $G'=(N\cup\{S'\}, \Sigma, P', S')$ be the *augmented* grammar for G, defined as follows.

(1) S' is a new nonterminal.

(2) P' is P preceded by a production numbered 0, namely $S'\rightarrow S$.

The augmented grammar allows us to treat "reduction" by production $S'\rightarrow S$ as the successful completion of the algorithm.

Suppose we have two derivations in G':

(1) $S'\underset{rm}{\overset{*}{\Rightarrow}}\alpha Ax\underset{rm}{\Rightarrow}\alpha\beta x$

(2) $S'\underset{rm}{\overset{*}{\Rightarrow}}\gamma By\underset{rm}{\Rightarrow}\gamma\delta y$

and we can write $\gamma\delta y$ as $\alpha\beta y'$, where $y'{:}k=x{:}k$. If we can always conclude that $\gamma By=\alpha Ay'$ (i.e., $y=y'$, $A=B$ and $\gamma=\alpha$), then we say G is $LR(k)$.

Stated informally, suppose we are constructing a rightmost derivation of w, in reverse, in such a way that we never observe symbols of w that are more than k symbols beyond the handle. Suppose that we have done some reductions, and reduced some prefix of w to $\alpha\beta$. We still do not know what the tail end of w is; it could be x or y', among other things. However, we do know that the next k symbols of our current right sentential form are $x{:}k$ (equivalently, $y'{:}k$). Then if G is $LR(k)$, we may determine that β is the handle and must be reduced to A. We can make this determination independent of whether the input actually ends with x or y'.

Example: Consider the grammar

$$S\rightarrow aS \mid a$$

The grammar is not $LR(O)$. For in the augmented grammar, we have derivations

$$S'\underset{rm}{\overset{*}{\Rightarrow}}S\underset{rm}{\Rightarrow}a$$

$$S'\underset{rm}{\overset{*}{\Rightarrow}}aS\underset{rm}{\Rightarrow}aa$$

We may compare these derivations with those of the $LR(k)$ definition, letting $\alpha=e$, $A=B=S$, $\beta=\gamma=\delta=a$, $x=y=e$ and $y'=a$. Then $x{:}0=y'{:}0=e$, but γBy, which is aS, is not equal to $\alpha Ay'$, which is Sa.

However, this grammar is $LR(l)$. The only possible right sentential forms $\alpha\beta x$ are:

(i) $\alpha=x=e$, $\beta=S$, in which the last step replaced S' by S,

(ii) $\alpha=a^i$ for some $i\geq 0$, $x=e$, and $\beta=aS$. (The last step replaced S by aS.), or

(iii) $\alpha=a^i$, $\beta=a$ and $x=e$, where S was replaced by a at the last step.

The above three possibilities hold also if we refer to γ, δ and y instead of α, β and x. If we have a violation of the $LR(1)$ condition, since $x{:}1=e$, we must have $\gamma\delta y=\alpha\beta y'$ and $y'{:}1=e$, but $\gamma By\neq\alpha Ay'$. If $y'{:}1=e$, then $y'=e$. Moreover, as we argued in (i)-(iii) above, we must have $y=e$ in the right sentential form $\gamma\delta y$. Thus, $\gamma\delta=\alpha\beta$.

If $\alpha\beta=S$, then $\gamma\delta=S$, and $\gamma=e$ and $\delta=S$ follows. Then $B=A=S'$, and we have $\gamma By=\alpha Ay'$, which we assumed not to be the case.

If $\alpha=a^i$ and $\beta=aS$, it similarly follows that $\gamma=a^i$ and $\delta=aS$; $A=B=S$. Again $\gamma By=\alpha Ay'$.

Finally, if $\alpha=a^i$ and $\beta=a$, we may conclude that $\gamma=a^i$ and $\delta=a$. Again, $A=B=S$, and $\gamma By=\alpha Ay'$.

We conclude that the grammar is $LR(l)$.

PRECEDENCE GRAMMARS

Many practical classes of grammars admit of shift-reduce type parsing algorithms, as outlined in the previous section, but without the need for extra information on the pushdown list. We shall here discuss several classes that go under the heading of precedence grammars. The initial idea of operator precedence parsing is from Reference 14, while the most common current notion of a precedence grammar first appeared in Reference 15. The theory of precedence parsing has been developed in References 16 through 21. We now give the basic precedence definitions.

Definition: Let $G=(N, \Sigma, P, S)$ be a CFG with no production $A\rightarrow e$, no derivation $A\overset{+}{\Rightarrow}A$, and no symbols not appearing in the derivation of some word in $L(G)$. We assume $ is not in $N\cup\Sigma$. We define three *precedence relations*, $<\cdot$, $\doteq$ and $\cdot>$ on $N\cup\Sigma$ as follows.

(1) $X\doteq Y$ if and only if there is a production of the form $A\rightarrow\alpha XY\beta$.
(2) $X<\cdot Y$ if and only if there is a production $A\rightarrow\alpha XB\beta$ and $B\overset{+}{\Rightarrow}Y\gamma$.
(3) $X\cdot>Y$ if and only if Y is a terminal, there is a production $A\rightarrow\alpha BZ\beta$, $B\overset{+}{\Rightarrow}\gamma X$ and $Z\overset{*}{\Rightarrow}Y\delta$.

We also have $\$<\cdot X$ if $S\overset{+}{\Rightarrow}X\alpha$ and $X\cdot>\$$ if $S\overset{+}{\Rightarrow}\beta X$.

A grammar is *uniquely invertible* if it has no two productions of the form $A\rightarrow\alpha$ and $B\rightarrow\alpha$.

We say G is a *precedence grammar* if it satisfies the constraints mentioned above (no production $A\rightarrow e$, etc.), and the relations $<\cdot$, $\doteq$ and $\cdot>$ are disjoint from one another.

If, in addition, G is uniquely invertible, we say G is a *simple precedence grammar*.

Example: Let us consider the grammar with productions $S\rightarrow AA$, $A\rightarrow aA \mid b$. It is not a precedence grammar, because we have $A\cdot>a$ and $A<\cdot a$. That is, since AA is a right side, $A\overset{+}{\Rightarrow}aA$ and $A\overset{*}{\Rightarrow}aA$, we have $A\cdot>a$. Since AA is a right side and $A\overset{+}{\Rightarrow}aA$ again, we conclude $A<\cdot a$. However, the modified grammar

$$S\rightarrow BA$$

$$B\rightarrow A$$

$$A\rightarrow aA \mid b$$

is a simple precedence grammar. Its precedence relations are shown below.

	S	B	A	a	b	$
S						
B			≐	<·	<·	
A				·>	·>	·>
a			≐	<·	<·	
b				·>	·>	·>
$		<·	<·	<·	<·	

We can parse according to a simple precedence grammar as follows. An input, scanned left to right by a pointer is used, as is a pushdown list. Right sentential forms are represented as in the description of the $LR(k)$ parser. Initially, only $ appears on the pushdown list, and the leftmost symbol of the input is being scanned. The input has $ appended at the right. At each step of the algorithm, the following is done. Let $X_1\ldots X_m$ appear on the pushdown list (top right) and $a_1\ldots a_r$ be the remaining input.

(1) If $X_m<\cdot a_1$ or $X_m\doteq a_1$, a_1 is shifted onto the pushdown list, and the process repeats.
(2) If $X_m\cdot>a_1$, find k such that $X_{k-1}<\cdot X_k\doteq X_{k+1}\doteq\ldots\doteq X_m$. Let $A\rightarrow X_k\ldots X_m$ be a production. (A must be unique if G is a simple precedence grammar.) Then replace $X_k\ldots X_m$ by A on top of the pushdown list.
(3) If neither (1) nor (2) apply, accept the input if $X_l\ldots X_m=\$S$ and $a_l\ldots a_r=\$$. Declare an error otherwise.

SYNTAX DIRECTED TRANSLATIONS

We now turn to formalisms for specifying the code generation phase of a compiler. The general strategy is to work from a parse tree, building some "translations" at each node. One translation at the root of the tree is designated the output of the translation system. The most elementary system, called a (formal) *syntax directed translation scheme* was first expounded in Reference 22 and formalized in Reference 4. Some theoretical developments and generalizations appear in References 22 through 30.

Definition: A (formal) *syntax directed translation* scheme (SDTS) is a CFG $G=(N, \Sigma, P, S)$, together with a translation element for each production. The *translation element* associated with production $A \rightarrow \alpha$ is a string β in $(N \cup \Delta)^*$, where Δ is an alphabet of *output symbols*, disjoint from N. β must be such that there is a one to one mapping from its nonterminals to the nonterminals of α, where each nonterminal is mapped to an identical symbol. If the mapping preserves the (left to right) order of appearance of the nonterminals in α and β, then the SDTS is said to be *simple*.

We construct a translation from a parse tree in the CFG as follows. An order for the interior nodes is chosen so that each node follows all its descendants in the order. Each node is considered in its turn. If a particular node n has label A and its direct descendants have labels $X_1, \ldots, X_n$, from the left, then

$$A \rightarrow X_1 \ldots X_n$$

is a production. Let $\beta = Y_1 \ldots Y_m$ be the translation element for that production. The translation at n is formed from $Y_1 \ldots Y_m$ by substituting for each Y_i in N, the translation at the jth direct descendant of n if Y_i is associated with X_j.

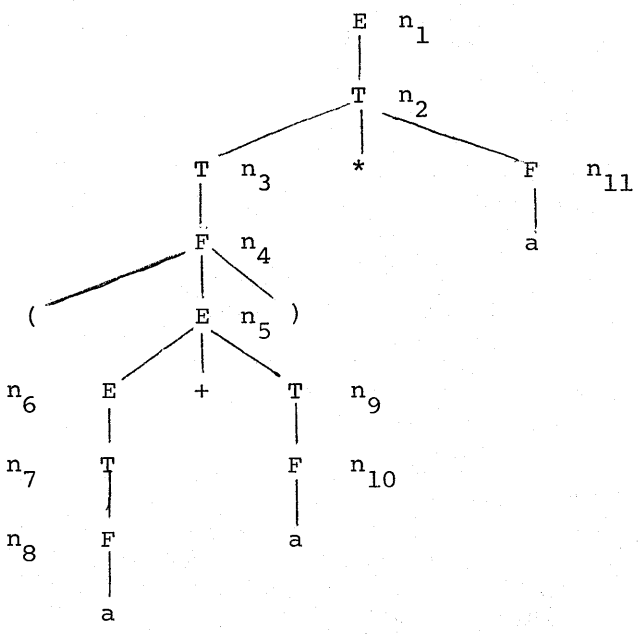
The *translation* defined by the SDTS is the set of pairs (w, x) such that w is the yield of some parse tree T and the translation defined at the root of T is x.

Example: We can build a translation on G_0 to translate infix arithmetic expressions to postfix (operator follows both operands) expressions.

production	*Translation element*
$E \rightarrow E+T$	$ET+$
$E \rightarrow T$	T
$T \rightarrow T*F$	$TF*$
$T \rightarrow F$	F
$F \rightarrow (E)$	E
$F \rightarrow a$	a

Since no production of G_0 has more than one occurrence of the same nonterminal on the right side of any production, the mapping between nonterminals of the translation elements and their productions is obvious. Note that the SDTS is simple.

The string $(a+a)*a$ has the parse tree shown below. Nodes have been numbered for reference. The following order of the interior nodes is acceptable. $n_8, n_7, n_6, n_{10}, n_9, n_5, n_4, n_{11}, n_2, n_1$.



The translation at n_8 is just a, since production $F \rightarrow a$ was applied there, and the associated translation element is a. To compute the translation at n_7, we substitute the translation at n_8 for F in the translation element associated with $T \rightarrow F$. Thus, the translation at n_7 is a, as is the translation at n_6, n_{10}, and n_9. The translation at n_5 is computed by substituting the translation at n_6 for E and that at n_9 for T in the translation element $ET+$. Thus, the translation at n_5 is $aa+$. Proceeding similarly, the translation at n, is $aa+a*$.

The Terminal IMP for the ARPA computer network*

by S. M. ORNSTEIN, F. E. HEART, W. R. CROWTHER, H. K. RISING, S. B. RUSSELL and A. MICHEL

Bolt Beranek and Newman Inc.
Cambridge, Massachusetts

INTRODUCTION

A little over three years ago the Advanced Research Projects Agency of the Department of Defense (ARPA) began implementation of an entirely new venture in computer communications: a network that would allow for the interconnection, via common-carrier circuits, of dissimilar computers at widely separated, ARPA-sponsored research centers. This network, which has come to be known as the ARPA Network, presently includes approximately 20 nodes and is steadily growing. Major goals of the network are (1) to permit resource sharing, whereby persons and programs at one research center may access data and interactively use programs that exist and run in other computers of the network, (2) to develop highly reliable and economic digital communications, and (3) to permit broad access to unique and powerful facilities which may be economically feasible only when widely shared.

The ARPA Network is a new kind of digital communication system employing wideband leased lines and message switching, wherein a path is not established in advance and instead each message carries an address. Messages normally traverse several nodes in going from source to destination, and the network is a store-and-forward system wherein, at each node, a copy of the message is stored until it is safely received at the following node. At each node a small processor (an *Interface Message Processor*, or *IMP*) acts as a nodal switching unit and also interconnects the research computer centers, or *Hosts*, with the high bandwidth leased lines.

A set of papers presented at the 1970 SJCC[1–5] described early work on the ARPA Network in some detail, and acquaintance with this background material (especially Reference 2) is important in understanding the current work. The present paper first discusses major developments that have taken place in the network over the last two years. We then describe the *Terminal IMP*, or *TIP*, a development which permits direct terminal access to the network. Finally we mention some general issues and discuss plans for the next stages in development of the network.

THE DEVELOPING NETWORK

The initial installation of the ARPA Network, in 1969, consisted of four nodes in the western part of the United States. A geographic map of the present ARPA Network is shown in Figure 1. Clearly, the most obvious development has been a substantial *growth*, which has transformed the initial limited experiment into a national assemblage of computer resources and user communities. The network has engendered considerable enthusiasm on the part of the participants, and it is increasingly apparent that the network represents a major new direction in both computer and communications technology.

Figure 2 is a logical map of the network, where the Host computer facilities are shown in ovals, all circuits are 50 kilobits, and dotted circuits/nodes represent planned installations. On this figure certain nodes are listed as a "316 IMP"; this machine is logically nearly identical to the original IMP, but can handle approximately two-thirds of the communication traffic bandwidth at a cost savings of approximately one-half. The original IMP includes a Honeywell 516 computer, and more recently Honeywell began to market the 316 computer as a cheaper, downward-compatible machine. As the network has grown, sites were identified which did not require the full bandwidth of the original IMP, and a decision was made to provide an IMP version built around the 316 computer. Also shown in Figure 2 are certain nodes listed as "TIP"; this new machine

* This work was sponsored by the Advanced Research Projects Agency under Contract No. DAHC15-69-C-0179.

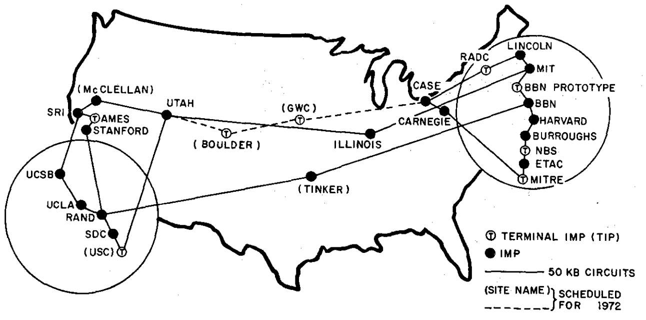

Figure 1—ARPA Network, geographic map, December 1971

is discussed in detail later in this paper. Site abbreviations shown on Figures 1 and 2 are explained in Table I.

As the network has grown, a great deal of work has been concentrated on the development of Host-to-Host protocol procedures. In order for programs within one Host computer system to communicate with programs in other Hosts, agreed-upon procedures and formats must be established throughout the network. This problem has, as predicted, turned out to be a difficult one. Nonetheless protocol procedures have evolved and are being accepted and implemented throughout the net. At the present writing, many of the Hosts have working "network control programs" which implement this protocol. Protocol development is more fully reported in a companion paper,[6] but we wish to make a general observation on this subject: the growth of the network has dynamically catalyzed an area of computer science which has to do with the quite general problem of *how programs should intercommunicate,* whether in a single computer or between computers. Thus the evolution of the Host-to-Host protocol represents a side benefit of the network that reaches well beyond its utility to the network alone.

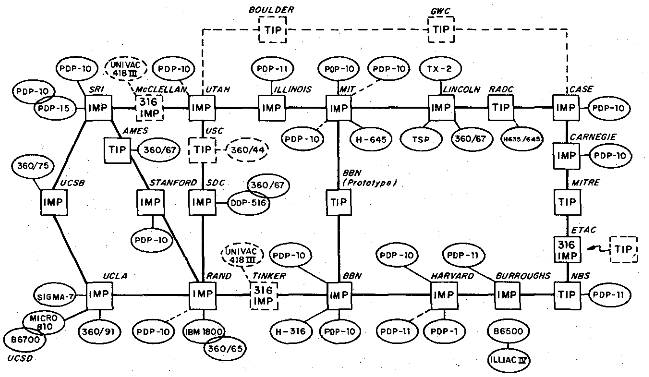

Figure 2—ARPA Network, logical map, December 1971

Since both hardware and software network connections must be implemented by each Host, it is important that the external characteristics of the IMP be relatively stable. This stability has been carefully maintained, while at the same time internal operation of the IMP program has undergone extensive revision and improvement. For example, trouble reporting, statistics gathering, and test procedures have been substantially improved. In addition to improvements that have already been incorporated into the program, there have also been extensive studies of performance and message flow control.[7] These studies have pointed up areas of vulnerability to perverse heavy traffic patterns and have suggested still other possible improvements in the routing and flow control mechanisms. Potential changes are presently being being studied in some detail and will be incorporated into one or more forthcoming major revisions of the program. They will hopefully anticipate problems which might be expected to arise as traffic flow in the network becomes heavier.

Somewhat belatedly in the network design, the need to connect a single IMP to several Hosts was recognized. This required multiple Host interfaces at the IMP as well as more complex IMP software. Further, the various Host computers at a site are often physically distant from one another, thus requiring an increase in the maximum allowable physical separation between a Host and its IMP. To connect to an arbitrarily remote Host would have meant a communications interface capable of attachment to common-carrier circuits via modems. It would furthermore have required cooperative error control from the Host end. At the time, we chose not to modify the logical way in which the IMP dealt with the Host and instead we provided more sophisticated line drivers which would handle distances of up to two thousand feet. Several such "Distant Host" installations are now working in the network. Unfortunately, as the network has grown, new sites have appeared where still greater Host/IMP distances are involved. The present scheme does not include error control, and use of this scheme over greater distances is not appropriate. At the present time we are therefore considering how best to arrange IMP/Host connections over large distances and additional options will be required in this domain.

Another facility which has been tested is the ability of the IMPs to communicate over 230.4 kilobit phone lines instead of 50 kilobit lines. A short, fast link was incorporated into the network for a brief period and no problems were encountered. To date, network loading has not justified upgrading any operational network circuits to 230.4 kilobits, but this will be considered as loading rises.

Substantial effort has gone into traffic and trouble reporting. A Network Control Center (NCC) has been built at Bolt Beranek and Newman Inc. in Cambridge, where a small dedicated Host computer receives reports each minute from every IMP on the network. Traffic summaries and status and trouble reports are then generated from this material. Specifically, a logger records any changes that the IMPs report to the NCC; it records line errors and IMP storage counts when they exceed certain limits, as well as unusual events, such as reloading from the net, checksum errors, etc. Figure 3 shows an example of this log. (The comments, in parentheses to the right, are not part of the log but have been added to explain the meaning of the entries.) In addition to this detailed log of interesting events, one may at any time obtain a quick summary of the status of the network. Finally, detailed and summary logs of Host and line traffic are produced. The NCC is a focal point not only for monitoring the network but also for testing and diagnosing remote troubles. Lines throughout the network can be looped from here in order to isolate difficulties. Personnel of the center coordinate all debugging, maintenance, repair and modification of equipment.

Figure 3—Typical segment of NCC log

DIRECT TERMINAL ACCESS

During the early phases of network development a typical node has consisted of one or more large time-shared computer systems connected to an IMP. The IMPs at the various sites are connected together into a subnet by 50 kilobit phone lines and the large Host computers communicate with one another through this subnet. This arrangement provides a means for sharing resources between such interconnected centers, each site potentially acting both as a user and as a provider of resources. *This total complex of facilities constitutes a nationwide resource which could be made available to users who have no special facilities of their own to contribute to the resource pool.* Such a user might be at a site either with no Host computer or where the existing computer might not be a terminal-oriented time-sharing system.

A great deal of thought went into considering how best to provide for direct terminal access to the network. One possibility, which would have essentially been a non-solution, was to require a user to dial direct to the appropriate Host. Once connected he could, of course, take advantage of the fact that that Host was tied to other Hosts in the net; however, the network lines would not have been used to facilitate his initial connection, and such an arrangement limits the terminal bandwidth to what may be available on the switched common-carrier networks.

A similar solution was to allow terminals to access the network through a Host at a nearby node. In such a case, for example, a worker in the New England area wishing to use facilities at a California site might connect into a local Boston Host and use that Host as a tap into the network to get at the facilities in California. This approach would have required Hosts to provide hardware access facilities for many terminals which would use their systems only in passing. For many Hosts, the kinds of terminals which can be connected directly are limited in speed, character set, etc. In terms of reliability, the user would have been dependent on the local Host for access; when that Host was down, his port into the network would be unavailable. Furthermore, the Hosts would have been confronted with all of the problems of composing terminal characters into network messages and vice versa as well as directing these messages to the proper terminals and remote Hosts. Time-sharing systems are generally already overburdened with processing of characters to and from terminals and many are configured with front end processors employed explicitly to off-load this burden from the main processor. Increasing the amount of such work for the Hosts therefore seemed unreasonable and would have resulted in limiting terminal access. Instead, a completely separate means for accessing the network directly seemed called for: an IMP with a flexible terminal handling capability—a *Terminal IMP*, or *TIP*.

One of the fundamental questions that arises when considering this problem is: what is the proper distribution of computational power among the remote big facility, the terminal processor, and the terminal? Shall the terminal processor be clever, have sizable storage, be user programmable, etc., or shall it be a simpler device whose basic job is multiplexing in a flexible way? Serious work with interactive graphics seems to require the terminal to include, or be in propinquity to, a user-programmable processor and considerable storage. To date, such work has primarily been done with terminals attached directly to a Host. Some elaborate terminals, such as the Adage, include a powerful processor. Other kinds of terminals, including Teletype-like devices, alphanumeric displays, or simple graphic displays (excluding serious interactive graphics), do *not* require a user-programmable local processor or significant local storage.

We believe that the great majority of potential groups needing access to the ARPA Network will not need powerful interactive graphics facilities. Further, for the minority that will need powerful terminals, we believe that individual terminals with built-in or accompanying processors will become more common. For these reasons, we decided that the terminal processor should be simple and not programmable from the terminals. *The computational load and the storage should be in the Hosts or in the terminals and not in the terminal processor.* This simple multiplexing approach is amenable to some standardization and is philosophically close to the original IMP notion of a standard nodal device.

Another major question we faced was whether to build a separate terminal handler and then connect it to the IMP or to build an integrated unit that was housed in a common cabinet and used the IMP processor. One advantage of the two-machine approach is that it isolates the IMP functions from the terminal functions, thereby providing a barrier of safety for the net. This approach also provides the processing power of two machines and a potentially greater degree of user freedom in modifying or writing programs. Another interesting reason for considering separate machines was to reduce the large cost associated with I/O equipment (such as line controllers) by making use of the extra processing power. We discussed with several manufacturers the possibility of bringing terminal wires "into" their processors and decoding the basic line information directly in software. However, even with some of the new state-of-the-art machines, like the Meta-4, with fast 90 nsec read-only memories to handle character decoding, the I/O cost was still high, and in large part the necessary I/O equipment was yet to be designed. We therefore concluded that it was still somewhat early to proceed in this fashion, and two processors did not appear to save I/O equipment.

The principal disadvantages of the two-machine approach were the higher initial cost, the difficulties of maintaining two machines, and the software problems of dealing with two machines. In particular, the communication between two machines would require two hardware Host interfaces, and two software Host/IMP programs. This would result in a much poorer communication between the IMP program and the terminal handling program than would exist in a single machine. In either case, one machine or two, the

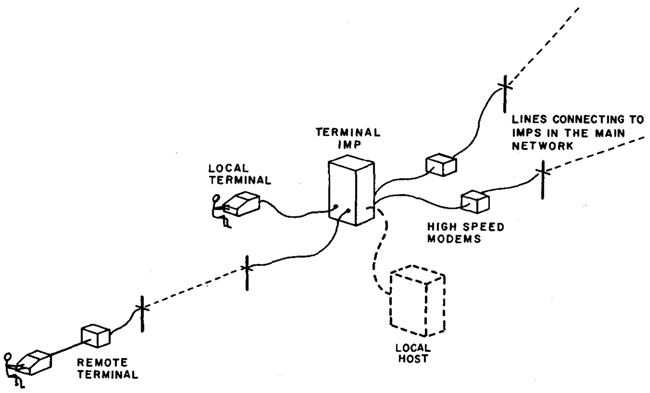

Figure 4—A TIP in the network

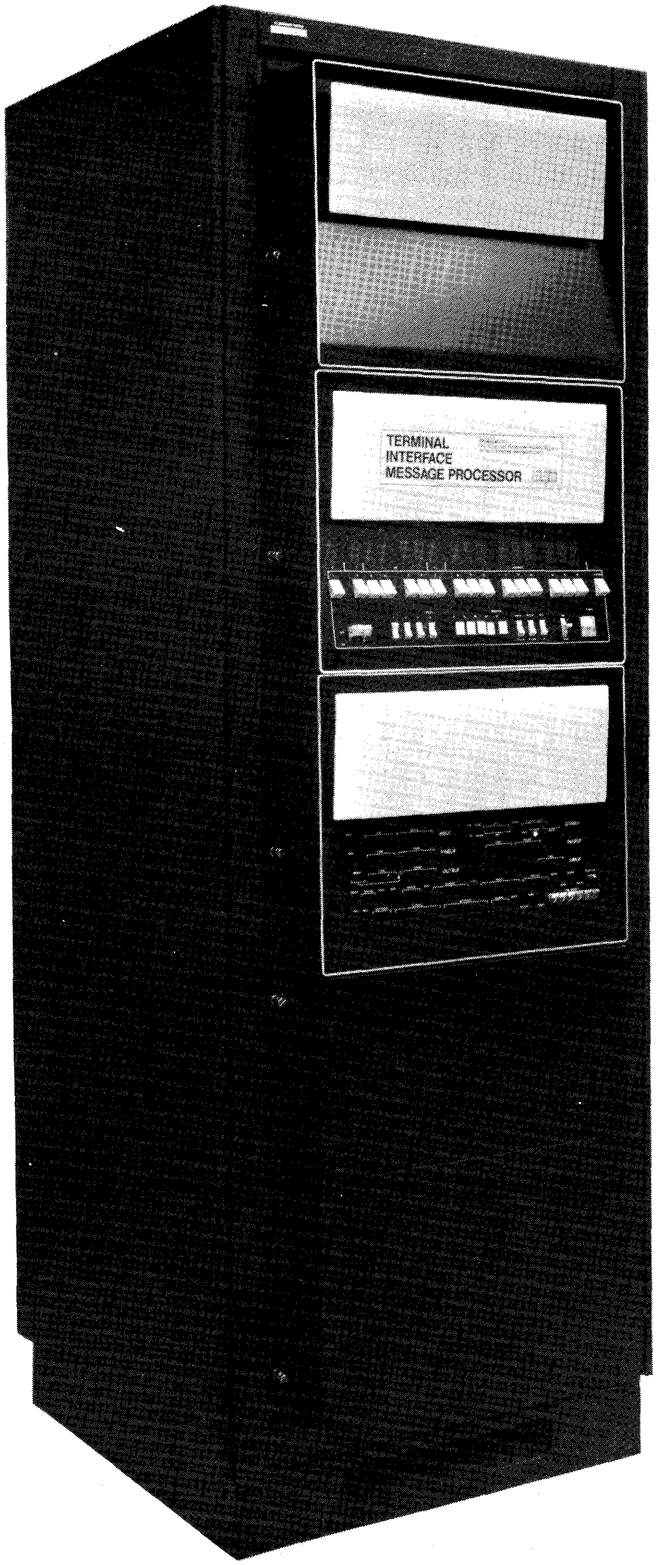

Figure 5—Photograph of TIP

terminal handling process required the implementation of a version of Host protocol.

We finally decided that the least expensive and most sensible technical alternative was to build the IMP and the terminal handler (with the necessary subset of Host protocol) together into a single machine. Then, since certain new machines appeared attractive in cost/performance relative to the Honeywell 16 series, we spent considerable time thinking about what machine to use. We decided that no alternate choice was sufficiently attractive to justify rewriting the main IMP program and redesigning the Host and modem interface hardware. This left us with a decision between the Honeywell 516 and 316 computers. We chose the 316 on the basis of size and cost, feeling that the somewhat higher bandwidth of the 516 was not essential to the job and did not justify its higher price and the second cabinet which would have been required.

TERMINAL IMP HARDWARE

Figure 4 shows how the TIP fits the user into the network. Up to 63* terminals, either remote or local, of widely diverse characteristics may be connected to a given TIP and thereby "talk" into the network. It is also possible to connect a Host to a TIP in the usual way.

The TIP is shown in Figure 5. It is built around a Honeywell H-316 computer with 20K (20,480 words) of core. It embodies a standard 16 port multiplexed memory channel with priority interrupts and includes a Teletype for debugging and program reloading. Other features of the standard IMP also present are a real-time clock, power-fail and auto-restart mechanisms, and a program-generated interrupt feature.[2] As in the standard IMP, interfaces are provided for connecting to high-speed (50 kilobit, 230.4 kilobit, etc.) modems as well as to Hosts. The single-cabinet version limits the configuration to a total of three modem and/or Host interfaces, but an expansion cabinet may be used to increase this limit. More basic limits are set by the machine's logical organization (specifically the number of available memory channels) and the program bandwidth capability as discussed below.

Aside from the additional 8K of core memory, the primary hardware feature which distinguishes the TIP from a standard IMP is a Multi-Line Controller (MLC) which allows for connection of terminals to the

* There are 64 hardware lines but line Ø is logically reserved by the program for special use.

IMP. Any of the MLC lines may go to local terminals or via modems to remote terminals. As shown in Figure 6 the MLC consists of two portions, one a piece of central logic which handles the assembly and disassembly of characters and transfers them to and from memory, and the other a set of individual Line Interface Units (all identical except for small number of option jumpers) which synchronize reporting to individual data bits between the central logic and the terminal devices and provide for control and status information to and from the modem or device. Line Interface Units may be physically incorporated one at a time as required.

The MLC connects to the high-speed multiplexed memory channel option of the H-316, and uses three of its channels as well as two priority interrupts and a small number of control instructions. The MLC is fabricated by BBN and is built from TTL integrated circuits. The MLC central controller, complete with power supply, is housed in an H-316 expansion chassis, and the entire MLC, as well as the computer itself, is mounted in a standard six-foot rack. Additional space is provided in the bottom of the rack for up to sixteen card-mounted modems of the Bell 103, 201, or 202 variety, together with their power supplies.

In order to accommodate a variety of devices, the controller handles a wide range of data rates and character sizes, in both synchronous and asynchronous modes. Data characters of length 5-, 6-, 7-, or 8-bits are allowed by the controller. Since no interpretation of characters is done by the hardware, any character set, such as Baudot, Transcode ASCII or EBCDIC may be used.

The following is a list of data rates accepted by the controller:

SYNCHRONOUS	*ASYNCHRONOUS* (Nominal Rates)		
Any rate up to and including 19.2 Kb/s	75	1200	
	110	1800	
	134.5	2400	
	150	4800	output only
	300	9600	output only
	600	19200	output only

All above in bits/second

The data format required of all devices is bit serial and each character indicates its own beginning by means of a start bit which precedes the data and includes one or more stop bits at the end of the character. This per-character framing is quite standard for asynchronous lines but synchronous lines, generally designed for higher bandwidths, frequently adopt some form of "binary synchronous communication" where the characters are packed tightly together into messages which are then framed by special characters. Framing is thereby amortized over the entire message, thus consuming a smaller fraction of the available bandwidth than the per-character framing which uses two or more bits for every character. The difficulties with this scheme, however, are that it is more complex, requiring more sophisticated hardware at each end, and that no real standards exist which are adhered to by all or even most types of synchronous devices. We therefore decided to adopt per-character framing with start and stop bits even on synchronous lines. At a cost of some twenty percent of the bandwidth for framing, a very simple and general scheme is thus arrived at. A number of high speed terminal manufacturers, faced with the same problems, have arrived at a similar conclusion.

Given these characteristics, then, the controller will connect to the great majority of normal terminal devices such as Teletypes, alphanumeric CRT units, and modems, and also (with suitable remote interface units) to many peripheral devices such as card readers, line printers, and graphics terminals. Either full or half duplex devices can be accommodated. The standard TIP program cannot deal with a magnetic tape unit through the MLC. However, as a special option, and with the use of additional core memory, standard Honeywell tape drives can be connected to the TIP as normal peripherals.

The individual terminal line levels are consistent with EIA RS-232C convention. Data rates and character length are individually set for each line *by the the program*. For incoming asynchronous lines, the program includes the capability for detecting character length and line data rate as discussed below.

Logically, the controller consists of 64 input ports and 64 output ports. Each input/output pair is brought out to a single connector which is normally connected to a single device. However, by using a special "Y"

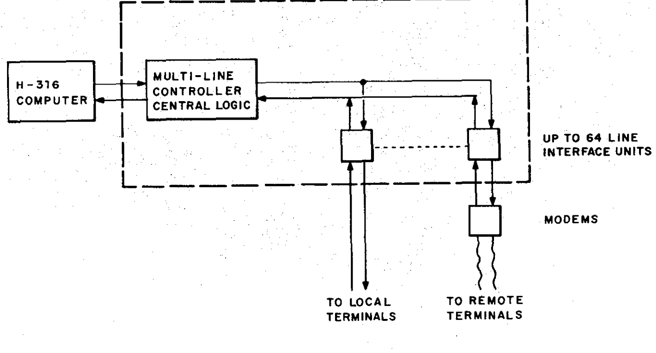

Figure 6—Block diagram of TIP hardware

cable, the ports may go to completely separate devices of entirely different properties. Thus, *input* port 16 may connect to a slow, asynchronous, 5-bit character keyboard while *output* port 16 connects to a high speed, synchronous display of some sort. In order to achieve this flexibility, the MLC stores information about each input and each output port and the program sets up this information for each half of each port in turn as it turns the ports "ON."

Several aspects of the MLC design are noteworthy. The central logic treats each of the 64 ports in succession, each port getting 800 ns of attention per cycle. The port then waits the remainder of the cycle (51.2 μs) for its next turn. For both input and output, two full characters are buffered in the central logic, the one currently being assembled or disassembled and one further character to allow for delays in memory accessing.

During input, characters from the various lines stream into a tumble table in memory on a first come, first served basis. Periodically a clock interrupt causes the program to switch tables and look for input.

Output characters are fed to all lines from a single output table. Ordering the characters in this table in such a way as to keep a set of lines of widely diverse speeds solidly occupied is a difficult task. To assist the program in this, a novel mechanism has been built into the MLC hardware whereby each line, as it uses up a character from the output table, enters a request consisting of its line number into a "request" table in memory. This table is periodically inspected by the program and the requests are used in building the next output table with the characters in proper line sequence.

The design of the terminal interface portion of the MLC is modular. Each Line Interface Unit (LIU) contains all the logic required for full duplex, bit serial communication and consists of a basic bi-directional data section and a control and status section. The data section contains transmit and receive portions each with clock and data lines. For asynchronous devices the clock line is ignored and timing is provided by the MLC itself. (For received asynchronous characters, timing is triggered by the leading edge of the start bit of each character.)

The control and status monitor functions are provided for modems as required by the RS-232C specification. Four outputs are available for control functions and six inputs are available to monitor status. The outputs are under program control and are available for non-standard functions if the data terminal is not a modem. For example, these lines could be used to operate a local line printer. RS-232C connectors are mounted directly on the LIU cards. To allow for variations in terminal and modem pin assignments, the signals are brought to connector pins via jumpers on the card.

The central MLC contains 256 ICs, many of which are MSI and some of which are LSI circuits, and it is thus about the same complexity as the basic H-316. In addition each LIU contains 31 ICs. A Terminal IMP including the MLC and with a typical interface configuration to high-speed circuits and Hosts is, order of magnitude, a $100,000 device.

THE TERMINAL USER'S VIEW

This section describes how a TIP user gains access to the network. The protocol described is of very recent origin and will undoubtedly change in response to usage which, as of this writing, is just commencing.

In general a user must have some foreknowledge of the resource which he expects to access via the network. The TIP program implements a set of commands[8] for connecting to and disconnecting from remote sites, but once a terminal is connected to a particular system, the TIP becomes transparent to the conversation unless specially signalled. This is equivalent to a timesharing system where the executive program is essentially out of the picture during periods while the user is dealing directly with his own set of programs.

Because of the large number of different terminal types used in the network, the concept of the Network Virtual Terminal was developed. This is an imaginary but well-defined type of terminal. The TIP translates typed data to virtual terminal code before shipping it into the network, and conversely translates the remote system's response back into the local terminal's code. Thus, each Host system must deal only with this single terminal type.

When the user at a terminal needs to talk directly to his TIP instead of to the remote Host, he issues a command which is distinguished by the fact that it always starts with the symbol @. One or more words, perhaps followed by a single parameter, then identify the type of command.

Normally a user will go through four more or less distinct stages in typing into the net. First, he will be concerned with hardware, power, dialing in, etc. Then he will establish a dialogue with the TIP to get a comfortable set of parameters for his usage. Next, he will instruct the TIP to make a connection to a remote Host, and finally, he will mostly ignore the TIP as he talks to the remote Host.

One of the more interesting features of the TIP is that it permits great flexibility in the types of terminals which may be attached to any port. This

TABLE II—Tip Commands

CLOSE	close all outstanding connections
HOST #	focus attention on this host 0<#<256
LOGIN	start the initial connection procedure to get Telnet connections
SEND BREAK	send a Telnet break character
SEND SYNC	send a Telnet sync character and an INTERRUPT SENDER message
ECHO ALL	local TIP-generated echo—TIP echoes everything
ECHO NONE	remote Host-generated echo—TIP will echo commands
ECHO HALFDUPLEX	terminal-generated echo—TIP echoes nothing
FLUSH	delete all characters in input buffer
TRANSMIT EVERY #	send off input buffer at least every #th character 0<#<256
TRANSMIT ON EVERY CHARACTER	like TRANSMIT EVERY 1
TRANSMIT ON LINEFEED	send input buffer every time a linefeed encountered
TRANSMIT ON MESSAGE-END	send input buffer every time an EOM encountered
TRANSMIT ON NO CHARACTER	do not transmit on linefeed or EOM
TRANSMIT NOW	send off input buffer now
DEVICE RATE #	# is a 13 bit code specifying hardware rate and character size settings
DEVICE CODE ASCII	establish code conversion
DEVICE CODE 2741	
DEVICE CODE EXECUPORT	
DEVICE CODE ODEC	
SEND TO HOST #	establish parameters for manual initiation of connections
RECEIVE FROM HOST #	
SEND TO SOCKET #	
RECEIVE FROM SOCKET #	
PROTOCOL TO TRANSMIT	initiate connection protocol manually
PROTOCOL TO RECEIVE	
PROTOCOL TO CLOSE TRANSMIT	
PROTOCOL TO COSE RECEIVE	
PROTOCOL BOTH	abbreviations for simultaneous transmit and receive protocols
PROTOCOL TO CLOSE BOTH	
# GIVE BACK	release control of captured device
# DIVERT OUTPUT	capture device # and divert this terminal's output to it
ABORT LOGIN	abort the outstanding initial connection procedure

flexibility presents a problem to the program which must determine what kind of terminal (speed, character size, etc.) is attached to a given port before a sensible exchange of information is possible. To solve this problem, each terminal is assigned a special identifying character which the user types repeatedly when starting to use a terminal. When information starts to appear from a previously idle port, the TIP enters a "hunt" mode in which it interprets the arriving characters trying various combinations of terminal characteristics. All except the proper combination will cause the character to be garbled, producing something other than one of the legal terminal identifying characters. When the TIP thus identifies the correct set (which generally requires the user to repeat the identifier less than half a dozen times), it types out ‘HELLO in the terminal's own language.

In the next stage, the user initializes certain conversation parameters relating to message size and when to echo. He then establishes connection to a remote site using two commands which identify the desired remote site and the fact that the user wishes to be connected to the logger at that site. These commands are:

@ HOST 15

@ LOGIN

The LOGIN command actually sets in motion an elaborate exchange of messages between the TIP and the remote Host which normally result in a connection being made to that remote system. This command will be answered by an appropriate comment to the user indicating either that a connection has been made, that the remote site is not up, that it is up but actively refusing to converse, or that it is up but not responding enough even to refuse the connection.

Once a connection is established, the user types directly to the logger. The TIP does not execute the actual login since this procedure varies from site to site.

Throughout the user-to-Host dialogue, commands remain available at any time. Prior to closing the connection, the user must log out as required by the system he is using. He then gives the command

@ CLOSE

which causes the TIP to close the connection, informing the user when the process is finished.

In addition to the above more or less standard procedures, there are a number of less usual commands which set such things as device rate, character size, code types, etc. Such commands are used by a terminal on one port in setting parameters for a non-interactive terminal, such as a printer or card reader, on some other port. Other special commands permit conversations directly between terminals on the same or different TIPs, allow for binary mode, etc. Table II is a list of the commands with a brief explanation. For details refer to Reference 8. Figure 7 gives an example of typical dialogue.

THE SOFTWARE

Because the terminals connected to a TIP communicate with Hosts at remote sites, the TIP, in addition to performing the IMP function, also acts as intermediary between the terminal and the distant Host. This means that network standards for format and protocol must be implemented in the TIP. One can thus think of the TIP software as containing both a very simpleminded mini-Host and a regular IMP program.

Figure 8 gives a simplified diagrammatic view of the program. The lower block marked "IMP" represents the usual IMP program. The two lines into and out of that block are logically equivalent to input and output from a Host. The code conversion blocks are in fact surprisingly complex and include all of the material for dealing with diverse (and perverse) types of terminals.

As the user types on the keyboard, characters go, via input code conversion, to the input block. Information for remote sites is formed into regular network messages and passes through the OR switch to the IMP program for transmittal. Command characters are fed off to the side to the command block where commands are decoded. The commands are then "performed" in that they either set some appropriate parameter or a flag which calls for later action. An example of this is the LOGIN command. Such a command in fact triggers a complex network protocol procedure, the various steps of which are performed by the PROTOCOL block working in conjunction with the remote Host through the IMPs. As part of this process an appropriate special message will be sent to the terminal via the Special Messages block indicating the status (success, failure, etc.) of the procedure.

```
1               Character typed just after terminal turned on.  Used to
                identify the terminal type for the Terminal IMP program.

HELLO           TIP indicates that terminal is ready for use.

@ HOST 1        User tells Terminal IMP which Host to connect to.

                (Terminal IMP echoes extra carriage return line feed to
                indicate it has accepted a command.)
@ LOGIN         User tells Terminal IMP to form a connection.
                (TIP echoes extra carriage return line feed.)

T R OPEN        Terminal IMP has formed a connection.

Figure 7—Typical terminal user dialogue

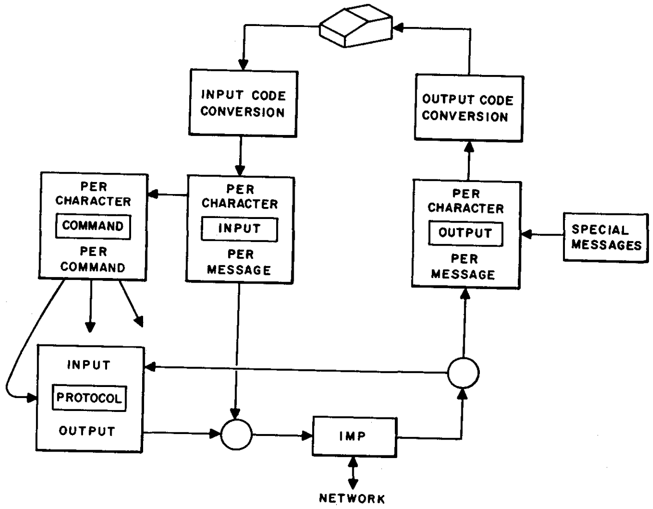

Figure 8—Block diagram of TIP program

Once connection to a remote Host is established, regular messages flow directly through the Input block and on through the IMP program. Returning responses come in through the IMP, into the OUTPUT program where they are fed through the OUTPUT Code Conversion block to the terminal itself.

Storage for the TIP program, including the standard IMP program, is just over 20K. This is roughly as follows:

Standard IMP Program with buffers & tables	12,000
Special TIP code	2,650
Tables of Parameters	1,800
Buffer Storage for messages to and from terminals	1,880
Miscellaneous—I/O buffers, constants, etc.	1,880

PERFORMANCE

The program can handle approximately 100 kilobits of one-way terminal traffic provided the message size is sufficiently large that per-message processing is amortized over many characters. Overhead per message is such that if individual characters are sent one at a time there is a loss of somewhere between a factor of ten and twenty in bandwidth. A different way to look at program performance is to observe that the per-character processing time is about 75 μs.

These figures ignore the fact that the machine must devote some of its bandwidth to acting as an IMP, both for terminal traffic and for regular network traffic. About 5% of the machine is lost to acting as an IMP, even in the absence of traffic. If there is network traffic, more of the machine bandwidth is used up. Five hundred kilobits of two-way phone line and Host traffic saturates the machine without any terminal traffic*.

In addition to bandwidth which goes into the IMP part of the job, another 10 percent of the (total) machine is taken up simply in fielding clock interrupts from the Multi-Line Controller. This again is bandwidth used in idling even with no actual terminal traffic.

The following formula summarizes, approximately, the bandwidth capabilities:

$$P + H + 11T \leq 850$$

where:

P = total phone line traffic (in kilobits/sec) wherein, for example, a full duplex 50 Kb phone line counts as 100;

H = total Host traffic (in kilobits/sec) wherein the usual full duplex Host interface, with its usual 10 μs/bit setting, counts as 200; and

T = total terminal traffic (in kilobits/sec) wherein an ASCII terminal such as a (110-baud) full-duplex Teletype (ASR-33) counts as twice its baud rate (i.e., 0.220 Kb).

This means that it takes eleven times as much program time to service every terminal character as it does to service a character's worth of phone line or Host message.

A further factor that influences terminal traffic handling capability has to do with the terminals themselves. Certain types of terminals require more attention from the program than others, independent of their speed but based rather on their complexity. In particular, for example, while an IBM 2741 nominally runs at 134.5 bits per second, the complexity is such that it uses nearly three times the program bandwidth that would be used in servicing a half-duplex ASCII terminal of equivalent speed. Allowances for such variations must be made in computing the machine's ability to service a particular configuration. It must be borne in mind that all of these performance figures are approximations and that the actual rules are extremely complex, and will change as the program matures.

DISCUSSION

As the ARPA Network grows, a number of areas of development seem likely to require attention. Certain of these are already pressing problems whereas others will begin to appear primarily as the network continues to grow and mature.

Perhaps the most difficult aspect of a network such as this is the problem of reliability. A great deal of thought and effort has gone into trying to make the system reliable and network topology has been designed with the need for redundancy in mind. Nonetheless the problem of keeping a large number of computer systems going at widely separated sites is non-trivial. An IMP's mean-time-between-failure (MTBF) has been on the order of one month; considerably lower than expected. The problems arise from a variety of sources and the system is sufficiently complex that frequently the cause has been masked by the time the failure has been noted. Often the same failure will recur several times until the problem is identified and eliminated and this fact tends to decrease the apparent MTBF. In general a preponderance of the troubles stem from hardware failures, and we are currently modifying several noisy and/or marginal portions of the I/O and interface hardware in hopes of obtaining significant improvement.

Our strategy has generally been to spend time identifying the source of trouble, keeping the machine off the air if necessary, so that eventually the MTBF will increase. This has often meant, however, that a "down" was much longer than it would have been, had the foremost goal been to get the machine running again immediately. With this strategy the average down time has been about 9 hours, giving rise to an average per-machine down rate of about 2 percent. We hope to improve this situation in the near future by providing improved facilities for obtaining "program dumps" when a failure occurs. This will make it possible to bring machines back on the air almost immediately in many cases, without jeopardizing valuable debugging data.

* The number 500 kilobits is for full size (8000 bit) messages. Shorter messages use up more capability per bit and thus reduce the overall bandwidth capability.

A word about our experience with the phone lines appears appropriate here as well. We have apparently been an unusual, if not unique, customer for the common carriers in our degree of attention to line failures. Our ability to detect and report even brief outages has led through measured skepticism to eventual acceptance by the carriers. In general, tests have indicated that the phone line error rates are about as predicted, i.e., approximately one in 10^5. These occasional errors or error bursts do not appear to affect network performance adversely. The IMP-to-IMP error checking procedure has not, to our knowledge, admitted a single erroneous message. We have, however, had some difficulty with lines which were simply out of commission from time to time for extended periods (hours or even days). The reliability of the phone lines is roughly equivalent to the reliability of the IMPs, based on the number and duration of outages. Down times have decreased as the carriers have come to accept our complaints as generally legitimate. *Overall the performance of the telephone equipment does not appear to constitute a problem in network growth.*

From a strictly technical viewpoint we view the incorporation of higher bandwidth facilities as a natural and key part of network growth. While the present facilities are not saturated by the present loads, we view this situation as a temporary one and something of a period of grace. As the network continues to grow over the next few years traffic can be expected to increase in a very non-linear fashion. Host protocol procedures (which have presented a sizable stumbling block to usage) are settling down so that software commitments can be made, and the advent of the Terminal IMP will bring an influx of new users who do not have the alternative of local resources. As a result we expect that traffic will begin to saturate some parts of the network. Terminal IMPs may well be called upon to service a larger number of terminals of higher bandwidth than can be handled by the present version.

In anticipation of these requirements we are presently considering the design of a significantly faster and more modular version of the IMP. Its higher speed will permit it to take advantage of high speed (i.e., megabit and above) communication lines which the common carriers are currently developing. More generally it will be able to service high bandwidth requirements whenever and however they occur within the net. We are currently studying a modular design which will permit connection of a greater number of interfaces than the present IMP can handle. While this work is only in the preliminary design stage, we feel that the interest and enthusiasm which have greeted the initial network suggest that it is not too early to consider ways to cope with growing traffic requirements.

Another area of network development which has already received a great deal of attention and will require much more in the future is that of technical information interchange between the sites. To the user, the resources which are becoming available are staggering if not overwhelming. It is very difficult for an individual to discover what, if any, of the mass of programs that will be available through the network may be of interest or of use to him. To aid in this process a number of mechanisms are being implemented and we are cooperating closely with these efforts. In particular, at the Stanford Research Institute a Network Information Center (NIC) acts essentially as a library for documentation concerning the network. Here are maintained a number of pointer documents, specifically, (1) a Directory of Participants which lists critical personnel, phone numbers, etc., for each participating site, (2) a catalogue of the NIC Collection which lists the available documents indexed in a variety of ways, (3) a Resource Notebook which is a compendium that attempts to familiarize the reader with available program resources at each of the participating sites.

Finally, there is the broad and exciting issue of how to cope with success. As the ARPA Network grows, and as diverse resources and users join the net, it is clear that a technology transfer must occur; the network probably must shift from a government-supported research and development activity to an ongoing national *service* of some kind. However, the computer-communications environment in the U.S. is rather complex, and is populated with many legal, economic, and political constraints. Within this environment, it is not easy to perform the technology transfer, and many groups, including ARPA and BBN, have been considering possible alternative plans. We are optimistic that a way will be found to provide a suitable legal and political base for expansion of the present ARPA Network into a widely useful public communication system.

ACKNOWLEDGMENTS

In addition to the authors, a great many people have contributed to the work reported here. Dr. L. G. Roberts of the Advanced Research Projects Agency has continued to lend crucial support and encouragement to the project. Messrs. Blue, Dolan, and Crocker of the ARPA office have been understanding and helpful. Suggestions and helpful criticism have come from many present and prospective participants in the network community.

At BBN, W. B. Barker is responsible for much of the cleverness which appears in the MLC hardware; R. E. Kahn has contributed in many areas and has been deeply involved in studying traffic flow control; A. McKenzie has compiled the Network Resource Notebook and been concerned with Host relations and many Host protocol issues; M. Thrope has managed the Network Control Center and has kept the network on the air; J. Levin helped in implementation of the TIP software; B. P. Cosell has patiently labored with the IMP software, with help from J. McQuillan and M. Kraley; and R. Alter has offered much helpful advice and criticism.

INTRODUCTION

The ARPA Network (ARPANET) project brought together many individuals with diverse backgrounds, philosophies, and technical approaches from the fields of computer science, communication theory, operations research and others. The project was aimed at providing an efficient and reliable computer communications system (using message switching techniques) in which computer resources such as programs, data, storage, special purpose hardware etc., could be shared among computers and among many users.[38] The variety of design methods, ranging from theoretical modeling to hardware development, were primarily employed independently, although cooperative efforts among designers occurred on occasion. As of November, 1971, the network has been an operational facility for many months, with about 20 participating sites, a network information center accessible via the net, and well over a hundred researchers, system programmers, computer center directors and other technical and administrative personnel involved in its operation.

In this paper, we review and evaluate the methods used in the ARPANET design from the vantage of over two years' experience in the development of the network. In writing this paper, the authors have each made equal contributions during a series of intensive discussions and debates. Rather than present merely a summary of the procedures that were used in the network design, we have attempted to evaluate each other's methods to determine their advantages and drawbacks. Our approaches and philosophies have often differed radically and, as a result, this has not been an easy or undisturbing process. On the other hand, we have found our collaboration to be extremely rewarding and, notably, we have arrived at many similar conclusions about the network's behavior that seem to be generally applicable to message switched networks.

The essence of a network is its design philosophy, its performance characteristics, and its cost of implementation and operation. Unfortunately, there is no generally accepted definition of an "optimal" network or even of a "good" network. For example, a network designed to transmit large amounts of data only during late evening hours might call for structural and performance characteristics far different from one servicing large numbers of users who are rapidly exchanging short messages during business hours. We expect this topic, and others such as the merits of message switching vs. circuit switching or distributed vs. centralized control to be a subject of discussion for many years.[1,14,24,32,34,37]

A cost analysis performed in 1967-1968 for the ARPA Network indicated that the use of message switching would lead to more economical communications and better overall availability and utilization of resources than other methods.[36,38] In addition to its impact on the availability of computer resources, this decision has generated widespread interest in store-and-forward communications. In many instances, the use of store-and-forward communication techniques can result in

greater flexibility, higher reliability, significant technical advantage, and substantial economic savings over the use of conventional common carrier offerings. An obvious trend toward increased computer and communication interaction has begun. In addition to the ARPANET, research in several laboratories is under way, small experimental networks are being built, and a few examples of other government and commercial networks are already apparent.[6,7,31,40,41,47,48,52]

In the ARPANET, each time-sharing or batch processing computer, called a Host, is connected to a small computer called an Interface Message Processor (IMP). The IMPs, which are interconnected by leased 50 kilobit/second circuits,' handle all network communication for their Hosts. To send a message to another Host, a Host precedes the text of its message with an address and simply delivers it to its IMP. The IMPs then determine the route, provide error control, and notify the sender of its receipt. The collection of Hosts, IMPs, and circuits forms the message switched resource sharing network. A good description of the ARPANET, and some early results on protocol development and modeling are given in References 3, 12, 15, 23 and 38. Some experimental utilization of the ARPANET is described in Reference 42. A more recent evaluation of such networks and a forward look is given in References 35 and 39.

The development of the Network involved four principal activities:

(1) The design of the IMPs to act as nodal store-and-forward switches,
(2) The topological design to specify the capacity and location of each communication circuit within the network,
(3) The design of higher level protocols for the use of the network by time-sharing, batch processing and other data processing systems, and
(4) System modeling and measurement of network performance.

Each of the first three activities were essentially performed independently of each other, whereas the modeling effort partly affected the IMP design effort, and closely interacted with the topological design project.

The IMPs were designed by Bolt Beranek and Newman Inc. (BBN) and were built to operate independent of the exact network connectivity; the topological structure was specified by Network Analysis Corporation (NAC) using models of network performance developed by NAC and by the University of California at Los Angeles (UCLA). The major efforts in the area of system modeling were performed at UCLA using theoretical and simulation techniques. Network performance measurements have been conducted during the development of the network by BBN and by the Network Measurement Center at UCLA. To facilitate effective use of the net, higher level (user) protocols are under development by a group of representatives of universities and research centers. This group, known as the Network Working Group, has already specified a Host to Host protocol and a Telnet protocol, and is in the process of completing other function oriented protocols.[4,29] We make no attempt to elaborate on the Host to Host protocol design problems in this paper.

THE NETWORK DESIGN PROBLEM

A variety of performance requirements and system constraints were considered in the design of the net. Unfortunately, many of the key design objectives had to be specified long before the actual user requirements could be known. Once the decision to employ message switching was made, and fifty kilobit/second circuits were chosen, the critical design variables were the network operating procedure and the network topology; the desired values of throughput, delay, reliability and cost were system performance and constraint variables. Other constraints affected the structure of the network, but not its overall properties, such as those arising from decisions about the length of time a message could remain within the network, the location of IMPs relative to location of Hosts, and the number of Hosts to be handled by a single IMP.

In this section, we identify the central issues related to IMP design, topological design, and network modeling. In the remainder of the paper, we describe the major design techniques which have evolved.

IMP properties

The key issue in the design of the IMPs was the definition of a relationship between the IMP subnet and the Hosts to partition responsibilities so that reliable and efficient operation would be achieved. The decision was made to build an autonomous subnet, independent (as much as possible) of the operation of any Host. The subnet was designed to function as a "communications system"; issues concerning the use of the subnet by the Hosts (such as protocol development) were initially left to the Hosts. For reliability, the IMPs were designed to be robust against all line failures and the vast majority of IMP and Host failures. This decision required routing strategies that dynamically adapt to changes in the states of IMPs and circuits, and an elaborate flow control strategy to protect the subnet against Host malfunction and congestion due to IMP buffer limitations. In addition, a statistics and status reporting mechanism was needed to monitor the behavior of the network.

The number of circuits that an IMP must handle is a design constraint directly affecting both the structure of the IMP and the topological design. The speed of the IMP and the required storage for program and buffers depend directly upon the total required processing capacity, which must be high enough to switch traffic from one line to another when all are fully occupied. Of great importance is the property that all IMPs operate with identical programs. This technique greatly simplifies the problem of network planning and maintenance and makes network modifications easy to perform.

The detailed physical structure of the IMP is not discussed in this paper.[2,15] However, the operating procedure, which guides packets through the net, is very much of interest here. The flow control, routing, and error control techniques are integral parts of the operating procedure and can be studied apart from the hardware by which they are implemented. Most hardware modifications require changes to many IMPs already installed in the field, while a change in the operating procedure can often be made more conveniently by a change to the single operating program common to all IMPs, which can then be propagated from a single location via the net.

Topological properties

The topological design resulted in the specification of the location and capacity of all circuits in the network. Projected Host—Host traffic estimates were known at the start to be either unreliable or wrong. Therefore, the network was designed under the assumption of equal traffic between all pairs of nodes. (Additional superimposed traffic was sometimes included for those nodes with expectation of higher traffic requirements.) The topological structure was determined with the aid of specially developed heuristic programs to achieve a low cost, reliable network with a high throughput and a general insensitivity to the exact traffic distribution. Currently, only 50 kilobit/second circuits are being used in the ARPANET. This speed line was chosen to allow rapid transmission of short messages for interactive processing (e.g., less than 0.2 seconds average packet delay) as well as to achieve high throughput (e.g., at least 50 kilobits/second) for transmission of long messages. For reliability, the network was constrained to have at least two independent paths between each pair of IMPs.

The topological design problem requires consideration of the following two questions:

(1) Starting with a given state of the network topology, what circuit modifications are required to add or delete a set of IMPs?

(2) Starting with a given state of network topology, when and where should circuits be added or deleted to account for long term changes in network traffic?

If the locations of all network nodes are known in advance, it is clearly most efficient to design the topological structure as a single global effort. However, in the ARPANET, as in most actual networks, the initial designation of node locations is modified on numerous occasions. On each such occasion, the topology can be completely reoptimized to determine a new set of circuit locations.

In practice, there is a long lead time between the ordering and the delivery of a circuit, and major topological modifications cannot be made without substantial difficulty. It is therefore prudent to add or delete nodes with as little disturbance as possible to the basic network structure consistent with overall economical operation. Figure 1 shows the evolution of the ARPANET from the basic four IMP design in 1969 to the presently planned 27 IMP version. Inspection of the 24 and 27 IMP network designs reveals a few substantial changes in topology that take advantage of the new nodes being added. Surprisingly enough, a complete "reoptimization" of the 27 IMP topology yields a network only slightly less expensive (about 1 percent) than the present network design.[28]

Network models

The development of an accurate mathematical model for the evaluation of time delay in computer networks is among the more difficult of the topics discussed in this paper. On the one hand, the model must properly reflect the relevant features of the network structure and operation, including practical constraints. On the other hand, the model must result in a mathematical formulation which is tractable and from which meaningful results can be extracted. However, the two requirements are often incompatible and we search for an acceptable compromise between these two extremes.

The major modeling effort thus far has been the study of the behavior of networks of queues.[21] This emphasis is logical since in message switched systems, messages experience queueing delays as they pass from node to node and thus a significant performance measure is the

speed at which messages can be delivered. The queueing models were developed at a time when there were no operational networks available for experimentation and model validation, and simulation was the only tool capable of testing their validity. The models, which at all times were recognized to be idealized statements about the real network, were nonetheless crucial to the ARPANET topological design effort since they afforded the only known way to quantitatively predict the properties of different routing schemes and topological structures. The models have been subsequently demonstrated to be very accurate predictors of network throughput and indispensable in providing analytical insight into the network's behavior.

The key to the successful development of tractable models has been to factor the problem into a set of simpler queueing problems. There are also heuristic design procedures that one can use in this case. These procedures seem to work quite well and are described later in the paper. However, if one specializes the problem and removes some of the real constraints, theory and analysis become useful to provide understanding, intuition and design guidelines for the original constrained problem. This approach uncovers global properties of network behavior, which provide keys to good heuristic design procedures and ideal performance bounds.

DESIGN TECHNIQUES

In this section we describe the approaches taken to the design problems introduced in the previous section. We first summarize the important properties of the ARPANET design:

(1) A communications cost of less than 30 cents per thousand packets (approximately a megabit).
(2) Average packet delays under 0.2 seconds through the net.
(3) Capacity for expansion to 64 IMPs without major hardware or software redesign.
(4) Average total throughput capability of 10-15 kilobits/second for all Hosts at an IMP.
(5) Peak throughput capability of 85 kilobits/second per pair of IMPs in an otherwise unloaded network.
(6) Transparent communications with maximum message size of approximately 8000 bits and error rates of one bit in 10^{12} or less.

(7) Approximately 98 percent availability of any IMP and close to 100 percent availability of all operating IMPs from any operable IMP.

The relationships between the various design efforts are illustrated by these properties. The topological design provides for both a desired average throughput and for two or more paths to be fully used for communication between any pair of Hosts. The operating procedure should allow any pair of Hosts to achieve those objectives. The availability of IMPs to communicate reflects both the fact that IMPs are down about 2 percent of the time and that the topology is selected so that circuit failures contribute little additional to the total system downtime.

IMP design

The IMP design consists of two closely coupled but nonetheless separable pieces—the physical hardware specification (based on timing and reliability considerations and the operating procedure) and the design and implementation of the operating procedure using the specified IMP hardware. The IMP originally developed for the ARPANET contains a 16-bit one microsecond computer that can handle a total of about ¾ megabits/second of "useful" information on a total of approximately one megabit/second of circuit capacity (e.g., twenty 50 kilobit/second circuits). Hardware is likely to change as a function of the required IMP capacity but an operating procedure that operates well at one IMP capacity is likely to be transferable to machines that provide different capacity. However, as a network grows in size and utilization, a more comprehensive operating procedure that takes account of known structural properties, such as a hierarchical topology, is appropriate.

Four primary areas of IMP design, namely message handling and buffering, error control, flow control, and routing are discussed in this section. The IMP provides buffering to handle messages for its Host and packets for other IMPs. Error control is required to provide reliable communication of Host messages in the presence of noisy communication circuits. The design of the operating procedure should allow high throughput in the net under heavy traffic loads. Two potential obstacles to achieving this objective are: (1) The net can become congested and cause the throughput to *decrease* with increasing load, and (2) The routing procedure may be unable to always adapt sufficiently fast to the rapid movement of packets to insure efficient routing. A flow control and routing procedure is needed that can efficiently meet this requirement.

Message handling and buffering

In the ARPANET, the maximum message size was constrained to be approximately 8000 bits. A pair of Hosts will typically communicate over the net via a sequence of transmitted messages. To obtain delays of a few tenths of a second for such messages and to lower the required IMP buffer storage, the IMP program partitions each message into one or more packets each containing at most approximately 1000 bits. Each packet of a message is transmitted independently to the destination where the message is reassembled by the IMP before shipment to that destination Host. Alternately, the Hosts could assume the responsibility for reassembling messages. For an asynchronous IMP-Host channel, this marginally simplifies the IMP's task. However, if *every* IMP-Host channel were synchronous, and the Host provided the reassembly, the IMP task can be further simplified. In this latter case, "IMP-like" software would have to be provided in each Host.

The method of handling buffers should be simple to allow for fast processing and a small amount of program. The number of buffers should be sufficient to store enough packets for the circuits to be used to capacity; the size of the buffers may be intuitively selected with the aid of simple analytical techniques. For example, fixed buffer sizes are useful in the IMP for simplicity of design and speed of operation, but inefficient utilization can arise because of variable length packets. If each buffer contains A words of overhead and provides space for M words of text, and if message sizes are uniformly distributed between 1 and L, it can be shown[45] that the choice of M that minimizes the expected storage is approximately $\sqrt{AL}$. In practice, M is chosen to be somewhat smaller on the assumption that most traffic will be short and that the amount of overhead can be as much as, say, 25 percent of buffer storage.

Error control

The IMPs must assume the responsibility for providing error control. There are four possibilities to consider:

(1) Messages are delivered to their destination out of order.

(2) Duplicate messages are delivered to the destination.

(3) Messages are delivered with errors.

(4) Messages are not delivered.

The task of proper sequencing of messages for delivery to the destination Host actually falls in the province of both error control and flow control. If at most one message at a time is allowed in the net between a pair of Hosts, proper sequencing occurs naturally. A duplicate packet will arrive at the destination IMP after an acknowledgment has been missed, thus causing a successfully received packet to be retransmitted. The IMPs can handle the first two conditions by assigning a sequence number to each packet as it enters the network and processing the sequence number at the destination IMP. A Host that performs reassembly can also assign and process sequence numbers and check for duplicate packets. For many applications, the order of delivery to the destination is immaterial. For priority messages, however, it is typically the case that fast delivery requires a perturbation to the sequence.

Errors are primarily caused by noise on the communication circuits and are handled most simply by error detection and retransmission between each pair of IMPs along the transmission path. This technique requires extra storage in the IMP if either circuit speeds or circuit lengths substantially increase. Failures in detecting errors can be made to occur on the order of years to centuries apart with little extra overhead (20-30 parity bits per packet with the 50 kilobit/second circuits in the ARPANET). Standard cyclic error detection codes have been usefully applied here.

A reliable system design insures that each transmitted message is accurately delivered to its intended destination. The occasional time when an IMP fails and destroys a useful in-transit message is likely to occur far less often than a similar failure in the Hosts and has proven to be unimportant in practice, as are errors due to IMP memory failures. A simple end to end retransmission strategy will protect against these situations, if the practical need should arise. However, the IMPs are designed so that they can be removed from the network without destroying their internally stored packets.

Flow control

A network in which packets may freely enter and leave can become congested or logically deadlocked and cause the movement of traffic to halt.[5,17] Flow control techniques are required to prevent these conditions from occurring. The provision of extra buffer storage will mitigate against congestion and deadlocks, but cannot in general prevent them.

The sustained failure of a destination Host to accept packets from its IMP at the rate of arrival will cause the net to fill up and become congested. Two kinds of logical deadlocks, known as reassembly lockup and store-and-forward lockup may also occur. In reassembly lockup, the remaining packets of partially reassembled messages are blocked from reaching the destination IMP (thus preventing the message from being completed and the reassembly space freed) by other packets in the net that are waiting for reassembly space at that destination to become free. In a store-and-forward lockup, the destination has room to accept arriving packets, but the packets interfere with each other by tying up buffers in transit in such a way that none of the packets are able to reach the destination.[17] These phenomena have only been made to occur during very carefully arranged testing of the ARPANET and by simulation.[49]

In the original ARPANET design, the use of software links and RFNMS protected against congestion by a single link or a small set of links. However, the combined traffic on a large number of links could still produce congestion. Although this strategy did not protect against lockup, the method has provided ample protection for the levels of traffic encountered by the net to date.

A particularly simple flow control algorithm that augments the original IMP design to prevent congestion and lockup is also described in Reference 17. This scheme includes a mechanism whereby packets may be discarded from the net at the destination IMP when congestion is about to occur, with a copy of each discarded packet to be retransmitted a short time later by the originating Host's IMP. Rather than experience excessive delays within the net as traffic levels are increased, the traffic is queued outside the net so that the transit time delays internal to the net continue to remain small. This strategy prevents the insertion of more traffic into the net than it can handle.

It is important to note the dual requirement for small delays for interactive traffic and high bandwidth for the fast transfer of files. To allow high bandwidth between a pair of Hosts, the net must be able to accept a steady flow of packets from one Host and at the same time be able to rapidly quench the flow at the entrance to the source IMP in the event of imminent congestion at the destination. This usually requires that a separate provision be made in the algorithm to protect short interactive messages from experiencing unnecessarily high delays.

Routing

Network routing strategies for distributed networks require routing decisions to be made with only information available to an IMP and the IMP must execute those decisions to effect the routing.[14,15] A simple example of such a strategy is to have each IMP handling a packet independently route it along its current estimate of the shortest path to the destination.

For many applications, it suffices to deal with an idealized routing strategy which may not simulate the IMP routing functions in detail or which uses information not available to the IMP. The general properties of both strategies are usually similar, differing mainly in certain implementation details such as the availability of buffers or the constraint of counters and the need for the routing to quickly adapt to changes in IMP and circuit status.

The IMPs perform the routing computations using information received from other IMPs and local information such as the alive/dead state of its circuits. In the normal case of time varying loads, local information alone, such as the length of internal queues, is insufficient to provide an efficient routing strategy without assistance from the neighboring IMPs. It is possible to obtain sufficient information from the neighbors to provide efficient routing, with a small amount of computation needed per IMP and without each IMP requiring a topological map of the network. In certain applications where traffic patterns exhibit regularity, the use of a central controller might be preferable. However, for most applications which involve dynamically varying traffic flow, it appears that a central controller cannot be used more effectively than the IMPs to update routing tables if such a controller is constrained to derive its information via the net. It is also a less reliable approach to routing than to distribute the routing decisions among the IMPs.

The routing information cannot be propagated about the net in sufficient time to accurately characterize the instantaneous traffic flow. An efficient algorithm, therefore, should not focus on the movement of individual packets, but rather use topological or statistical information in the selection of routes. For example, by using an averaging procedure, the flow of traffic can be made to build up smoothly. This allows the routing algorithm ample time to adjust its tables in each IMP in advance of the build-up of traffic.

The scheme originally used in the ARPA network had each IMP select one output line per destination onto which to route packets. The line was chosen to be the one with minimum estimated time delay to the destination. The selection was updated every half second using minimum time estimates from the neighboring IMPs and internal estimates of the delay to each of the neighbors. Even though the routing algorithm only selects one line at a time per destination, two output lines will be used if a queue of packets waiting transmission on one line builds up before the routing update occurs and another line is chosen. Modifications to the scheme which allow several lines per destination to be used in an update interval (during which the routing is not changed) are possible using two or more time delay estimates to select the paths.

In practice, this approach has worked quite effectively with the moderate levels of traffic experienced in the net. For heavy traffic flow, this strategy may be inefficient, since the routing information is based on the length of queues, which we have seen can change much faster than the information about the change can be distributed. Fortunately, this information is still usable, although it can be substantially out of date and will not, in general, be helpful in making efficient routing decisions in the heavy traffic case.

A more intricate scheme, recently developed by BBN, allows multiple paths to be efficiently used even during heavy traffic.[18] Preliminary simulation studies indicate that it can be tailored to provide efficient routing in a network with a variety of heavy traffic conditions. This method separates the problem of defining routes onto which packets may be routed from the problem of selecting a route when a particular packet must be routed. By this technique, it is possible to send packets down a path with the fewest IMPs and excess capacity, or when that path is filled, the one with the next fewest IMPs and excess capacity, etc.

A similar approach to routing was independently derived by NAC using an idealized method that did not require the IMPs to participate in the routing decisions. Another approach using a flow deviation technique has recently been under study at UCLA.[13] The intricacies of the exact approach lead to a metering procedure that allows the overall network flow to be changed slowly for stability and to perturb existing flow patterns to obtain an increased flow. These approaches all possess, in common, essential ingredients of a desirable routing strategy.

Topological considerations

An efficient topological design provides a high throughput for a given cost. Although many measures of throughput are possible, a convenient one is the average amount of traffic that a single IMP can send into the network when all other IMPs are transmitting according to a specified traffic pattern. Often, it is assumed that all other IMPs are behaving identically and each IMP is sending equal amounts of traffic to each other IMP. The constraints on the topological design are the available common carrier circuits, the target cost or throughput, the desired reliability, and

the cost of computation required to perform the topological design.

Since, there was no clear specification of the amount of traffic that the network would have to accommodate initially, it was first constructed with enough excess capacity to accommodate any reasonable traffic requirements. Then as new IMPs were added to the system, the capacity was and is still being systematically reduced until the traffic level occupies a substantial fraction of the network's total capacity. At this point, the net's capacity will be increased to maintain the desired percentage of loading. At the initial stages of network design, the "two-connected" reliability constraint essentially determined a minimum value of maximum throughput. This constraint forces the average throughput to be in the range 10-15 kilobits per second per IMP, when 50 kilobit/sec circuits are used throughout the network, since two communication paths between every pair of IMPs are needed. Alternatively, if this level of throughput is required, then the reliability specification of "two-connectivity" can be obtained without additional cost.

Reliability computations

A simple and natural characterization of network reliability is the ability of the network to sustain communication between all operable pairs of IMPs. For design purposes, the requirement of two independent paths between nodes insures that at least two IMPs and/or circuits must fail before any pair of operable IMPs cannot communicate. This criterion is independent of the properties of the IMPs and circuits, does not take into account the "degree" of disruption that may occur and hence, does not reflect the actual availability of resources in the network. A more meaningful measure is the average fraction of IMP pairs that cannct communicate because of IMP and circuit failures. This calculation requires knowledge of the IMP and circuit failure rates, and could not be performed until enough operating data was gathered to make valid predictions.

To calculate network reliability, we must consider elementary network structures known as cutsets. A

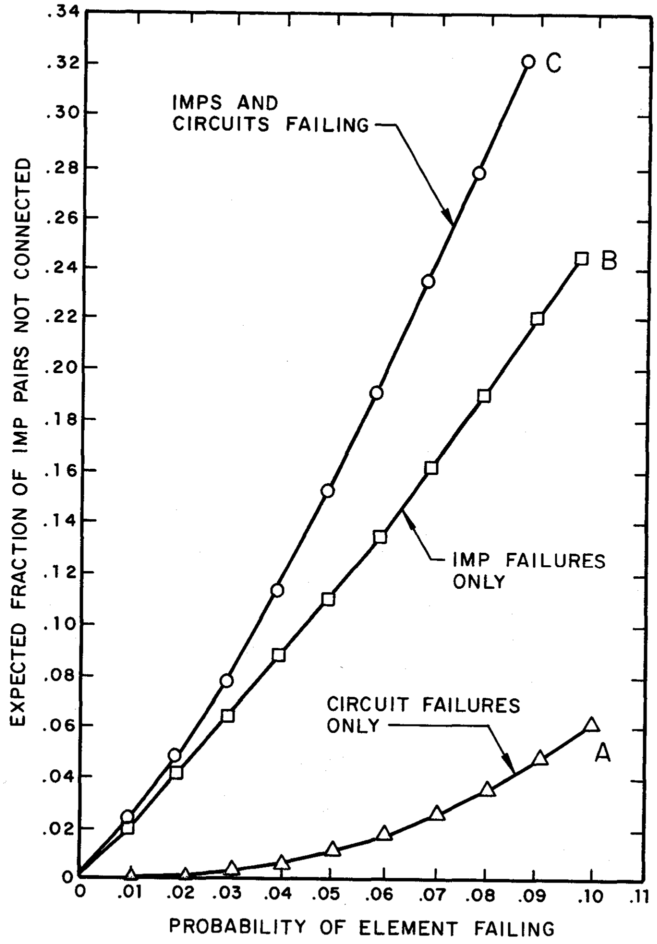

Figure 2—Network availability vs. IMP and circuit reliability

cutset is a set of circuits and/or IMPs whose removal from the network breaks all communication paths between at least two operable IMPs. To calculate reliability, it is often the case that all cutsets must be either enumerated or estimated. As an example, in a 23 IMP, 28 circuit ARPA Network design similar to the one shown in Figure 1(d), there are over twenty million ways of deleting only circuits so that the remaining network has at least one operable pair of IMPs with no intact communication paths. Table 1 indicates the numbers of cutsets in the 23 IMP network as a function of the number of circuits they contain.

A combination of analysis and simulation can be used to compute the average fraction of non-communicating IMP pairs. Detailed descriptions of the analysis methods are given in Reference 44 while their application to the analysis of the ARPANET is discussed in Reference 43. The results of an analysis of the 23 IMP version of the network are shown in Figure 2. The curve marked A shows the results under the assumption that IMPs do not fail, while the curve marked B shows the case where circuits do not fail. The curve marked C assumes that both IMPs and circuits fail with equal probability. In actual operation, the average failure probability of both IMPs and circuits is about 0.02. For this value, it can be seen that the effect of circuit failures is far less significant than the effect of IMP failures. If an IMP fails in a network with n IMPs, at least $n-1$ other IMPs cannot communicate with it. Thus, good network design cannot improve upon the effect directly due to IMP failures, which in the ARPANET is the major factor affecting the reliability of the communications. Further, more intricate reliability analyses which consider the loss of throughput capacity because of circuit failures have also been performed and these losses have been shown to be negligible.[28] Finally, unequal failure rates due to differences in line lengths have been shown to have only minor effects on the analysis and can usually be neglected.[27]

Topological optimization

During the computer optimization process, the reliability of the topology is assumed to be acceptable if the network is at least two-connected. The object of the optimization is to decrease the ratio of cost to throughput subject to an overall cost limitation. This technique employs a sophisticated network optimization program that utilizes circuit exchange heuristics, routing and flow analysis algorithms, to generate low cost designs. In addition, two time delay models were initially used to (1) calculate the throughput corresponding to an average time delay of 0.2 seconds, (2) estimate the packet rejection rate due to all buffers filling at an IMP. As experience with these models grew, the packet rejection rate was found to be negligible and the computation discontinued. The delay computation (Equation (7) in a later section) was subsequently first replaced by a heuristic calculation to speed the computation and later eliminated after it was found that time delays could be guaranteed to be acceptably low by preventing cutsets from being saturated. This "threshold" behavior is discussed further in the next section.

The basic method of optimization was described in Reference 12 while extensions to the design of large networks are discussed in Reference 9. The method operates by initially generating, either manually or by computer, a "starting network" that satisfies the overall network constraints but is not, in general, a low cost network. The computer then iteratively modifies the starting network in simple steps until a lower cost network is found that satisfies the constraints or the process is terminated. The process is repeated until no further improvements can be found. Using a different starting network can result in a different solution. However, by incorporating sensible heuristics and by using a variety of *carefully chosen* starting networks and some degree of man-machine interaction, "excellent" final networks usually result. Experience has shown that there are a wide variety of such networks with different topological structures but similar cost and performance.

The key to this design effort is the heuristic procedure by which the iterative network modifications are made. The method used in the ARPANET design involves the removal and addition of one or two circuits at a time. Many methods have been employed, at various times, to identify the appropriate circuits for potential addition or deletion. For example, to delete uneconomical circuits a straightforward procedure simply deletes single circuits in numerical order, reroutes traffic and reevaluates cost until a decrease in cost per megabit is found. At this point, the deletion is made permanent and the process begins again. A somewhat more sophisticated procedure deletes circuits in order of increasing utilization, while a more complex method attempts to evaluate the effect of the removal of any circuit before any deletion is attempted. The circuit with the greatest likelihood of an improvement is then considered for removal and so on.

There are a huge number of reasonable heuristics for circuit exchanges. After a great deal of experimentation with many of these, it appears that the choice of a particular heuristic is not critical. Instead, the speed and efficiency with which potential exchanges can be investigated appears to be the limiting factor affecting the quality of the final design. Finally, as the size of the network increases, the greater the cost becomes to perform *any* circuit exchange optimization. Decomposition of the network design into regions becomes necessary and additional heuristics are needed to determine effective decompositions. It presently appears that these methods can be used to design relatively efficient networks with a few hundred IMPs while substantially new procedures will be necessary for networks of greater size.

The topological design requires a routing algorithm to evaluate the throughput capability of any given network. Its properties must reflect those of an implementable routing algorithm, for example, within the ARPANET. Although the routing problem can be formulated as a "multicommodity flow problem"[10] and solved by linear programming for networks with 20-30 IMPs,[8] faster techniques are needed when the routing algorithm is incorporated in a design procedure. The design procedure for the ARPA Network topology iteratively analyzes thousands of networks. To satisfy the requirements for speed, an algorithm which selects the least utilized path with the minimum number of IMPs was initially used.[12] This algorithm was later replaced by one which sends as much traffic as possible along such paths until one or more circuits approach a few percent of full utilization.[28] These highly utilized circuits are then no longer allowed to carry additional flow. Instead, new paths with excess capacity and possibly more intermediate nodes are found. The procedure continues until some cutset contains only nearly fully utilized circuits. At this point no additional flow can be sent. For design purposes, this algorithm is a highly satisfactory replacement for the more complicated multi-commodity approach. Using the algorithm, it has been shown that the throughput capabilities of the ARPA Network are substantially insensitive to the distribution of traffic and depend mainly only on the total traffic flow within the network.[8]

Analytic models of network performance

The effort to determine analytic models of system performance has proceeded in two phases: (1) the prediction of average time delay encountered by a message as it passes through the network, and (2) the use of these queueing models to calculate optimum channel capacity assignments for minimum possible delay. The model used as a standard for the average message delay was first described in Reference 21 where it served to predict delays in stochastic communication networks. In Reference 22, it was modified to describe the behavior of ARPA-like computer networks while in Reference 23 it was refined further to apply directly to the ARPANET.

The single server model

Queueing theory[20] provides an effective set of analytical tools for studying packet delay. Much of this theory considers systems in which messages place demands for transmission (service) upon a single communication channel (the single server). These systems are characterized by $A(\tau)$, the distribution of interarrival times between demands and $B(t)$, the distribution of service times. When the average demand for service is less than the capacity of the channel, the system is said to be stable.

When $A(\tau)$ is exponential (i.e., Poisson arrivals), and messages are transmitted on a first-come first-served basis, the average time T in the stable system is

$$T=\frac{\lambda\overline{t^2}}{2(1-\rho)}+\bar{t} \tag{1}$$

where λ is the average arrival rate of messages, $\bar{t}$ and $\overline{t^2}$ are the first and second moments of $B(t)$ respectively, and $\rho=\lambda\bar{t}<1$. If the service time is also exponential,

$$T=\frac{\bar{t}}{1-\rho} \tag{2}$$

When $A(\tau)$ and $B(t)$ are arbitrary distributions, the situation becomes complex and only weak results are available. For example, no expression is available for T; however the following upper bound yields an excellent approximation[19] as $\rho\rightarrow 1$:

$$T\leq\frac{\lambda(\sigma_a{}^2+\sigma_b{}^2)}{2(1-\rho)}+\bar{t} \tag{3}$$

where $\sigma_a{}^2$ and $\sigma_b{}^2$ are the variance of the interarrival time and service time distributions, respectively.

Networks of queues

Multiple channels in a network environment give rise to queueing problems that are far more difficult to solve than single server systems. For example, the variability in the choice of source and destination for a message is a network phenomenon which contributes to delay. A principal analytical difficulty results from the fact that flows throughout the network are correlated. The basic approach to solving these stochastic network problems is to *decompose* them into analyzable single-server problems which reflect the original network structure and traffic flow.

Early studies of queueing networks indicated that such a decomposition was possible;[50,51] however, those results do not carry over to message switched computer networks due to the correlation of traffic flows. In Reference 21 it was shown for a wide variety of communication nets that this correlation could be removed by considering the length of a given packet to be an independent random variable as it passes from node to node. Although this "independence" assumption is not physically realistic, it results in a mathematically tractable model which does not seem to affect the accuracy of the predicted time delays. As the size and connectivity of the network increases, the assumption becomes increasingly more realistic. With this assumption, a successful decomposition which permits a channel-by-channel analysis is possible, as follows.

The packet delay is defined as the time which a packet spends in the network from its entry until it reaches its destination. The average packet delay is denoted as T. Let Z_{jk} be the average delay for those packets whose origin is IMP j and whose destination is IMP k. We assume a Poisson arrival process for such packets with an average of γ_{jk} packets per second and an exponential distribution of packet lengths with an average of $1/\mu$ bits per packet. With these definitions, if γ is the sum of the quantities γ_{jk}, then[21]

$$T=\sum_{j,k}\frac{\gamma_{jk}}{\gamma}Z_{jk} \tag{4}$$

Let us now reformulate Equation (4) in terms of single channel delays. We first define the following quantities for the ith channel: C_i as its capacity (bits/second); λ_i as the average packet traffic it carries (packets/second); and T_i as the average time a packet spends waiting for and using the ith channel. By relating the $\{\lambda_i\}$ to the $\{\gamma_{jk}\}$ via the paths selected by the routing algorithm, it is easy to see that[21]

$$T=\sum_{i}\frac{\lambda_i}{\gamma}T_i \tag{5}$$

With the assumption of Poisson traffic and exponential service times, the quantities T_i are given by Equation (2). For an average packet length of $1/\mu$ bits, $\bar{t}=1/\mu C_i$ seconds and thus

$$T_i=\frac{1}{\mu C_i-\lambda_i} \tag{6}$$

Thus we have successfully decomposed the analysis problem into a set of simple single-channel problems.

A refinement of the decomposition permits a non-exponential packet length distribution and uses Equation (1) rather than Equation (2) to calculate T_i; as an approximation, the Markovian character of the traffic is assumed to be preserved. Furthermore, for computer networks we include the effect of propagation time and overhead traffic to obtain the following equation for average packet delay[22,23]

$$T=K+\sum_{i}\frac{\lambda_i}{\gamma}\left[\frac{1}{\mu' C_i}+\frac{\lambda_i/\mu C_i}{\mu C_i-\lambda_i}+P_i+K\right] \tag{7}$$

Here, $1/\mu'$ represents the average length of a Host packet, and $1/\mu$ represents the average length of all packets (including acknowledgments, headers, requests for next messages, parity checks, etc.) within the network. The expression $1/\mu' C_i+[(\lambda_i/\mu C_i)/(\mu C_i-\lambda_i)]+P_i$ represents the average packet delay on the ith channel. The term $(\lambda_i/\mu C_i)/(\mu C_i-\lambda_i)$ is the average time a packet spends waiting at the IMP for the ith channel to become available. Since the packet must compete with acknowledgments and other overhead traffic, the overall average packet length $1/\mu$ appears in the expression. The term $1/\mu' C_i$ is the time required to transmit a packet of average length μ'. Finally: K is the nodal processing time, assumed constant, and for the ARPA IMP approximately equal to 0.35 ms; P_i is the propagation time on the ith channel (about 20 ms for a 3000 mile channel).

Assuming a relatively homogeneous set of C_i and P_i, no individual term in the expression for delay will dominate the summation until the flow λ_i/μ in one channel (say channel i_o) approaches the capacity C_{i_o}. At that point, the term T_{i_o}, and hence T will grow rapidly. The expression for delay is then dominated by one (or more) terms and exhibits a threshold behavior. Prior to this threshold, T remains relatively constant.

The accuracy of the time delay model, as well as this threshold phenomenon was demonstrated on a 19 node network[14] and on the ten node ARPA net derived from Figure 1(c) by deleting the rightmost five IMPs. Using the routing procedure described in the last section[28] and equal traffic between all node pairs, the channel flows λ_i were found for the ten node net and the delay curves shown in Figure 3 were obtained. Curve A was obtained with fixed 1000 bit packets,* while curve B was generated for exponentially distributed variable length packets with average size of 500 bits. In both cases A and B, all overhead factors were ignored. Note that the delay remains small until a

* In case A, the application of Equation (1) allows for constant packet lengths (i.e., zero variance).

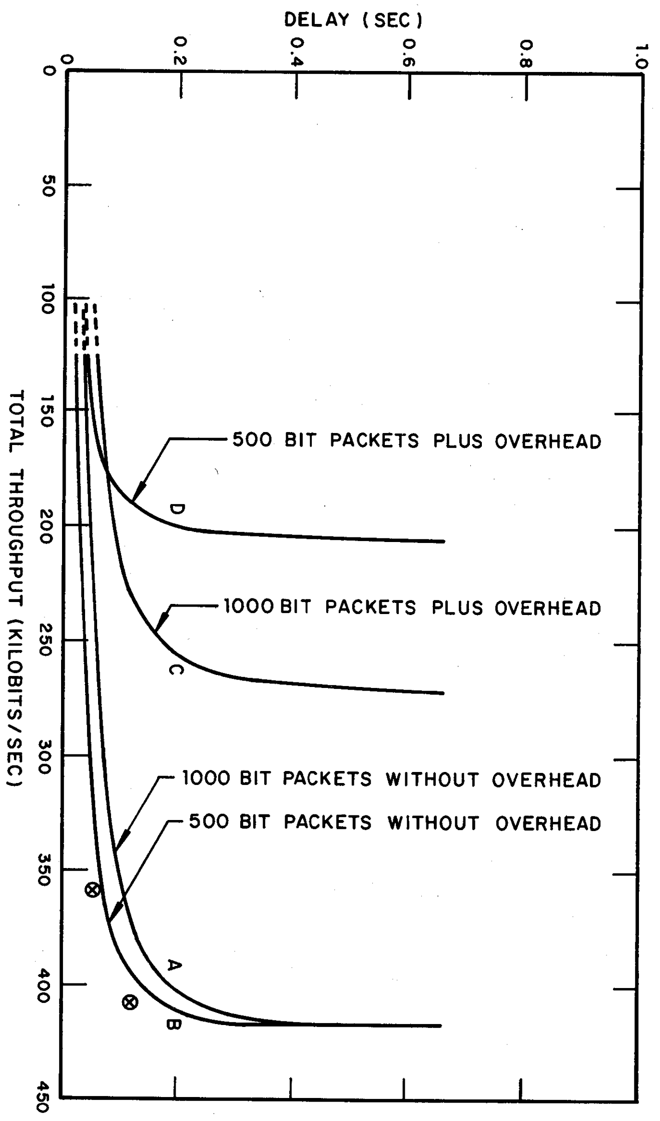

Figure 3—Delay vs. throughput

total throughput slightly greater than 400 kilobits/second is reached. The delay then increases rapidly. Curves *C* and *D* respectively represent the same situations when the overhead of 136 bits per packet and per RFNM and 152 bits per acknowledgment are included. Notice that the total throughput per IMP is reduced to 250 kilobits/second in case *C* and to approximately 200 kilobits/second in case *D*.

In the same figure, we have illustrated with x's the results of a simulation performed with a realistic routing and metering strategy. The simulation omitted all network overhead and assumed fixed lengths of 1000 bits for all packets.

It is difficult to develop a practical routing and flow control procedure that will allow each IMP to input identical amounts of traffic. To compare the delay curve *A* with the points obtained by simulation, the curve should actually be recomputed for the slightly skewed distribution that resulted. It is notable that the delay estimates from the simulation (which used a dynamic routing strategy) and the computation (which used a static routing strategy and the time delay formula) are in close agreement. In particular, they both accurately determined the vertical rise of the delay curve in the range just above 400 kilobits/second, the formula by predicting infinite delay and the simulation by rejecting the further input of traffic.

In practice and from the analytic and simulation studies of the ARPANET, the average queueing delay is observed to remain small (almost that of an unloaded net) and well within the design constraint of 0.2 seconds until the traffic within the network approaches the capacity of a cutset. The delay then increases rapidly. *Thus, as long as traffic is low enough and the routing adaptive enough to avoid the premature saturation of cutsets by guiding traffic along paths with excess capacity, queueing delays are not significant.*

Channel capacity optimization

One of the most difficult design problems is the optimal selection of capacities from a *finite* set of options. Although there are many heuristic approaches to this problem, analytic results are relatively scarce. (For the specialized case of centralized networks, an algorithm yielding optimal results is available.[11]) While it is possible to find an economical assignment of discrete capacities for, say, a 200 IMP network, very little is known about the relation between such capacity assignments, message delay, and cost.

To obtain theoretical properties of optimal capacity assignments, one may ignore the constraint that capacities are obtainable only in discrete sizes. In Reference 21 such a problem was posed where the network topology and average traffic flow were assumed to be known and fixed and an optimal match of capacities to traffic flow was found. Also, the traffic was assumed to be Markovian (Poisson arrivals and exponential packet lengths) and the independence assumption and decomposition method were applied. For each channel, the capacity C_i was found which minimized the average message delay T, at a fixed total system cost D. Since λ_i/μ is the average bit rate on the ith channel, the solution to *any* optimal assignment problem must provide more than this minimal capacity to each channel. This is clear since both Equations (6) and (7) indicate that T_i will become arbitrarily large with less than (or equal to) this amount of capacity. It is not critical exactly how the *excess* capacity is assigned, as long as $C_i > \lambda_i/\mu$. Other important parameters and insights have been identified in studying the continuous capacity optimization problem. For example, the number of excess dollars, D_e, remaining after the minimum capacity λ_i/μ is assigned to each channel is of great importance. As $D_e \rightarrow 0$, the average delay must grow arbitrarily large. In this range, the critical parameters become ρ and $\bar{n}$ where $\rho = \gamma/\mu C$ is the ratio of the rate γ/μ at which bits enter the network to the rate C at which the net can handle bits and $\bar{n} = \lambda/\gamma$, where $\lambda = \sum \lambda_i$ is the total rate at which packets flow within the net. The quantity ρ represents a dimensionless form of network "load" whereas $\bar{n}$ is easily shown to represent the average path length for a packet.

As the load ρ approaches $1/\bar{n}$, the delay T grows very quickly, and this point $\rho = 1/\bar{n}$ represents the maximum load which the network can support. If capacities are assigned optimally, all channels saturate simultaneously at this point. In this formulation $\bar{n}$ is a design parameter which depends upon the topology and the routing procedure, while ρ is a parameter which depends upon the input rate and the total capacity of the network. In studying the ARPANET[23] a closer representation of the actual tariffs for high speed telephone data channels used in that network was provided by setting $D = \sum_i d_i C_i$ where $0 \leq \alpha \leq 1$.* This approach requires the solution of a non-linear equation by numerical techniques. On solving the equation, it can be shown that the packet delay T varies insignificantly with α for $.3 \leq \alpha \leq 1$. This indicates that the closed form solution discussed earlier with $\alpha = 1$ is a reasonable approximation to the more difficult non-linear problem. These continuous capacity studies have application to general network studies (e.g., satellite communications)[33] and are under continued investigation.[25,26,46]

In practice, the selection of channel capacities must be made from a small finite set. Although some theoretical work has been done in this case by approximating the discrete cost-capacity functions by continuous ones, much remains to be done.[13,25] Because of the discrete capacities and the time varying nature of network traffic, it is *not* generally possible to match channel capacities to the anticipated flows within the channels. If this were possible, all channels would saturate at the same externally applied load. Instead, capacities are assigned on the basis of reasonable estimates of average or peak traffic flows. It is the responsibility of the routing procedure to permit the traffic to adapt to the available capacity.[14] Often two IMP sites will engage in heavy communication and thus saturate one or more critical network cutsets. In such cases, the routing will not be able to send additional flow across these cuts. The network will therefore experience "premature" saturation in one or a small set of channels leading to the threshold behavior described earlier.

DISCUSSION

A major conclusion from our experience in network design is that message switched networks of the ARPA type are no longer difficult to specify. They may be implemented straightforwardly from the specifications; they can be less expensive than other currently available technical approaches; they perform remarkably well as a communication system for interconnecting time-sharing and batch processing computers and can be adapted to directly handle teletypes, displays and many other kinds of terminal devices and data processing equipment.[16,30]

The principal tools available for the design of networks are analysis, simulation, heuristic procedures, and experimentation. Analysis, simulation and heuristics have been the mainstays of the work on modeling and topological optimization while simulation, heuristic procedures and experimental techniques have been the major tools for the actual network implementation. Experience has shown that all of these methods are useful while none are all powerful. The most valuable approach has been the simultaneous use of several of these tools.

Each approach has room for considerable improvement. The analysis efforts have not yet yielded results in many important areas such as routing. However, for prediction of delay, this approach leads to a simple threshold model which is both accurate and understandable. Heuristic procedures all suffer from the problem that it is presently unclear how to select appropriate heuristics. It has been the innovative use of computers and analysis that has made the approach work well. For designing networks with no more than a few hundred IMPs, present heuristics appear adequate but a good deal of additional work is required for networks of greater size. Simulation is a well developed tool that is both expensive to apply and limited in the overall understanding that it yields. For these reasons, simulation appears to be most useful only in validating models, and in assisting in detailed design decisions such as the number of buffers that an IMP should contain. As the size of networks continues to grow, it appears that simulation will become virtually useless as a total design tool. The ultimate standard by which all models and

* Of course the tariffs reflect the discrete nature of available channels. The use of the exponent α provides a continuous fit to the discrete cost function. For the ARPANET, $\alpha \cong .8$.

conclusions can be tested is experimentation. Experimentation with the actual network is conceptually relatively straightforward and very useful. Although, experiments are often logistically difficult to perform, they can provide an easy means for testing models, heuristics and design parameters.

The outstanding design problems currently facing the network designer are to specify and determine the properties of the routing, flow control and topological structure for large networks. This specification must make full use of a wide variety of circuit options. Preliminary studies indicate that initially, the most fruitful approaches will be based on the partitioning of the network into regions, or equivalently, constructing a large network by connecting a number of regional networks. To send a message, a Host would specify both the destination region and the destination IMP in that region. No detailed implementation of a large network has yet been specified but early studies of their properties indicate that factors such as cost, throughput, delay and reliability are similar to those of the present ARPANET, if the ARPA technology is used.[9]

Techniques applicable to the design of large networks are presently under intensive study. These techniques appear to split into the same four categories as small network design but approaches may differ significantly. For example, large nets are likely to demand the placement of high bandwidth circuits at certain key locations in the topology to concentrate flow. These circuits will require the development of a high speed IMP to connect them into the net. It is likely that this high speed IMP will have the structure of a high speed multiplexor, and may require several cooperating processors to obtain the needed computer power for the job. Flow control strategies for large networks seem to extrapolate nicely from small network strategies if each region in the large network is viewed as a node in a smaller network. However, this area will require additional study as will the problem of specifying effective adaptive routing mechanisms. Recent efforts indicate that efficient practical schemes for small networks will soon be available. These schemes seem to be applicable for adaptive routing and flow control in networks constructed from regional subnetworks. The development of practical algorithms to handle routing and flow control is still an art rather than a science. Simulation is useful for studying the properties of a given heuristic, but intuition still plays a dominant role in the system design.

Several open questions in network design presently are: (1) what structure should a high bandwidth IMP have; (2) how can full use be made of a variety of high bandwidth circuits; (3) how should large networks be partitioned for both effective design and operation; and (4) what operational procedures should large networks follow? Much work has already been done in these areas but much more remains to be done. We expect substantial progress to be achieved in the next few years, and accordingly, the increased understanding of the properties of message switched networks of all sizes.

ACKNOWLEDGMENT

The ARPA Network is in large part the conception of Dr. L. G. Roberts of the Advanced Research Projects Agency to whom we owe a debt of gratitude for his support and encouragement. We also acknowledge the helpful contributions of S. Crocker and B. Dolan of ARPA. At BBN, NAC, and UCLA many individuals, too numerous to list, participated in the network effort and we gratefully acknowledge their contributions.

INTRODUCTION

Much has been said about the mechanics of the ARPA Computer Network (ARPANET) and especially about the organization of its communications subnet.[1,2,3,4,5] Until recently the main effort has gone into the implementation of an ARPANET user-level communications interface. Operating just above the communications subnet in ARPANET HOST Computers, this ARPANET interface is intended to serve as a foundation for the organization of function-oriented communications.[6,7] See Figures 1 and 2 for our view of a computer system and the scheme for user-level process-to-process communications. It is now appropriate to review the development of protocols which have been constructed to promote particular substantive uses of the ARPANET, namely function-oriented protocols.

We should begin this brief examination by stating what we mean by the word "protocol" and how protocols fit in the plan for useful work on the ARPANET. When we have two processes facing each other across some communication link, the protocol is the set of their agreements on the format and relative timing of messages to be exchanged. When we speak of a protocol, there is usually an important goal to be fulfilled. Although any set of agreements between cooperating (i.e., communicating) processes is a protocol, the protocols of interest are those which are constructed for general application by a large population of processes in solving a large class of problems.

In the understanding and generation of protocols there are two kinds of distinctions made. Protocols in the ARPANET are *layered* and we speak of high or low level protocols. High level protocols are those most closely matched to functions and low level protocols deal with communications mechanics. The lowest level software protocols in the ARPANET involve reliable message exchange between ARPANET Interface Message Processors (IMPs).[2,5] A high level protocol is one with primitives closely related to a substantive use. At the lowest levels the contents of messages are unspecified. At higher levels, more and more is stated about the meaning of message contents and timing. The layers of protocol are shown in Figure 3.

A second way of structuring sets of protocols and their design is bound up in the word *factoring.* At any level of protocol are sets of format and timing rules associated with particular groupings of agreements. In the IMPs we find certain protocols pertaining to error handling, while others to flow control, and still others to message routing. At the ARPANET's user-level communications interface there are, among others, separable protocols associated with establishing connections and logical data blocking. These protocols do not nest, but join as modules at the same level.

Before moving on to consider the higher level function-oriented protocols, let us first make a few statements about underlying protocols. There are three lower level software protocols which nest in support of the user-level communications interface for the ARPANET. The lowest of these is the IMP-IMP protocol which provides for reliable communication among IMPs. This protocol handles transmission-error detection and correction, flow control to avoid message congestion, and routing. At the next higher level is the IMP-HOST protocol which provides for the passage of messages between HOSTs and IMPs in such a way as to create virtual communication paths between HOSTs. With IMP-HOST protocol, a HOST has operating rules which permit it to send messages to specified HOSTs on the ARPANET and to be informed of the dispensation of those messages. In particular, the IMP-HOST protocol constrains HOSTs in their transmissions so that they can make good use of available

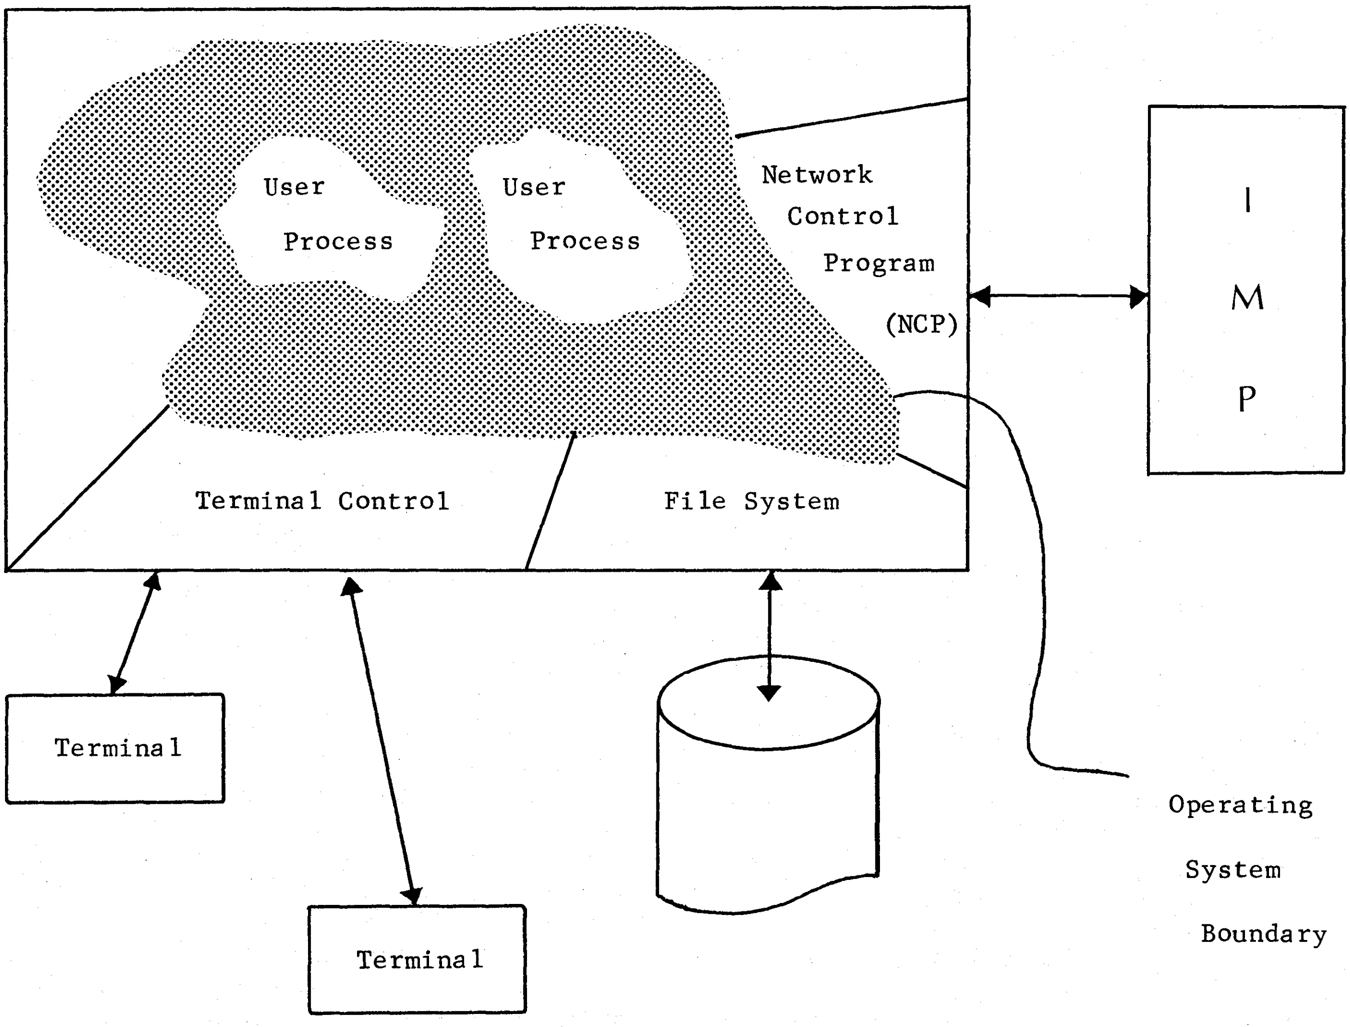

Figure 1—Our view of a computer system

communications capacity without denying such availability to other HOSTs.

The HOST-HOST protocol, finally, is the set of rules whereby HOSTs construct and maintain communication between processes (user jobs) running on remote computers. One process requiring communications with another on some remote computer system makes requests on its local supervisor to act on its behalf in establishing and maintaining those communications under HOST-HOST protocol.

In constructing these low levels of protocol it was the intention to provide user processes with a general set of useful communication primitives to isolate them from many of the details of operating systems and communications. At this user-level interface function-oriented protocols join as an open-ended collection of modules to make use of ARPANET capabilities.

The communications environment facing the designers of function-oriented protocols in the ARPANET is essentially that of a system of one-way byte-oriented connections. Technically speaking, a "connection" is a pair: a "send socket" at one end and a "receive socket" at the other. Primitives provided at the user-level interface include:

1. Initiate connection (local socket, foreign socket),
2. Wait for connection (local socket),
3. Send, Receive (local socket, data),
4. Close (local socket),
5. Send interrupt signal (local socket).

Processes in this virtual process network can create connections and transmit bytes. Connections are subject to HOST-HOST flow control and the vagaries of timing in a widely distributed computing environment, but care has been taken to give user processes control over their communications so as to make full use of network parallelism and redundancy. The kind of agreements which must be made in the creation of

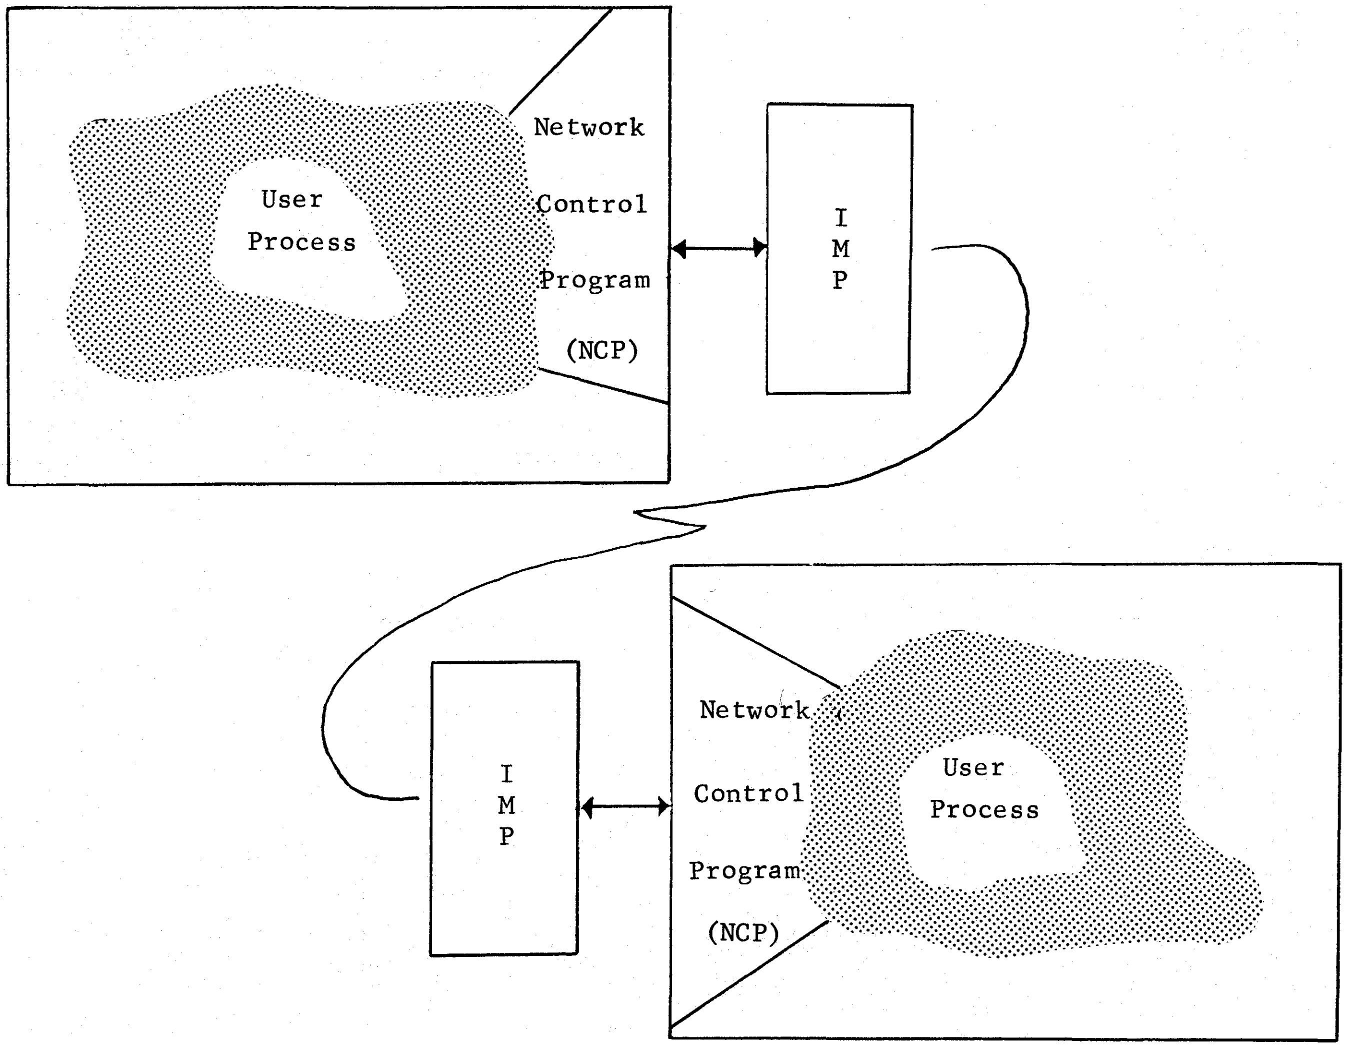

Figure 2—Two communicating processes

function-oriented protocols relate to rules for establishing connections, to the timing rules which govern transmission sequences, and to the content of the byte-streams themselves.

USE OF REMOTE INTERACTIVE SYSTEMS

The application which currently dominates ARPANET activity is the remote use of interactive systems. A Telecommunications Network (TELNET) protocol is followed by processes cooperating to support this application.[8] A user at a terminal, connected to his local HOST, controls a process in a remote HOST as if he were a local user of the remote HOST. His local HOST copies characters between his terminal and TELNET connections over the ARPANET. We refer to the HOST where the user sits as the *using HOST*, and to the remote HOST as the *serving HOST*. See Figure 4.

At the using HOST, the user must be able to perform the following functions through his TELNET user process ("user-TELNET"):

1. Initiate a pair of connections to a serving HOST,
2. Send characters to the serving HOST,
3. Receive characters from the serving HOST,
4. Send a HOST-HOST interrupt signal,
5. Terminate connections.

The user-TELNET needs to be able to distinguish between (1) commands to be acted on locally and (2) input intended for the serving HOST. An escape character is reserved to mark local commands. Conventions for the ARPANET Terminal IMP (TIP) user-TELNET are typical.[9]

In most using HOSTs, the above functions are provided by a user-TELNET which is a *user-level program*. A minimal user-TELNET need only implement the above functions, but several additional support func-

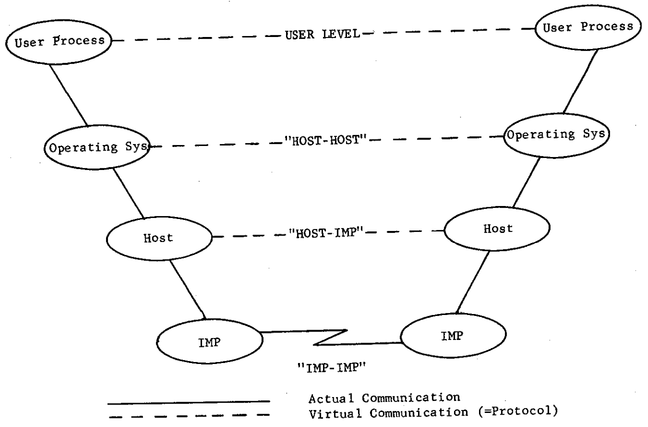

Figure 3—The layers of protocol

tions are often provided (e.g., saving a transcript of a session in a local file, sending a file in place of user-typed input, reporting whether various HOSTs are or have been up).

In the serving HOST it is desirable that a process controlled over the ARPANET behave as it would if controlled locally. The cleanest way to achieve this goal is to generalize the terminal control portion (TCP) of the operating system to accept ARPANET terminal interaction. It is unpleasant to modify any portion of a working computer system and modification could be avoided if it were possible to use a non-supervisor process (e.g., "server-TELNET" or "LOGGER") to perform the job creation, login, terminal input-output, interrupt, and logout functions in exactly the same way

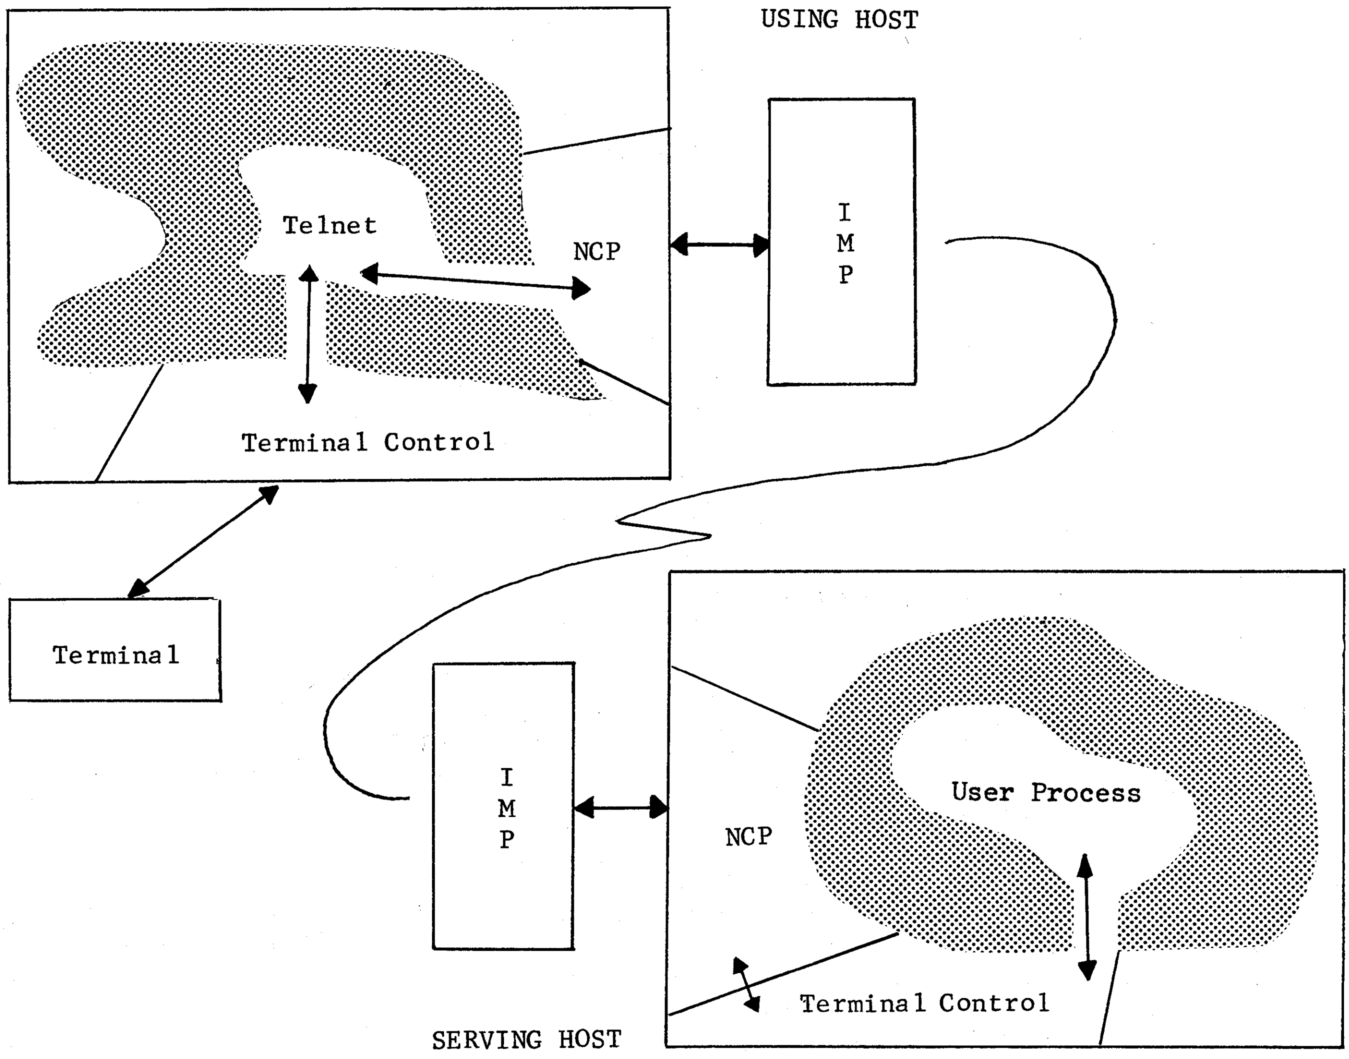

Figure 4—Data flow for remote interactive use

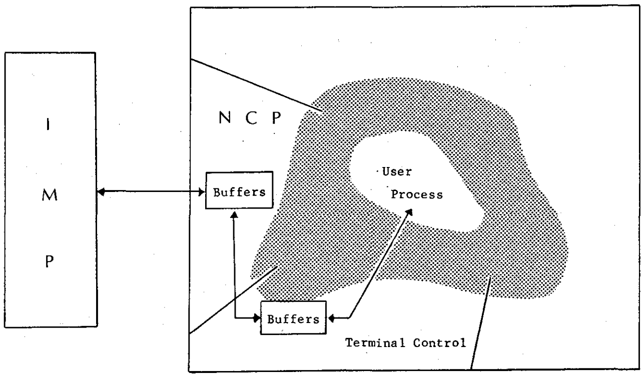

Figure 5—Data flow scheme for server

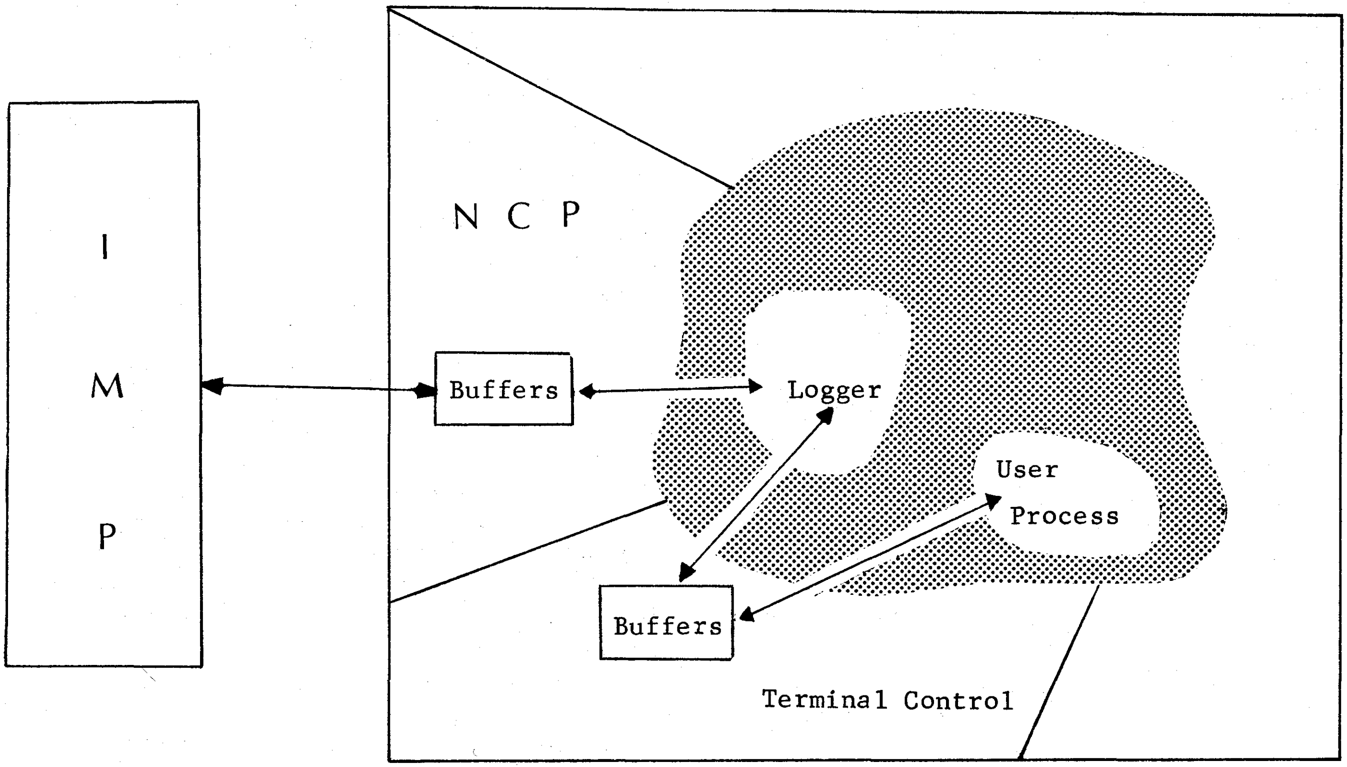
as a direct console user. Prior to the development of the ARPANET, no operating system provided these functions to non-supervisor processes in anywhere near the required completeness. Some systems have since been modified to support this generalized job control scheme. See Figures 5 and 6.

Efforts to standardize communications in the TELNET protocol focused on four issues: character set, echoing, establishing connections, and attention handling.

The chosen character set is 7-bit ASCII in 8-bit fields with the high-order bit off. Codes with the high-order bit on are reserved for TELNET control functions. Two such TELNET control function codes are the "long-space" which stands for the 200 millisecond space generated by the teletype BREAK button, and the synchronization character (SYNCH) discussed below in conjunction with the purpose of the TELNET interrupt signal.

Much controversy existed regarding echoing. The basic problem is that some systems expect to echo, while some terminals always echo locally. A set of conventions and signals was developed to control which side of a TELNET connection should echo. In practice, those systems which echo have been modified to include provision for locally echoing terminals. This is a nontrivial change affecting many parts of a serving HOST. For example, normally echoing server HOSTs do not echo passwords so as to help maintain their security. Terminals which echo locally defeat this strategy, how-



LOGGER must be a background service program capable of initiating jobs

Figure 6—Alternate data flow scheme for a server

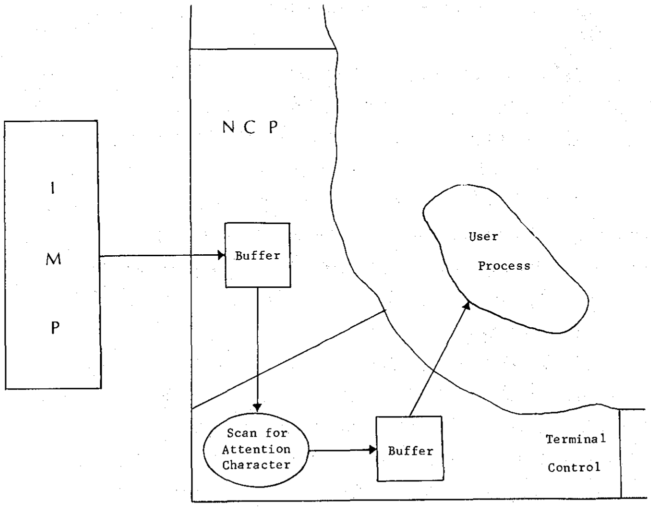


Figure 7—Data flow and processing of the character input stream

ever, and some other protection scheme is necessary. Covering the password with noise characters is the usual solution.

The HOST-HOST protocol provides a large number of sockets for each HOST, but carefully refrains from specifying which ones are to be used for what. To establish communication between a user-TELNET and a server-TELNET some convention is required. The Initial Connection Protocol (ICP)[10] is used:

1. Connection is initiated from a user-TELNET's receive socket to a serving HOST's socket 1 (a send socket).
2. When the initial connection is established, the serving HOST sends a generated socket number and closes the connection. This socket number identifies an adjacent socket pair at the serving HOST through which the user-TELNET can communicate with a server-TELNET.
3. TELNET connections are then initiated between the now specified pairs of sockets. Two connections are used to provide bi-directional communication.

Note that socket 1 at the serving HOST is in use only long enough to send another socket number with which to make the actual service connections.

One of the functions performed by a terminal control program within an operating system is the scanning of an input stream for attention characters intended to stop an errant process and to return control to the executive. Terminal control programs which buffer input sometimes run out of space. When this happens to a local terminal's input stream, a "bell" or a question mark is echoed and the overflow character discarded, *after checking to see if it is the attention character.* See Figure 7. This strategy works well in practice, but it depends rather strongly on the intelligence of the human user, the invariant time delay in the input transmission system, and a lack of buffering between type-in and attention checking. None of these conditions exists for interactive traffic over the net: The serving HOST cannot control the speed (except to slow it down) or the buffering within the using HOST, nor can it even know whether a human user is supplying the input. It is thus necessary that the terminal control program or server-TELNET not, in general, discard characters from a network input stream; instead it must suspend its acceptance of characters via the HOST-HOST flow control mechanism. Since a HOST may only send messages when there is room at the destination, the responsibility for dealing with too much input is thus transferred back to the using HOST. This scheme assures that no characters accepted by the using HOST are inadvertently lost. However, if the process in the serving HOST stops accepting input, the pipeline of buffers between the user-TELNET and remote process will fill up so that attention characters cannot get through to the serving executive. In the TELNET protocol, the solution to this problem calls for the user-TELNET to send, on request, a HOST-HOST interrupt signal forcing the server-TELNET to switch input modes to process network input for attention characters. The server-TELNET is required to scan for attention characters in its network input, even if some input must be discarded while doing so. The effect of the interrupt signal to a server-TELNET from its user is to cause the buffers between them to be emptied for the priority processing of attention characters.

To flip an attention scanning server-TELNET back into its normal mode, a special TELNET synchronization character (SYNCH) is defined. When the server-TELNET encounters this character, it returns to the strategy of accepting terminal input only as buffer space permits. There is a possible race condition if the SYNCH character arrives before the HOST-HOST interrupt signal, but the race is handled by keeping a count of SYNCHs without matching signals. Note that attention characters are HOST specific and may be any of 129 characters—128 ASCII plus "long space"—while SYNCH is a TELNET control character recognized by all server-TELNETs. It would not do to use the HOST-HOST signal alone in place of the signal-SYNCH combination in attention processing, because the position of the SYNCH character in the TELNET input stream is required to determine where attention processing ends and where normal mode input processing begins.

FILE TRANSFER

When viewing the ARPANET as a distributed computer operating system, one initial question is that of how to construct a distributed file system. Although it is constructive to entertain speculation on how the ultimate, automated distributed file system might look, one important first step is to provide for the simplest kinds of explicit file transfer to support early substantive use.

During and immediately after the construction of the ARPANET user-level process interface, several *ad hoc* file transfer mechanisms developed to provide support for initial use. These mechanisms took two forms: (1) use of the TELNET data paths for text file transfer and (2) use of raw byte-stream communication between compatible systems.

By adding two simple features to the user-TELNET, text file transfer became an immediate reality. By adding a "SCRIPT" feature to user-TELNETS whereby all text typed on the user's console can be directed to a file on the user's local file system, a user need only request of a remote HOST that a particular text file be typed on his console to get that file transferred to his local file system. By adding a "SEND-FILE" feature to a user-TELNET whereby the contents of a text file can be substituted for console type-in, a user need only start a remote system's editor as if to enter new text and then send his local file as type-in to get it transferred to the remote file system. Though crude, both of these mechanisms have been used with much success in getting real work done.

Between two identical systems it has been a simple matter to produce programs at two ends of a connection to copy raw bits from one file system to another. This mechanism has also served well in the absence of a more general and powerful file transfer system.

Ways in which these early *ad hoc* file transfer mechanisms are deficient are that (1) they require explicit and often elaborate user intervention and (2) they depend a great deal on the compatibility of the file systems involved. There is an on-going effort to construct a File Transfer Protocol (FTP)[11,12] worthy of wide implementation which will make it possible to exchange structured sequential files among widely differing file systems with a minimum (if any) explicit user intervention. In short, the file transfer protocol being developed provides for the connection of a file transfer user process ("user-FTP") and file transfer server process ("server-FTP") according to the Initial Connection Protocol discussed above. See Figure 8. A user will be able to request that specific file manipulation operations be performed on his behalf. The File Transfer Protocol will support file operations including (1) list remote directory, (2) send local file, (3) retrieve remote file, (4) rename remote file, and (5) delete remote file.

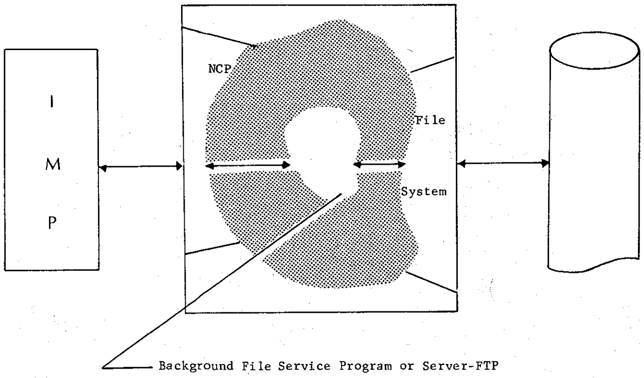

Figure 8—Data flow for file transfer

It is the intention of the protocol designers to regularize the protocol so that file transfer commands can be exchanged by consoles file transfer jobs engaged in such exotic activities as automatic back-up and dynamic file migration. The transfers envisioned will be accompanied with a Data Transfer Protocol (DTP)[11] rich enough to preserve sequential file structure and in a general enough way to permit data to flow between different file systems.

USING THE ARPANET FOR REMOTE JOB ENTRY

A very important use of the ARPANET is to give a wide community of users access to specialized facilities. One type of facility of interest is that of a very powerful number-cruncher. Users in the distributed ARPANET community need to have access to powerful machines for compute-intensive applications and the mode of operation most suited to these uses has been batch Remote Job Entry (RJE). Typically, a user will generate a "deck" for submission to a batch system. See Figure 9. He expects to wait for a period on the order of tens of minutes or hours for that "deck" to be processed, and then to receive the usually voluminous output thereby generated. See Figure 10.

As in the case of file transfer, there are a few useful *ad hoc* ARPANET RJE protocols. A standard RJE protocol is being developed to provide for job submission to a number of facilities in the ARPANET. This protocol is being constructed using the TELNET and File Transfer protocols. A scenario which sketches how the protocol provides the RJE in the simplest, most explicit way is as follows:

Via an ARPANET RJE process, a user connects his

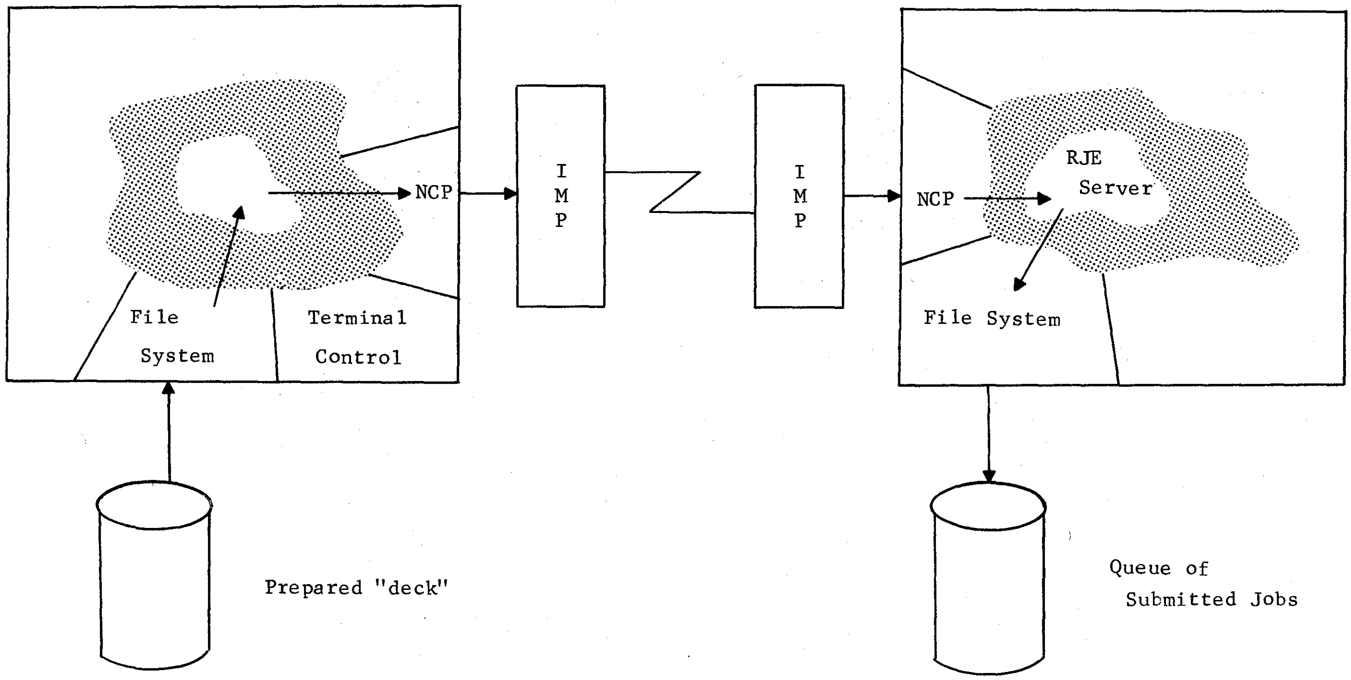

Figure 9—Submission of RJE input

terminal to an RJE server process at the HOST to which he intends to submit his job "deck." Through a short dialogue, he establishes the source of his input and initiates its transfer using the File Transfer Protocol. At some later time, the user reconnects to the appropriate RJE server and makes an inquiry on the

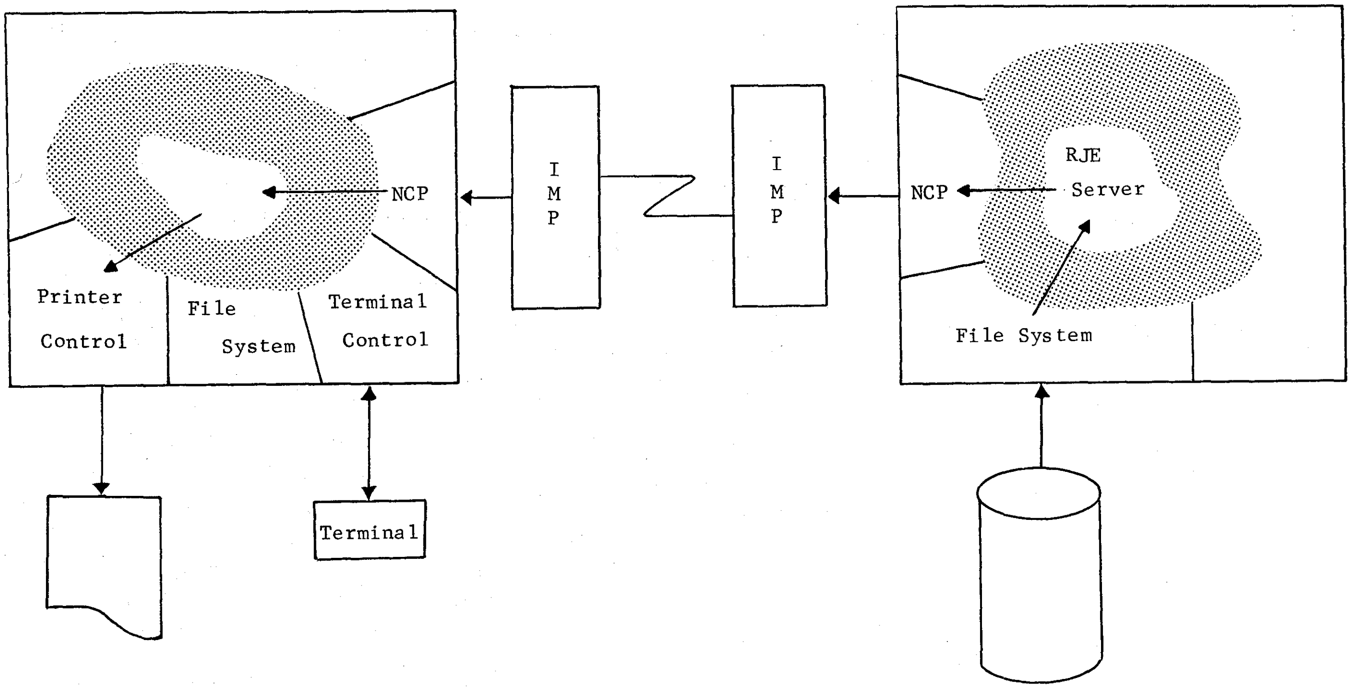

Figure 10—Retrieval of RJE output

status of his job. When notified that his input has been processed, he then issues commands to the serving HOST to transfer his output back.

We can of course imagine more automatic ways of achieving these same functions. A user might need only type a job submission command to his local system. Automatically and invisibly, then, the local system would connect and converse with the specified RJE server causing the desired output to later appear in the users file area or perhaps on a local line printer. The intention is to design the RJE protocol so that the explicit use can start immediately and the more automatic RJE systems can be built as desired.

OTHER PROTOCOLS AND CONCLUSIONS

One of the more difficult problems in utilizing a network of diverse computers and operating systems is that of dealing with incompatible data streams. Computers and their language processors have many ways of representing data. To make use of different computers it is necessary to (1) produce a mediation scheme for each incompatibility or (2) produce a standard representation. There are many strong arguments for a standard representation, but it has been hypothesized that if there were a simple way of expressing a limited set of transformations on data streams, that a large number of incompatibilities could be resolved and a great deal of computer-computer cooperation expedited.

The bulk of protocol work is being done with the invention of standard representations. The TELNET protocol, as discussed, is founded on the notion of a standard terminal called the Network Virtual Terminal (NVT). The File Transfer Protocol is working toward a standard sequential file (a Network Virtual File?). So it is also with less advanced protocol work in graphics and data management.

There is one experiment which is taking the transformational approach to dealing with incompatibilities. The Data Reconfiguration Service (DRS) is to be generally available for mediating between incompatible stream configurations as directed by user-supplied transformations.[13]

ACKNOWLEDGMENTS

Function-oriented protocols have been the principal concern of the ARPANET Network Working Group (NWG). A list of people who have contributed to the development of the protocols discussed would include, Robert Braden, Howard Brodie, Abhay Bhushan, Steve Carr, Vint Cerf, Will Crowther, Eric Harslem, Peggy Karp, Charles Kline, Douglas McKay, Alex McKenzie, John Melvin, Ed Meyer, Jim Michener, Tom O'Sullivan, Mike Padlipsky, Arie Shoshani, Bob Sundberg, Al Vezza, Dave Walden, Jim White, and Steve Wolfe. We would like to acknowledge the contribution of these researchers and others in the ARPA Network Working Group, without assigning any responsibility for the content of this paper.

McROSS—A multi-computer programming system*

by ROBERT H. THOMAS and D. AUSTIN HENDERSON

Bolt, Beranek and Newman, Inc.
Cambridge, Massachusetts

INTRODUCTION

This paper describes an experimental "distributed" programming system which makes it possible to create multi-computer programs and to run them on computers connected by the ARPA computer network (ARPANET).[1] The programming system, which is called McROSS (for **M**ulti-**C**omputer **R**oute **O**riented **S**imulation **S**ystem), is an extension of a single-computer simulation system for modelling air traffic situations[2] developed by Bolt, Beranek and Newman, Inc. (BBN) as a tool for air traffic control research. The McROSS system provides two basic capabilities. One is the ability to program air traffic simulations composed of a number of "parts" which run in geographically separated computers, the distributed parts forming the nodes of a "simulator network." The second is the ability of such a simulator network to permit programs running at arbitrary sites in the ARPANET to "attach" to particular nodes in it for the purpose of remotely monitoring or controlling the node's operation.

The McROSS distributed programming system is unique in several ways:

(a) Use of McROSS generates inter-computer traffic in which a group of programs are engaged in substantive conversation. There is relatively little previous experience with such inter-computer, program-to-program conversations.

(b) The component nodes of a simulator network are not bound to particular ARPANET sites until simulation "run time." Thus on different runs the same distributed program can be distributed in different ways over the ARPANET. For example, in one run all the nodes of a simulator network might be run at BBN and on the next some might be run at BBN, others at RAND and still others at the University of Utah. This mode of using the ARPANET is significantly different from the normal one in which programs are bound to particular network sites at program composition time. (The only constraint on the binding of nodes to ARPANET sites is the requirement that each node run on a PDP-10 under the TENEX operating system.[5])

(c) The responsibilities of a node in a simulator network can be conveniently partitioned into subtasks which can be performed more or less independently of one another. The McROSS implementation mirrors this partitioning. Functions performed at the nodes are realized by groups of loosely connected, concurrently evolving processes.

The distributed simulation system represents an initial step in an on-going research program which is investigating techniques to make it easy to create, run and debug computations involving the coordinated behavior of many computers. The McROSS system is intended to serve both as an experimental vehicle for studying problems related to distributed computation and as a tool for air traffic control research. Its two goals are well matched. A satisfactory solution to the nation's air traffic problems is likely to include a network of airborne and ground based computers working together on a single distributed computation: the scheduling and control of aircraft maneuvers. Thus, the air traffic control problem is a rich source of interesting problems in partitioned computation which can be used to measure the usefulness of the distributed computational techniques developed.

This paper is a report on one phase of a continuing research program. The intent is to describe interesting aspects of an experimental distributed programming

* This work was supported by the Advanced Projects Research Agency of the Department of Defense under Contract No. DAHC-71-C-0088.

system and to share our experience with others considering the construction of such systems. The paper does no more than hint at how the McROSS system can be used in air traffic control research.

The next section provides background useful for subsequent discussion of the distributed programming system. After than, the McROSS system is described, first in terms of the facilities it provides for creating distributed simulations, and then in terms of interesting aspects of its implementation. The paper closes with a discussion of some of the issues brought into focus by the experience of implementing and using a distributed programming system.

COMPONENTS OF THE McROSS SYSTEM

The main components of the distributed programming system are:

1. The ARPA computer network;
2. The TENEX operating system for the PDP-10; and
3. A simulation programming system known as ROSS (for **R**oute **O**riented **S**imulation **S**ystem).

These components became operational within 6-10 months of one another, at which time it became feasible to implement the distributed programming system being described.

The ARPANET

The ARPA computer network[1,3,4] is a set of autonomous computer systems (*hosts*) which are interconnected to permit resource sharing between any pair of them. The goal of the ARPANET is for each host to make its resources accessible from other hosts in the net thereby permitting persons or programs residing at one network site to use data and programs that reside and run at any other. Each host interfaces with the network through an Interface Message Processor (*IMP*),[3] a small dedicated general-purpose computer. The IMPs, which reside at the various ARPANET sites, are connected by 50 kilobit common carrier lines and are programmed to implement a store and forward communication network. In passing from host A to host B a message passes from host A to IMP A, through the IMP communication network from IMP A to IMP B (in general passing through a number of intermediate IMPS) and finally from IMP B to host B.

At each host there is a Network Control Program (*NCP*) whose function is to provide an interface between the network and processes within the host. The NCPs use the IMP store and forward network to provide processes with a connection switching network. Thus, they enable processes in different hosts to establish connections with one another and to exchange information without directly concerning themselves with details of network implementation such as the way in which hosts are connected to and communicate with IMPs.

Information can flow in only one direction on an ARPANET *connection*. Thus, before two processes are able to engage in a dialogue they must establish two such connections between them. A connection is completely specified by its two ends which are called *sockets*. A network socket is itself uniquely specified by a host identifier and a socket identifier. The purpose of the socket identifier is to specify a process or group of processes within a host and a socket relative to that process or process group. Thus, it is useful to think of a socket as having a three component "socket name" of the form H.P.N. H is the "host" component which identifies an ARPANET host, P is the "process" component which identifies a process group within H and N is the "process-local" component which identifies a socket relative to P. In the sequel

$$H_1.P_1.N_1 \rightarrow H_2.P_2.N_2$$

is used to denote a connection between sockets $H_1.P_1.N_1$ and $H_2.P_2.N_2$ where → indicates the direction of information flow over the connection.

For a connection to be established between two processes each must request that it be established. There are two common ways in which connections are established. In the first, the processes play symmetric roles. Each specifies, as part of a "request for connection" (*RFC*), the socket name at its end of the connection, the socket name at the remote end of the connection and the direction of information flow. If the two RFCs "match" the connection is established. This connection procedure requires *a priori* agreement upon the sockets to be used for the connection. The second common connection procedure is used in situations in which one process wishes to provide some sort of service to other processes. The "serving" process establishes a *listening* socket within its host which is receptive to RFCs from any other process in the network and then "listens" for connection attempts. The serving process uses facilities provided by its NCP to detect the occurrence of a connection attempt and to determine its source. When such an attempt is made the serving process can choose to accept or reject it. This connection procedure requires that only one socket name, that of the serving process's listening socket, be known *a priori*. In the remainder of this paper

$$[\mathrm{H.P.N}\rightarrow]_{\mathrm{L}}$$

and

$$[\mathrm{H.P.N}\leftarrow]_{\mathrm{L}}$$

are used to denote connections established in a listening state.

The TENEX operating system

TENEX[5] is a time sharing system for the DEC PDP-10 processor augmented with paging hardware developed at BBN. For purposes of this paper it is useful to describe TENEX in terms of the virtual processor it implements for each logged-in user (i.e., user time sharing job).

The instruction repetoire of the TENEX virtual processor includes the PDP-10 instruction set with the exception of the direct I/O instructions. In addition, it includes instructions which provide access to virtual processor capabilities implemented by the combination of the TENEX software and hardware.

The TENEX virtual processor permits a user job to create a tree-structured hierarchy of processes. Such processes have independent memory spaces and computational power. At different stages in its lifetime a single user job may include different numbers of processes in various states of activity. Several mechanisms for interprocess communication are provided by the TENEX virtual machine. Processes can interact by sharing memory, by interrupts and by direct process control (e.g., one process stops, modifies and restarts another which is "inferior" to it in the hierarchy).

A memory space is provided by the virtual processor which is independent of the system configuration of core memory. Each process has a memory space of 256K words which is divided into 512 pages each of 512 words. A process can specify read, write and execute protection for pages in its memory space as it sees fit.

The virtual machine includes a file system which provides a mechanism for storing information on and retrieving it from external devices attached to TENEX. Processes refer to files using symbolic names, part of which identifies the particular device on which the file resides. The instruction set of the virtual machine includes operations for data transfer to and from files which a process can execute without explicitly arranging for buffering.

The NCP resident in TENEX makes the ARPANET appear to TENEX processes as an I/O device. The name of a "file" corresponding to a network connection includes the names of both the local socket and the remote socket which define the connection. A process requests TENEX to establish a connection by attempting to open an appropriately named "network" file. The open attempt succeeds and the connection is established if and when another process issues a matching RFC. TENEX processes transmit and receive information over network connections by executing the normal file data transfer instructions.

ROSS

ROSS is a programming system for modelling air traffic situations.[2] It includes facilities for creating and running simulation experiments involving air traffic in an experimenter-defined airspace. The system is currently being used in a number of air traffic control research projects.

To create a simulation experiment the experimenter uses ROSS language forms to write a "program" which defines the geography of an airspace, the wind profile for the airspace, aircraft flight characteristics and a set of "route procedures." A *route procedure* consists of a sequence of one or more "instructions" for monitoring or controlling the progress of an aircraft through the simulated airspace. Execution of a route procedure is the ROSS counterpart of pilot and/or controller actions. The "flight" of a simulated aircraft through the airspace is accomplished by the execution of a series of route procedures. ROSS includes "primitive" route procedures to "create" aircraft, "inject" them into and remove them from the simulated airspace as well as ones which cause aircraft to accelerate, turn, climb and descend.

By compiling his program the experimenter creates a simulator for traffic in the airspace he has defined. To perform a simulation experiment the experimenter runs his program. The simulated airspace remains empty until the program is supplied with input which inject aircraft into the airspace and control their flight through it. Each input line the simulator receives is passed to an internal parsing mechanism which issues a call to an appropriate experimenter-defined or primitive route procedure. The program can accept input from an on-line terminal, a predefined "scenario" file, or both. Input lines from the scenario file are identical to ones from the on-line keyboard with the exception that scenario file input lines include a time field which specifies the (simulated) time at which the program is to accept them. A user can manually "vector" aircraft through the airspace by supplying input at the on-line keyboard.

A ROSS simulator can drive displays of the airspace and, in addition, can generate output which can be written into files, typed on the on-line keyboard or sent back into the simulator input parser.

THE McROSS PROGRAMMING SYSTEM

The McROSS system provides the ability to define simulation experiments involving a number of airspaces or "simulation centers" which can be interconnected to form a simulator network. Adjacent centers in the simulator network are connected to one another by way of the ARPANET. The components of a simulator network may run as user jobs distributed among different TENEXs or as different user jobs on the same TENEX. (As of January 1972 the ARPANET included five TENEX hosts.)

Computational responsibility for performing a multicomputer McROSS simulation is truly distributed. For example, as an aircraft flies from one airspace into an adjacent one the responsibility for simulating its dynamics shifts from one computer to another.

Goals

The McROSS system was implemented to achieve the following goals:

1. Autonomy of parts:
   Individual components of a McROSS network should be able to operate independently of one another (to the extent that each is independent of the others for traffic). Furthermore, no center should be able to cause another to malfunction. Autonomy of parts enables a multi-computer simulation to run when only some of its components are operational. Failure of a component center in a multi-center simulation results in degradation of the total simulation rather than forced termination of it. A beneficial side effect of autonomy is that individual centers can be partially debugged without running the entire simulator network.
2. Deferral of process/processor binding:
   The binding of centers in a McROSS network to host computers in the ARPANET should be deferred until run time. This goal can be stated in more general terms. The program for a distributed computation defines a logical configuration made up of abstract relations between the computation's parts. A given execution of the program is accomplished by a particular physical configuration of computers. The two configurations, logical and physical, are by necessity related. However, the programmer should have the option of specifying them separately. By deferring process/processor binding the configurations can be separately specified. As a result the programmer is free while composing his program to concentrate on the logical structure he wants his program to define without concerning himself with details of the physical structure on which it is to be run.
3. Capability for dynamic reconfiguration:
   In the course of a simulation it should be possible for adjacent centers to dynamically break and reestablish connections with one another. Furthermore, it should be possible for process/processor binding to be changed during a simulation. That is, it should be possible to change the physical location of a center from one ARPANET host to another. The ability to dynamically reconfigure makes it possible to remove an improperly operating center from the simulator network and replace it with another at the same ARPANET host or at a different one.
4. Decentralization of control:
   McROSS is to be used as a tool for investigating distributed computation. Among the subjects to be studied are methods for controlling such computations. In particular, various techniques for distributing control responsibilities among the parts of a computation are to be experimentally investigated. It is important, therefore, that operation of the McROSS system not require a central control mechanism for coordinating simulator networks. Stated somewhat differently, the only components required for a McROSS simulation should be simulation centers defined by McROSS programs. The realization of this goal, which makes experimentation with distributed control possible, should not preclude experimentation with centralized control.
5. Remote monitoring capability:
   A McROSS simulator network should provide ports through which its components are accessible to any ARPANET host. An appropriately programmed process running at any ARPANET host should be able to "attach" to a component of a simulator network to monitor and control its operation. A remote monitoring process should be able to:

   a. obtain sufficient information to display traffic in the airspace it is monitoring.
   b. serve as the on-line keyboard for the center it is monitoring;

c. "detach" from one center and "attach" to another in the course of a simulation run.

McROSS as seen by the user

A McROSS simulator network is defined by a program composed of a "network geometry" sub-program and sub-programs corresponding to each of the centers in the network.

The network geometry sub-program defines the logical geometry for a simulator network. Conceptually, a network is composed of nodes and arcs. Nodes in a McROSS network are simulation centers and arcs are duplex connections between centers. Figure 1 shows a four node simulator network which could be used to simulate air traffic between Boston and New York. The following geometry sub-program defines that network:

```
netbegin
    netcen BOSTRM, BOSCEN, NYCEN,
           NYTRM
    netcon BOSTRM, BOSCEN
    netcon BOSCEN, NYCEN
    netcon NYCEN, NYTRM
netend
```

The *netcen* statement declares that the network contains four nodes (Boston terminal control, Boston en route control, New York en route control and New York terminal control). The *netcon* statements declare the three arcs; *netbegin* and *netend* serve to bracket the geometry declarations.

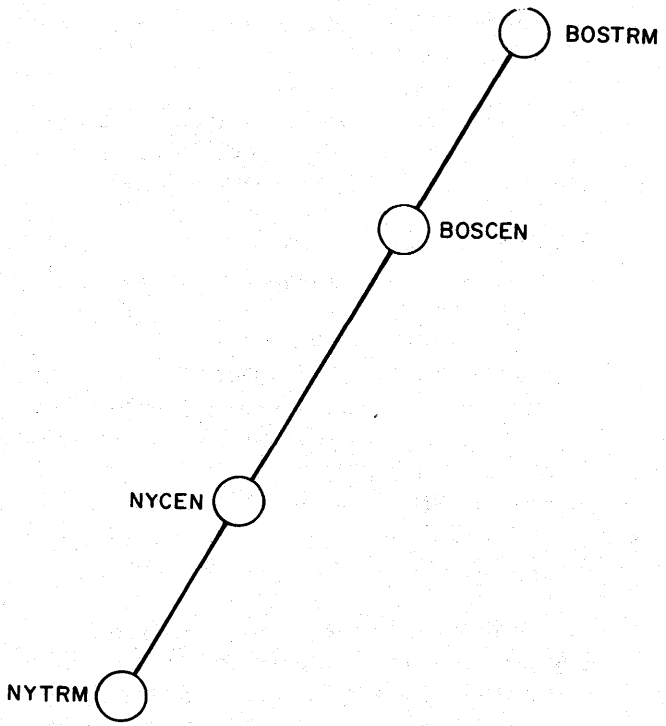

Figure 1—A simulator network which could be used to simulate air traffic between Boston and New York

In general, the sub-program for each center has four parts:

- a route procedure module
- a local geography module
- a wind profile module
- an aircraft characteristics module.

In addition to defining procedures followed by aircraft as they fly through a center's airspace, the route procedure module includes routines specifying how the center interacts with its neighbors. Information exchange between adjacent centers is accomplished by sending messages across the connection between them. A center handles messages from neighboring centers by submitting them to its input parsing mechanism. Such messages are treated identically to input from its on-line console and scenario file.

The ability of adjacent centers to interact depends upon the state of the connection between them as each sees it from its end of the connection. A center may consider a connection to be in one of three states:

1. uninitialized:
   the "physical location" of the neighbor is unknown;
2. closed:
   the "physical location" of the neighbor is known but the connection is not capable of carrying messages (either because it has not yet been established or because it has been broken);
3. open:
   the connection may be used for information exchange with the neighbor.

In the current implementation of McROSS the "physical location" of a neighbor includes both the ARPANET host the center is running on (e.g., BBN) and the identification of the user it is running under (e.g., Jones).

McROSS provides the operations *init*, *conn*, *dsconn* and *abort* for changing the state of a connection. The effect these operations have on the end of a connection is illustrated by the state transition diagram of Figure 2.

Consider the geometry for the Boston-New York simulation. Execution of

conn BOSTRM

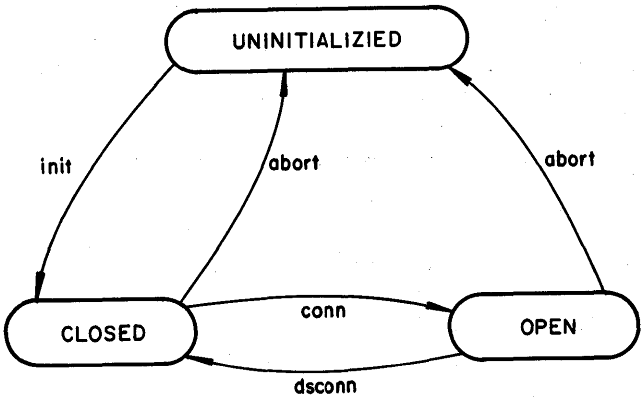

Figure 2—Transition diagram for the state of the end of a connection showing the effect of the operations *init, conn, dsconn* and *abort*

within the BOSCEN initiates an attempt to open a connection with BOSTRM. The connection attempt succeeds if a matching *conn* is executed by the BOSTRM center. The effect of executing

dsconn NYCEN

within the BOSCEN center simulator is to break the connection between the NYCEN and BOSCEN centers by forcing both ends of it into the closed state; *abort* works in an analogous manner. Execution of the *init* operation results in a center-user dialogue in which the human user is asked by the center program to specify the physical location of the neighbor.

Two language primitives are provided for sending messages from one center to another. One takes a single operand, a message, which it sends to every neighbor whose connection is in the open state. The other takes two operands, a message and the name of a neighboring center. If the connection to the center is open, the message is sent to the center; otherwise the operation has no effect. Because they are submitted to the input parsing mechanism care must be taken that messages sent to a neighbor are formatted correctly.

McROSS includes operations which can be used by a center to obtain information about the simulator network and its immediate neighbors. For example, there is a primitive which produces a list of all nodes in the network (i.e., all centers declared by the *netcen* declaration); another one produces a list of all neighboring centers for which connections are in the open state. In addition, a center can examine the state of the connection to each of its neighbors individually.

The local geography module defines the airspace of a center by specifying names and locations (x-y coordinates) of important geographic features such as navigational aids, obstructions and airports. In addition it includes a declarative statement which names the simulation center. For example, the geography module for the BOSTRM center would include the declaration

atccen BOSTRM.

This declaration has the effect of binding the identifier THISIS to the name BOSTRM. Thus in the BOSTRM center THISIS is bound to BOSTRM while in the NYTRM center it is bound to NYTRM. Route procedures which access the simulator center name can be written in terms of THISIS to enable their use at any center in a simulator network.

A properly authorized process at any ARPANET host can attach to a center in a McROSS simulator network and request output from it and direct input to it thereby monitoring and controlling its operation. McROSS center programs are prepared to offer two kinds of service to remote monitors:

1. broadcast service:
   Centers continuously broadcast certain information to monitors attached to them. Presently centers broadcast flight parameters of each aircraft in their air space (speed, heading, altitude, x-position, y-position, acceleration, aircraft id) and the (simulated) time. A remote monitor can use broadcast information to drive a display of traffic in a center's airspace or it can record it for later analysis.
2. demand service:
   Each center is prepared to respond to certain specific requests from monitors. In the current implementation a monitor can request that a center:
   a. transmit its map of the airspace (which can be used as background for displaying the center's air traffic);
   b. stop the continuous broadcast;
   c. resume the continuous broadcast;
   d. treat the monitor as its on-line keyboard by directing keyboard output to the monitor and accepting input from it;
   e. cease treating the monitor as its on-line keyboard;
   f. break its connection with the monitor.

The monitoring facility has proven useful both for debugging and for demonstration purposes. One difficulty a user faces in debugging a multi-center simulation is determining what is happening at centers suspected to be malfunctioning. A monitor, constructed appropriately, can serve as a "graphical probe" and be used to watch the operation of first one suspect center and then another. For example, we have used such a monitor to follow the trajectory of an aircraft as it passes through several centers.

By enabling processes at arbitrary ARPANET sites to observe and control McROSS simulations, the monitoring facility provides a mechanism for using hardware and software features which are unique to various network installations. By using monitors which play an active role in his simulations a McROSS user can experiment with different ways of partitioning computational and control responsibilities in air traffic situations. He could, for example, experiment with a monitor built to provide a weather advisory service for simulator centers. Such a monitor would presumably have access to an on-line weather data base. (A weather data base to be accessible through the ARPANET is currently being designed.[10]) To perform its service for a center the monitor would attach to the center, requesting that the center broadcast aircraft flight parameters to it and accept input lines from it. It would then "watch" the airspace of the center and send instructions to it, as necessary, to vector aircraft around severe weather.

Unless he chooses to do so, the simulation programmer need not concern himself with remote monitoring beyond specifying at simulation run time which centers in his network are to be receptive to remote monitors. Monitors themselves are not part of the McROSS system. McROSS merely provides a mechanism for remote monitoring. No effort has been made to provide linguistic features within the McROSS system to make it easy to write programs to do monitoring.

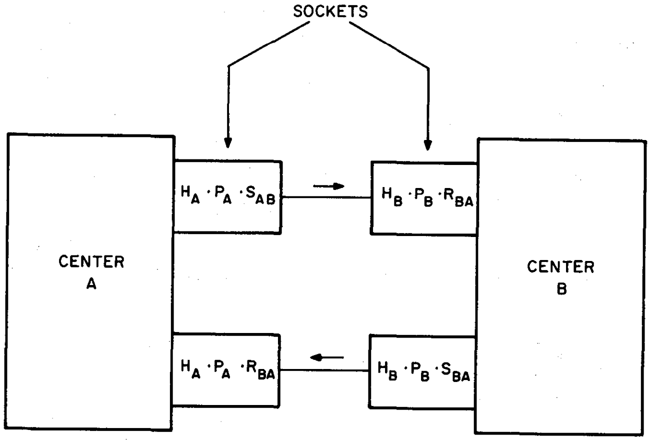
THE McROSS IMPLEMENTATION

Some interesting aspects of the McROSS implementation are discussed in this section. The section focuses on strategy rather than detail. The result is a simplified but nonetheless accurate sketch of the implementation.

The ROSS implementation

Implementation of McROSS was accomplished by extending the existing ROSS simulation system. A ROSS simulation consists of initialization, simulation and termination phases. The simulation phase is implemented as a loop. Each pass through the loop represents a "tick" of the clock which maintains simulation time. On each tick the simulator:

1. parses and interprets input directed to it from its scenario file and on-line console since the last tick;
2. interprets the route procedure each aircraft is currently following;
3. advances each aircraft along its trajectory taking into account the aircraft's speed, acceleration and heading and the wind profile of the airspace;
4. directs output generated since the last tick to the appropriate devices;
5. performs actions necessary to maintain the local display of its airspace:
6. increments the simulated time.



SOCKETS
CENTER A
$H_A \cdot P_A \cdot S_{AB}$
$H_B \cdot P_B \cdot R_{BA}$
CENTER B
$H_A \cdot P_A \cdot R_{BA}$
$H_B \cdot P_B \cdot S_{BA}$

Figure 3—Schematic of center-center connection between adjacent centers A and B. S_{AB}, R_{AB}, S_{BA} and R_{BA} are assigned at program translation time; H_A, H_B, P_A and P_B are determined at run time

A ROSS simulation can be run either in a "real time" mode in which simulated time is locked to real time, or in a "hyper fast" mode in which the simulation proceeds as fast as it can.

Process/processor binding and center-center connections

Connections between pairs of simulator network centers are duplex. Each center-center connection is implemented by two ARPANET connections. More specifically, an open connection between centers A and B is realized by the two ARPANET connections (see Figure 3):

$$H_A.P_A.S_{AB} \rightarrow H_B.P_B.R_{BA}$$

$$H_A.P_A.R_{AB} \leftarrow H_B.P_B.S_{BA}$$

To establish such a center-center connection two pairs of matching RFCs must be issued by centers A and B. To issue the correct RFCs A must know H_B, P_B, R_{BA} and S_{BA}; similarly, B must know H_A, P_A, R_{AB} and S_{AB}.

The host (H) and process (P) components of the socket names for a center-center connection cannot be determined until run-time because process/processor binding is deferred until then. However, the process-local components (R and S) of the socket names can be pre-assigned and, in fact, the effect of the declarations in the network geometry sub-program for a particular McROSS network is to do exactly that.

The process local components for the four socket names corresponding to a center-center connection are always the same whereas the host and process components may change from run to run or even within the same run if either neighbor is involved in a dynamic reconfiguration.

When a center's end of a center-center connection is in the uninitialized state the host and process components of the socket names corresponding to the remote end are unknown to it. To move its end of a connection from the uninitialized state the center engages in a dialogue with the user requesting from him the physical location of the neighbor. After successfully completing the dialogue the center has sufficient information to issue the two RFCs required of it to establish the connection.

Center-monitor connections

The connection between a center C and an attached remote monitor M is realized by two ARPANET connections. One of them

$$H_C.P_C.S_{CM}\rightarrow H_M.P_M.R_{MC}$$

is a "broadcast" connection used for continuously broadcasting information to M. The other

$$[H_C.P_C.R\leftarrow]_L$$

is a "request" connection maintained by C in a listening state for M to use to make requests of C. Each monitor attached to C has its own broadcast connection but may share a request connection with other monitors.

To make a request of C, M connects to the request socket, transmits its request over it and then closes the request connection, freeing it for use by other monitors. The action taken by C of course depends upon the request. If the request were for the display map, C would transmit the map data over the broadcast connection to M.

Before the RFCs required to establish a center-monitor connection between C and M can be issued C must know H_M, P_M and R_{MC} and M must know H_C, P_C, S_{CM} and R. To obtain the required information, M and C engage in a connection protocol which is similar to the "initial connection protocol" developed by the ARPANET network working group.[6]

Each center willing to service monitors maintains as an "attach" socket a send socket in a listening state (see Figure 4.a). The attach socket for C could be denoted

$$[H_C.P_C.A\rightarrow]_L$$

The process local component (A) of the name for attach sockets is the same for all centers and is "well-advertised." Therefore, if M knows the physical location of C it can issue an RFC for C's attach socket. The effect of such an RFC is to establish the connection (Figure 4.b)

$$H_C.P_C.A\rightarrow H_M.P_M.R_M$$

Upon detecting an RFC for its attach socket, C notes H_M and P_M and transmits S_{CM} and R over the connection. Next both C and M break the connection and

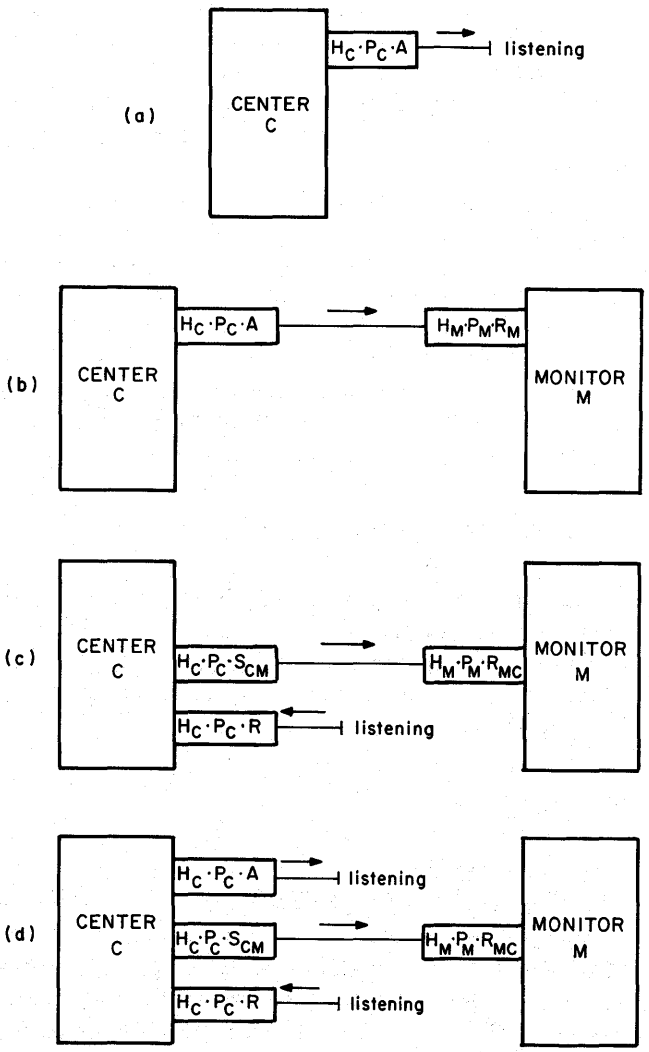


Figure 4—Schematic of connection protocol exchange between center C and monitor M

issue the RFCs necessary to establish the broadcast connection (Figure 4.c)

$$H_C.P_C.S_{CM} \rightarrow H_M.P_M.R_{MC}$$

where $R_{MC}=f(R_M)$, a pre-agreed upon function of R_M. C, if it has not done so previously for another monitor, sets up the listening connection

$$[H_C.P_C.R \leftarrow]_L$$

and finally, reestablishes its attach connection so that other monitors can attach to it (Figure 4.d). Currently the process-local components for ARPANET socket names are numbers and f is taken to be

$$f(x)=x+2.$$

If R_M rather than $f(R_M)$ were used for R_{MC} a race condition would result when M and C attempt to establish the broadcast connection. The race involves the order in which the connection with socket $H_M.P_M.R_M$ would be closed and reopened by C and M. In particular, the current TENEX NCP is such that an attempt by C to open the network file corresponding to its end of the (broadcast) connection

$$H_C.P_C.S_{CM} \rightarrow H_M.P_M.R_M$$

before M closes the network file corresponding to its end of the connection

$$H_C.P_C.A \rightarrow H_M.P_M.R_M$$

would fail. Use of $f(R_M)$ for R_{MC} avoids the race. A similar race condition, discovered in an early version of the ARPANET initial connection protocol,[7] is avoided in the current protocol by the same technique.[8]

Process structure at McROSS centers

A McROSS center is realized by a collection of cooperating, asynchronously evolving, sequential processes. The collection corresponds to a partitioning of the center's responsibilities into more or less independent sub-tasks. It includes:

1. a process (SIM) to perform the ROSS functions;
2. a process (CONN) for each center-center connection to establish and maintain the connection; and
3. a monitor server process (MONSER) to service remote monitors.

The CONN process at center A corresponding to the center-center connection to center B is responsible for establishing ARPANET send and receive connections with B. After it establishes the center-center connection with B the CONN process maintains the connection. When messages from B arrive it passes them on to the SIM process for parsing.

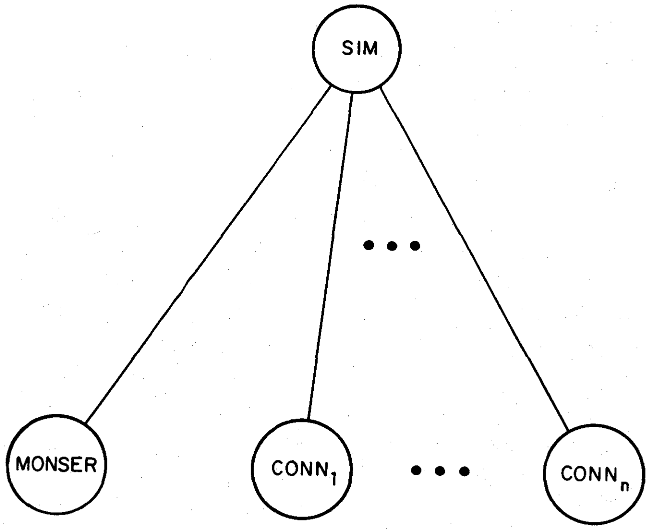

Figure 5—The process hierarchy which implements a McROSS simulation center with *n* neighbors

The job of the MONSER process at a center is twofold: to engage in an initial connection protocol exchange with monitors attempting to attach to the center and to respond to requests made by attached monitors.

The processes at a center exist in a hierarchy (see Figure 5). The hierarchical structure is less the result of any one process being more important than any other than it is a consequence of the TENEX constraint that process groups be hierarchically arranged. During initialization the SIM process creates the MONSER and CONN processes. Thereafter, the processes evolve more or less independently.

The process structure at each center helps achieve autonomy of parts. The CONN processes and the MONSER process serve to protect the SIM process by insulating it from direct interaction with other centers and remote monitors.

Protocols

The current implementation of the TENEX NCP is such that if a center were to unilaterally break a connection with a neighbor (by closing the two corresponding ARPANET connections) it could leave processes in the neighboring center in an irrecoverable state. For example, a process in the neighbor sending information across the connection at the time it is broken would "feel" the close as if it had executed an illegal instruction. To prevent such situations McROSS centers engage in a protocol exchange prior to breaking connections.

The center-center protocol is relatively simple. To perform an *abort* or *dsconn* operation a center sends its neighbor a "request for abort" or "request for disconnect" message and waits until it receives an acknowledgment before actually breaking the connection. Existence of the center-center protocol has two major implications. The first is that a center-center connection has more states than the three noted earlier. The additional states are transient ones which the connection passes through as the center and its neighbor advance through protocol exchanges initiated when one attempts to change the state of the connection. The transient states are invisible to the McROSS user. Immediately after a *dsconn* (or *abort*) is initiated the SIM process treats subsequent operations involving the connection as if the connection were already in the closed (or uninitialized) state. The second implication is that center-center connections carry "control" messages used in center-center protocol exchange in addition to "ordinary" messages intended for the receiver's parsing mechanism. The CONN process for each connection must be prepared to recognize and respond appropriately to both kinds of messages.

McROSS centers expect remote monitors to observe a center-monitor protocol. In addition to the connection and request procedures described earlier, the center-monitor protocol includes a disconnection procedure much like the one used in the center-center protocol.

Interprocess communication

To perform their tasks the processes at a simulation center must interact occasionally. For example, the arrival of a message from a neighbor requires interaction between the SIM and CONN processes. The CONN process receives the message and passes it onto the SIM process for parsing and interpretation.

One way the processes interact is through shared memory. For example, the SIM and CONN processes have read and write access to a shared "connection table." There is an entry in the table for each center-center connection which includes the state of the connection, a semaphore[9] and other information relevent to the connection. Use of the table is coordinated by strict adherence to a convention which requires every "critical" access (every write access and certain read accesses) to an entry to be bracketed by P (lock) and V (unlock) operations on the entry's semaphore.

The situation arising at a center when a neighbor attempts to break connection with the center is a typical one which requires interprocess communication. The CONN process corresponding to the center-center connection receives a "request for disconnect" message from the neighbor. Center-center protocol requires the CONN process acknowledge the request so that the neighbor can break the connection. The purpose of the protocol exchange is to warn the center that the connection is about to be broken and that it should no longer attempt to use it. Therefore before it acknowledges the neighbor's request it is important that the CONN process communicate this information to the other processes at its center. The CONN process does this by the following sequence of actions:

```
P(CONNECTION SEMAPHORE);
set connection-state to "not open";
V(CONNECTION SEMAPHORE);
acknowledge neighbor's request
```

As long as processes at the center perform the following sequence of actions to send over center-center connections there is no danger of sending after the connection has been closed:

```
P(CONNECTION SEMAPHORE);
if connection-state = open
    then send
    else abort the send;
V(CONNECTION SEMAPHORE)
```

Stated somewhat differently, sending over a center-center connection should be regarded as an operation which involves a "critical" read access of the corresponding connection table entry.

In addition to memory sharing, direct process control is used as a mechanism for interprocess communication in the McROSS system. Because of its superior position in the process hierarchy the SIM process can exert direct control over the other processes. A few situations occur in which it does so. For example, when a center-center connection has been closed or aborted (via *dsconn* or *abort*) the SIM process forces the corresponding CONN process to halt. If and when an attempt is initiated to reestablish the connection (via *conn*) SIM restarts it.

SOME OPEN QUESTIONS

This section briefly discusses questions representative of ones which have arisen in the course of using the McROSS system. The questions have been resolved to the extent that useful simulations can be performed using McROSS. However, none has been resolved in a totally satisfactory manner. The intent of this section is to leave the reader with an appreciation for the issues raised by these questions; a thorough discussion of them is well beyond the scope of this paper.

Synchronization

Simulated time is important in the operation of the McROSS system. In particular, whenever an interaction between adjacent centers occurs it is important that the clocks kept by the centers show approximately the same time. Time synchronization is a specific example of the general problem of control in distributed computation. It is compounded by the fact that centers can start up and shut down independently of one another. A centralized approach to synchronization has been used with success in McROSS simulations. In it, one center acts as a synchronizer for an entire simulator network. When a center starts up it connects to the synchronizer and receives a synchronization message from it. Thereafter, to stay in synch with other centers in the network, the center makes use of the real time clock in the computer it runs on. A distributed approach to synchronization which does not require a synchronizing center is under consideration.

Locally unknown names

Names that are well defined within a simulator network as a whole are not necessarily defined at every node in the network. How should references to such names occurring within centers in which they are not defined be handled? For a specific example in which such a reference is reasonable, reconsider the four node network for simulating Boston-New York traffic. A user controlling the simulator for Boston Terminal who is manually vectoring an aircraft leaving Logan airport might reasonably issue the clearance

fly (V205, PAWLING)

which specifies that the aircraft is to follow Victor Airway #205 to Pawling. Assume that V205 is defined within the geography modules for BOSTRM, BOSCEN and NYCEN and the PAWLING is defined within NYCEN but not within BOSTRM or BOSCEN. The BOSTRM center can't fly the aircraft to Pawling because Pawling is not defined within its airspace. Ideally it should fly the aircraft along V205 to the boundary of the BOSCEN airspace and then hand it off to the BOSCEN simulator. Certainly it should be able to do better than report an error and abort the route procedure. Techniques for handling references to locally unknown names in certain limited contexts are being investigated. However, the general problem of handling such references is an open question.

Program residence

Where should the program (route procedures) required to fly an aircraft through several simulator centers reside? Should the program be associated with the aircraft and passed with it from center to center or should parts of the program be distributed among the relevant centers? The approach currently used in McROSS simulations is to distribute the program and pass only the aircraft and its flight parameters from center to center.

Interruption and resumption of route procedures

Aircraft frequently interrupt their flight plans temporarily in order to avoid severe weather or heavy traffic. The simulation analogy to a flight plan is the route procedure. How should a center handle interruption and subsequent resumption of route procedures? Interrupting the execution of a route procedure in order to follow another one is not difficult. The difficulty arises in determining how to appropriately resume the interrupted procedure. In general, the point of interruption is inappropriate as a resumption point. A considerable amount of (simulated) time can elapse between interruption and resumption during which the flight parameters (position, speed, altitude and heading) of the aircraft can change significantly. Therefore, the usual programming technique of saving the "state" when an interrupt occurs and restoring it after the interrupt has been handled is inadequate. The interruption/resumption problem is made more complex by the possibility that between interruption and resumption the aircraft may fly out of the airspace of one center and into the airspace of another. The current McROSS implementation is not prepared to handle interruption and subsequent resumption of route procedures.

Error handling techniques for distributed systems

The question of how to handle error situations in a distributed computational system is a challenging one. In McROSS considerable attention has been given to making nodes in a simulator network autonomous. The strategy for handling errors is to try to achieve a "local" error recovery whereby a node attempts to preserve its autonomy. As a result, while the actions it takes are locally optimal in the sense that its continued operation is insured, they may be sub-optimal in the more global context of the entire simulation network.

Errors occurring in inter-node messages are simply handled in the current McROSS implementation. Recall from an earlier section that inter-node messages are submitted to the parsing mechanism of the destination node. When a node receives a message which is syntactically incorrect or semantically meaningless (to it) from a neighbor, it reports the error on its on-line keyboard, sends a message to the neighbor causing the error to be reported on the neighbor's on-line keyboard, and ignores the message. This procedure is locally satisfactory in the sense that it guarantees that messages which are not well-formed cannot cause the node to malfunction. However, if the incorrect message from the neighbor is one critical to the outcome of the simulation, this procedure is not globally acceptable. Ideally, upon detecting an error in a message, the node should engage in a dialogue with its neighbor in an attempt to resolve the error. The difficulty in implementing this strategy is that it is frequently unclear what should be done to resolve an error. Often the cause has been masked by the time the error is detected.

While the simple techniques used in McROSS for error handling have proven adequate, it is clear that more effective techniques can be developed.

CONCLUDING REMARKS

The results of the work reported in this paper are applicable in two areas.

One area is research in air traffic control. Researchers can use the McROSS system to conduct simulation studies preliminary to the design of an automated multi-component air traffic control system. For example, McROSS could be used to evaluate various ways of partitioning responsibility among components of such a system. Or, it could be used to compare different strategies for automated scheduling and control of aircraft. Because it exhibits autonomy of parts and the ability to dynamically reconfigure, it could be used to experimentally study the behavior of failure handling techniques for a multi-center system under various air traffic loads.

The other area is the design and implementation of distributed computation systems. The results in this area are incomplete and tentative consisting primarily of insights and attitudes developed from the experience of building and using a distributed computation system. These are summarized by reviewing the goals for the McROSS system in terms of problems they posed and techniques useful in realizing them.

Of the five goals, autonomy of parts and deferral of process/processor binding were the most significant in terms of effort required to achieve them and influence on the appearance of the system to users. Given their realization, the other three goals (the ability to dynamically reconfigure a simulator network, decentralization of control and ports for monitoring) were relatively easy to achieve.

The strategy of implementing parts of the distributed computation by process groups rather than solitary processes contributed significantly to achieving autonomy of parts. The multi-process implementation made it possible to dedicate certain processes at a node to maintaining an interface with other nodes and to dedicate other processes to performing functions crucial to the node's existence. In addition to insulating vital internal node functions from the actions of other nodes, the functional modularity resulting from multi-process nodes had the effect of reducing the complexity of the implementation: each individual process being considerably less complex than an entire node. The multi-process capability which the TENEX operating system supports for each user job was invaluable in carrying out the multi-process strategy. It is unfortunate that few operating systems allow users to create and maintain process structures.

Equally useful in realizing autonomy was the establishment of and strict adherence to protocols for part-part interactions. A center can expect monitors and adjacent centers which are functioning properly to observe protocol and can therefore interpret a breach of protocol as a warning that the offender may be malfunctioning. A consequence of the multi-process implementation of nodes is that interprocess communication occurs within McROSS at two levels: inter-node and intra-node. Use of a protocol for intra-node interactions helps insure that internal node data bases always accurately reflect the condition of the node's interface with other nodes. A useful implementation rule was to reject any technique whose success depended upon the order in which events in different centers or in different processes within the same center occur.

The major problem in implementing deferred process/processor binding was providing a way for parts of the computation to determine the location of logically adjacent parts at run time. The solution used in the current McROSS implementation, which requires run time interaction with the user, is not totally satisfactory. A more satisfactory alternative might be for each part to engage in a network-wide search for logically adjacent parts.

We expect to see a trend toward distributed multi-computer systems in the future. By its existence McROSS demonstrates that the construction of such systems is currently feasible.

ACKNOWLEDGMENT

The McROSS system grew from an idea proposed by Dr. W. R. Sutherland of BBN; we gratefully acknowledge his guidance and enthusiasm.

The realization of the current McROSS implementation is the result of building upon the work of others, most significantly the designers and implementers of the ARPA computer network and of the TENEX operating system.

Extensions of packet communication technology to a hand held personal terminal

by LAWRENCE G. ROBERTS

Advanced Research Projects Agency
Arlington, Virginia

INTRODUCTION

Electronic communications technology has developed historically almost completely within what might be called the circuit switching domain. Not until the last decade has the other basic mode of communication, packet switching, become competitive. Thus, as a technology, packet communication has only begun to be explored. Circuit switching can be defined in the broad sense as the technique of establishing a complete path between two parties for as long as they wish to communicate, whereas packet switching is where the communication is broken up into small messages or packets, attaching to each packet of information its source and destination and sending each of these packets off independently and asynchronously to find its way to the destination. In circuit switching all conflicts and allocations of resources must be made before the circuit can be established thereby permitting the traffic to flow with no conflicts. In packet switching there is no dedication of resources and conflict resolution occurs during the actual flow perhaps resulting in somewhat uneven delays being encountered by the traffic. Clearly, without the speed and capability of modern computers, circuit switching represented a cheaper and more effective way to handle communications. For radio frequency assignment and telephone exchanges the resource allocation decisions could be made infrequently enough that manual techniques were originally sufficient. Also, since voice was the main information being communicated, the traffic statistics were sufficiently compatible with this approach to make it quite economic for the period. Packet switching of a kind, the telegram, persisted throughout this period but due to the high cost of switching and the limited demand for fast message traffic never attracted much attention.

For almost a century circuit switching dominated the communications field and thus dominated the development of communications theory and technology. Now, within the last decade or less, the advances in digital computers and electronics have, in many cases, reversed the economic balance between circuit and packet communication technology. Perhaps the best proof of this is the economy of the ARPA Network[1–6] for country-wide computer to computer communication, but many other examples are beginning to appear such as the University of Hawaii's ALOHA System[7] utilizing packet radio transmission for console communications and the experiments with digital loops for local distribution. However, most of the experiments with packet communications have been undertaken by computer scientists, and it is not even generally recognized yet in the communications field that a revolution is taking place. Even where the knowledge of one of these experiments has penetrated the communications field, it is generally written off as a possibly useful new twist in communications utilization, and not recognized as a very different technology requiring a whole new body of theory. Throughout the development of the ARPA Network, communication engineers compared it with conventional circuit switched systems but, perhaps unconsciously, used rules of thumb, statistics and experience applicable only to circuit switched systems as a basis for comparison. A century of experience and tradition is not easy to ignore and in fact should not be ignored, only it should be properly classified and segregated as resulting from a different technology.

Packet communication technology is only beginning to be explored but already it is clear that the design of all forms of communications channels and systems should be rethought. As an example of the kind of difference packet communications can make in a perhaps unexpected area, the design of a personal terminal will be explored in some detail. Although such a terminal has never been built, it is most likely completely feasible to build and would provide many unique advantages.

HAND HELD PERSONAL TERMINAL

Let us start with the goal of providing each individual with a pocket-sized, highly reliable and secure communications device which would permit him to send and receive messages to other individuals or to coputers. Leaving the consideration of design alternatives muntil the end, a device fulfilling these objectives is as follows:

Output

Text or graphics displayed on a 2.8″×1″ plasma panel with 80 dots per inch resolution. The screen, divided into 7×10 dot rectangles, using 5×7 characters would hold 8 lines of 32 characters each for a total of 256 characters. Text this size is almost the same size as typewriter print, except that the lines are closer together. The plasma panel has internal storage and is digitally addressed to write or erase a point.

Input

Five capacity or stress sensitive buttons used by the five fingers of one hand simultaneously to indicate one of 31 characters. This five finger keyboard technique was developed by Doug Englebart at SRI[8] to permit users to type with only one hand while working on a display console. Recently the keyboard has become fairly widely used at SRI due to its great convenience. Training time for a new user is evidently less than a day and speeds of 30 words per minute can be achieved.[9] Although somewhat slower than a good typist (½ speed) the speed is clearly sufficient for a terminal device even at 10 words/minute.

Transmission

Each input character will be transmitted to a central controller station using the random access radio transmission techniques developed at the University of Hawaii.[7] The 5 bit character is embodied in a 64 bit packet containing:

30 bits—Terminal Identification Number
8 bits—Character plus alternation bit, or Count
2 bits—Type of packet (CHAR, ACK, CNT, ERR, ST ERR)
24 bits—Cyclic Sum Check
64 bits

All terminals transmit their packets independently and asynchronously on a single frequency and the receiver at the central controller merely listens for a complete packet which has a correct sum check. If two terminals' transmissions overlap the sum check will be wrong, and the terminals will retransmit when they find they don't receive an acknowledgment. Retransmission time-out intervals are randomized between the terminals to avoid recurrence of the problem. Upon receipt of a good packet, the central station transmits a display-acknowledgment packet back to the terminal on a second frequency. This 144 bit packet contains a 70 bit display raster field and an 8 bit position on the screen. The display raster is a 7×10 dot array for the character sent in and the position includes 3 bits for vertical by 5 bits for horizontal. Current position information for each active user is kept by the central station by user ID in a hash table. Thus, the individual terminal needs no character generation logic, position advancement logic, or any other local verification of the input since the response from the central station both acknowledges the character and displays it in an input text line at the top of the display. If a character display-acknowledgment is somehow lost in transmission the terminal will continue to time-out and retransmit the character. The central station must somehow differentiate this from a new character. This is achieved by an alternation bit[10,11] in the terminal's packet which is complemented for each *new* character. On a repeat the bit is the same as previously and the central station just retransmits the same character and position again. When a prearranged terminating character is sent the central station examines the message and takes an appropriate action. Considerable flexibility exists here, and operational modes could be established. However, the first message of a sequence should contain a destination as the first item. This might be the ID of another terminal in the same area, it might be the address of a service computer or it might be the ID of another terminal halfway around the world. In the latter two cases, a more global network such as the ARPA Network comes into play. It would be perfectly feasible for a message to another terminal to be sent to a central or area-coded directory computer to locate the particular control station the other terminal was near. Note that the location of neither man was given to the other, only the message and the ID of the sender. (Based on ARPA Network cost estimates and international satellite tariff trends, such a message exchange should cost less than 0.1 cents, independent of distance.)

Reception

At any time when a message destined for a terminal arrives at the central control station, a transmission to the terminal may begin, character by character, each in its own 144 bit packet as follows:

30 bits—Terminal Identification Number
70 bits—7×10 dot pattern, character display
8 bits—position of character
1 bit —alternation bit
1 bit —broadcast mode
3 bits—Message Type (Response, initial, normal)
8 bits—Characters Left in message
24 bits—Cyclic Sum Check
144 bits

The terminal must always be checking all transmission to detect those with its ID and a correct sum check. When one occurs which is not a "response" to an input character, a message is being sent. The first character of a message is marked type "initial," and has the count of the remaining characters. Each character is displayed where the central station placed it. Following the "initial" character "normal" characters are checked to make sure the count only decreases by one each time. After the character with count zero, an acknowledgment type packet is sent by the terminal. If this is lost (as it may be due to conflicts) the central control will retransmit the final character over again without complementing the alternation bit until it is acknowledged (or it determines the station is dead). If a count is skipped the terminal sends a CNT ERR message with the count of the character expected. The transmitter then starts over at that count. If a "normal" type character is received before an "initial" type a ST ERR message is sent and the message is restarted. A broadcase bit is included which overrides the ID check for general messages.

Security

Since all transmissions are digital, encryption is possible and would be important no matter what the application, military or civilian. Most private uses such as personal name files, income-expense records, family conversations, etc., would be far more sensitive than current computer console use.

Bandwidth

Personal terminals for occasional use for message exchange, maintaining personal files, querying computer data bases for reference data, etc., would not lead to very heavy use, probably no more than two query-responses per hour. The query we might estimate at 64 characters in length and the response at 256. (Clearly 256 character response could also consist of an 80×224 point graphic display since each character is sent as a full 7×10 raster.) The average bandwidth consumed by each terminal is therefore 2.3 bits/second transmitted and 25.6 bits/second received. The random access technique used for transmission requires the channel bandwidth to be six times the average bandwidth actually utilized in order to resolve all conflicts properly. Thus, the terminal transmission bandwidth consumption is 14 bits/second, still less than the receiver bandwidth needed. Thus, the central control station's transmitter bandwidth is the limiting factor assuming equal bandwidths on both transmitter and receiver. If a 50KHz bandwidth is used for each and modulated at 50K bits/sec, then a total of 2000 terminals can be accommodated. Of course this number depends on the activity factor. At one interaction every two minutes a data rate equal to average time shared console use is obtained and even at this activity 130 terminals can be supported, more than most time-sharing systems can support. With 50 KB channels, the time required to write 256 characters is about one second. Lower bandwidths require increased time, thus, 10KB (5 sec write time) would be the lowest bandwidth reasonable. Even at this bandwidth, with the estimated 2 interactions per hour, 400 terminals could be supported.

COMPARISON

Comparing the effect of the packet technology with the same terminal operating with preassigned Frequency or Time Division Multiplexed channels (ignoring the losses due to TDM sync bits or FDM guard bands) the circuit oriented terminal would require a 40 bit/sec transmit channel and a 4KB receive channel if a 5 sec write time is to be achieved. For 400 terminals with a 5 sec write time, the circuit method would require a total of 16 Megabits/sec bandwidth whereas the packet method only requires 20 Kilobits/sec bandwidth. Thus, the circuit technology requires a factor of 800 more bandwidth than the packet technique. Of course, the circuit mode terminals could interact more often within the same bandwidth right up to continual rewrite of the display every five sec, but you would have to massively reshape the user statistics to suit the technology.

Another possibility, to design the terminal so that it performed more effectively in a circuit oriented mode, would be to put character generation logic and position logic in the terminal. This would considerably increase the cost of the terminal, which originally had very little logic except shift registers. The result of adding this logic, however, is to reduce the bandwidth by a factor of 10 to 1.6MB or still 80 times the packet technique. The same logic would help reduce the packet size but, in order to maintain the graphic output capability and gross simplicity, it does not seem to pay.

CONCLUSION

As can be seen from the example, packet technology is far superior to circuit technology, even on the simplest radio transmission level, so long as the ratio of peak bandwidth to average bandwidth is large. Most likely, the only feasible way to design a useful and economically attractive personal terminal is through some type of packet communication technology. Otherwise one is restricted to uselessly small numbers of terminals on one channel. This result may also apply to many other important developments, only to be discovered as the technology of packet communication is further developed.

An overview of programming languages for specialized application areas

by J. E. SAMMET

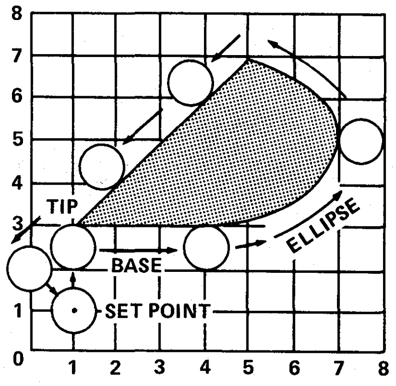
IBM Corporation
Cambridge, Massachusetts

INTRODUCTION

There are more than 165 different programming languages in use in the United States today, where only higher level languages are considered as programming languages. If assembly languages were considered in this total it would obviously be much higher. The total number would be still greater if programming languages in use outside the United States were included. (They are excluded here only because of the difficulty of obtaining accurate and sufficiently detailed information.) As individuals, and as an industry, we should ask ourselves, "What is the reason for this enormous proliferation?", particularly since many of these languages claim to be "general purpose." Some languages *do* serve a wide variety of users and applications, whereas others are restricted in intended usage. The languages which have few users are usually in that category because (a) they are basically for a narrow application area which has relatively few users* or (b) information about the language has not been widely disseminated, or (c) the language and/or its implementation is ineffective and/or has inadequate support, or (d) the language is implemented only on a computer not widely used. The purpose of this paper is to provide some of the background and perspective on the existence, classifications, and general characteristics of those languages which are oriented toward a specialized application area.

The earliest of the *major* "specialized languages" seems to be APT, developed at MIT by 1955, for numerical machine tool control. A small program—shown in Figure 1—illustrates in an intuitive way the type of language with which this paper is concerned. It is perhaps unfortunate—but is certainly quite true—that one of the major reasons for the proliferation of programming languages is that designing and implementing languages are fun, and there is a very large NIH (Not Invented Here) factor that makes even minor deficiencies in an existing language a justifiable cause for the development of a new one. This represents the less productive aspect of the proliferation. However, the important cases (meaning the languages widely used) fulfill a bona fide need for a language that can be used by people who don't really understand programming. The specialized languages help these people work in their own professional jargon. The motivation for the development usually comes when individuals find that for each existing language there are facilities that they want, and which they think the language should legitimately contain, but which are not basically available in the language. It is important to emphasize the "not basically available" aspect, as well as recognizing that there is a value judgment involved on this issue. There are certainly cases where FORTRAN has been used to write payroll programs but it is unlikely that anybody would seriously contend that such usage was appropriate; alternatively, people should not condemn FORTRAN for being ill-suited for writing data processing applications since that was not its intent. Similarly, COBOL has been used to generate differential equation programs, but that is certainly a perversion of its major intent. Thus, in considering whether an existing language should be used for a particular problem, its avowed intent must be kept well in mind. This applies not only to the syntax and semantics of the language itself, but also to the type of the machine or environment for which it was designed. A language suitable for use in a batch system is not necessarily well-suited for use in an interactive mode, even though a compiler or an interpreter for the language can indeed be put into a time sharing system. Similarly, a language which provides very good inter-

* Some languages which have a narrow area of intended usage may actually have a large number of users, e.g., COGO.



Part to be cut

Part Program	*Explanation*
CUTTER/1	Use a one inch diameter cutter.
TOLER/.005	Tolerance of cut is .005 inch.
FEDRAT/80	Use feedrate of 80 inches per minute.
HEAD/1	Use head number 1.
MODE/1	Operate tool in mode number 1.
SPINDL/2400	Turn on spindle. Set at 2400 rpm.
COOLNT/FLOOD	Turn on coolant. Use flood setting.
PT1 = POINT/4, 5	Define a reference point, PT1, as the point with coordinates (4, 5).
FROM/(SETPT = POINT/1, 1)	Start the tool from the point called SETPT, which is defined as the point with coordinates (1, 1).
INDIRP/(TIP = POINT/1, 3)	Aim the tool in the direction of the point called TIP, which is defined as the point with coordinates (1, 3).
BASE = LINE/TIP, AT ANGL, 0	Defined the line called BASE as the line through the point TIP which makes an angle of 0 degrees with the horizontal.
GOTO/BASE	Go to the line BASE.
TL RGT, GORGT/BASE	With the tool on the right, go right along the line BASE.
GOFWD/(ELLIPS/ CENTER, PT1, 3, 2, 0)	Go forward along the ellipse with center at PT1, semi-major axis = 3, semi-minor axis = 2, and major axis making an angle of 0 degrees with the horizontal.
GOLFT/(LINE/2, 4, 1, 3,), PAST, BASE	Go left along the line joining the points (2, 4) and (1, 3) past the line BASE.
GOTO/SETPT	Go to the point SETPT in a straight line.
COOLNT/OFF	Turn off coolant flow.
SPINDL/OFF	Turn off spindle.

Figure 1—APT (machine tool control)

active facilities does not necessarily provide the broad flexibility and control normally found (or needed) in batch programs of great complexity.

In order to more explicitly establish the level of language that is being discussed, the defining characteristics of a higher level language are considered to be the following: (1) machine code knowledge is unnecessary, i.e., the user does not have to know the machine instructions available on any computer; (2) there must be good potential for converting a program written in a higher level language onto another machine; that is equivalent to saying that the language must be basically machine-independent (but since we know that no languages to date are *completely* machine-independent, what is being stipulated is a good potential for conversion to another computer); (3) there must be an instruction explosion, i.e., for most of the statements that the user writes in the higher level language, the computer (through a compilation or interpretive process) should generate many more machine instructions; (4) the notation of the higher level language should be more problem-oriented than that of an assembly language, i.e., it should be more "natural" for the class of problems being solved.

MEANING OF, AND STATISTICS ON, APPLICATION-ORIENTED LANGUAGES

Terminology

Many people refer to special-application-oriented languages as "special purpose" languages. This is misleading since the term "special purpose" really applies to a single or a limited set of objectives. For example, one might design a language that was intended to be very easy to use (e.g., BASIC). On the other hand, a major objective of the language might be easy and rapid compilation (e.g., MAD). Alternatively, the objective might be a language in which it was easy to generate efficient object code. Finally, as a particular type of "special purpose," a language might be designed to be useful for a specific application area.

Another term which is frequently used for the class of languages discussed in this paper is "problem-oriented." This is bad terminology, because *all* programming languages are problem-oriented. The main distinctions pertain to the width or narrowness of the problem area involved.

In the most fundamental sense, *all* programming languages are "application-oriented." Every programming language which has been developed has been aimed at a particular class of applications, which may be narrow or broad. In the latter case, the so-called general purpose languages such as PL/I and ALGOL 68 attempt to be suitable for *every* application area and they clearly don't succeed. This is not surprising when one considers the enormous variety of uses to which computers are put today, including calculation of space trajectories, medical diagnosis, inventory control, numerical machine tool control, graphic displays, and movie animation. With the sole exception of medical diagnosis, all of these applications have fairly general (e.g., FORTRAN, COBOL) or very specialized (e.g., APT) languages used for their solutions. Hence, it is inaccurate to refer to some programming languages as "application-oriented" while others are not. *All* programming languages are application-oriented, and the only question that can meaningfully be asked is "what type of application?". The answer can be narrow or broad, and also can be classified by either technique or application area, or both. For example, matrix manipulation is both a technique and a class of applications, depending on your viewpoint. (This is of course analogous to the concept that one person's program is somebody else's subroutine.)

In contrast with the technique and/or application of mathematics, one might consider the application area of technical computation with engineering as a major subcategory; underneath the latter can be logical design and civil engineering (which in turn has subdivisions of structural engineering and coordinate geometry). In parallel with engineering we might have astronomy. The area of computations in medicine could be considered a subset of technical computations, or might be considered a major category. It is really up to the individual as to how fine a line he wants to draw. Table I represents one possible schematic, and the reader can easily develop similar tables to reflect his own approach to problem areas. It is important to note

TABLE I—A Schematic for Types of Application Areas

- Mathematics

that the distance of the observer from an application area affects his view of it. Thus, civil engineering is one application area from the viewpoint of a computer scientist, but has many levels and subdivisions for a person involved in building bridges.

Another method of classifying the application areas is through the realization that some types of applications involve a particular specialized discipline or specific technology, whereas others are specialized but can be used across many areas. Illustrations of the former include civil engineering, movie animation, social science, etc., whereas the latter include simulation, graphics, etc. A more complete list is given in Table II.

This paper specifically deals with, and includes in the category of "languages for specialized application areas," all programming languages *except* those specifically intended for mathematical computations (both numeric and non-numeric, i.e., formula manipulation), business data processing, string and list processing, or any combinations of these. (The use of a language outside its intended application area does *not* cause it to be considered specialized, nor change the definition of its primary intended use.) This list of excluded categories is certainly debatable on the grounds of what it does and does not contain. The applications cited seem so fundamental to the use of computers that none should be considered as being specialized. Of the categories of specialization (discussed later) only simulation seems to have a reasonable potential for consideration as fundamental, and at this point in time such a conclusion does not seem justified to the author. Note also that systems programming is considered one of the specialized application areas; this view refutes the concept which has been expressed by some people that a language can only be considered good if it can be used to write its own compiler.

The terms "special-application-languages" and "application-oriented languages" will be used in this paper as synonyms for the phrase "languages for specialized application areas."

TABLE II—Categories and Statistics on Languages for Special Application Areas

	Number of Languages					
	Pre 1966			1966–1971		
	1–2	3–5	over 5	1–2	3–5	over 5
Specialized Application Disciplines						
automated equipment checkout	X					X
civil engineering	X					X

logical design (including simulation of digital computers)			X		X	
machine tool control		X				X
movie animation		X			X	
real time/process control		X				X
social science/humanities	X				X	
systems programming			X			X
Narrow Applications Across MultiDisciplines						
computer aided design	X			X		
graphic and on-line display		X				X
query (excluding data base management systems)			X		X	
simulation—continuous (including block diagrams and analogue computers)		X				X
simulation—discrete			X			X

Specific application areas and statistical trends

In Table II is a list of special application areas which have had programming languages developed for them. Some statistics are also given; the latter are presented in categories rather than specific numbers in order to show trends. It is virtually impossible to obtain a completely accurate count because of the existence of dialects, multigeneration languages (e.g., SIMSCRIPT I, I.5, II, II.5, and II Plus), and the differences between dates of definition, implementation, and actual usage. The distinction between pre-1966 and more recent years largely reflects existence on second generation computers. However, not all languages on second generation computers were implemented on third generation machines. The most complete lists of languages available—although they are by no means perfect or complete—are in References 15, 16, 17, 18. Discussions of almost all those languages developed by 1967 are in Reference 14, Chapter IX.

General statistical trends

As indicated just above, it is virtually impossible to obtain accurate statistics. This is due not only to the language generation problem but also to the fallibility of any single human attempting to track this field. Until we get some scientific methodology for defining language generations, dialects, etc., and until a reliable reporting system is developed, the most we can hope for is some statistical trends. (See Reference 19, for a first attempt at dealing with the dialect problem.)

The trends that can be observed are all based on References 15, 16, 17, 18. While the figures cited have inaccuracies and in particular are based on date of inclusion of a language in the roster rather than its actual development, it seems fair to state that all the errors are probably consistent and hence relatively unbiased.

The first year in which any serious attempt was made to list "all" the special-application-oriented languages was 1968. In each of the four years 1968-1971 the number of special application languages was approximately 50 percent of the total number of languages listed. The latter were 82, 125, 139, and 164 in the four cited years. In 1969, 1970 and 1971 the *total* number of new languages added from the previous year was between 35 and 40 each year. In 1970 and 1971 the percentage of new special-application-languages was between 40 and 60 percent of all the new ones.* In both 1970 and 1971 the number of special-application-languages dropped from the roster (meaning clear non-use of the language) was about 50 percent of the total number of languages dropped. (The latter numbers are small, ranging between 5 and 10 percent of the total.)

These numbers are presented because of the trends they indicate, and certainly should not be used as definitive representations of the actual situation. For that reason these figures were deliberately *not* presented in a table or graph because that would imply more accuracy than is justified.

NEEDS TO BE MET IN DEVELOPING THE LANGUAGES

There are several needs which must be met by a new language or a modification of an existing one. The major needs are functional capability, a style suitable fcr the application area, and efficiency.

Functional capability

The inclusion of specific functional capability is probably the single most important need to be met by the application-oriented languages. Most of the deficiencies in a particular language actually reflect the omission of functional capabilities which a certain class of users need. For example, the FORTRAN user often wishes to do character manipulation, the COBOL user might wish to do floating point calculations, and the PL/I user might wish to do simulation. In considering functional capability, the three major issues are (a) the specific features which must be included (i.e., commands and data types), (b) the distinction between subroutines and a specific language facility, and (c) the facilities provided by the system. Each of these is now discussed in more detail.

Specific features

The specific features representing the functional capability of *any* language are the operations (i.e., commands) to be performed, and the data types. The kinds of operations to be provided depend completely on the application area, and of course must be consistent with the data types. As a very simple example, the existence of floating point numbers is extremely important in any language to be used for scientific computation, whereas they have little or no importance for business data processing. Therefore, the existence of a floating point or complex number data type is a functional requirement of many scientific problems, and naturally there must be executable statements which can operate on these data types. A less elementary example occurs in the civil engineering field where the ability to calculate the point of intersection of the tangents to two circles may be deemed important enough to incorporate directly into the language. Furthermore, a "point" with coordinates might be defined as a data type with operations provided to calculate areas. In the case of an application involving simulation, some indication of time and time-dependencies in both the data types and commands is absolutely crucial. In the case of a language developed for animated movies, the user must be able to address and manipulate pointers or markers on a screen. In the general area of graphics, a "graphical" data type is normally needed.

Subroutine versus language facility

Since all major languages have a subroutine capability of one kind or another, the question can legitimately be asked as to why the needs cannot simply be met through adding subroutines rather than either developing a new language or adding syntax and se-

* A similar figure for 1969 would be very misleading because the 1968 Roster did not contain any of the languages developed for CAI and their inclusion in 1969 perverts the statistics.

mantics to the existing language. It must be emphasized very strongly that there is a fundamental difference between functional capability (which can be represented either directly in the languages *or* via subroutines) and specific language facilities.

The easiest way to show this is by means of an example within the field of mathematics. (Since this was ruled out earlier as not being specialized, its use here is primarily to illustrate the concept of subroutines versus specific language facilities.) Suppose a person wished to do MATRIX addition in a language like FORTRAN. One could add a subroutine to perform those calculations and then invoke this facility by writing

```
CALL MATADD (A, B, C)
```

This is fundamentally different in several ways from writing something of the following kind:

```
DECLARE A, B, C MATRICES
C=A+B
```

In the first instance, the user (meaning both the writer and reader of the program) has lost a certain mnemonic advantage and furthermore has the difficulty of remembering the types, sequence, and restrictions on the parameters that he is using. In this particular example, the main difficulty is to remember whether the stated call would provide A as the sum of B and C, or C as the sum of A and B; this is something which must be remembered or looked up in a manual. In the second example, what is happening is far clearer. In addition to the lack of "problem-oriented notation" inherent in using the CALL or equivalent statement, there are implementation difficulties and inefficiencies relative to linkages. In many cases, there is a great deal of extra code generated to invoke a subroutine, although the latter may in fact be quite small and would be more efficient placed in line. Unless the compiler is very sophisticated, it is likely to generate the linkage coding rather than placing the subroutine in line.

While subroutines do serve a very useful purpose in making additional functional capability available to the user, they should not be viewed as substitutes for additions to a language.

System provided facilities

Another aspect of functional capability is the built-in facility of the language and its associated compiler to do things which might need to be programmed in another language. For example, in the languages for computer assisted instruction, it is assumed that they will be used in an interactive mode and hence the language translators automatically provide for input and output from a terminal without the programmer having to specify much (if anything) about input/output. Furthermore, certain types of control flow are assumed by the system and handled automatically. In the case of graphic languages, the language (and its processor) automatically provide the necessary instructions to the graphics equipment.

Style suitable for application area

In the development of languages for special application areas, the style plays a major role, primarily because the users are normally not professional programmers. Style in a programming language has many facets, ranging from personal views on the importance (or non-importance) of blanks and punctuation, to the use(or non-use) of a GOTO command, to the selection of a particular word for getting input data (e.g., READ vs. GET). The major identifiable elements of style are vocabulary, personal preferences, and requirements affecting style.

Vocabulary

The second* most important need in an application-oriented language is the vocabulary or professional jargon that is involved. The whole *raison d'etre* of many languages for specialized application areas is to allow the user to write his specialized jargon in a natural manner. Whereas he can certainly develop subroutines to accomplish what he wants, the ability to use his own terminology in a style natural to him is of paramount importance. It is normal that a person outside a particular area will find the nomenclature confusing or not understandable. All figures in this paper reflect this issue, i.e., the programs as written are generally not understandable to any reader outside the specific application area.

Personal preferences

It is unfortunate—but quite true—that in the development of one of these special-application-languages, the personal preferences of the developer have a significant effect, although they should of course be subordinated to the functional requirements and the vocabulary. For example, people who wish to have short data names and short statements in a language because

* The first is the functional capability.

they like that style may be forced into a different mode because the professional jargon of the field constantly uses long words. (In some systems, e.g., COGO, both short and long forms of key words are allowed to provide short cuts for experienced users.) The choice of a fairly rigid format versus a free form, or the selection of specific key words (e.g., READ versus GET) can sometimes make the difference between successful usage of the language versus constant unhappiness by the users. In some instances, people have strong views on punctuation and will change an existing language to eliminate (or include) punctuation in lieu of some other syntactic restriction. (It has been said facetiously that by choosing the correct subset of PL/I one merely has FORTRAN with semicolons.)

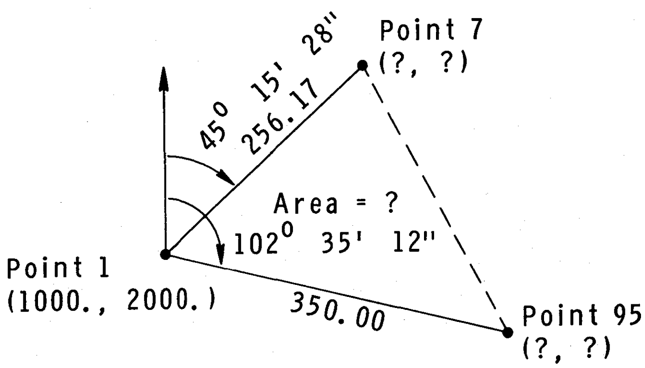
Background and past experience with specific equipment often have a strong personal influence. People who have used punched cards extensively tend to favor rigid formats with card columns used as syntactic delimiters. Those who have used on-line terminals generally tend to favor free form. Even in this latter case, there is considerable difference of opinion on the value of limiting each statement to the length of a single line.

The use of very simplistic styles, as illustrated in Figure 2, primarily consisting of a single key word at the beginning of a line, followed by some parameters, certainly forces one to reconsider the border line between programming languages and powerful macros. Certainly such a style is generally not "problem-oriented" which was described as one of the characteristics of a higher level language. However, such languages (e.g., COGO—see Figure 2) can be justified as higher level languages because of the distance of these operations from normal machine code. Thus, there is a large amount of information built into the compiler or the interpreter to perform specific functions which are directly related to an application (rather than merely enhancing normal machine code).

It should be emphasized that there is little or no way of determining which of two styles is better; in virtually every case it is a matter of individual taste, preference, previous usage, and jargon common to the application area.

Requirements affecting style

It should not be thought that *all* matters of style are arbitrary; some are influenced or forced by specific requirements of equipment—particularly the character set. In other cases, the intended use may affect the style of the language and environment will have a very specific effect. If the language is to be used in an interactive mode, it is pointless to be highly concerned about card columns. On the other hand, if the primary use of the language involves relatively simple statements and a large number of numeric parameters or data, then it may be most effective to orient the style of the language toward card columns.



```
STORE                 1     1000.       2000.
LOCATE/AZIMUTH   7    1      256.17     45 15 28
LOCATE/AZIMUTH  95    1      350.00    102 35 12
AREA                  1  7    95
PAUSE
```

Explanation:

Small COGO program for figure shown. In the figure above, given the coordinates of point 1, the length and azimuth (clockwise angle from north) of lines 1–7 and 1–95, the COGO program shown computes the coordinates of points 7 and 95 and the area of the triangle. In the program, the second line reads: Locate point 7 by going from point 1 a distance of 256.17 at an azimuth of 45 degrees 15 minutes 28 seconds.

Reprinted by permission from *Proceedings of the IBM Scientific Computing Symposium on Man-Machine Communications*, Data Processing Division, 320–1941, © 1966 by International Business Machines Corporation.

Figure 2—COGO (civil engineering)

In some instances, the style can be justified on fairly concrete grounds. For example, in situations where time is critical (e.g., command and control) there may be much more need for brief fixed formats with little flexibility. In other areas where documentation plays an important role, the desire may be for lengthy free form syntax which clearly conveys the meaning of the program to a large number of persons long after the program is written.

Efficiency

It is obvious that one of the reasons for developing these application-oriented languages is efficiency. This involves the efficiency which comes both from ease of writing the programs and from suitable processors.

One major way in which an attempt is made to increase efficiency is to delete unwanted parts of a major language while (perhaps) adding on the functional capability (in the form of new language elements). While the person or group which has a large language available to them is under no obligation to use all of its facilities, it is perfectly clear that they are paying for the implementation of these unwanted features. The common and obvious practical solution to this problem is merely to have a compiler which implements a subset of a language, and this is frequently done. However, to the extent that the individual or group wants to clearly define a certain subset of syntax and semantics and give it a name, he has in effect defined a new language. It is *not* true that all languages can have subsets properly defined, if a program written in the subset is also to run on a compiler for the full language.

The ways in which suitable processors can be obtained are discussed in the next section.

DESIGN PARAMETERS OF SPECIAL APPLICATION LANGUAGES

The design parameters of the languages for special application areas essentially reflect the needs which were discussed in the previous section. Thus, the functional capability, a style suitable for the application area, and efficiency are clearly design parameters. However, there are two additional issues which were not discussed in the previous section but which are very significant in the development of these languages, namely the methods actually used to design and implement the languages. It is well-known that those issues are important in the design of any language, but they are perhaps more significant in the languages within the scope of this paper because the intended users are not professional programmers and hence are less likely to be tolerant of unnecessary idiosyncrasies. In more general languages, some of the idiosyncrasies are (unfortunately) forced into existence by the methodology used for language design and/or implementation. Finally, it is possible to summarize the potential language requirements.

Methods of defining language

There are three basic methods for defining a language. The first is the most obvious—namely, a straightforward definition. In this instance, the individual or group merely sits down and writes out a definition of the language. Depending upon their sophistication and the complexity of the language, they may use something like Backus Normal Form, or alternatively may simply use ordinary English and examples. A special case of this method involves making specific changes to an existing language, which may involve addition, deletion, changes, or all of these.

The second method of defining a language is through an extensible language system. This is an area which has become increasingly important over the past few years, although there is not much evidence of practical systems or significant usage as yet (see Reference 1). In this situation, the developer of the language for a special application area is limited in two ways. First, he is limited by the inherent style and capability of the base language, and second, he is constrained by the mechanism given to him to produce the extensions. If the extension facilities do not allow new data types to be added, then he is limited to the syntax and functional operations of new commands. For example, any macro system (e.g., PL/I) tends to allow new commands and/or new syntax to be developed but does not provide for new data types. Alternatively, other extensible systems, e.g., IMP[8] allow for both new commands and new data types, but do not allow for major changes in language style or format.

The third method of defining the language is via some system. In this case, which seems to be the most important and the most promising, the user or application programmer states his wishes to a person who can be defined as a "language designer" who then interacts with a system which produces *relatively easily* a language definition which meets the needs of the original user or programmer. While many people have talked about this for years, relatively little has actually been accomplished—see a later section. In the long run, it is clear to me that we must allow the user ample facilities to easily define and implement his own language subject to whatever constraints and quirks he may have. The key word here is "easily" and that is the major difficulty in achieving the general goal.

Methods of implementation

Just as there are several different ways of defining a language, so there are different broad techniques for implementing them, and to some extent (but not entirely) they match the methods of defining the language. The first and most obvious method of implementation is a specific compiler or interpreter. This would tend to be used most often in a case where a language had been designed from scratch. Second, paralleling exactly the use of extensible languages is the extensible language compiler or equivalent facility. This method might conceivably be used with a language designed in another way, but it is highly unlikely to be applicable. A third possibility is a very powerful macro assembler which then allows the user quite a bit of flexibility in terms of jargon, lists of parameters, etc., but gives him virtually no flexibility in style and overall format. Finally, roughly corresponding to the user-defined language via a system, is a system which generates a compiler or interpreter. This method of implementation can be used even with the first case where the individual has designed and defined the language from scratch. The compiler generators that have been the vogue for many years come close to satisfying this requirement in theory, although none seem to do it in practice. (See a later section.)

TABLE III—Considerations in Language Design

Syntax

1. Form
   - Free
   - Fixed tabular, as in report writers or decision tables
   - Rigid with required parameters, i.e., essentially macro style
2. Punctuation
   - Critical with many symbols or not very significant
   - Blank character is critical delimiter or not significant
   - Single or multicharacter
3. Identifiers and Key Words
   - Single or few characters vs. lengthy
   - Abbreviations optional vs. not allowed
   - Specialized vocabulary
4. Full power of a language like PL/I (for systems programming)
5. Declarations—see under Data

Data

1. Types
   - Specialized to application, e.g., length
   - Many vs. few
   - Implicit vs. specifically declared
   - Determined by position in statement
2. Declarations
   - Grouped by attribute vs. grouped by data item
   - Implicit from other syntactic rules
   - Default conditions

Semantics

1. Specialized computational routines
2. Non-standard use of common characters (e.g., plus sign)

Program/Control Structure

1. Generally quite simple with no block structure nor compound statements
2. Very powerful (for systems programming)

Potential language requirements

A brief summary of requirements (or considerations) for potential desired language features is shown in Table III. Obviously, any one language will only use some of these. However, it is possible to find at least one specialized language which requires or uses each of these approaches or features.

SOME SPECIFIC APPLICATION AREAS WITH EXAMPLES

Almost all special application areas tend to look small and homogeneous when viewed from outside, but large and filled with differing problems and issues when

```
qu Who discovered America?
aa Ericson
ab Leif Ericson
ty Your answer would be accepted by some.
ca Columbus
ty Yes
wa Ponce de Leon
ty No. He looked for the "Fountain of Youth."
   Try again.
un bl
```

Explanation:

Example uses the aa and ab operation codes. If the student enters a response of "Ericson," or "Leif Ericson," the message "Your answer would be accepted by some," is typed to the student. After the aa or ab match, the system continues to scan statements until it finds the un statement. It then types the contents of buffer 1. If the student responds with an answer which does not match an aa, ab, ca, or wa statement, only the un argument (the contents of buffer 1) is typed to the student. The contents of buffer 1 might be, "Please try again." Using a buffer in this way saves the author from repeatedly entering the same text for many un statements in the course.

Figure 3—COURSEWRITER III
(computer assisted instruction)

viewed by those familiar with the field. A very good illustration of this can be seen merely by glancing at the papers on numerical control programming languages.[10] Even though one language—namely APT—predominates, there are still enough technical issues surrounding its utility and implementation to cause the existence of numerous other languages. In particular, 32 others are listed.[11]

In the field of computer-assisted instruction, there are over 30* languages utilizing different syntactic and conceptual approaches. Just glancing at Figures 3 and 4, for Coursewriter and FOIL, respectively, shows the wide variety of style, ranging from two-letter mnemonics to a PL/I-like language. A comparison of CAI languages can be found in Reference 23.

The situation in graphics is similar, but with another dimension of concept involved. In the computer-assisted instruction application area it can reasonably be argued that the application is unique and that there is little relevance to existing languages of somewhat wider purpose, e.g., FORTRAN, COBOL. (However, even in the CAI situation, the case can be made for the desirability of control statements, conditionals, and numeric calculations expressable by formulas as in FORTRAN.) In the field of graphic languages there is certainly a special facility that can be used by many applications (including, for example, computer-assisted instruction). The technical approaches and issues in graphics are as diverse as in other applications. In this case more of an argument can be made for providing the facilities as extensions to existing languages, e.g., GRAF,[5] which is an extension of FORTRAN. However, most developers went to the other extreme with entire new languages, for example General Purpose Graphic Language.[9] (See Figures 5 and 6, respectively.) Some languages take a middle ground by retaining some of the style of more popular languages, such as ALGOL or FORTRAN, but by no means accept compatibility with them as a constraint. (See for example Euler-G[12].) In each case the developer of the language was reflecting his view of how graphic information should be stored internally, and the most effective way in which it could be displayed and manipulated on a screen. In this application area, the physical environment plays a major role in the development of the language; thus the existence of lightpens, keyboards, push-buttons, etc., must be supported—if they are to be used by the graphic language.

```
TY WOULD YOU LIKE TO CONTINUE THE
  EXERCISE?
ACCEPT
    IF 'NO', GO TO FINISH
    IF 'YES, OK'
      NUM=NUM+1
      GO TO NEXT
    GO BACK PLEASE ANSWER YES OR NO
```

Explanation:

The TY causes the indicated typeout to be made. If the student responds with a NO there is a branch to a statement labeled FINISH. If either YES or OK are typed in the variable NUM has 1 added to it and control is transferred to the statement labeled NEXT. Any answer not including YES, NO, or OK causes the typeout from the system of PLEASE ANSWER YES OR NO and a return of control to the ACCEPT statement.

Source: Hesselbart, J. C. "FOIL- A File-Oriented Interpretive Language," *Proceedings of the 23rd National Conference of the Association for Computing Machinery*, 1968, p. 94. © 1968 Association for Computing Machinery, Inc. Reprinted by permission.

Figure 4—FOIL (computer assisted instruction)

SYSTEMS FOR DEVELOPING LANGUAGES FOR SPECIAL APPLICATION AREAS

It is unfortunate, but appears to be a fact, that there are no currently available systems which have actually been used in a practical way for the development of a *significant number* of languages (and their processors) for special application areas. It is not even

```
DISPLAY A, B, PDQ, POLE (11), K72A (7, 2, 4)
PDQ=A+POINT (0, XY2)+B
K72A(2, 1, 3)=PLACE (0, 1)+PRINT 13,
  (YY(I), I=1, 8)+PLACE (100, 200)
```

Explanation:

The names in the DISPLAY statement are display variables. PDQ is assigned the value which is obtained by first generating the graphic orders of A followed by the orders generated by the built-in function POINT, followed by the orders generated by B. Similarly, the value of K72A(2, 1, 3) is obtained by taking each of the graphic orders indicated in turn. The built-in display function POINT generates orders for plotting the point with indicated coordinates; the built-in function PLACE changes the beam position without plotting, and PRINT plots the indicated string of characters.

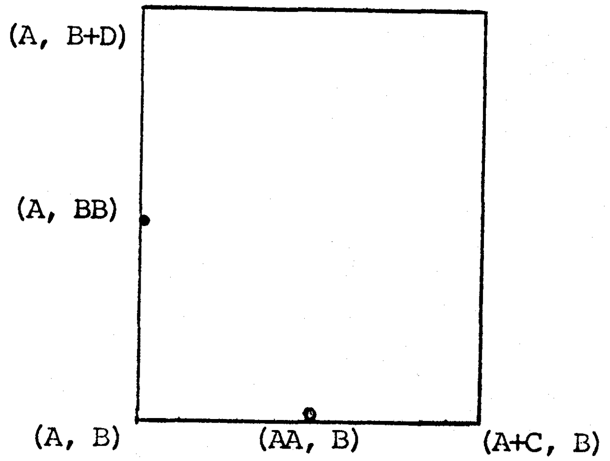
Figure 5—GRAF (addition to FORTRAN to do graphics)

* Not all of these are listed in Reference 18.

```
BEGIN WINDOW (A, B, C, D)
RECT (A, B, C, D)
AA=A+C/2
BB=B+D/2
LINE AA, B; AA, B+D
LINE A, BB; A+C, BB
END
```



Explanation:

A subroutine WINDOW is defined where A and B are the coordinates of one corner of a rectangle and C and D represent the horizontal and vertical dimensions. The subroutine to draw a rectangle is called and executed. The drawings of these windows are to have horizontal and vertical lines midway in the window so AA and BB compute the coordinates of the midpoints. The LINE commands cause the "midway" lines to be drawn.

Figure 6—General purpose graphic language

clear that any of the systems now in prototype stage will ever be satisfactory for that purpose. Virtually all of the systems known to the author have one or more of the following characteristics: (1) they require a compiler expert for their use; (2) they have been used to produce some minor variations on "normal" languages such as FORTRAN, ALGOL, etc.; (3) they are not *really* intended to be used to develop the types of languages discussed in this paper; (4) they give lip service—although little else—to the concept of allowing the average user to be able to define his own language and easily get a processor for it.

In theory, any compiler-compiler, meta-compiler or similarly designated system could be used for this purpose. However, there is a different emphasis in most of those developed to date. They have been designed primarily to provide an easy means of implementing known and widely used languages (e.g., FORTRAN, COBOL, ALGOL, PL/I) rather than as a tool for the development of new languages with uncommon requirements, and their processors. Thus the major considerations have pertained to efficiency of the resulting compiler, with an easy way to make minor changes in the syntax. A discussion of the past and potential use of such systems or translator writing systems in general is beyond the scope of this paper. A good survey is given in Reference 3.

Although no systems seem to have been widely, or even significantly, used for developing the types of languages within this paper, several have had limited use and/or have such intent for the future. A brief description of these will now be given.

(a) ICES

The Integrated Civil Engineering System (ICES) provides an overall system within which many language processors suitable for civil engineering can reside and use common facilities.[13] There is also the capability of allowing the user to define new languages, or add facilities to one of the existing languages. This is done by means of the Command Definition Language (CDL). Although CDL has not been used very much in practice, at least one language, namely STRUDL,[22] was developed using it. (A brief but relatively accessible summary of ICES, including CDL, is in Reference 14.)

(b) REL

The Rapidly Extensible Language (REL) System was (and is) intended for use by researchers in the fields of complex social and environmental processes.[20]

It has a powerful English grammar, thus permitting individuals to communicate with the computer in a fairly "natural" language. In 1970 an experimental system was in operation on the IBM System 360/50 and was used to develop an animated film language and also by some social scientists.

(c) PLAN

The Problem Language ANalyzer (PLAN) has many facets to it, but the only one of interest in this context is its facility to allow the user to define simple new languages in an easy manner.[6] A version providing graphics support allows the user to develop his language at an IBM 2250 and also provides him with many built-in graphics facilities.[7]

(d) UAL

The User Adaptive Language (UAL) is another attempt to provide a user with the ability to dynamically create and modify a language in an interactive mode.[4] This system provides the user with fairly sophisticated programming concepts (e.g., lists), but does not require him to use them.

(e) SDF

The Syntax Definition Facility (SDF) allows the user to define his language by means of illustrative sentences.[2] The system indicates whether the input is ambiguous or contradictory to earlier information. By late 1971, it had been used primarily to implement the syntax of fairly standard language subunits, e.g., arithmetic and Boolean expressions.

(f) Extensible Languages

All extensible languages should—in theory—be usable for creating specialized languages. By late 1971, none seem to have been used in this way. See Reference 1.

BRIEF COMMENTS ON THE FUTURE

It seems unfortunate but true that the proliferation of higher level languages is likely to continue at about the same rate. The reason for this is that some of the causes and motivations behind the development of these languages rest in quirks of human nature rather than technological progress or lack thereof. Thus, as long as people find it fun to develop languages, as long as they want something which is specifically tailored exactly to their needs, and as long as they are going to find picayune faults with the existing languages, there is very little that technical progress can do to reduce the number of languages. On the other hand, there are some areas in which improved technology will have an enormous effect. For example, the existence of good extensible language systems, or good systems which can easily generate a language and its translator based on appropriate input from a language designer, will have a considerable effect. We might even envision specialized language generators, i.e., a system designed to allow the easy creation and implementation of languages in a single application area, e.g., CAI, graphics. ICES[13] is a simple attempt in this direction for civil engineering.

In the opinion of this author, the ease and efficiency of using a language particularly suited to a specific application area is a desirable result which outweighs the disadvantages of the proliferation. A thorough discussion on the pressures and resources involved in the future development of these specialized languages is given in Reference 20.

SUMMARY

This paper has defined and discussed the class of languages which are designed for use in specialized application areas. These languages include about half of all higher level languages used in the United States at the time of this writing. A discussion of terminology showed why some of the commonly used terms for this class of languages are technically inappropriate.

The major needs to be met in developing these languages were shown to be functional capability, deletion of parts of an existing language, and a suitable style. Two specific application areas, namely CAI and graphics, were used to illustrate the existence of significantly different language styles within the same application area. Although there are a number of systems which purport to allow the user to easily define and implement his own language, and they are mentioned, none have actually been significantly used. A few brief comments on the future indicate that the proliferation serves a useful purpose and will continue.

The future of specialized languages

by F. B. THOMPSON and B. H. DOSTERT

California Institute of Technology
Pasadena, California

INTRODUCTION

The prediction of the future, like the review of the past, has as its sole usefulness, the organization and purposeful direction of the present. Thus, in situations where there is rapid change, as there certainly is in the field of computing, prediction—though more difficult—is all the more necessary. Suppose that you, as a computer specialist, are considering whether to design and implement a language for your own special application area or to consolidate your programming within the framework of a single, general language. You will certainly want your decision to be responsive to, though perhaps not dictated by, your perception of the directions computers and computing will be taking.

Our own perception concerning programming language development rests on two considerations. The first consideration is to understand the nature of the pressures that will bring about change. New languages for specialized application areas don't just happen; they arise because of a felt need, a dissatisfaction with trying to write programs for a specialized domain using programming languages not specifically tailored to that domain. Our first task, then, is to understand the essential nature of this need.

The second consideration on which our perception of future developments rests is to assess the technological and economic restraints and resources for change. Big computers, batch processing, and further professionalization of programmers will stimulate certain trends in programming language design; mini-computers, interactive processing, and widespread knowledge of programming will stimulate different trends. Thus, our second task will be an assessment of the major developments in hardware and software, and of the economic environment within which the pressures for change will be resolved.

These considerations should then put us into a position where we can bring into some focus what to expect in language development for specialized application areas. The past and current situation has been reviewed by Jean Sammet in *An Overview of Programming Languages for Specialized Application Areas.*[19] Our final task, therefore, is to identify the major trends these developments are likely to take in the future.

SOURCES OF PRESSURE FOR LANGUAGE DEVELOPMENT

In talking about languages for computing, we should first like to consider certain aspects of the nature of language. To do this it will be useful to develop an analogy between a language, on the one hand, and the design engineer's laboratory, on the other. Imagine yourself to be an electrical engineer designing a new computer central processing unit. As your design progresses, you and your team actually construct a model or "breadboard" out of flip-flops, amplifiers, "and" gates and other components. You wire these together often using clips rather than solder, because as you try out your design, you may wish to modify it as your breadboard model reveals unexpected relationships and possibilities for improvement. This model has a second important function: it expresses in a most articulate way the sum total of ideas contributed by the various members of the design team and is thus a vehicle for communication between them.

The design engineer's laboratory provides a great variety of basic components and the means of hooking them together into meaningful arrays. As the design proceeds, selection is made of certain components and they are built into combinations that express the functions that the designer wishes to execute. The same is true of a language. A language is based upon a great variety of basic concepts and its syntax is the means of hooking them together into meaningful arrays. As a programmer proceeds, he selects certain components, building them into combinations that express the functions that he wishes to execute. This then is the analogy between design laboratory and programming language we now wish to exploit.

Suppose you were called upon, as a computer specialist, to develop the configuration of a new computer for your installation. You would have to choose the main CPU, the size of high speed memory, what peripherals you would want, etc. Suppose you were told that the components you had at your disposal were diodes, resistors, capacitors and the like and that you had to build your computer installation from this point up. You would surely go about your job far differently than if you had been provided as building blocks the major pieces of computer equipment available from computer manufacturers. Consider these two situations carefully. If you had diodes and resistors you would have to be a different kind of engineer than if you had disk drives and printers to work with; your design would take considerably longer, and your expectation, design considerations and final output would be distinctly different. Our activities, the direction of our thinking, our efficiency, and our results are all greatly influenced by the basic components with which we must work and the means at our disposal for building them into more meaningful structures.

These same observations apply with equal force to the languages we use in dealing with our various problem areas. Language is the principal tool of our conceptual processes. And different styles of thought reflect and are reflected in the languages we use. Notice the correlation between artificial intelligence and LISP; engineering mathematics and FORTRAN or PL/I; operating systems programming and assembly language. This notion that language conditions the modes of thought is not new. Benjamin Whorf, the MIT chemist-turned-linguist, expresses the matter in the following words:

> *"We dissect nature along lines laid down by our native languages. The categories and types that we isolate from the world of phenomena we do not find there because they stare every observer in the face; on the contrary, the world is presented in a kaleidoscopic flux of impressions which has to be organized by our minds—and this means largely by the linguistic systems in our minds."* [1]

Whorf was referring, of course, to natural languages. But surely there is every reason to suspect that the programming languages we use will also have an effect on the kinds of problems and the character of the programs to which we apply the computer.

To illustrate this interdependence, consider the relation between languages and the kinds of management information systems that are currently in vogue. The original development of concepts for dealing with business data came at a time when punch cards and magnetic tape were the only large size repository for machine readable data. Thus the whole nomenclature of sequential files, fields, records, file update, report generation, etc., became an integral part of the language of data processing and the conceptual environment for the development of COBOL. Now we find that the inertia resulting from these common language concepts inhibits the acceptance of new systems based upon random access to data and time shared environments. A whole generation of programmers, information systems designers, and middle management people have come to think of systems for formatted file management and report generation as coextensive with management information systems, even though such systems are a travesty on what management wants and needs.

If Whorf's hypothesis is true, it can be turned around and applied in reverse. We, ourselves, build the artificial languages for programming computers. As language builders, we will have significant effects on those who use them. Thus, when we apply this Whorfian notion to artificial languages we ourselves can build, a new perspective opens up. The computer is a uniquely powerful instrument for conceptual design and structuring. The "special application" languages we provide are the major interface between the "designer" and this powerful design laboratory. The conceptual elements and syntactic tools made available to him cannot but influence the effectiveness, even the direction, his work will take.

Who is this "designer" in the case of the computer? He is the industrial manager who is seeking to direct the intricate interactions of product lines, production capabilities, markets and finance. He is the anthropologist searching for those causal laws of human behavior that lurk within his voluminous data on family relationships, vocational histories and patterns of ownership. He is the test engineer whose task is to chart the strengths and weaknesses of an aircraft wing from the thousands of data points of a destructive test procedure. He is the government agency head whose response to public need is dependent on his sensitivity to changing conditions as reflected in census statistics and spot surveys. Can we indeed say that all of these are well served by FORTRAN or PL/I? Is it not obvious that the basic conceptual elements of each of these diverse areas of computer application are themselves equally diverse, each with their own logical interrelationships and implicit assumptions? This logic and these assumptions can be built once and for all into the software support of a special application language. They can exist at that tacit level which is natural for the given application area and free the creative mind of the manager, researcher or engineer to build his programs on a conceptual platform appropriate and natural for his concerns.

We would like to illustrate this point by a reference to experience in the area of theorem proving on the computer. The resolution strategies of Robinson[2] and their refinement by a number of researchers has progressed to the point where interesting applications can be made to highly restricted areas such as the control of robots that move blocks.[3,15] However, application of theorem proving to problems of everyday business appears to be a long way away. One of the reasons for this is the necessity, if theorem proving is to give realistic results, to describe in specific axioms the very large number of tacit assumptions that are implicitly understood in these areas. Using explicit statements of these assumptions turns out to be very much more expensive in processing time than building them implicitly into heuristics and procedures. Think of the task of stating all of the tacit assumptions that underly just the personnel files of a modern business. But these same assumptions, known implicitly to the applications programmer, are built into the procedures for processing that data. To be sure, these procedures are specific to the application area. Indeed it is just such idiosyncratic procedures that become embodied as the interpretive routines of a language which is "natural" to such a specialized area. An example is the inclusion of efficient differential equation solving algorithms in applied mathematics systems such as NAPSS,[4] algorithms that are automatically invoked in response to natural syntax for the expression of such an equation. From there on, they are no longer conscious considerations in further program writing, or processed internally as axioms. They are now implicit, pressed down below the level of the explicit considerations of the researcher or manager who is using his own natural language. There are two advantages here. One is the advantage that accrues to the user in the efficiency of his language in dealing with matters that are directly of his concern. The second is the advantage in the underlying processing algorithms that make use of the underlying implicit assumptions of the domain. *These enormous economic advantages that the computer can thereby put at the fingertips of the specialist in his area are the true source of the pressure for special application languages.*

THE PRESENT RESOURCE ENVIRONMENT

When the computer was the scarce resource and programming was the domain of a small community of professionals—and indeed these conditions still residually apply—the powerful multipurpose language was the natural tool for man/computer communication. But this situation has been changing. We will examine four significant developments in this regard.

Training of computer scientists

In the first place, our universities are turning out a swelling stream of graduates in each of the various professions who, over and above their professional specialty, are also knowledgeable in computing. Our major schools, and even many smaller institutions, include as an integral part of their professional curriculum creditable courses in programming and computer systems. So far, most of these are limited to a few widely used algebraic languages such as FORTRAN. However, more and more, specialized languages are being taught: COBOL in business schools, LISP in psychology, SIMSCRIPT[5] in industrial management, various applied mathematics languages, such as NAPSS,[4] in areas of engineering, data analysis languages, such as SPSS,[6] in the social sciences.

More important than the large number of students taking these computing courses is that much smaller minority in the various disciplines who take the more advanced courses in the computer science curriculum. They go into their professional areas fully competent to bring to their disciplines the full power of the computer, and they are highly motivated to do just that. It is these cross disciplinary people who will spawn the new languages for their specialized application areas. They will know the conceptual elements and implicit logic essential to their substantive discipline and they will also know how to embody these within efficient programs and with linguistic sophistication reflecting their training in computer science.

Let's review a case history in this regard. Dr. Harry Markowitz received his doctor's degree in economics, concentrating in areas which required a high degree of knowledge of mathematics and computing. At the RAND Corporation his work involved the development of some economic models and their implementation on the computer. He then became one of the leading scientists in the RAND logistics project where he was instrumental in the development and application of simulation techniques. Subsequently Markowitz worked within the executive office of the General Electric Company, applying digital simulation to manufacturing and corporate problems. As he developed his simulation programs, his style and program organization became clearer and more modularized. Also, the scope of application of his work grew. Upon returning to the RAND Corporation, it was natural for him to distill from all of the various simulation programs he had written and supervised, a general technique that was widely applicable. The result was one of the first and still one of the best discrete simulation languages, SIMSCRIPT.[5,20]

The number of such able, interdisciplinary people need not be large to make a significant impact, and both the number and quality are growing.

Advances in hardware

The second development we would like to cite is in the hardware area. The price of computers and peripheral equipment continues to come down. There will, of course, always be the super-jobs which can utilize unlimited amounts of computer time. However, as computer costs drop, not only is the market widened, but the experienced user can afford to shift more of his task onto the computer and thus demand that the computer do more for him. One form of this extra service is to move the man/machine interface closer to the man. One of the principal ways this can be accomplished is through the development of languages that are more natural for the various application areas.

However, more significant than the general downward trend of cost per cycle time is the advent of the mini-computer. Many project teams in industry, in the university and other research institutions, in all walks of life are now finding they can afford their own computer. Up to now the main market for mini-computers has been in areas of process control or in connection with special input devices and sensing equipment. Those applications of computers which are not tied directly to special sensors or control devices but which require complex application programs have tended to gravitate to central computing centers with their large programming staffs and facilities for batch processing the many debugging runs that characterize application software development. But the cost advantage of one's own mini-computer which avoids the growing overhead costs of the big computer centers will tend to reverse this. A preliminary look indicates that very high level conversational languages can be implemented as dedicated mini-computer systems.

The development of effective programming languages for specialized application areas can be instrumental in the opening up of sizable markets for the mini-computers. As these versatile devices are brought to bear on the sophisticated problems of competent professionals, with their small group of captive programmers, we can again and again expect to see the evolution from special application programs, to module libraries, to monitors, to special application languages. Once such languages are developed, they stimulate similar installations elsewhere. The heavy attendance at specialized area sessions at computer conferences attest to the interest in learning about just such developments. Because of the low cost and considerable capability of the mini-computer, one can expect a general shift toward single user installations with a corresponding increase in independence and innovation. The result cannot help but have a considerable effect on the development of languages for specialized application areas.

Developments in systems programming

The third general area of development is that of systems programming of which extensible programming language research is a part. Here the rapid growth of interest and importance of extensible programming languages is a key development that will have a profound effect on the proliferation of specialized application languages.[21] To see this, one needs to be aware of the nature of the problems that those working in the area of extensible languages are attacking. The deep problems of this domain have to do with the building of optimizing compilers. It is no great trick for the experienced systems programmer to build a programming language that provides for complex structures declarations, at least when he can implement these without consideration of run time efficiency or storage management. The real problems are how to achieve optimization of both storage and computing efficiency. Important inroads into this difficult and central area are being made. We cite, for example, the work of Cheatham and his group at Harvard.[7]

As work progresses on extensible programming languages, one of its primary applications will surely be to the definition of higher and higher level languages, languages that include more and more implicit structural logic, indeed languages that fit closely the specialized needs of significant application areas. The ability to produce such languages efficiently and at the same time to retain reasonable levels of optimization in the actual encoding provides a powerful tool for specialized language building. These specialized application languages need not be limited to domains outside computer science. The language Planner, developed by the Artificial Intelligence Group at MIT,[8] is an excellent example of such a language to be used by computer scientists themselves. In this case it is built on LISP which is surely an example of an extensible language.

Science of linguistics

The fourth area of development is linguistics itself. We are indeed learning more and more about the structures of languages and the underlying reasons why language is such a powerful tool for conceptual structuring and communication. In particular, we are rapidly gaining sufficient knowledge of the mechanisms of natural language so that useful segments of natural language can be understood and responded to by the computer. Our own work on the REL system is a good example of where this is being successfully accomplished.[9,10] In our system, we combine results from recent work in theoretical linguistics, namely modern deep case grammar as developed by Fillmore,[11] with an efficient application of the notions of syntax-directed compiling. We believe we are only a very few years away from an English driven system for conversational data analysis with levels of efficiency that will markedly improve upon present formal language batch systems. Another system, that of Terry Winograd at MIT has demonstrated the ability to control intelligently the complex behavior of a robot in response to directions given in a comprehensive subset of natural English.

The importance of these types of systems does not lie in some magical quality of "English." There is a rather general understanding by computational linguists working on actual systems that "natural" languages are full of idiosyncratic notions and expressions that derive from the particular domain of discourse for which they are adapted. What is important about this natural language research is not the vocabulary, which is surely not a universal of the native fluent speaker. Rather the important insights from this research concern syntactic mechanisms and their interaction with semantics. We have referred to the need in a language not only for the right conceptual elements but for a sufficiently powerful syntax that will allow the efficient expression of interrelationships, as indeed is found in natural language.

Natural language has a variety of powerful mechanisms for combining conceptual elements. Ambiguity is an excellent example. Usually, when ambiguity in a language is mentioned, one thinks of ambiguous sentences. However, consider how ambiguity is involved in phrases, i.e., segments of sentences. In the phrase:

"the computer just moved into the laboratory"

the words "computer," "moved," and "laboratory" are essentially all ambiguous when standing alone in that they do not designate a unique piece of equipment, action or location. The phrase "moved into the laboratory" also could be used in many contexts where it would have quite different meanings. However, the above phrase, when taken as a whole and in context is not ambiguous at all. This ability to use general nouns and verbs in such a way as to balance off their ambiguous referents to achieve in a parsimonious way a totally unambiguous description is a powerful and ubiquitous tool of natural language, and one that is not difficult at all to include in computer languages where the context is delimited to a specialized application area. Thus, work on natural language will indeed go far in providing both understanding and specific techniques for building specialized application languages with sufficient expressiveness to truly serve as effective design laboratories for conceptual structuring.

Our growing knowledge of computational linguistics goes beyond knowledge of natural language to all areas of language communication. In particular in the domain of graphic languages and man/machine communications using graphic consoles, specialized man/machine communication languages have been and surely will increasingly be developed.

The rapid growth in linguistic knowledge will stimulate advances beyond the immediate effect of more effective computer languages and language systems. When a domain of human knowledge expands as linguistic knowledge is expanding today, it has far reaching consequences. The simulation of more effective systems built upon these new linguistic insights, insights that span from English syntax to psycholinguistics and the mechanisms of language acquisition, cannot help but be great. And greater understanding has always led to higher degrees of specialization, specialization that spells efficiency.

TRENDS IN PROGRAMMING LANGUAGES

The pressures and developments discussed in the previous two sections give evidence that programming languages for specialized application areas will continue to proliferate. Moreover, they imply several more specific trends. We shall identify and examine several of these.

As knowledge of linguistics grows and the application of computers to specialized areas continues, we realize that our old algebraic languages—FORTRAN, ALGOL, PL/I—are really quite special purpose after all. Certainly there is a need for good algebraic languages in physical science and engineering. However, other language developments, for example LISP, have already demonstrated the need for programming languages with quite different characteristics.

The attempt to include in PL/I a wide range of data structure declaration capabilities has led to an interesting and perhaps significant development. PL/I has not replaced FORTRAN for writing special application programs. It does appear that it is being used by some systems programmers and by programmers who are writing languages for special application areas. The problem with using PL/I for these systems programming purposes is that the resulting code is not sufficiently optimized. But it is exactly in this area of optimizing compilers that progress of the greatest importance is being sought in extensible language research. The confluence of these developments will lead to a movement toward powerful system programming languages of the extensible type. They will be based upon our increasing understanding of the nature and importance of data structure.

The advent of these systems programming languages will mean that we will have greatly increased ability to create languages that are carefully tailored to the conceptual and structural needs of specialized areas. The mini-computer, the computer utility and the general lowering of computing costs are creating a ready market for such language developments.

Thus we foresee that systems programmers will be turning away from their traditional preoccupation with the architecture of, and compilers for, classical algebraic programming languages. System programming will turn more of its attention to the efficient implementation of a much wider class of language mechanisms and the building of these mechanisms into a far more diverse family of application languages. These developments will obviously be greatly influenced by the spreading acceptance of conversational, interactive computing.

A second major trend will be toward natural language systems. We emphasize that by natural language we do not mean the general English of some mythical native fluent speaker. By natural we mean computer languages which reflect the conceptual elements and the syntax of the application areas in which they are employed. These languages will be specialized languages, idiosyncratic, reflecting the physical as well as the conceptual environment in which they are to be employed. For example, they will be influenced by the kinds of terminals or displays to be used, whether they refer to very large files of data, whether the application area naturally employs advanced mathematics, the interactive reaction times required, etc.

There are two technical characteristics, however, which many of these languages for specialized application areas will share. First they will tend more and more in the years ahead to be problem definition languages rather than procedural languages. The distinctions between problem definition languages and procedural languages is extensively discussed in the computer science literature without definitive conclusions.[12] Thus it will do no harm if we add to that discussion a distinction that we feel to be an important one. A procedural language talks essentially about the computer; statements in such a language are instructions to the computer about what it is to do. A problem definition language talks essentially about the domain of application; statements in such a language either describe, ask for descriptions or direct the computer concerning the subject matter of the application. It appears to us that higher level languages and languages for more highly specialized languages tend to be closer to problem definition than to procedural languages. We feel that there will be an increasing trend toward problem definition languages.

The second technical characteristic that we foresee is a trend toward natural language syntax. English as a programming language has been discussed for a good number of years and often fervently wished for but thought of as something for the distant future.[13,24,22] Through these same years solid progress has been made—in theoretical understanding of linguistic structure, in computational linguistic practice, and toward operational English language systems.[9,10,15,16,17] Pragmatic work on machine translation has been showing practical results,[18] contrary to some expressed opinions. As a result, the next few years will see operational systems for specialized areas where the structure of the language is closely related to our native English. Once this capability has been conclusively demonstrated, prejudice against it will be forgotten and we will make use of the powerful syntactic mechanisms of natural language in many application areas.

SUMMARY

Return for a final look at the Whorfian hypothesis, that language shapes the thought and culture of those who use it. As we develop powerful systems programming languages for application language development, as we incorporate the power and expressibility of natural language syntax into our application languages, as the economic costs of hardware and language software come down, and particularly as our rapidly expanding knowledge of linguistics continues to grow, a new dimension in artificial language development will come into being. We will recognize that language design is a powerful means of direction and control. The tasks of professionals can and will be directed by the languages they must use in communicating with their computers.

AMBUSH—A case history in language design

by STEPHEN WARSHALL

Applied Data Research, Inc.
Wakefield, Massachusetts

INTRODUCTION

AMBUSH is a language in which the user can describe a materials-processing/transportation network in an allegedly readable form. The AMBUSH Compiler transforms this description into a set of linear equations and inequalities and edits this set into an input file for a linear programming package.

Although the language is powerful enough to handle both materials-processing and transportation, its design is heavily biased toward processing, with transportation expected to appear only occasionally, around the "edges" of the network. Thus, a typical subject for AMBUSH description might be a very complex oil refinery with a few arcs representing transport of crude oils into and final products out of the refinery.

AMBUSH was designed by Applied Data Research for the Shell Oil Company, to facilitate the preparation of very large linear programming problems. This project followed a long history of experimental language design by Shell and its contractors, which had yielded a very valuable crop: Shell was able to summarize, fairly confidently and economically, the set of meanings to be expressed. The present language is the result of collusion (and sometimes collision) between Shell's body of experience and ADR's background in language and compiler design.

AMBUSH, as actually designed and implemented, represents a conscious compromise between two styles of language design: the "template" style, with a large set of different statement types, corresponding roughly one-to-one to the kinds of utterances the user is accustomed to; and the recursive style, in which the designer hunts for a minimal number of logical primitives sufficient to express all meanings and devises the shortest (in number of types) and most highly recursive grammar possible for combining the primitives. This stylistic tension and, indeed, the historical sequence from pure template languages toward more recursive ones exhibited in the AMBUSH project are, we believe, common characteristics in the development of languages for new problem areas.

Whenever any body of informal discourse about a subject is analyzed in order to create a formal language for saying the same things, the primary effort is concentrated on verifying that the formal language under creation is complete—that one can express every meaning—with little concern for ease of use or its close relative, grammatical simplicity. The first requirement is met by letting the language arise from, and comparing it to, a large body of utterances in the informal discourse. The loom of this body of utterances generally causes the second criterion—essentially that of linguistic "goodness"—to be quickly reinterpreted to mean superficial similarity to the informal language. Forms in the slowly developing formal language are adjudged good insofar as they "look like" the corresponding forms in the informal one. This perfectly natural criterion generally leads to first-cut designs which, although very valuable (for they effect the desired formalization), usually exhibit certain characteristic properties:

a. A syntax which is "broad" rather than "deep." By this we mean that they tend to have a large variety of different, special syntactic forms—each aping a familiar English one—rather than a small number of forms and a small set of rules for recursively combining them.
b. A proliferation of reserved identifiers, each of which once again apes a commonly used word in the informal language, even when several of these identifiers may be logically identical in function.
c. Extremely rigid format requirements, which mechanically copy the forms in which informal information is currently expressed.

These properties tend to characterize languages which, however easy to read, are very difficult to learn to write in, since each type of utterance has its own special construction rules and its own reserved identifiers; difficult to compile, since the grammars are so broad; and difficult to extend, since the grammars are so non-uniform and format-controlled.

It has been our general experience that a first-cut language design should be viewed as a formal characterization of the class of required utterances, rather than as an end product. What is required next, of course, is a redesign embodying deliberate infusion of the recursive style. The ever-present danger is the obvious one of going too far: users are willing to change their habits only so much, and a language which demands a complete reorganization of their styles of thought and expression sets an unacceptably high price, for perfectly understandable reasons.

In this paper we do eventually present a skeletal grammar of the AMBUSH language, as it was actually implemented. Our primary purpose, however, is not to describe a language. Rather we intend to treat the AMBUSH project as a case history of the language design process, which may give substance to our general remarks about the shift from template to recursive style.

We begin by summarizing how an engineer thinks about his model of an oil refinery: the appearance of his graph, the kinds of assertions he makes about flow in the graph, the packages of information he thinks of as single elements of model description. We then describe, in general terms, the structure of languages in the template style for expressing the engineer's meanings. Next we reexamine the engineer's utterances from the point of view of a designer in the recursive style, concerned with logical minimality and searching for opportunities to shorten the grammar by the use of recursion. In this last section, the general outline of the final grammar of AMBUSH takes shape. Then we present that grammar, so that the reader can verify our claim that AMBUSH is indeed a compromise: a language basically in the recursive style, but with elements of the template style still remaining, to render it more familiar-looking, and thus more palatable, to the user.

HOW THE ENGINEER DESCRIBES HIS MODEL

The directed graph

An engineer conceives of his model as a directed graph (with no self-loops), with labels on the nodes and arcs. [The bracketed examples in this paragraph refer to the figure in Appendix I.] The nodes of the graph are labeled with the names of the processing units of a plant or refinery, or the staging points of a transportation network ['EGG.PLANT,' 'BLEND.UNEX,' 'DEPOT']. The arcs of the graph represent the paths of flow of the various materials in the model. Each arc is a path for exactly one material and is labeled with the name of that material ['Exotic Liquid,' 'Unexciting Prod.']; if several materials flow from one node to another, there will be several "parallel" arcs (arcs with a common head node and a common tail node) between the nodes [Universal Solvent and Residue both flow from ICE.PLANT to BLEND.UNEX]. Node names are unique (no two nodes bear the same name), while arc names are not (several arcs may bear the same name: the same material may flow in numerous arcs of the graph [Residue flows from ICE.PLANT to BLEND.UNEX, to TRUCK, and to DEPOT1, and from DEPOT1 to DEPOT2]). Parallel arcs *must* have different labels: that is, there can be but one arc carrying a given material from a given node to a given other node.

Thus, an arc of the graph is completely specified by an ordered triple of names: ⟨node name, arc name, node name⟩.

The variables of the model correspond to the arcs of the graph or, more precisely, to the flow along the arcs. That is, the engineer states his restrictions on the model and his costs in terms of flows on arcs, and seeks an optimal solution stated in terms of flows on arcs.

The arcs of the graph will become the columns of a conventional LP matrix; the restrictions on the model will become rows of the matrix; and the various costs incurred in the model will become the objective function(s) of the matrix.

Restrictions on flow in the graph

Material balance

In general, at every node of the graph which possesses both inputs and outputs, the engineer wishes to relate the various flows entering to the flows leaving the node. These relations are conventionally expressed, in the LP matrix, as a set of "material balance equations" (rows). Each equation expresses the total amount of a single material flowing out of a node as a linear expression in the flows of the materials entering the node. The coefficients of such an expression are called "yield factors," and the engineer thinks in terms of these yield factors. It is important to note that a single material balance equation, while a natural element (a single row) of the LP matrix, does not necessarily correspond to a natural single utterance for the engineer. He may, for example, refer to a handbook of standard processing units which contains an array (inputs vs.

outputs) of yield factors, each of whose columns corresponds to a single equation; or an array of outputs vs. inputs, with rows corresponding to equations; here the entire array corresponds to a single utterance for the engineer. On the other hand, the engineer may assemble his description of material balance at a node from several sources, each of which supplies a few yield factors—each factor associated with an input/output pair—in no particular order. In sum, the engineer's natural utterance is an arbitrary subset of the yield factors at a single node, or a complete array of these yield factors organized in either of two ways.

Quantity restrictions

The engineer may set a limit (maximum, minimum, or fixed amount) on the total flow through a set of arcs. Each such restriction becomes a row of the LP matrix. It is noteworthy that the set of arcs in a single restriction is not at all arbitrarily chosen, but is always either a subset of the arcs entering a single node or a subset of those leaving a single node. This limitation imposes no logical restriction on the engineer, for he can always introduce further arcs and nodes so as to create a set of input arcs to a single node (or even a single arc) whose flow will be precisely equal to the sum of the flows in an arbitrary set of arcs. The point here is not that a certain kind of arc set is logically sufficient, but rather that it is the only kind that the engineer in fact uses as a domain for quantity restrictions.

"Quality" restrictions

The engineer may set a limit on the value of some physical property for the mixture of the flows on several arcs. For example, three arcs might carry three different materials each with a certain specific gravity. The engineer wishes to restrict the relative flows on the three arcs so that the specific gravity of the total flow satisfies some limit (maximum, minimum, or fixed value). If we denote the flows in the different arcs by f_i and the respective specific gravities by g_i, the engineer is setting a limit on the value of $\sum_i f_i g_i / \sum_i f_i$. Once again, as with the quantity restrictions, the set of arcs is always either a subset of the arcs entering, or a subset of the arcs leaving, a single node.

Ratio restrictions

The engineer may set a limit on the ratio of the total flow in one set of arcs to the total flow in another set of arcs. Again, it is a feature of user behavior that the union of the two sets of arcs referenced in a single ratio restriction is always a subset of the arcs entering or a subset of the arcs leaving a single node.

Cost and income

The engineer may wish to state that flow along certain arcs incurs cost or generates income. Eventually, all his remarks of this kind will become the objective function of the LP problem, a linear expression in flows on arcs which is to be minimized. The engineer's typical utterance does *not* correspond to an entire objective function, but rather to the supply of a single coefficient value for the objective function; such a coefficient value may apply to one arc or to a set of arcs: thus, the engineer may say, in effect, "flow on any of *this* set of arcs costs $3.50 per unit flow." It is no serious distortion of user behavior to say that the set of arcs to which a single cost/income coefficient applies is always either a subset of the arcs entering, or a subset of the arcs leaving, a single node.

TEMPLATE-STYLE LANGUAGES

Even from the rather brief picture given above of the engineer's view of his model, it should be clear that he has a fairly large number of different—or what he believes are different—kinds of things to say. He must be able to describe a graph, supply a set of yield factors, supply an array of yield factors in input/output form, supply the array in output/input form, state quantity restrictions on the output side of a node, or the input side, assign cost to an arc, assign income to an arc, and so forth.

It is important to note that, although the difference between some two elements of this list may seem quite trivial to the reader (input/output form versus output/input form of an array of yield factors, for example), the difference may look enormous to the engineer, who obtains the two kinds of information from different sources, uses them in different modeling contexts, and discusses them in a different vocabulary. In our effort to summarize the engineer's utterances concisely, we have made use of logical similarities between utterances which might, to him, look quite different. Thus, in our description of quantity restrictions, we took advantage of the fact that to set a quantity maximum is not unlike setting a quantity minimum. In some real problem, however, all the maxima may come from physical limitations (pipeline capacities, say), while all the minima may reflect business obligations (requirements to buy at least so much from various suppliers). The engineer in this situation is not working with maxima and minima (which even *sound* similar) but with capacities and obligations, which he may customarily treat with quite dissimilar vocabularies.

A common characteristic of the early language designs for the description of these models was a strong tendency to preserve, more or less uncritically, the many logically empty distinctions between "different kinds" of information. Thus, such a language would typically consist of a large number of dissimilar-looking templates, composed of reserved words; each template would correspond to one of the different kinds of information, and the reserved words would guarantee a familiar-looking quasi-sentence appropriate to that kind. The holes in the templates were to be filled with nothing more complex than lists of numbers or lists of names.

It would be grossly unfair to early workers in the area to suggest that the number of templates in any real language design was anywhere near as large as completely uncritical acceptance of the engineer's discriminations would have implied. Considerable, and quite fruitful, effort was devoted to the reduction of this number to even more manageable limits. Nonetheless, it *is* fair to say that even the latest of the pre-AMBUSH languages retained all the stigmata of the template approach:

a. An extremely broad and shallow grammar: a very large number of syntactic types at the "statement" level, with almost no phrases in common (above the level of name list or number list).
b. A very large number of reserved words.
c. Inconsistencies of lexical style: the use of punctuation marks as separators when the templates were to look sentence-like, the use of spaces or position-on-card to delimit symbols if the templates were to look like arrays.
d. Prefix characters to signal statement type: since the templates possessed little or no common phrase structure, the analyzer was likely to consist of many essentially independent recognizers entered through a common switch and thus a prefix character was required to control the switch.

ANOTHER LOOK AT THE ENGINEER'S UTTERANCES, BY DESIGNERS IN THE RECURSIVE STYLE

Reduction in variety of user's statement forms

Let us set aside for the moment the problem of specifying the structure of the graph itself, and confine our attention to those of the engineer's utterances which include numerical information—these are the statements of restrictions or remarks about cost and income. The most striking fact about these numerical assertions is that each concerns an extremely small portion of the whole graph. Thus, a remark about material balance always talks about a subset of the arcs entering or leaving a single node; and the other numerical assertions only refer either to a subset of the arcs entering, or a subset of the arcs leaving, a single node.

This immediately suggested the possibility of turning the language "inside out" in the following sense: instead of having one statement type per "kind of information," each containing its subgraph specification after its own fashion, we could have a far smaller number of statement types, one per kind of subgraph, each containing the kind-of-information specification in a more uniform fashion. This inversion had several attractions:

a. It dropped to a lower syntactic level the vast array of special forms, with their reserved words and need for special recognizers; above this level, phrase structure could be quite simple and uniform.
b. It simplified the job of persuading the user of the logical emptiness of many of his discriminations; if the template for pipeline capacities looks completely different from that for purchase obligations, with reserved words scattered non-analogously throughout the two forms, it is hard to convince him that they are logically similar; if, however, he sees the differences entirely embodied—reserved words and all—in two short phrases which fit in exactly the same larger structure, he becomes far more willing to drop the reserved words for his 10 different kinds of quantity restriction and simply say "maximum" or "minimum."
c. It became trivial (indeed, almost inevitable) in grammar design, and very palatable to the engineer, to take advantage of the symmetry between the inputs of a node and its outputs. The syntactic type for discussing the one could look identical to that for discussing the other, to within a reserved word or two.
d. It suggested some interesting possibilities of nested information. The engineer frequently had several things to say about the same subgraph, or about two subgraphs, one of which was a proper subgraph of the other. We could perhaps arrange our grammar to permit him to nest his subgraph specifications, and to associate with each nesting level a *set* of (say) restrictions.

The redundancy of graph specification

A notable feature of the numerical assertions described above (the restrictions and income/cost utterances) is that, whether they be written in engineer's jargon, some template language, or in some new, recursive language, they inevitably contain information about the structure of the graph. This is perhaps obvious, for—as we have earlier indicated—every numerical assertion must contain a specification of the subgraph to which the assertion applies.

Thus, to say that the maximum amount of M flowing out of A is less than five surely suggests that the graph contains a node named A with at least one arc labeled M leaving it. Every numerical assertion contains some such topological information, and the set of such information collected from all assertions appeared to yield a fairly good picture of the overall shape of the graph. Initially, this redundancy was expected to provide a check: the topological implications of each assertion might be verified against a previously given graph description.

Then a further observation was made. A very large number of the nodes in a graph did not represent either processing units or staging points, but were essentially formal: they represented "pools" of intermediate products. Within a model, the engineer deals with two kinds of materials: the "pooled" ones, like intermediate products in a refinery, such that any consuming node can obtain them from any producing node; and the non-"pooled" ones, like raw materials and final products, which flow from each producing node to certain consuming nodes, and no others. For each pooled material, the engineer establishes a single pool represented by a node, with arcs to the node for each producer and arcs from the node for each consumer.

Moreover, since our user population modeled very large refineries with only a small amount of transportation at the edges of the graph, it turned out that virtually all materials in a typical model were of pooled type. This implied that, if we required the user to declare explicitly his non-pooled materials (which should be but a small burden, for they were not numerous), the Compiler could draw far stronger topological inferences from his numerical assertions than we had originally thought. Thus, from the example given earlier in this section, one can deduce not only that at least one arc carries M out of A, but—if M is pooled—that the arc must go to the pool for M and must be unique (since parallel arcs must have different labels).

This analysis led to the conclusion that the set of topological implications contained in all the engineer's numerical utterances amounted to a virtually complete description of the graph, and thus separate statement types designed for graph specification were quite unnecessary. True, there might be an occasional piece of graph left ill-defined after the numerical statements were written, but our statements for making numerical assertions were going to incorporate the specification of little subgraphs to which a set of numerical remarks would apply. If we simply permitted these types to contain an empty set of numerical remarks, we would have a mechanism for describing little subgraphs, thereby filling in the holes in the graph definition. (The fact that this degenerate form would be inappropriate for describing a whole graph was entirely irrelevant.)

THE GRAMMAR OF AMBUSH

The grammar of AMBUSH derives directly from the observations of the preceding section. There is no statement type intended exclusively for graph description; there are three statement types for making numerical assertions, differentiated semantically by the kinds of arc set (subgraph) they discuss:

a. The YIELDS statement, for discussing the inputs and outputs of a node; this is used exclusively for the supply of yield factors.
b. The SENDS statement, for discussing subsets of the arcs leaving a node; this is used for all numerical assertions except the supply of yield factors.
c. The TAKES statement, for discussing subsets of the arcs entering a node.

(Note: In this section, we have permitted ourselves the liberty, in stating our rules of grammar, of using, without definition, the types ⟨identifier⟩ and ⟨numex⟩, which latter type corresponds to "numeric expression.")

The YIELDS statement

Grammar

```
              ⟨row⟩::= ⟨identifier⟩, ⟨numex⟩ | ⟨row⟩,
                       ⟨numex⟩
         ⟨row list⟩::= ⟨row⟩ | ⟨row list⟩, ⟨row⟩
        ⟨name list⟩::= ⟨identifier⟩ | ⟨name list⟩,
                       ⟨identifier⟩
⟨yields statement⟩::= ⟨identifier⟩ RUNNING
                       ⟨name list⟩ YIELDS
                       ⟨row list⟩ | ⟨identifier⟩
                       YIELDS ⟨name list⟩
                       RUNNING ⟨row list⟩
```

Examples

```
a. U YIELDS          S1,  S2,  S3
   RUNNING      S4,  .1,  .4,  .5,
                S5,  .6,  .1,  .1
b. U RUNNING         S4,  S5,
   YIELDS       S1,  .1,  .6,
                S2,  .4,  .1,
                S3,  .5,  .1
c. U RUNNING    S1 YIELDS S2, .4, S3, .5
```

Discussion

It should be clear from the first two examples (which are identical in meaning) that the grammar has been designed to facilitate supply of a large array of yield factors in either input/output or output/input form. The more "linear" style, exhibited in Example c, for the supply of a few yield factors, is identical grammatically to the array style.

It should be noted that the grammar demands that the set of yield factors supplied in a single statement always correspond to some array (the cross product of a set of inputs and a set of outputs), however small. This requirement is made less troublesome than might appear, for the Compiler systematically fails to distinguish between a yield factor of zero and no yield factor at all. Thus, the engineer can, for example, write one statement to cover all but one of the yield factors at a node (representing the missing one by zero) and a second statement to supply the omission.

The SENDS statement

Grammar

a. Modifier

```
            ⟨limit⟩::=MAX | MIN | FIX
           ⟨qlimit⟩::=QMAX | QMIN | QFIX
             ⟨cost⟩::=COST | COST0 | COST1 |
                       . . . | COST9 |
                       INCOME | INCOME0 |
                       INCOME1 | . . . |
                       INCOME9
  ⟨quantity phrase⟩::= ⟨limit⟩ ⟨numex⟩
   ⟨quality phrase⟩::= ⟨identifier⟩ ⟨qlimit⟩
                       ⟨numex⟩
     ⟨ratio phrase⟩::= ⟨limit⟩ ⟨numex⟩
                       ⟨stream/node factor⟩
      ⟨cost phrase⟩::= ⟨cost⟩ ⟨numex⟩
         ⟨modifier⟩::= ⟨quantity phrase⟩ |
                       ⟨cost phrase⟩ |
                       ⟨quality phrase⟩ |
                       ⟨ratio phrase⟩
```

b. SENDS Statement

```
    ⟨stream/node factor⟩::= ⟨identifier⟩ |
                            (⟨stream/node
                            expression⟩)
      ⟨stream/node term⟩::= ⟨stream/node
                            factor⟩ |
                            ⟨stream/node
                            term⟩,
                            ⟨modifier⟩
⟨stream/node expression⟩::= ⟨stream/node
                            term⟩ |
                            ⟨stream/node
                            expression⟩,
                            ⟨stream/node
                            term⟩
          ⟨sends clause⟩::=SENDS
                            ⟨stream/node
                            expression⟩ TO
                            ⟨stream/node
                            expression⟩ |
                            SENDS
                            ⟨stream/node
                            expression⟩
       ⟨sends statement⟩::= ⟨identifier⟩
                            ⟨sends clause⟩
```

Examples

a. Modifier

1. MAX 50
2. SPEC.GRAV QFIX .75
3. MAX .5 (M_1, M_2)
4. COST3 −3.50
5. INCOME3 3.50

b. SENDS Statement

1. U SENDS A, MAX 50
   The maximum quantity of A output by U is 50.
2. U SENDS (A, MAX 50, MIN 40, B, MAX 50), COST 3.50
   The maximum quantity of A output by U is 50.
   The minimum quantity of A output by U is 40.
   The maximum quantity of B output by U is 50.
   A cost of 3.50 is incurred per unit of either A or B flowing out of U.
3. U SENDS (A, MAX 50, MIN 40, B, MAX 50), COST 3.50 TO X, MAX 10, Y, MIN 10
   All the meanings included in Example 2, plus:

The total flow of A or B from U to X has a maximum of 10.

The total flow of A or B from U to Y has a minimum of 10.

4. U SENDS A, B TO X

   This example includes *no* numerical assertion, and is thus "degenerate." It informs the Compiler that there is one arc carrying A, and another carrying B, from node U to node X.

5. U SENDS A, MAX .5 (B, C, MIN 10)

   The minimum quantity of C output by U is 10.

   The quantity of A output by U is nc more than .5 times the total quantity of B and C output by U.

Discussion

The four varieties of modifier correspond to the four kinds of numerical assertion (other than supply of yield factors) covered in earlier sections: quantity, quality, and ratio restrictions and income/cost assertions. The large number of reserved words in the definition of ⟨cost⟩ derives from the desire of the user to define several objective functions and from his preference *not* to treat an income as a negative cost (modifier Examples 4 and 5 are identical in meaning).

Each modifier must apply to a certain subgraph (set of arcs) of the graph and the only difficulty in understanding the SENDS statement is that of learning the rules which determine to which subgraph a given modifier applies.

First it should be noted that every SENDS statement begins with an identifier; this names a node of the graph, which we will—in this section—call the "subject node" of the statement. The word SENDS indicates that we are discussing arcs leaving the subject node. Next follows a stream/node expression in which appear identifiers which are the names of physical materials. Within this expression, such a name M is to be read as shorthand for "the set of all arcs carrying M out of the subject node," and thus defines a subgraph.

The syntactic type ⟨stream/node factor⟩ corresponds to the notion of subgraph. If a given stream/node factor is a single identifier, we have already indicated what subgraph is meant. If the factor is a parenthesized expression, the subgraph meant is the union of the subgraphs defined by all material names found in the expression. Thus the stream/node factor (M_1, M_2) is to be read as "the set of all arcs carrying either M_1 or M_2 out of the subject node."

The reader will observe that the type ⟨stream/node term⟩ is defined as a single ⟨stream/node factor⟩ followed by an arbitrarily long list of modifiers (with appropriate separation by commas). The meaning here is that each modifier in the list is to be independently applied to the subgraph defined by the factor.

In sum, then, the recursive nature of the ⟨stream/node term⟩ definition permits application of a *set* of modifiers to a single subgraph; the recursion in ⟨stream/node factor⟩ definition (i.e., the ability to parenthesize a ⟨stream/node expression⟩ to make a new factor) permits nested subgraph definition; and, finally, the recursive structure of a ⟨stream/node expression⟩ permits assertions about overlapping or disjoint subgraphs to be included in the same statement (so long as each subgraph is a subset of the arcs having the subject node).

The engineer may continue his statement, after the stream/node expression, with the reserved word TO followed by a second stream/node expression. In this latter expression, the identifiers are the names of *nodes*; each identifier N acts as shorthand for "the set of all arcs carrying any of the materials named in the first stream/node expression from the subject node to the node N," and thus defines a subgraph. The rules for applying modifiers to factors, treating parenthesization as subgraph union, etc., are exactly as before.

The TAKES statement

Grammar

⟨takes clause⟩: : = TAKES ⟨stream/node expression⟩
FROM ⟨stream/node expression⟩ |
TAKES ⟨stream/node expression⟩

Examples and Discussion

The TAKES statement is completely analogous to the SENDS statement, both grammatically and semantically. With appropriate substitution of TAKES and FROM for SENDS and TO, the examples of the previous section will be correct. With similar substitutions in the discussion section, that section will work also.

Final notes on the grammar

The basic skeleton of AMBUSH consists of the three statement types described above and a few declarations: notably, one to list non-pooled materials and another for the supply of physical property values for materials which participate in quality restrictions.

The language has a full macro capability, including the insertion, at macro-expansion time, of actual parameters for formal parameters in the macro definition. Macros are, of course, used for abbreviation and to reduce copying errors. But they also serve as a way to parametrize a model: an identifier may be used in place of any numeric quantity, and its value may be changed from run to run. Other methods of parametrization, without recompilation, are also available.

For the sake of completeness, it should be added that:

a. The Compiler treats the AMBUSH program as a string, and consumes 72-column card images stringwise without format requirements.
b. AMBUSH (like many languages without a statement terminator) has a statement initiator (the # character).
c. An AMBUSH program is bracketed by the reserved strings BEGIN and END.
d. An AMBUSH identifier is built of alphanumerics and the period character; the initial character must be alphabetic and the character limit is twelve.
e. An AMBUSH number is a string of up to 14 digits among which at most one decimal point may appear.
f. All arithmetic is performed in floating point.
g. Numeric expressions are built in the customary way out of numbers, the four arithmetic operators, parentheses, and the special functions EXP and LOG. Unary minus is permitted. The evaluation rule is left-to-right and gives equal precedence to * and / and equal precedence to + and −.
h. A comment may be inserted between any two tokens of the language (roughly, in any place a space would be allowable). The comment is delimited by < and >; the # sign is prohibited within comments so that, when the programmer neglects to close his comment, it will be closed automatically by the initiator of the next statement.

AMBUSH AS A COMPROMISE IN STYLES

It should be clear to the reader that the grammar of AMBUSH follows fairly directly from the observations made in Section 4, and in general exemplifies the recursive style:

a. The grammar clearly reflects the search for a logically minimal description of the user's utterances.
b. The syntax is "narrow" (a small number of types at the statement) level and "deep" (highly recursive, at least within the SENDS and TAKES statements).
c. There are relatively few reserved words.
d. Lexical strategy is uniform; the input is treated as a string.

On the other hand, there still remain certain elements of template style; for example:

a. The two forms of YIELDS statement (input vs. output *and* output vs. input) are a logical redundancy.
b. The reserved words QMIN, QMAX, and QFIX could be replaced by MIN, MAX and FIX. The ⟨qlimit⟩ forms remain as a reflection of the user's habits of thought: a quantity limit is somehow *different* from a quality limit.

Finally, it should be noted that the grammar we have given above is incomplete. Most of the differences between that grammar and AMBUSH as actually implemented come from the deliberate introduction of a few totally redundant templates to reduce the language's unfamiliarity. The interested reader will find several examples of these templates in the sample problem in Appendix I.

The reader will probably have noticed a feature which makes AMBUSH rather different from most languages which programmers use: there are no imperative statements in the language. All the sentences the programmer writes are in the indicative mood: they are either declarations, giving global information about the materials which flow in the network, or are local statements about individual nodes of the network. Thus the language is not algorithmic—there is no flow of control, no modification of values in the course of computation. This implies that the order of inputting sentences to the compiler is irrelevant, and this is essentially true. (The exception is that, if conflicting numerical values are given, the last one input is used.)

STATUS

The AMBUSH Compiler was written for the IBM 360/65 and has since been moved to the 360/85; it was designed to interface with the IBM LP package (MPS and MPSX). By the Fall of 1971, it had also been moved to the UNIVAC 1108, and was being shaken down on that hardware.

The AMBUSH Compiler was delivered near the end of 1969, and has been in regular use by Shell since that time. We understand that, as of late 1971, there were approximately 35 qualified AMBUSH programmers at Shell. The language is, apparently, fairly easy to learn, since fully half of the 35 received no formal instruction: they were given a language manual and a certain amount of hand-holding by more experienced users.

The language appears to permit the expression of most meanings fairly naturally, although occasional user models have exhibited structures which were unanticipated at language design time (and thus expressible only clumsily). The frequency of the need for tricks and clumsy expressions tends to reduce with time, since the need arises less from the nature of the application than from the habits of thought of the user. Experience with a new language inevitably alters the style of thought. Clear understanding of the problem comes to *mean* clear expressibility of the problem in the programming language.

Applied Data Research has been licensed by Shell to market the AMBUSH package in the United States and Canada. Initial explorations of the suitability of the language for various classes of LP users were under way at the end of 1971.

ACKNOWLEDGMENTS

We wish to express our appreciation to the many employees of the Shell Oil Company who gave unstintingly of their time and expertise in the course of this language design. We further wish to thank Shell for the use of the sample problem in Appendix I.

The Compiler for AMBUSH was actually built by a team led by Naomi Rotenberg; the other members of this crew were Barbara Butler, Margaret Carlin, and David Goldberg.

Finally, the author wishes to acknowledge the assistance of his colleague, Kirk Sattley, who undertook overseeing the final preparation of the manuscript when the author was out of the country.

APPENDIX I: EXAMPLE PROBLEM

A simple problem in processing/transportation typical of the process industries follows. While only a small problem, it permits invoking most of the AMBUSH syntactic forms. The AMBUSH description (a listing of the input to the AMBUSH Compiler) follows the statement of the problem itself.

A few statement forms are used in this example which are not described in detail in the paper, or in the skeleton grammar. The reader will probably understand them immediately from the problem description, but in any case, some explanatory notes are given following the listing.

Statement of problem

Choose the most profitable set of operations for the following situation.

The Archetype Manufacturing Company Inc., operates two processing plants:

1. ICE processing plant
2. EGG processing plant

The ICE plant operates with an inexpensive raw material which is obtainable as follows:

SOURCE	COST $/TON	MAXIMUM AVAILABILITY, TONS/DAY
Arkansas	7.00	120
Louisiana	7.50	300

Furthermore, Archetype has a long term contract with the Louisiana supplier guaranteeing the purchase of at least 180 tons/day at the $7.50/ton price. The ICE plant can process up to 250 tons per day of raw materials at a cost of $.20 per ton yielding three products as follows:

	RAW MATERIAL SOURCE	
PRODUCT	ARKANSAS	LOUISIANA
Gas	.10	.12
Universal Solvent	.70	.74
Residue	.20	.14

The EGG plant operates with a more expensive raw material obtained as follows:

SOURCE	COST $/TON	MAXIMUM AVAILABILITY, TONS/DAY
Alaska	20.00	100
Labrador	25.00	150

The EGG plant has capacity to process all the raw material available at a cost of $.50 per ton and produces two streams.

	RAW MATERIAL SOURCE	
PRODUCT	ALASKA	LABRADOR
Exotic Liquid	.60	.70
Reject	.40	.30

The process requires .11 tons fuel gas per ton of raw material. The fuel gas must be obtained from the ICE plant. Any fuel gas not used in the EGG plant must be burned on site.

The Exotic Liquid can be blended with Universal Solvent to produce Exotic Product which has the following specification requirements.

	EXOTIC PRODUCT SPECIFICATIONS
Blue Color Index	12.0 Minimum
Specific Gravity	1.1 Maximum

The corresponding properties of the two components are:

	BLUE COLOR INDEX	SPECIFIC GRAVITY
Exotic Liquid	11.5	1.2
Universal Solvent	10.0	0.9

In order to meet the blue color index, Blue Dye must be added. One gram of Blue Dye will raise the blue color index of one ton of Exotic Product .7 units and will have an insignificant effect on specific gravity. Blue Dye costs $.80 per gram.

Universal Solvent can also be blended with Reject from EGG plant and Residue from ICE plant to make Unexciting Product. The blend has the following formula:

Universal Solvent	.25
Reject	.45
Residue	.30

All Reject must be disposed of in this manner. Any remaining Universal Solvent and/or Residue may be sold as produced.

All products leave Archetype by Pipeline except Residue which can also be removed by Truck. Pipeline carries products to Depot 1 and from there to Depot 2. Pipeline pumping limitations for each product and prices and demands at each depot are given below.

	MAX PIPELINE FLOW		SALES			
	TONS/DAY		DEPOT 1		DEPOT 2	
PRODUCT	ARCHETYPE/ DEPOT 1	DEPOT 1/ DEPOT 2	DEMAND TONS/DAY	NET PRICE $/TON	DEMAND TONS/DAY	NET PRICE $/TON
Exotic Product	500	225	125 Max.	40	120 Max.	35
Universal Solvent	400	175	60 Max.	30	20 Fix.	25
Unexciting Product	450	200	120 Max.	15	80 Fix.	10
Residue	300	125	Unlimited	3	Unlimited	3

Note that the pipeline capacity effects are cumulative. That is, 250 tons/day of Exotic Product plus 150 tons/day of residue would be permissible, but would use all of the capacity.

Residue removed by truck costs Archetype $.50/ton for hauling it away. In addition, handling problems limit to 30 tons/day the Residue disposed of as Residue.

The AMBUSH statements describing this problem follow. The AMBUSH compiler will convert these statements into a matrix which can be optimized by an LP code to give the combination of operating choices which will maximize profit by Archetype.

```

Notes to the listing

Card numbers:

400,500: These illustrate the form of simple declarations—a declarative reserved word, followed by a colon, followed by a list of identifiers used as names of materials. Note that FOUR.PRODUCT is a list of four material-names by virtue of the MACRO definition on cards 200-300.

400: NOPOOL tells the compiler *not* to automatically set up a POOL node for the material(s) named in the declaration. This implies that arcs carrying these materials must have both end points specified (see cards 5800-6100 for the FOUR.PRODUCT materials). Compare this to cards 2000, 3100, and 5500 which together describe the handling of FUEL.GAS: ICEPLANT "yields" it (to its pool), and EGGPLANT and BURNING "take" it (from the pool).

500: The material BLUE.DYE is declared to be an additive. This informs the compiler that the quantity of blue dye coming into a node (card 4100) has no effect on material-balance calculations, but only on quality determinations.

1600,2400: This is a shorthand statement for applying modifiers to the total capacity or throughput of a node. Formally, such a statement is interpreted by the compiler as a degenerate form of the TAKES statement, with the modifiers applying to the set of all input arcs to the node.

3500-3900: This declaration gives, for each relevant material, the coefficient to be used in "quality" calculations, described in an earlier section.

4400-4800: This is one of the "totally redundant template statements" retained in the language because of its familiarity; the MAKES . . . BLENDING statement is a variant of the YIELDS statement, used to describe a node which produces a single material, by giving the "recipe" for its product in terms of its inputs.

The data-text system—An application language for the social sciences

by D. J. ARMOR

Harvard University
Cambridge, Massachusetts

INTRODUCTION

The enormous growth of special applications software has been the subject of much speculation and debate. While many of the developments are natural expansions into new application areas, many computer specialists argue that applications programming is a prime example of the tendency to reinvent the wheel. No area receives this accusation more than that of statistical packages or languages, particularly those developed for applications in the social and behavioral sciences. A recent study by Hugh F. Cline shows that in 130 universities which grant higher degrees in these fields, there are over 170 such packages or languages in use.[1] This is more than one per university! No one could possibly maintain that all of these systems are unique; the duplication of effort has been rampant.

Now that I have said that, I want to take the other side. While I cannot defend outright duplication, I want to present some of the reasons why many of these developments were necessary and why they represent a significant stage in the evolution of computer software. In illustrating my argument, I will draw upon examples from the Data-Text system, a data processing and statistical analysis language developed at Harvard.[2] Although other systems could be used to make the same points, Data-Text may represent the most comprehensive attempt in this field to date. Besides, since I helped to develop it, I know it better than others!

EARLY DEVELOPMENTS

One insight into the rationale behind Data-Text and other similar attempts can be gained by considering the origin of languages like FORTRAN. Why was FORTRAN developed and why did it become so popular? All modern computers have had symbolic machine or assembler languages since at least the IBM 704 generation. Why did the symbolic machine languages fail to suffice for all application software, being supplanted almost exclusively by FORTRAN for problems involving numerical computations? In retrospect the answers are obvious. First, programming in a machine language requires a good deal of detailed knowledge of the internal structure of the machine; second, the atomistic nature of the instruction set means a great deal of programming effort even for simple mathematical expressions—not to speak of the coding required for routine input-output procedures. For the engineer or scientist with a particular type of mathematical expression to evaluate, the investment of time and energy in learning and programming in machine language was costly. FORTRAN and other languages like it solved this problem for many quantitative applications in the physical sciences. FORTRAN was relatively machine independent (at least by the end of the 1950's) and could be learned very quickly by those with some background in mathematics. Most mathematical formulas could be expressed in a fairly natural way, and most of the troublesome clerical problems of I/O were handled with a minimum of complexity (at least in comparison with machine language solutions). In other words, the FORTRAN-type languages were "natural" languages for those programmers working in numerical mathematical applications. The same can be said of many other languages, such as COBOL in the business realm and SNOBOL in the field of text processing.

For many other fields, however, FORTRAN is not a "natural" language. In the social and behavioral sciences, where mathematical proficiency is not predominant, a great many statistical analyses are commonly used even though their mathematical bases are not fully comprehended by the user. Two examples are the techniques of regression analysis and factor analysis. The first requires inversion of a matrix of correlation coefficients, and the second requires extraction of eigenvalues and eigenvectors. Although a competent social scientist can understand the results of these analyses, very few actually understand the mathematical techniques which are required to derive the results. (In defense of the social scientist, I should hasten to add that a great number of physical scientists I have known are likewise in the dark.) Even in the case of less complex statistical methods, many researchers are not able to provide precise computational formulas without careful review of a statistics textbook.

The result of this is that the social scientist finds it difficult to program in a language which requires that he provide the mathematical or statistical formulas for all of his ordinary analyses. Thus languages like FORTRAN, ALGOL, BASIC, PL/I, and COBOL are not natural languages for the social scientist. I think this argument can be extended to other fields as well where standard algorithms exist for data analysis problems. In these cases, if a language is to earn the label "natural," it should embody terms or macros which call in these entire algorithms, just as FORTRAN calls in a routine in response to a function name such as SQRT or LOG. In other words, FORTRAN and similar languages are natural languages for the programmer who wants to *implement* a statistical or mathematical algorithm, but they are not natural languages for those who simply want to *apply* those algorithms to analyze a particular set of data.

I do not want to give the impression that the only limitation of FORTRAN-type languages has to do with statistical algorithms. There are a variety of other data processing problems which are commonplace in the social sciences which can be extremely tedious to program in FORTRAN. One example is the problem of missing observations. These occur whenever a variable cannot be measured for a given subject or some other unit of analysis. There are a variety of standardized procedures which a social scientist follows to deal with this problem but no general language that I know of has implemented them. Another problem has to do with a variety of farily common transformations which social scientists apply to their variables but which do not exist in the FORTRAN-type languages. Perhaps the most common of these is what we call "recoding" of an original measurement. This involves transforming the original values of a variable into some arbitrary set of new values, as when we want to collapse a continuous-type variable into one with a small number of values or categories. Although these kinds of transformations can be coded in a FORTRAN-type language, they can frequently lead a fairly lengthy and repetitive program. As we shall illustrate, a recoding operation in Data-Text stands in the same relationship to the necessary FORTRAN steps as an algebraic formula in FORTRAN stands in relation to the necessary steps in a machine language. The same can be said for a number of other transformational capabilities commonly available in the more popular social science languages. Finally, there are a number of other data processing and routine clerical problems which are not easy to handle without special languages. Included are full labeling of variables and their values (or categories), input of multiple-punch data, selecting or sampling sub-sets of the input data, and controls to classify the input data into an arbitrary number of sub-groups.

The earliest attempts to solve some of these problems for the social scientists led to the development of "canned" programs. By "canned" program I mean one written—usually in FORTRAN—to perform a particular statistical analysis, but written so that it can be used over and over again by different researchers with different data. A user prepares "control" or "parameter" cards which specify the necessary information about his data (e.g., number of variables) and any options which are available; the control cards are used by the program to read in the data properly and to produce the desired results. Canned programs are still used widely by social scientists today, and for some applications canned programs continue to be the most efficient computational solution.

As canned programs became a popular method of computer analysis, collections or "packages" were put together at various locations (usually university research centers) and distributed to researchers at other locations. The oldest, most well-known and widely used of these collections is the BMD series, started by Dixon and his associates at UCLA.[3] The BMD collection for the IBM System/360 contains over 40 programs for almost every type of standard statistical analysis found in applied statistics textbooks. Another collection for the IBM System/360 is the OSIRIS package.[4] Developed at the University of Michigan, OSIRIS represents a significant advance in that the canned programs are "integrated" into one large system which recognizes a "standardized" data file. A file of data can be described and then any number of different statistical routines can be requested which use that file.

The canned program approach still leaves many problems unsolved for the social scientist. While canned programs have largely solved the problem of knowing complicated statistical algorithms, little relief is gained for the many other data processing problems which I have mentioned (special transformations, missing observations, labeling, and the like). Moreover, two new problems have surfaced. Both of these problems result from the fact that most canned program developers are not professional programmers, and therefore they are usually more interested in the statistical algorithm than in program elegance.

The first problem is that all kinds of arbitrary restrictions are placed upon various parameters in the problem—the number of variables allowed, the number of subjects, the number of values or categories of variables, the number of analyses, etc. I wonder how many hundreds of researchers have had a 110-variable factor analysis problem with a program which would accept only 100 variables; or a cross-tabulation requiring 60 cells with a program limited to 50? This would be like a FORTRAN programmer being limited to a total of 5 DO-loops or to arbitrary subscript limits of 50. Of course, any language has some limitations, but all good compilers do dynamic core allocation so that limits are encountered only when available memory is exhausted. Most canned program limits are due to programmer short-cuts such as fixed dimension statements.

Second, little effort is given to making the control cards "readable" to the analyst in the sense that FORTRAN is readable to a programmer. Most control cards consist of arbitrary numeric codes in fixed-format positions. It is practically impossible to remember the set-up procedures from one run to another without a program write-up literally in front of you. For the data analysts, having to "read" these control cards is somewhat analogous to a FORTRAN programmer having to read a hexadecimal dump in order to interpret the steps in his program.

THE DATA-TEXT SYSTEM

The Data-Text system was designed to solve some of these problems and limitations of the package approach. Data-Text is designed to be a "natural" language for the social scientist, just as FORTRAN is a natural language for those familiar with mathematical expressions. In this sense, I think Data-Text represents a further stage in the evolution of "problem-oriented" computer languages. With Data-Text, the social scientist can request complex data analyses as easily as the engineer can write complex formulas in FORTRAN. The first version of the Data-Text system was designed by Couch and others for the IBM 7090/94 series, and it became operational in 1963-64.[5] This version became widely used at more than 20 universities and research centers during the middle 1960s. A substantially revised version of Data-Text has been designed and programmed for third generation computers and a version for the IBM System/360 series became operational in the spring of 1971.*

It should be mentioned that in the latter part of the 1960s other computer systems with similar design goals appeared. One example is the Statistical Package for the Social Sciences (SPSS), created by Nie and his associates at Stanford University and the University of Chicago.[6] Other social scientists have begun experimenting with interactive (or "time-sharing") data analysis systems, such as Meyers' IMPRESS system at Dartmouth College,[7] Miller's DATANAL system at Stanford,[8] the ADMINS system at MIT,[9] Shure's TRACE system at SCD and UCLA,[10] the Brooking's Institution BEAST,[11] and Kuh's TROLL system.[12]

The unique aspects of the Data-Text system in relation to other computer systems is its ability to handle very complicated data processing problems and extremely intricate statistical analyses with a minimum of technical knowledge about the computer and a minimum of familiarity with statistical formulas and algorithms. The requirements for a user are: (1) that he have a concrete research problem which demands a standard statistical analysis of data; (2) that the data are recorded in some systematic format on IBM punched cards (or certain other media, such as magnetic tape or disc); (3) that he understands the type of statistical analysis required for his problem; and (4) that he knows the names of the appropriate statistical analysis procedures. Given such a situation, Data-Text can be used for defining or transforming input variables, for giving them appropriate descriptive labels, and for requesting a great variety of different statistical analyses. The variable definitions and statistical analysis requests are made in a flexible, easy-to-learn "natural" language which makes heavy use of terms familiar to most social science researchers. Data processing features include automatic missing observation procedures, input and manipulation of multipunched data, subgrouping controls, and many others.

A sample of the Data-Text language is probably the easiest way to introduce this idea and to show how Data-Text differs from FORTRAN-type languages. Assume that a researcher has collected data from a group of several hundred college students (the actual number is not important). The data might include measurements of age, sex, race, father's education, family income, college class, an ability test score, expected work after college, several yes-no questions regarding current political-social issues, and a series of questions about school activities. We will assume that the non-numeric measures (for example, sex) have been given codes of some kind (for example, 0 for male, 1 for female) and that the data has been punched onto IBM cards with two cards for each person. The Data-Text instructions shown in Figure 1 define the set of original variables, derive some new variables as transformations

* The original Data-Text system was supported by grants from the National Science Foundation (#GS287 & GS1424). The revised Data-Text system was made possible by a grant from the National Institutes for Mental Health (#MH15884) and by donated computer time from the Harvard Computing Center.

Figure 1—A sample data-text program

of the original set, and request several types of statistical analyses. (In many cases these instructions are punched onto IBM cards, one instruction per card. In other instances, they might be lines typed at a remote typewriter console.)

The instructions fall into several types. The instruction

```
*DECK COLLEGE STUDENT STUDY
```

is a header instruction which signifies the start of a set of Data-Text instructions and which provides a title that will appear on every page of computer print-out.

The next two instructions relate to I/O operations:

```
*READ CARDS
*CARD(1-2)FORMAT/UNIT=COL(1-4),
                  CARD=COL(5)
```

The READ identifies the mode of data input (punched cards), while the FORMAT provides information about the number of cards per student and some special identification fields. The term CARD(1-2) indicates 2 cards per subject; the term UNIT refers to a field in each card for identifying the unit of analysis (such as a subject number); the term CARD refers to a field for identifying the different data cards for each UNIT. Thus, this example indicates two cards per UNIT, a subject number in columns 1 to 4 of each card, and a card number in column 5. Although there is some syntactic similarity to FORTRAN in these two instructions, their effect is quite different. First, no looping controls are required around the READ instruction; all data cards will be processed automatically according to the other operations specified in the program.* Second, the FORMAT instruction in this ex-

* A special *SELECT . . . IF instruction is available for selecting sub-sets of the data file; see Figure 2.

ample only provides information about the number of cards per subject and the identification fields; variable fields are defined in separate instructions. Moreover, if the UNIT and CARD fields are specified as in the example, the cards for each subject are automatically checked for consistent subject numbers and card sequence (taking the first subject as the prototype). These checking operations are extremely important for some of the large-scale survey research studies.

The next set of instructions define the variables to be used in the statistical analysis requests. For example, the instruction

```
*SEX=COL(7/1)
     =STUDENT'S SEX(0=MALE/1=FEMALE)
```

defines a variable named SEX which appears in column 7 of card 1 for each subject. It also gives a user-supplied descriptive label and, within the parentheses, it describes the values actually punched in column 7 and relates them to user-supplied category labels (e.g., 0= MALE means that 0's were punched to represent males). The ability to specify labels and values enables an analyst to construct a true "machine readable" codebook for his data set. Moreover, the use of the variable and category labels is not confined to the instruction listing; they are also used in all computer print-out of statistical results which use the variables and/or their categories.

Alphabetic-coded variables can be indicated by preceding the COL-specification with the letter "A":

```
*RACE=ACOL(8/1)
      =RACIAL BACKGROUND
    (B=BLACK/W=WHITE/O=OTHER)
```

This definition indicates a variable which was coded in column 8 with the letter values B, W, and O.

Entire arrays of variables can also be defined without the use of explicit looping controls, as in the example

```
*ACTIVITY(1-50)=COL(6-55(50)/2)
               =SCHOOL ACTIVITIES
               (0=NO/1=YES)
```

In this case the variable and value descriptions will apply to all 50 variables in the array. The example *ITEM(1-4) shows how several variables can be defined with the same value descriptions but different variable labels.

The example in Figure 1 illustrates several of the special transformation capabilities of Data-Text. While the logical and arithmetic transformations used to create VAR(4) and VAR(6) resemble those available in most languages, the special functions MEAN, SUM and RECODE used in defining VAR(3), INDEX, and VAR(5) are unique. The MEAN and SUM are "summary" functions which operate *across* the variables for a given subject, so that an average score (for the MEAN) and a count (for the SUM) are derived for each subject in the sample. Again, no looping controls are necessary for these operations.

The RECODE function embodies a great deal of power. It works in conjunction with a code statement (*CODE(A) in the example) which specifies the recoding equations. Each equation consists of a series of original values together with the new value they are to be assigned in the transformed variable. Thus, only two instructions are required to transform one set of values into any combination of new values. Although this kind of operation is programmable in FORTRAN, it requires a great many assignment, IF and GO TO statements.

One of the equations in the *CODE statement is 5=BLANK. The term BLANK is a special constant in Data-Text which denotes a missing observation. This means that a subject with a score of 5 in VAR(2) will be treated as missing in VAR(5). BLANK values are automatically assigned to variables for subjects with blank columns in the input data fields. That is, if columns 5 and 6 in card 1 are blank for a given subject, then a BLANK value is automatically assigned to the AGE variable for that case. Regardless of where BLANK values come from, they are handled automatically in all transfomation and statistical routines. A series of default rules exist which are appropriate to the type of transformation or the type of statistical procedure. For example, BLANK's are ignored by the MEAN function in the VAR(3) instruction, so that the average is taken only of non-BLANK values. In the VAR(6) instruction, however, which uses a regular arithmetic expression, the opposite is true: if either of the arguments ABILITY or AGE is BLANK for a subject, then the result is BLANK. In most of the statistical routines indicated by the COMPUTE instructions, the default is to ignore BLANK values; but options exist which will do other things (like excluding a subject from the analysis if any variable has a BLANK value). This automatic processing of missing observations has proved to be an extremely valuable feature in social science applications.

Before turning to the statistical controls, another instruction should be noted. The instruction

```
*CHANGE(1-10)=POSTEST(1-10)
             -PRETEST(1-10)
```

illustrates what we call a "list" expression. The subtraction operator is applied element-wise to the two argument lists, so that each variable in the CHANGE array is the difference between the POSTEST and PRETEST variable in the corresponding list position.

```
*DECK COLLEGE STUDENT STUDY—SECOND RUN
*READ DATATEXT DISC 4
*LEVEL=ORDER ABILITY=ABILITY LEVEL(0-9=LOW/10-24=MIDDLE/OVER 24=HIGH)
*SELECT UNIT IF SEX= 0
*COMPUTE CROSSTABS(LEVEL BY RACE, CLASS), CHI SQUARE
*START
```

Figure 2—Using a data-text file

Lists of variables can be combined into any arbitrary arithmetic expression, and the expression is evaluated for each element in the list. This provides a very powerful transformational ability without the necessity of looping controls.

The COMPUTE instructions are commands for statistical analyses on the variables defined in the preceding instructions. The statistical procedure is requested by name, such as T-TEST or CROSSTAB or CORRELATION. Generally speaking, the only parameters required are the lists of variables to be included in the analysis and any special options which are desired. The instruction

```
*COMPUTE STATISTICS(AGE, INCOME,
    ITEM, VAR(6)), SKEW
```

will compute means, standard deviations, and the number of nonmissing observations for each variable in the list across the whole sample of students; the option SKEW will also cause a measure of skewness to be computed. The instruction

```
*COMPUTE CORRELATIONS(ACTIVITY),
    TEST
```

will cause a 50 by 50 matrix of product-moment correlations to be computed for the array ACTIVITY(1-50), and the TEST option will result in a statistical test of significance for each correlation.

While there is some resemblance here between the COMPUTE instruction and a subroutine call in many languages, the analogy cannot be pushed too far. First, the "arguments" include reference only to the variable names and not to the many other quantities and arrays which are used by the routine, such as variable labels, value description, number of categories, and so forth. Second, and more important, some of the statistical requests have special key words embedded in the variable list which must be encoded by a special compiler tailored to each statistical procedure.

For example, in the instruction

```
*COMPUTE REGRESSION(ABILITY ON AGE,
    SEX, VAR(1), INCOME),
    GROUP BY CLASS
```

the key word ON indicates the independent variables (AGE, SEX, VAR(1), INCOME) on which the dependent variable (ABILITY) is to be regressed. The GROUP option indicates the analysis is to be carried out on the four college class subgroups defined by the CLASS variable. In the COMPUTE ANOVA instruction,*

```
*COMPUTE ANOVA(SEX BY RACE BY
    VAR(4)), ABILITY
```

the key word BY indicates a 3-way factorial analysis of variance design with ABILITY as the dependent or criterion measure. In other words, the COMPUTE instructions are also expressed in a natural language which contain operators and a syntax meaningful to each particular analysis.

All of the statistical routines are almost literally without limitations. Correlation matrices are not limited to available core; a cross-tabulation can be *n*-ways, with no limit to *n*; a variable used for classification purposes in a cross-tabulation, an anova, or in the GROUP BY option can have any number of categories; and if all the analyses requested will not fit in available core, the data is automatically saved in internal form so that repeated passes can be made over the data to satisfy all the requests. These features reduce the frustrations often encountered with other statistical packages which have established arbitrary parameter limitations.

It is rarely the case that an analyst will obtain all of his statistical results in a single run. Sometimes the same data set will be analyzed several dozen times. Data-Text offers a method for saving all of the defined variables, labels, and data in a standardized binary file. Since no compilation, transformation, and data conversion needs to be done, the time required to process this file is substantially less than the time it takes to process the original raw data.* In our sample program, the instruction

```
*WRITE DATATEXT DISC 4
```

creates a standardized file for this set of data.

Input of a DATATEXT file does not preclude the use of the full transformational language. New vari-

* The term ANOVA is a fairly standard abbreviation for "analysis of variance."

* The savings range from 50 percent to 90 percent of CPU time, depending upon the size of the data file (the larger the file, the greater the savings).

Figure 3—Sample output from a data-text run

ables can be derived from existing variables just as in a regular run. Figure 2 shows a run using the DATATEXT file created in the first example. A new variable, LEVEL, is derived by collapsing the existing variable ABILITY using the special collapsing function ORDER. Some new cross-tabulations are requested, and the SELECT instruction will restrict processing to the sub-group of males. It is clear from this example that using a DATATEXT file results in a much shorter and simpler program.

Figure 3c

As I have noted, the use of labeling specifications illustrated in Figures 1 and 2 is not confined to a program listing. All of the Data-Text statistical routines use the labels to produce readable output. Since the sample programs were hypothetical, we cannot show output for them. However, Figure 3 illustrates partial output from an actual run using real data. The Data-Text program which defines the variables and requests the analyses is shown on the first page of output.* The remaining pages show the output resulting from the STATISTICS and ANOVA instructions.

LIMITATIONS OF THE DATA-TEXT SYSTEM

While a computer system may look good on paper, any real implementation always involves sacrifices and compromises. Some of the more obvious limitations and deficiencies involve the actual number of features which are available. Our investment of time and energy in making certain features as flexible as possible meant that other features could not be developed. In the transformational language, for example, there are no DO-loop and variable subscript capabilities. While the list expressions and summary functions available in Data-Text make these features less crucial than in other languages, on occasion a very complex transformation is desired for which these controls would be useful. Perhaps the best way to solve this would be to permit a subroutine call to a regular FORTRAN routime. The addition of such a feature would substantially enhance the transformational power of Data-Text (or any other social science language).

On the statistical side, we have confined the system to what might be called "standard" statistical routines that enjoy a wide usage in the social sciences. Some of the packaged program collections mentioned earlier (BMD, OSIRIS) offer many more statistical routines (discriminant function analysis, canonical correlation, Guttman scaling, etc.). This limitation is not a fatal one, however, since in Data-Text it is possible to write out a new transformed data set which can be fed into these other routines. But it would be more convenient to have all statistical analysis within the same integrated system.*

One of the major goals of the revised Data-Text system is machine independence. Therefore, almost all coding was done in a standard subset of FORTRAN IV. This fact coupled with the heavy overhead common to all large systems means that Data-Text is fairly slow and bulky. The load module requires about 200 tracks of an IBM 2314 disc, and although it has been extensively overlaid, the minimum region size is about 200K (250K is sufficient to run most jobs). Regarding speed, Data-Text is far more expensive to run than a FORTRAN program written to perform the same specific task. For example, the run illustrated in Figure 3 required 637 accesses and 20 seconds of CPU time on an IBM 360/65. In determining cost effectiveness, of course, one must take into account the time to do the programming. An argument about the cost of Data-Text versus FORTRAN is not dissimilar to the same one about FORTRAN versus assembler language.

Another implication of machine independence is that we were confined to a basic subset of special symbols. This is one of the reasons (although not the only one) why our syntax may look strange to some language designers. The symbols =) / (are used heavily as separators and sometimes with different meaning. Slashes mean division in arithmetic statements, but they are also used to separate different category labels and recoding transformations.* Another reason for "strange" syntax has to do with maintaining upward-compatibility with the original Data-Text system. In the original system there was no *START instruction to separate instruction cards from data cards; instead, instructions were recognized by an * in column 1. Since we tried to keep the revised version compatible, we inherited this feature.

COMPARISON WITH OTHER SYSTEMS

I have noted that there are other systems developed for social science data analysis which are similar to Data-Text. Accordingly, there is a great deal of interest in the potential user community in the differences among the systems. While there is not sufficient room to present a detailed comparison here, some of the major differences can be summarized. I must state at the outset that I am not an unbiased observer in this regard, and knowledgeable users may well have different opinions.

Since Data-Text was developed primarily as a batch system, the biggest differences are with interactive systems. We can take IMPRESS[7] as a popular representative. The main advantage of IMPRESS is that its command structure assumes that a student or researcher is in front of a console requesting one kind of analysis at a time. The result is that a great deal of communication can occur to help guide the analysis. This is extremely valuable for teaching purposes. For the researcher doing large-scale runs on his own data, however, most time-sharing systems (including IMPRESS) lack a variable definition and labeling capability which works on raw data. The raw data is put into a standardized, labeled form as a *separate* step (and without a language); in Data-Text this step is integrated with the transformational and statistical language. Also, most time-sharing systems are understandably less concerned about fixed parameter limits.

* The Cambridge Project under way at MIT and Harvard represents one very comprehensive attempt to do this on a time-sharing system.

* Commas could not have been used without making certain expressions look confusing; for example, consider (1 = 2/2, 3, 5 = 1) on a CODE statement.

Space is generally at a premium, and it is not uncommon to find fairly low limits on the number of cells in a table, the number of variables in a regression, and so forth.

The package collections such as BMD[3] and OSIRIS[4] are also quite different from Data-Text. For one thing, they offer many more statistical or analytic routines than Data-Text. Also, since they are really sets of individual programs, there is no system overhead and jobs can generally be executed in a smaller region and with much less CPU time than the same jobs in Data-Text. On the other hand, the lack of integration means that a lot of information has to be repeated for each separate analysis; that the control cards for different routines often have different syntax; and that, like time-sharing systems, variable definitions and transformations using raw data comprise a step *separate* from the analysis.

The system most similar to Data-Text is SPSS. Both are batch-oriented; both are integrated so that variable definition, transformation, and statistical analysis instructions are given in the same program; and both overlap considerably in their analytic routines.

Aside from syntax, the major differences in the transformational language have to do with speed versus power. Unlike Data-Text, SPSS does not have list expression or summary function capability, and it does not handle missing observations automatically in all variable transformations. This means that a SPSS program will generally require many more statements than Data-Text if there are conditions which require these features. On the other hand, for simple problems which do not need these features SPSS will take much less CPU time.

While analytic routines such as cross-tabulation, regression, and factor analysis are fairly similar in both systems, SPSS alone has Guttman scaling, partial correlations, and histograms. Data-Text alone has scatterplots, t-tests, and a generalized analysis of variance routine; the latter makes it possible to request just about any kind of analysis of variance design with a simple language tailored to this statistical procedure. Also, the Data-Text cross-tabulation routine will handle multivalued variables which can arise from multiple-choice response categories in a survey (it can also read in and transform multiple-punched cards). A more important difference for some researchers may be the parameter-free character of the Data-Text routines. The size of the matrix for the Data-Text correlation and factor analysis routines is not limited by available memory. This means that even in relatively small work space (e.g., 70K) a 500-by-500 (or one of any size, for that matter) correlation matrix or factor analysis can be computed.

THE IBM SYSTEM/360 IMPLEMENTATION

A brief amount of information about the implementation of Data-Text will supply perspective. Data-Text is a "compiler/interpreter" system programmed largely in ANSI FORTRAN IV on the IBM System/360 and 370 (a version is also underway for the CDC 6000 series).* During the compile phase the variable definitions and transformations are compiled into an intermediate language, and the statistical COMPUTE requests are encoded into sets of internal signals. During a second phase, the intermediate language is operated on by an interpreter for each unit of analysis to produce the final variables for the statistical routines. In addition, this set of variables is passed to each of the requested statistical routines for accumulation of the necessary quantities according to the encoded signals (e.g., sums, sums of squares, etc.). In the third and final phase each statistical routine computes and prints out their respective results using the accumulations from the second phase and the encoded signals from the compile phase.

The avoidance of fixed parameter limits in statistical routines is achieved in several ways. First, if there are more COMPUTE requests than there is room in available memory to accumulate the necessary quantities, then the data for the variable in question is automatically saved in a special file and subsequent passes are made over the file until all statistical requests are satisfied. Second, the programs for each statistical procedure are written using "dynamic" core allocation. That is, all accumulation arrays are linear, and subscripting is accomplished by use of linear subscript functions. Therefore, each statistical routine will use only as much space as is absolutely necessary for the analysis requested. Finally, certain statistical routines are programmed to use scratch data set space if necessary to process a request that will not fit in available memory. For example, the factor analysis routine will compute and save a correlation matrix in "pieces" if the whole matrix does not fit in available memory; the factoring is likewise computed in a iterative procedure which processes successive "pieces" of correlation matrix.

SUMMARY AND CONCLUSIONS

I began by stating that while there has been a lot of duplication of effort in the field of social science software, much of it was necessary for the normal develop-

* Major parts of the non-statistical systems design and programming has been carried out by Cambridge Computer Associates, Cambridge, Massachusetts.

ment of the field. Perhaps that claim can be better understood now. The standard languages distributed routinely by the hardware manufacturers did not meet many of the special statistical needs of social and behavioral scientists. The result was that almost every university computing center developed a package of canned programs to meet these needs. As the solutions became somewhat standardized, it became possible to develop more comprehensive languages like Data-Text and SPSS. By combining procedures for many different data processing tasks into one integrated language, these systems offer users considerably more power and convenience.

LSI—Implications for future design and architecture

by S. F. DENNIS and M. G. SMITH

IBM Thomas J. Watson Research Center
Yorktown Heights, New York

INTRODUCTION

We attempt to justify a number of ways in which we believe LSI is most likely to affect systems design and architecture. It is not only the physical componentry of systems that will undergo change, but also our thinking, as an industry, about the goals, methods, uses and people associated with data processing. LSI will enlarge the scope of computer usage, while simultaneously reducing and altering the human effort required to install and use systems.

More specifically, we will review the major factors that motivate and limit the use of LSI. We will examine how LSI will change the distribution of costs in systems, and thereby change our present priorities in design and architecture. We will mention some general hardware functions, and as an illustration of some of these, we will explore how hardware and software might be structured in a large-scale teleprocessing system in the future.

WHY IS LSI EXCITING?

LSI takes many forms, directed to both logic and memory. For our purposes, it is hundreds and thousands of circuits or memory cells per chip. LSI is usually implemented via semiconductor technology, e.g., bipolar or field-effect technology (FET), but conceptually could include the magnetic "bubble" technology.

Probably the most interesting property of LSI is its potential cost. The trade and engineering literature reflects a pattern[1,2,3] which can be reduced to a crude rule-of-thumb cost model. It assumes that the level of integration chosen at any given time is such as to produce a modest chip yield at a cost comparable to the cost to package that level of integration.* We will calibrate our rule-of-thumb model at the \$0.0003/memory cell (bit) recently projected for the field-effect transistor random access memory (FET RAM) by Bob Noyce of Intel.[3] (The authors also believe this is possible.) A plausible "good" wafer cost is projected to be somewhere around \$25. (A "good" wafer is one that passes quality control tests.) Ten good chips might be an acceptable yield per wafer.

We conjecture that LSI costs will break down as follows:

Chip Costs:

$$\frac{\$25/\text{wafer}}{10\text{ good chips/wafer}} \equiv \$2.50/\text{chip}.$$

The part number cost, i.e., the cost to generate and handle a different part type,** must also be included. Thus, assuming comparable a packaging cost, and a part number generation cost term for "N" parts, the overall chip part cost is:

$$\$2.50/\text{chip} + \$2.50/\text{chip package} + \frac{\text{part number cost}}{\text{N}}$$

Therefore, the cost of a circuit, assuming n circuits per chip, is:

$$\frac{1}{\text{n}}\left(\$5.00 + \frac{\text{part number cost}}{\text{N}}\right).$$

By selecting a part number cost, introducing relative densities for the various technologies and the type of part (i.e., logic, Read-Only Memory [ROM], Random Access Memory [RAM], etc.), and estimating production quantities, we can project the costs which form the basis for our considerations.

First, we examine part number cost. If this cost is high, then LSI designs for all but high production parts

* Slices of silicon, called wafers, have patterns of hundreds or thousands of circuits or memory cells which, when the wafer is diced, become chips. These chips are first packaged, typically one to a package, and subsequently interconnected by higher-level packaging into logic or memory subsystems.

** The part number costs are those costs attributed to the uniqueness of a part, starting after the logic design and continuing through the fabrication, testing and handling of the part.

TABLE I—Postulated Device Costs

Semiconductor Hardware	*Circuits or Cells Per Chip*	*Mfg. Cost Per Circuit or Cell in Cents Number of Parts per Part Number*		
		10	*100*	*10,000*
ROS	64,000	0.16	0.023	0.008
RAM (FET)	16,000	0.66	0.09	0.032
RAM (Bipolar)	4,000	2.6	0.38	0.13
Logic (FET)	2,000	5.3	0.75	0.25
Logic (Bipolar)	1,000	10.0	1.5	0.5

will be questionable or prohibitive.[4,5] This might inspire novel design approaches in which like parts could be used. On the other hand, we believe that design automation techniques will bring part number costs eventually to something like $1000, as opposed to tens of thousands of dollars in the past. The pressures to make LSI a tool of the designer rather than his master will certainly bring this about.

The next step is to estimate densities. For example, in random access memory, FET designs have been reported with 4000 cells per chip. In recent years, integration levels have more than doubled every year, and while obstacles in photolithography and packaging certainly exist, there are at least several more doublings likely. (Further, the densities used below are not the most optimistic estimates in the industry.)[3] Based upon a $1000 part number cost and the rule-of-thumb formula given above, we might expect to see the following costs of LSI manufacture (Table I):
These costs could be thought of as representative of maximum yield-density configurations in that pushing performance in any of the five hardware categories would result in higher costs: higher performance logic or memory variations might cost considerably more. In addition, not all components could be expected to be produced in the same quantities; we would expect to see RAM components produced in very high quantities, whereas logic components would usually be produced in small quantities—a notable exception being logic for use in terminals.

IMPLICATIONS FOR SYSTEM COMPONENTS

What do these costs mean to CPU implementation? It has been estimated that there are around 100,000 digital processors in use today. Since most processors are small, let us suppose that there are about 5000 circuits and 20,000 bytes of main memory per machine. For today's processors with tomorrow's manufacturing costs of 0.5¢ a circuit and 0.03¢ per bit, the total logic and memory requirements for 100,000 processors would cost only $2.5 million for logic and only about $5 million for memory. Additional perspective is gained by examining what these costs would do to a "typical" large system. In Table II, we define a hypothetical contemporary system and apply costs to the various components typical of those in industry today. Then we reprice these components in terms of the conjectured LSI prices and our best guesses about the other components.[5] Smaller reductions are assumed in other than memory and logic costs, since we do not foresee technological breakthroughs in those costs.

Although the late 70's cost of some of the key componentry could be one-fiftieth that of today's cost, the overall cost ratio (today:late 70's) is about 6 to 1. With peripheral equipment added in, the ratio might be more nearly 3:1.

Cost of ownership

But this view ignores non-hardware expenses. If we look at system cost as classic "cost of ownership" (Figure 1), we see that the static costs of planning, programming and operations bring the cost reduction to only 28 percent. Of course, 28 percent is not to be callously ignored.

However, even "cost of ownership" is not the total cost. For example, data acquisition, its conversion to machine-readable form, and preparation of machine output for an ultimate consumer's use may cost a substantial amount in comparison with "cost of ownership." Further, the increasing complexity of our present

TABLE II—A Hypothetical Large Processor

	Today		Late 70's	
	Cost	*Percent of System Cost*	*Cost*	*Percent of System Cost*
Main Memory 1M byte	$120K	32	$ 2.7K	4
Special Memories	40K	11	2.0K	3
Logic	70K	19	1.2K	2
Special Circuits	25K	7	10.0K	15
Higher Level Packaging	35K	9	10.0K	15
Power Supplies & Cooling	40K	11	20.0K	30
Other	40K	11	20.0K	30
	$370K	~100	$65.9K	~100

systems design is adding to the costs of installing, extending and maintaining systems and of adding new applications. So, even the 28 percent is an overly optimistic estimate.

Cost of terminals

Since terminal costs will become steadily more important, we need to try to forecast them.[6] We define a hypothetical terminal, in this case a display terminal,[7] and assume the hardware required, along with prices retrieved from trade journals, circa 1970. Again, by applying our rule-of-thumb LSI projections to LSI parts, and lesser reductions to other components, we have approximately a 3-to-1 reduction, as shown in Table III.

Clearly, significantly more logic and memory function could be supplied at a modest additional cost, providing the user with more terminal function per dollar, rather than merely with lower cost components *per se.*

TABLE III—Display Terminal Cost Conjecture

CRT Head	$ 75	$ 60
Character Generator	50	2
Logic (1200 Circuits)	240	6 (.5¢/ckt)
Storage 10K	90	5 (.05¢/cell)
Special Circuits	100	50
Higher Level Packaging	50	25
Power	200	80
Keyboard	150	80
Other	145	86
TOTAL	$1100	~$400

GENERAL SYSTEMS IMPLICATIONS OF LSI COSTS

It is evident that LSI moves the major cost component of computer systems away from CPU-Memory and toward other system components. What effect should this have on our techniques? Novel systems or architectural approaches probably are now more feasible, but conventional approaches are also greatly enhanced. Evolutionary changes are certainly easiest to project—but also should be expected. As we see it, the general implications are these:

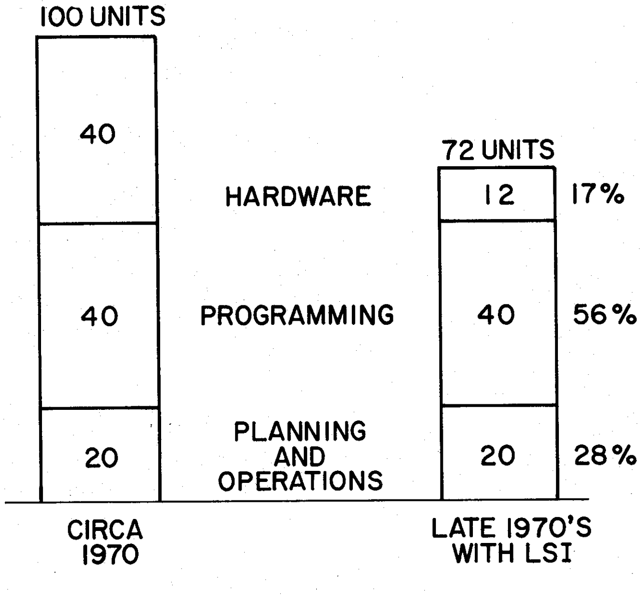

Figure 1—The usual costs of ownership

Interface capabilities—LSI gives us the opportunity to use low-cost logic and buffers for functional modularity and standardization. These features will improve ease of designing, installing, expanding, servicing and using systems, and will greatly increase flexibility. But, as always, there will be bottlenecks (e.g., response time) which can limit the number of functional interfaces—or require certain bypasses. However, providing a degree of universality to system components gives us the opportunity to build more components alike. This helps build up quantities per part number and aids in limiting the proliferation of development efforts. Such universality requires additional logic, because a part number has to be more versatile, but it is of benefit in reducing development costs.

Memory/logic clocking implications—One potential effect of LSI is the opportunity for design simplification afforded by a machine with equal memory and logic clock cycle times,[8] such as was the case in the days of tube computers. This possibility comes from using the faster bipolar memory (or a bipolar "cache" memory with additional slower memory), or smaller semiconductor memories which can be overlapped to gain speed with little penalty in cost. However, the access time is a higher percentage of the total cycle time than in core memories, leaving a smaller percentage for address generation or any logic operations on the accessed data.[9] To offset this requires relatively faster logic if the same functions are to be retained. An alternative is to limit the number of levels of logic, using higher memory speeds and simpler architecture. Either of these alternatives limits the economies of scale in going to higher performance machines. Of course, the option to not exploit the full memory speed-cost potential remains. The trade-offs are between speeds of logic and speeds of memory.

Interaction Among Costs, Task Management and Availability:

The Era of Multi-processors

1. *Costs*—At any technological point in time, there is an optimum processor size. The old rule that "bigger and faster" means "greater performance per dollar" does not hold over all combinations of conditions. In fact, at the high-power end of the spectrum today, cost approaches a linear relation with computing power.
2. *Task Management and Software*—Some features of programming systems can be simplified, if the speeds of processors and data storage devices can be brought closer together. If no more CPU resource is wasted by allowing the CPU to idle during a file read than would be consumed in overhead by task-switching, then it is preferable to let the processor idle—because of the potential reduction of time spent writing and debugging both operating systems and application programs. One way to approach this condition is to parallel-process with "slow" CPU's rather than single-process with a "fast" one. For example, a 1-million instructions per second (MIPS) processor executing 10,000 instructions per file access would be wasting only 10 percent of its time if it waited for a one millisecond average access time device, while a 5 MIPS processor idling during reading the same device would waste 50 percent of its time. In the past, we have multiprogrammed the "fast" CPU's to avoid waste because CPU costs were non-linear with speed. We have conserved CPU power by programming effort, but it may be time to reverse those factors, and multi-process instead.
3. *Availability*—Availability can be brought to any given level (excluding perfect!) by increasing the level of multi-processing.

Also, there will be workloads beyond the capacity of any processor that we will ever build; at this point, multiprocessing becomes a requirement, not an option. Of course, the processors might be packaged together under one cover; on the other hand, it might be prudent to separate them geographically to prevent non-hardware-caused reliability problems.

Software/firmware/hardware trade-offs—We hardly need to be reminded that micro-programming techniques will be important, and they are already widely accepted. LSI projections further enhance these techniques, particularly in writable control stores which offer greater flexibility. Many functions in teleprocessing systems today are handled by software, e.g., line control, bit handling, etc., but performance often warrants hardware solutions. Higher-level control programs and language programs in hardware or software become more realistic.[13] This will be the direction as the industry matures.

Extension of computer usage

There are a number of not necessarily independent ways in which LSI will extend the use of CPU's and memory:

- Broadening the user base in conventional areas.
- Extending small machine with large machine functions.
- Providing new and additional functions.
- Providing universality, standardization, flexibility.
- Meeting new performance criteria.
- Opening new application areas.

There is evidence of each of these today. Broadening the user base in conventional areas simply implies selling more systems to more users for established applications, usually at the small end of the line. More interesting is the addition of typically larger-machine functions to smaller machines,[4,5,8,10] e.g., more sophisticated instructions, memory protection, instruction retry. Such features could add an order of magnitude in logic and memory to today's small systems.

Adding function to existing systems is conceptually an extension of the aforementioned. For example, function will be directed at improving data acquisition and use, at extending the ability of a system to self-diagnose and reconfigure, at providing communications functions and security, or at converting current software functions. Clearly, this is an open-ended category and suggests the basis for many times present hardware levels.

Meeting new performance criteria, we believe, means placing higher priority on response time, availability, ease of installation and use—rather than on throughput. These objectives will require new approaches, and more logic and memory can profitably be put to use in their pursuit.

New application areas will be developed. However, there are many applications which are presently on the shelf because of either time or economic reasons. It is already apparent that environmental monitoring and control is an important area for development. Attempts at "duplicating" human function, e.g., constructing capable robots, will undoubtedly consume much circuitry. These today are analog functions and require two to three orders of magnitude more components when done digitally. Still, it is becoming more and more economical to digitize, and examples are well-known in the data transmission area. Other known areas such as pattern and speech recognition will consume extensive hardware when we exploit them to their fullest.

In the next section we will use a specific system, namely, a highly interactive data processing system, to *illustrate* the impact of LSI technology.

A HIGHLY INTERACTIVE TELEPROCESSING (TP) SYSTEM

One motivation for looking at this system is that we believe that ultimately there will be very large systems serving tens of thousands of users. The users will be indifferent and largely oblivious to the fact that they are using a computer system. They probably won't even call their terminals "terminals"; names such as "fact-finder," "stockinfo," and "smartmart" are more likely. In particular, these people will probably not be programmers, mathematicians, engineers, scientists, or accountants. Their applications will be logically trivial—at least from a systems person's point of view. What we today might expect to be a command language will be the jargon of their particular environment, and they will be largely innocent about how the data they reference was acquired or is organized.

The interesting features of the system are that (1) there will be a very high traffic rate, (2) the traffic will have to do mainly with references to or updates of a data base, and (3) response to an inquiry will have to be within no more than 1-2 seconds to satisfy the users psychologically. The terminals might be displays, keyboards, badge readers, etc.—with or without "intelligence." A high degree of reliability will be required, and we will not want to manually reprogram each such system for each environment. Airline reservations systems are a current example of such systems, but other systems of even larger size are destined for such areas as the financial, securities, and retail industries.

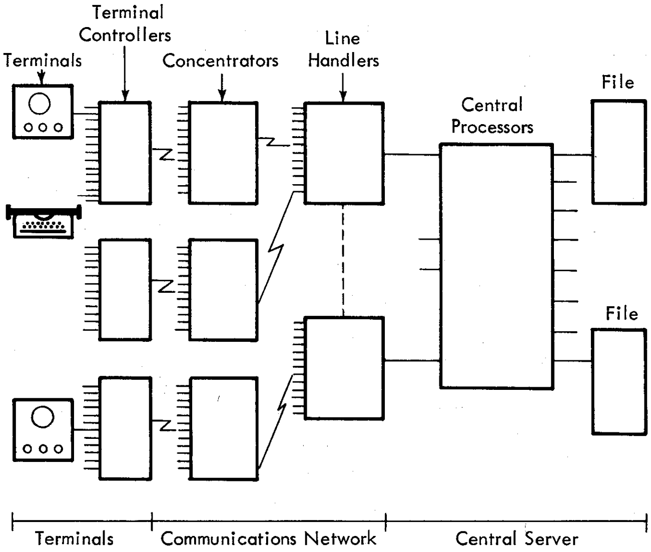

Figure 2—Schematic of interactive system

We postulate here an example of a hypothetical, highly interactive system for further discussion—in terms of potential LSI impact. The system is to have 10,000 terminals, and performance requirements are as follows:

Peak Message Rate	200 msgs/sec.
Simple Inquiry	30 percent
Simple Update	50 percent
Complex Inquiry and Update	20 percent
Data Base	10 billion bytes
Response Time (Simple Inquiry and Update)	1-2 sec.
Availability	1 failure/day with 2 min. recovery.

(In a real case, there should be additional qualifications on availability and recoverability.)

Some provision must be made for batch processing. Also, we have to look at data integrity, security, ease of installation, provision for growth and change, provision for on-line evaluation, etc.—each an area where hardware additions could contribute improvements.

Figure 2 illustrates the principal functions as we will describe them. Relating to current-day techniques, the peak load assigned to the central server can be projected to be the following:

Messages/sec.	200
File Accesses/sec.	1000
I/O Instructions/sec.	2.5×10^6
TP Access, Instructions/sec.	1.5×10^6
Instructions/sec. Total	5×10^6

For the purposes of this illustration, we assume that the configuration, in contemporary terms, uses four processors of the type described in Table II, plus two stand-by/batch processors (one might use fewer, but larger, processors). Using other component prices from reference sources[11] and our previous assumptions about changes in costs, we compute the cost comparison change shown in Table IV.

TABLE IV—A Hypothetical 10,000-Terminal Configuration

	*Cost Units** *Circa 1970*	*Cost Units** *Late '70's*	
Terminals (10,000)	59	20	60%
Lines and Modems	6	4	12
Multiplexors	1		
CPU Processor(s)	7	2	6
Channels, etc.	3		
Main Memory	4	.3	1
Bulk Memory	7		
Files	10	5	15
Other	3	2	6
	100 Units	~33 Units	100%

* Units: Equivalent to percentage of Circa 1970 costs.

Perhaps the most conspicuous feature of Table IV is the dominance of terminal costs. Secondly, perhaps, is the relative disappearance of the main and bulk memory costs. Next is the relatively small proportion of costs dedicated to transmission.

While the configuration assumed does not exist, it is at least realistic in the 1970 time frame, with some performance compromises. It is somewhat similar to an airlines reservation configuration in terms of the geographic assumptions made. The degree of terminal clustering achievable, relative to line requirements, makes it possible today to keep the percentage of transmission costs modest. However, it is assumed that line costs will not go down in cost as fast as the other components, and thus could constitute a higher percentage of costs—an opportunity for LSI to provide further concentration.

Even at the relatively low function level of 1200 logic gates per terminal, there is on the order of ten times as much cumulative logic at the terminals as at the central facility—and even more than 10 times as much memory if we use semiconductor storage at a display terminal for refresh memory. Clearly, it would be easy to increase these ratios significantly—if additional hardware at terminals could be utilized productively.

Just as important is the fact that with terminals dominating costs, and with logic and memory costs decreasing anyway, it will be less painful to add more function to the central facilities in support of systems which are more responsive and easier to install, use, and maintain. Of particular note here, again referring to Table IV, is the fact that the cost of a 20-fold increase in the size of main (and bulk) storage in the late 70's would still be possible within the indicated 1970 prices.

Figure 3 shows the response time breakdown that we would expect today, given a two-to-six second response time range and assuming relatively simple inquiry and update applications and moderate loading conditions. (The more conventional implementations would probably not achieve the one-to-two second response times we have postulated.)

The polling delay is half of the average polling cycle, initiated from the concentrator. The delays on the transmission lines are due to line speeds, message lengths, and queued waiting for the lines. Actual time delays in transmission are relatively negligible. Concentrator delays are principally queueing delays, with actual processing times in the 10 to 100 ms range. Central processing times are also mainly waiting times, particularly waits for file access, but also for channels and for processor service. Again, tens or hundreds of milliseconds are the range of actual processing times needed, subject, of course, to the processors' speed and the job to be processed.

It should be clear that these times are satisfactory for many applications; however, our contention is that a substantial segment of the potential user community will want response times in the one or two second range, or perhaps faster, at least for simple inquiry-update messages.

Design for the late 70's

Most systems used for interactive requirements today have been built upon batch systems. There have been attempts to achieve good throughput with acceptable response times. On this base, we are now adding more sophisticated user-oriented functions, in the area of data management, for example. In the future we must do more. The question is: "How far can we continue to build up the processing requirements on

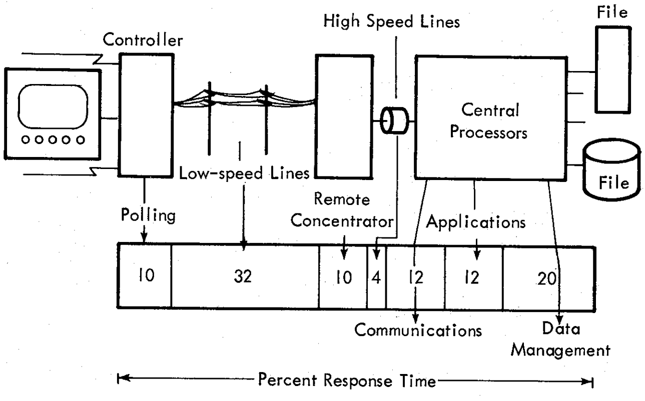

Figure 3—Factors in response time

the present base, and maintain, much less reduce, response times?"[11] We believe there are significant changes possible based upon the advances in LSI technology.

Present systems attempt to conserve processor resources. As we have said before, multiprogramming lets us use the processor while it would have been otherwise waiting on file accesses. Many-terminal systems, airlines for example, require us to maintain many messages active in the CPU concurrently, up to 50 in some systems. Caring for these messages is complex, and it is this type of complexity that causes much of the problems of installability, maintainability, etc.[12] In the future, processors, including memory, do not need to be conserved to the same degree.

LSI opens new possibilities which we could not consider in the past, particularly if we can appropriately partition the data bases (as we can in some environments today). We can bring the CPU speeds and random access speeds into better balance, we can afford to let the CPU idle during file reads and reduce the software and system complexity. The path to arriving at the balance appears to embrace (1) keeping the CPU suitably slow, (2) making direct access storage suitably fast, and (3) paralleling CPU's and direct access devices sufficiently to absorb traffic. In an environment where cost is nearly linear with CPU power, we can make the choice of reducing complexity at no cost, and into the bargain get increased reliability and perhaps improved security. Conceptually such a system might look like Figure 4.

Communications processing

The many functions relating to the handling of input and output messages may give rise to separate communication processors. The precise role of these processors in the total teleprocessing picture, and particularly the interface to other central processing functions, has not been universally defined. In fact, the communication processor function should be redefined in the context of the total teleprocessing requirement, including response times, to assure that there is no unnecessary data handling, and that the communication processor does, in fact, efficiently complement the central processors. Here LSI will permit us to build the necessary buffers and other interface hardware to afford a clean interface between the communications functions and other processing requirements, thus reducing device dependence and improving interprocessor communication.

Line attachment is another area where LSI will help. This area includes the physical attachment, modem functions, switching, i.e., functionally getting the information on and off lines and into and out of registers. Interface standards (EIA) usually have to be met, a variety of line speeds accommodated, and, often, provisions must be made for using the dial telephone network.

At the line end of the communications processor, we have a choice between hardware and software. The 10,000 terminals, for example, will require many connections—and in the past this would have been very expensive. This would have been particularly true if we had implemented sophisticated equalization equipment as well as the other modem functions digitally. On the other hand, done strictly with software, these functions would require extensive processing and processing times. Fast response time requirements and LSI costs make hardware the clear choice.

LSI has also made another communication processor design choice easier. Here, a writable control store (WCS) approach gives the flexibility needed to exist with the many variations found in practice, i.e., terminal and line types, line disciplines, formats, etc. When communications processors must be fast, bipolar techniques can be used for the WCS—and perhaps for their main memories as well.

The communications network

Communicating between the central site(s) and the terminal in the many-terminal system can be a relatively expensive proposition but in most cases it need not be. In the example of Table IV, it will be about 12 percent of the cost. This is a function of the distribution of terminals—and since in most applications terminals tend to be clustered, there is the opportunity for the terminals to share fewer transmission lines. This enables us either to use lower speed communications lines more effectively or to afford to use a broader transmission channel, where the potential costs per bit transmitted are significantly lower.

Concentration of line sharing can take place in several places, including the central site, intermediate remote points, and multiple-terminal sites. Concentrators, since they amortize their costs over more than one terminal, provide us with the opportunity to make them far more sophisticated, and LSI will help us to add the optimum amount of function. Functions directed toward increased availability might take the form of off-site processing capability, alternate path routing, forward error correction and backup storage. For our interactive teleprocessing example, the response time requirement forces us to limit queues, particularly on slow lines. LSI can help here by enabling us to extend line capacity (through multilevel modem equalization, error correction, etc.), or to speed up communications processing. Again, we can under-utilize facilities more economically to combat queue build-up.

Figure 3 shows a plausible breakdown of delays for a 1970 configuration. (There are faster airline systems but they are configured somewhat differently and are otherwise specialized.) If we have a one-second response time objective, some reduction in nearly all of the time components must be realized, but the use of additional hardware for faster polling and message processing makes the overall one-second response time very reasonable.

Terminal functions

With the assumption that LSI will enable us to expand terminal function significantly, what will it mean for the future terminal? Clearly, the minimal function of the terminal is its I/O: keyboard, printer, display, etc.; the I/O control; the basic communication functions including code conversion, serial/parallel conversion, and parity checking. We can expand these functions by adding character, line, and message buffering; various modem functions; line control; security provisions. Further expansion could include local user prompting, message format editing, header generation, and a variety of more sophisticated error control and automatic retransmission features. Continuing further, the high availability features of error correction, diagnostic ability, even self-repair, could be considered. Pre-processing, such as syntax checking and a limited degree of local problem solving, is a natural extension—continuing upward to significant stand-alone power.

To arrive at some idea of the level of logic complexity addressed here, we list in Table V the rough number of logic circuits (gates) and storage units (cells) associated with the various listed functions. (The reader should realize that the numbers are highly variable, subject to the particular application and the performance required. In addition, the functional hardware requirements are not necessarily additive since there may or may not be sharing of hardware, and in the more complex functions the option to perform them by mixes of software and hardware is generally warranted.) Hardware counts are rounded to the nearest 100.

Two of the more dynamic ranges in Table V are those of "Forward Error Correction" and the "Modem" functions, which could include very sophisticated forward error correction techniques and automatic equalization. It is not difficult to envision the use of substantially more logic and memory in the terminal. For example, if we add 10,000 circuits and 100,000 bits of memory at the projected costs (and also increment some of the other costs), the terminal will still be cheaper than its 1970 forerunner.

LSI will afford us the opportunity to define and economically design many functional interfaces. These interfaces will enable us to design terminal controllers, terminal I/O devices, and stand-alone terminals with extensive functional modularity—and to do this without jeopardizing the low-cost single-terminal requirement. Likely interfaces include the line-modem interface, the modem-data link control (DLC) interface, the DLC-terminal function—and eventually, the terminal I/O device interfaces. By choosing the appropriate

TABLE V—Hardware Requirements of Typical Functions

Function	*Gates*	*Cells*
Basic I/O Control	100-200	<50
Display Character Generation (ROS)	<50	1000-8000
Display Refresh (CRT)	<50	1000-25,000
Basic Communications Functions	100-200	<50
Extended Line Control Functions	500-1000	<50
Forward Error Correction	400-20,000	4000-6000
"Modem" Function	200-10,000	100-10,000
Line and Message Buffering	<50	200 & up
Editing Functions	200-400	500-3000
Calculator Functions	100-500	500-3000
"Typical" Small Computer	2000-4000	16,000-64,000 plus files

sub-function hardware modules, the controller is tailored to suit the appropriate line, the number and mix of terminal I/O devices, and other general functional requirements. Even within the smallest hardware module a degree of generality must exist which supports the standard interfaces. However, as our cost example illustrates, we can afford a significant increase in logic or memory count before we have a substantial increase in overall terminal cost.

SUMMARY

We have looked into the future of projected LSI logic and memory costs. The implications to the industry are dramatic. Without additional applications, the cost of the hardware base is a fraction of the cost of today's base. There will be an increased search for new applications and a change of emphasis on performance factors. LSI will support an era of greater accommodation of the user's desires, as opposed to forcing user conformity to machine—and data processing will be extended to a much larger user base.

Some important design and architecture trends are motivated by the need to meet other than batch processing and throughput requirements—for example, response time, availability, installability, usability. LSI will aid in establishing needed interfaces for both user and manufacturer, support the evolution of multiple processors, accelerate the use of firmware, and add many new functions to systems, some converted from software. It will not significantly restrict design freedom if the part number generation costs are as low as projected.

While LSI alone has not solved all problems, it has shifted the emphasis, changed the scale, enabled us to do some things better. "Large" will become larger, costs will be lower—and exploiting our new environment will be the major challenge.

The rationale for logic from semiconductor memory

by W. H. DAVIDOW

Signetics Memory Systems
Sunnyvale, California

INTRODUCTION

Memory is the LSI component which we know best how to fabricate. Compared to other LSI (Large Scale Integrated) circuits, it is almost "standard", and because of the regular interconnection patterns which exist between memory cells, it can achieve very high component densities and is relatively inexpensive to make.

A product such as a 4096-bit Bipolar ROS (Read Only Store) has some rather remarkable characteristics. When used properly, it can:

1. Become the logical equivalent of about 500 gates.
2. Be packaged efficiently in small 16 and 24 pin packages.
3. Dissipate about 1 MW per equivalent gating function.
4. Be customized for about $1.50 per gating function.

These benefits can only be obtained by using new logic design techniques which have not been extensively used in the past. One of these techniques is microprogramming. A great deal has been written about this technique but it has not really found wic'es)read application.

In this paper we will provide a brief introduction to microprogramming and then show how this technique, used in conjunction with semiconductor memory, can greatly reduce the cost of the control portion of a digital system.

INTRODUCTION TO MICROPROGRAMMING

The idea of microprogramming is normally attributed to Wilkes.[1] His stated objective was to provide "a systematic alternative to the usual somewhat *ad hoc* procedure used for designing the control system of a digital computer."[2] Actually, many logic devices being implemented today are far more complex than the computers which are deriving benefits from microprogrammed implementation. Some experts today are forecasting that most complex logic systems of the future will use microprogrammed techniques for the same reasons that motivated computer designers to select this alternative.

In a general sense, any sequential logic device can be viewed as transferring information from one set of storage elements to another through a logic network. In the case of a computer, the execution of an instruction involves a sequence of information transfers from one register in the processor to another, some of which take place directly and some through an adder or other logical network. A machine or computer instruction is made up of a number of these transfers which Wilkes likened to a program and hence, he termed the individual steps microinstructions and the sequence of steps a microprogram.

The mechanism Wilkes suggested for implementing the system is shown in Figure 1. The microprogram was held in a read-only diode memory or control store which is shown as consisting of two matrices A and B. The outputs of matrix A were used to control the transfers between the various registers. The outputs from matrix B were passed through a delay and were then used as inputs to a decoding tree. These inputs to the decoding tree directed the timing pulses to the next selected data line in the control store. Information from the sign flip-flop of the accumulator was used to select alternate paths through matrix B and hence to change the next selected data line in the memory. This is represented by one of the lines from matrix A which branches before it enters matrix B. The signals coming from matrix A control arithmetic gates, register paths, etc. Wilkes viewed these as incremental logical operations and called them micro-operations. A collection of these operations performed at one time was a microinstruction.

Wilkes' example segmented the microprogrammed control into two parts—one for operating the gates

TABLE I—Microinstructions for simple machine

CODE	MEANING
MARM	Gate MAR onto M bus
MBRM	Gate MBR onto M bus
PCD	Gate PC onto D bus
IAD	Gate IA (instruction address) onto D bus
ACD	Gate AC onto D bus
R	Read memory into MBR
W	Write MBR into memory
PLUS	Add M bus to D bus in adder and place on S bus
DTS	Gate D bus through adder to S bus
MTS	Gate M bus through adder to S bus
ONE	Gate D bus through adder to S bus and add one
SMAR	Gate S bus into MAR
SMBR	Gate S bus into MBR
SPC	Gate S bus into PC
SIR	Gate S bus into IR
SAC	Gate S bus into AC
JMP	Jump to address in address field of microinstruction
JIFO	Jump to address in address field of microinstruction if AC = 0
JOPC	Jump to address of OP code field

which control the data paths, and the other for selecting the next step in the control sequence. Today all microprogrammed devices are organized in a similar fashion. The essence of designing a good microprogrammed system is the selection of the proper strategies for data paths and logic function control, as well as the implementation of the control sequence section.

Figure 2 shows a simplified computing element. In reality it could be a word-organized single-address stored program computer. In this over-simplified version, assume the control portion of the machine generates the signals shown in Table I. These signals are called micro-operations. By combining these, instructions can be generated. Assume further that the control portion of the machine contains a ROS (Read Only Store) and that words are read from the ROS under the control of an address register. Words are read from the ROS in sequence unless one of the Jump instructions (JMP, JIFO or JOPC) is executed.

Figure 3 shows an example of a ROS instruction word with the appropriate fields labeled. The symbolic representations of the micro-operations are shown under the fields in which they appear in the microinstruction word. There are of course many different microinstruction formats. For example, the Interdata Mod IV or Micro 810 computers use 16 bit formats, whereas systems such as the IBM 360/85 use 128 bit formats.

Figure 4 shows a microprogram in which the contents of memory are added to the accumulator in the following manner:

Line 1 The contents of the program counter are transferred to the memory address register.

Line 2 The instruction is read from memory into the memory buffer register.

Line 3 The instruction is transferred from the memory buffer register to the instruction register.

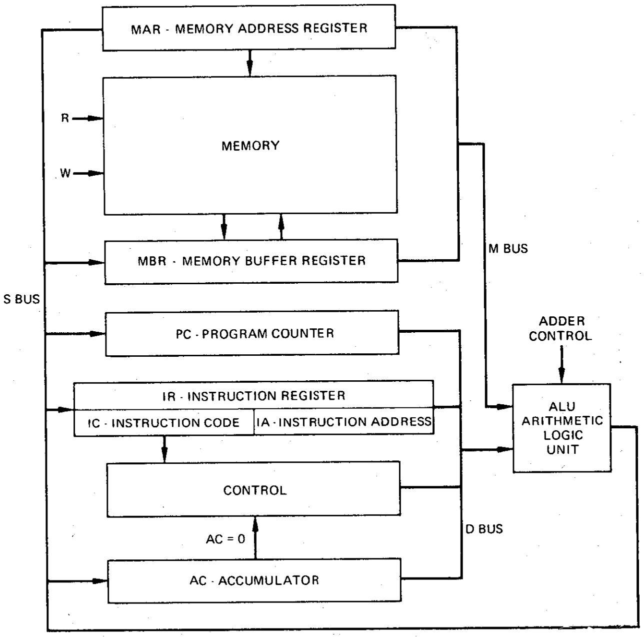

Figure 2—Simple microprogrammed machine

MEMORY CONTROL	JUMP INSTRUCTION	ADDER CONTROL	M BUS CONTROL	D BUS CONTROL	S BUS CONTROL	JUMP ADDRESS FIELD
R W	JMP JIFO JOPC	PLUS MTS ONE DTS	MARM MBRM	PCD IAD ACD	SMAR SMBR SPC SIR SAC	

Figure 3—Representation of a microinstruction word

Line 4 The control of the microprocessor is determined by the operation code of the instruction.

Line 5 The contents of the address portion of the instruction register are transferred to the memory address register.

Line 6 The desired data is read into the memory buffer register.

Line 7 The memory buffer register is added to the accumulator and the result stored in the accumulator.

Line 8 One is added to the program counter so it is ready to fetch the next instruction and the result is stored in the program counter.

Line 9 Control of the microprocessor is transferred to start the next sequence.

This example does not really discuss how the ROS is controlled. It merely points out that a control memory can emit signals capable of controlling the data paths in a system. The real essence of microprogramming is focused on controlling the address sequencing of the control memory itself.

CONTROL AND SEQUENCING OF THE CONTROL STORE

In every microprogrammed device there must be some logic which controls the ROS and does the basic system timing. The complexity of this logic depends to a high degree on the microprogrammed implementation. In a microprogrammed device with short ROS words where very few bits in the microprogrammed instruction word are devoted to determining the next instruction, the control logic will become fairly sophisticated. In these systems a ROS program counter will generally exist and the control logic will ensure that the next ROS control word is selected by augmenting the program counter by one just as the program counter is augmented in a typical computer system. In microprogrammed devices with longer words, the control will be conceptually simpler. For example, if each instruction contained the address of the next instruction, there would be no need for a program counter, only a ROS address register.

		MEMORY CONTROL	JUMP INSTRUCTION	ADDER CONTROL	M BUS CONTROL	D BUS CONTROL	S BUS CONTROL	JUMP ADDRESS FIELD
INSTRUCTION FETCH	1			DTS		PCD	SMAR	
	2	R						
	3			MTS	MBRM		SIR	
INSTRUCTION DECODE	4		JOPC					
EXECUTE	5			DTS		IAD	SMAR	
	6	R

RETURN	8			ONE		PCD	SPC	
	9		JMP					START

Figure 4—Microprogram to add contents of memory to accumulator

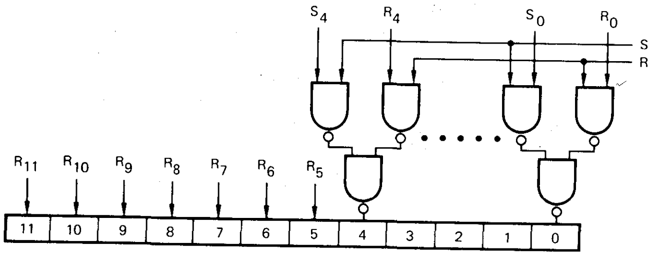

Figure 5—Two-address source for microprocessor address register

Wilkes' basic implementation shown in Figure 1 generated the address to read out the next microinstruction directly from the output of the B matrix. Therefore, if there were 1024 words of ROS, the output from this matrix would be a 10-bit code used to designate one of these words. While this technique is adequate, it fails to couple the microprocessing device in a tight fashion to its external environment and leads to an inordinately long response to an input stimulus. To see this, consider the problem of interpreting a 5-bit code and branching to one of thirty-two points determined by the code. This is the type of operation which occurs in interpreting the operation code of a computer. In the Wilkes' model, each bit must be tested separately and a branch must be taken at each step. This involves 5 separate tests, one for each bit and 31 branch-type instructions in a decision tree, plus an additional 32 branch instructions to get to the starting point of the various routines.

Wilkes' group suggested introducing multiple address sources. This greatly simplifies and speeds the solution to the above problem. To see this, consider the ROS address register shown in Figure 5 where the bits R_i are output from the address selection section of the ROS. Consider the bits S_j as bits from another register (for example, the instruction register in a computer). In order to interpret a 5-bit code, one need only let the bits R_{11} to R_5 select the starting address of a table in memory which contains 32 starting addresses of ROS sequences. The bits S_4 to S_0 could select any one of 32 entries in this table which could direct the microprocessing element to the proper location. Instruction decoding could, therefore, be accomplished with one microinstruction.

The importance of this technique goes far beyond the concept of instruction decoding. Any set of conditions could be introduced as an input in the low-order bit

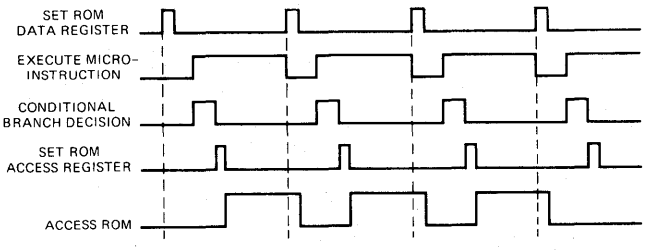

Figure 6—Typical ROS timing

positions and therefore, this represents one technique for developing a fast response based on the status of the external environment. For the example above, any one of 32 alternative courses of action could be taken in response to an input. This action could be initiated in one microinstruction cycle. With today's semiconductor memories, microprocessors with 100 nanoseconds cycle times are easily constructed, so that a response to an external stimulus can begin very quickly.

Figure 6 shows the timing in a typical microprogrammed system. The first set of timing pulses strobes the output from the ROS into the output buffer register.

As soon as the output buffer has settled, the execution of the microinstruction can begin. This is indicated in the second line of the timing diagram. The execution time will be long enough to permit the most basic microinstruction execution to take place. However, some of the longer operations might take two or more microinstruction times to execute. For example, suppose the time to gate data from source registers to the adder and to perform an "add" is 300 nanoseconds. If the basic microinstruction cycle is 150 nanoseconds, then an add operation would require two microinstruction times. This could be accomplished by executing the same microinstruction twice with the exception that data would not be stored in the destination register until the second instruction is executed. Another way to handle long instruction execution times is to let the microinstruction have a bit or bits which will be used to extend the microinstruction execution time. Still another obvious way for simpler systems is to merely let the longest instruction dominate the timing. For example, if 300 nanoseconds is the longest register-to-register cycle time, then the basic cycle could be selected as 300 nanoseconds. In most cases, however, a system will have certain microinstructions which require several basic machine cycles. For example, a fast microprogrammed device may be hooked to a slow core memory which has an access time of 800 nanoseconds compared with a basic microinstruction execution time of 200 nanoseconds. It is desirable to have some interlocks which enable this type of delay to be conveniently accommodated.

The fourth line in Figure 6 shows the time at which the ROS address register is loaded. This timing pulse will set the ROS address register. If a conditional branch is going to be executed, the logical decision must be made during the time shown in line 3 for the branch to be executed within the given cycle. Obviously, this is not always possible. For example, if a branch is to be made on overflow, it is likely that the information will not be developed by the adder until it is too late to enable a branch decision to be made for that instruction. Consequently, one instruction and one instruction execution time is lost because the branch decision must be made on the next instruction.

The fifth line of the timing diagram shows the time devoted to the access of the ROS. One reason for the importance of fast access in the ROS can now be understood. The shorter the access time, the more time is available for making decisions. Since a high percentage of microinstructions contain conditional branches, many instructions and instruction times can be saved by making the access time as small a percentage of the basic control cycle as is possible.

ADVANTAGES OF MICROPROGRAMMING

There are many reasons why it is desirable from a systems point of view to employ microprogramming. Some of these are:

1. Reduction of random logic, resulting in more structured organization.
2. Emulation of a number of devices (not just another processor) can be carried out by a single, general-purpose device.
3. Diagnostics and service aids may be implemented easily in the control portion of the system.
4. Field changes can be made easily by changing the contents of control stores.
5. Special-purpose adaptations can be made of a device by changing a few program cards.
6. The logical complexity of a device can be increased at lower cost than in a conventional system.
7. Final system definition can be postponed to a later time in the design cycle.
8. Documentation and service training costs can be reduced.

The prime motivation for interest in microprogramming today appears to be one of economy. To understand why, an analysis must be made of the cost of putting an IC (Integrated Circuit) into a system.

The direct cost of putting an IC into a system is over $1.00. Figure 7 shows a breakdown of these costs which one experienced manufacturer of digital systems considers reasonable. When all of the direct costs in fabricating a system are taken into account, such as indicator lamps, maintenance panels, system cabling, etc., and the total system manufacturing cost is divided by the number of IC's, one frequently arrives at a figure of $2.00 per IC. The $1.05 cost of Figure 7 will be used during the rest of this discussion because there seems to be general agreement that getting rid of one IC will usually save a manufacturer that much money.

It is interesting to note that under the assumption of Figure 7, even if IC's were free, the total manufacturing cost could be reduced by only 30 percent. Assuming designers continue to use conventional IC's and packaging approaches in design of their systems, there will be small, if not significant, decreases in the manufacturing cost of digital systems.

	$ 1.05

Figure 7—System cost for a 16 pin DIP on 88 pin 60 IC board

If one assumes that the average IC contains 3 gating functions, then the direct cost per gate installed in a system will be on the order of 35¢.

For the most elementary type of devices, random control logic will always be the most economical way to design a system. If, for example, a device can be controlled by a single pre-set counter, it is impractical to become involved in the intricacies of microprogrammed control. This is because a microprogrammed device has a base cost associated with the address sequencing and memory selection circuitry which is incurred no matter how simple the device is. This is shown in Figure 8. Properly designed semiconductor control storage has most of the memory selection circuitry integrated into the memory element and this greatly reduces the base cost.

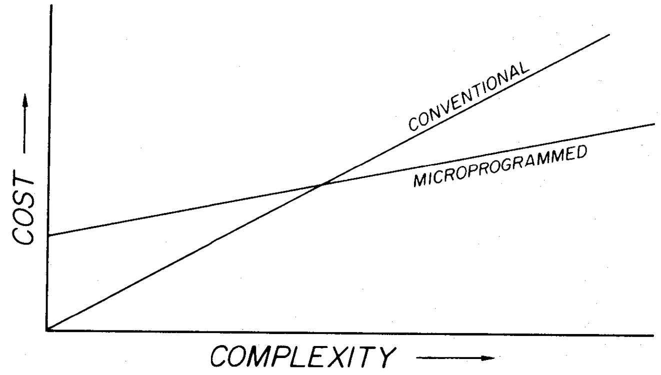

Figure 8—Cost comparison of conventional and microprogrammed control

Figure 8 shows the cost of microprogrammed control increasing slowly with the number of sequencing cycles. This is because each additional sequence cycle will, in general, require one additional word of control store. If, for example, the control memory of a device uses 32 bit words and the control store costs only 0.25¢/bit, as such devices will in the future, then the cost of an additional control cycle is only 8¢.

The cost of conventional control in Figure 8 is shown increasing at a fairly fast rate. One can see that if an additional control cycle required only one additional gating function or some type of storage element to distinguish it from all the other control states, then at least one gate or 35¢ in direct cost must be added to the system cost. For this simple example, the cost of conventional control increases at over four times the rate per sequencing cycle of microprogrammed control.

	1¢/BIT	0.5¢/BIT	0.25¢/BIT
• I C (4096 BIT ROM)	40.00	20.00	10.00
• Incoming Inspection	.50	.50	.50
• P C Card	.25	.25	.25
• Component Insertion and Fabrication	.03	.03	.03
• Board Check Out	.15	.15	.15
• Connector	.05	.05	.05
• Wiring	.12	.12	.12
• Power Supply $ 1.00 / Watt	.50	.50	.50
• Cabinetry / Card Guides / Fans / etc.	.10	.10	.10
	$ 41.70	$21.70	$11.70

Figure 9—Cost of ROM in microprogrammed system

There are a few hard facts to back up any estimates of the efficiency of microprogrammed devices, but most designers seem to agree that somewhere between 8 and 16 bits of ROM can be used to replace a gating function. If 16 is considered to be a pessimistic number and 8 an optimistic one, then a 4096-bit ROM is capable of replacing between 256 and 512 gating functions. This ratio provides a great incentive to the designer to employ microprogramming.

Figure 9 shows the direct cost of putting a 4096-bit ROM in a microprogrammed system, assuming costs per bit of 1¢, 0.5¢ and 0.25¢. If R bits of ROM replace a single gating function, then the dollars saved by employing a single 4096-bit ROM at 0.25¢/bit are:

$$\text{SAVINGS} = 0.35 \times \frac{(4096)}{\text{R}} - \$11.70$$

where $11.70 represents the cost of the ROM shown in Figure 9. These savings are plotted in Figure 10 for various costs of ROM.

While 12 bits is probably a realistic number per gating function replaced, it is interesting to note that the break-even points for 1¢, 0.5¢ and 0.25¢ per bit ROMS are 36, 66, and 122 bits. With a 4096-bit bipolar ROM there can be a tremendous margin of error in the assumptions, and still have microprogramming be the most economical approach to system design.

Other savings result as well. These are tabulated in Figure 11. For example, if one assumes 12 bits of ROM will replace a gate function, then the use of 4096-bit ROMs in the control portion of a digital system will save about 114 packages, 8.5 watts of power and 100 cubic inches of volume in addition to $119 per 4096-bit ROM employed.

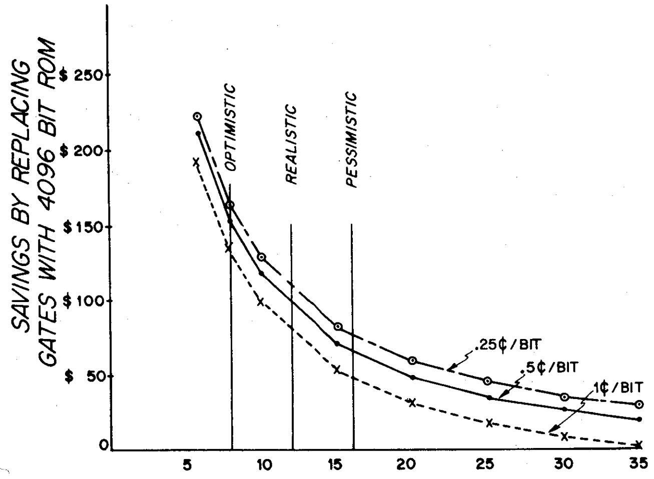

Figure 10—Number of ROM bits to replace a gate function

DOLLARS SAVED PER 4096 BIT ROM	$168	$119	$83

Figure 11—Savings by using 0.25¢/bit ROM in microprogrammed control of digital system

CONCLUSION

The true promise of LSI has not been realized in most digital systems simply because it has been unappealing to use custom designed parts in all but the highest volume applications. Microprogramming techniques used in conjunction with semiconductor memory can provide many of the benefits of LSI for a broad class of systems. The designer, to take advantage of this new component, will, however, have to change many of his design techniques and philosophies.

SYMBOL hardware debugging facilities

by M. A. CALHOUN

Kansas State University
Manhattan, Kansas

INTRODUCTION

The SYMBOL system is a full-scale working demonstration of an ALGOL-like, high-level, general-purpose, procedural language and a multi-processing, multiprogramming operating system implemented directly in hardware.[1,2,3,4] The results have proven the versatility of the design, construction, and testing techniques that were developed to enable a small number of people to implement such a major system in a reasonable time and at a relatively low cost.

Although the last items in the project to be developed, the methods used to test and debug SYMBOL were not the least important; delivery of the finished system would have been much delayed if more conventional methods of manual excitation and probing had been used. To facilitate fuller understanding of these testing techniques, a brief description of the architecture and physical characteristics of SYMBOL will be given first, followed by a more detailed description of the test facilities.

SYMBOL HARDWARE AND ARCHITECTURE

Logic in SYMBOL is implemented with Complementary Transistor Micro-Logic (CTμL), a positive AND/OR logic family with wired-OR capability at every output except that of the flip-flop.[5,6] The importance of the wired-OR capability must be emphasized: there are a significant number of two-way wired-OR ties with sources throughout the six-foot long main frame; if discrete OR gates had been required, the size of the finished system would have been considerably larger and its simple bus-oriented organization would not have been possible.

The dual-inline CTμL integrated circuits are assembled on about 110 large two-sided printed circuit boards with plated-through holes (see Figure 1). These boards contain all of the logic components in the system and are easily removed for incorporation of logic changes using discrete wire "patches" to the original printed circuitry. Figure 2 illustrates schematically how the boards are mounted between a pair of parallel two-sided printed circuit "motherboards".

Communication between boards is provided by two groups of 200 parallel printed circuit bus lines on the motherboards, the "connect" bus and the "bypass" bus. These buses provide all required system interconnections except for cables to peripheral devices and to the console. Physically, each large board can contact up to 200 bus lines and have the remaining 200 lines bypass it. A signal on the bypass bus may cross over a signal on the connect bus between board positions to allow a board to contact the corresponding position on the adjacent board or, alternatively, to a board several slots distant. In addition, either or both buses may have continuity breaks to isolate groups of boards.

There were eleven such isolated groups of boards in the original system, where each such Autonomous Functional Unit (AFU) acts as a specialized processor (see Figure 3). The Main Bus, a 111-wire subset of the 400 wires on the motherboards, runs the full length of the system and connects to each AFU. The lines in this time-shared, global communication path are distributed as follows:

64	bidirectional data lines
24	bidirectional address lines
10	bidirectional priority lines
6	operation code lines
5	terminal number lines
1	system clock
1	system reset

In order to fully appreciate the operation of the debugging facilities and the interactions between these facilities and SYMBOL, it is necessary first to under-

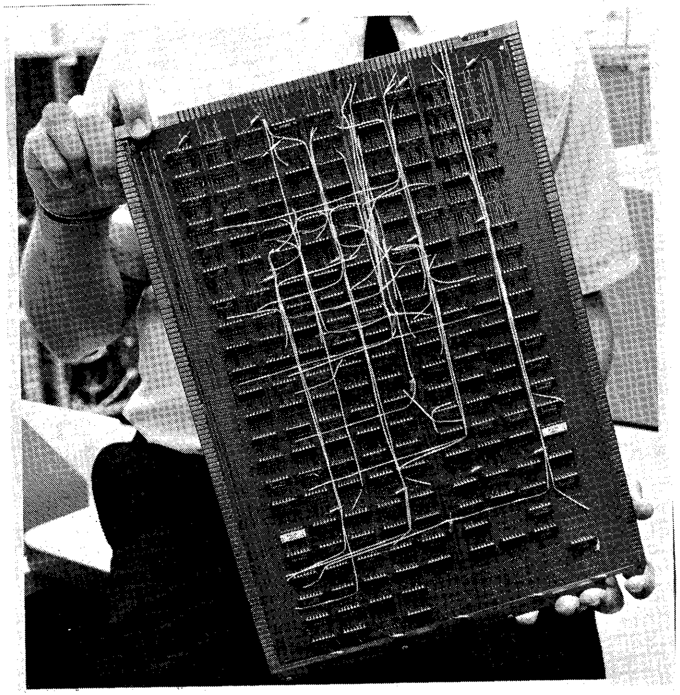

Figure 1—Typical 12″ × 17″ two-sided printed circuit board with logic additions and changes made with discrete wires

stand the various modes of communication which exist between the eleven AFU's. The foundation for this understanding is the knowledge that *everything* of importance that happens within an AFU eventually has some effect on the Main Bus. When the Instruction Sequencer finishes processing one instruction and needs another, a request to the Memory Controller is sent via the Main Bus. If the Arithmetic Processor runs out of data, a call for more goes to the Memory Controller. In both cases, information returned from the Memory Controller is sent over the Main Bus. If an input device completes its operation, the Channel Controller notifies the Interface Processor via the Main Bus. When the Translator is done with compilation of a program, the System Supervisor is notified via the Main Bus. Even if a processor fails catastrophically and refuses to function at all, the absence of Main Bus transfers originating from that AFU over a short period of time (20 clock cycles, perhaps) can be detected. Thus it can be said that whatever controls or watches the Main Bus thereby controls or watches SYMBOL. This concept of the Main Bus and the kinds of information that are transmitted through it are key features in the design of the total system and in the functioning of the debugging facilities.

Four distinct types of bus usage are possible. They are:

AFU to Memory Controller requests
Memory Controller to AFU returns
AFU to AFU transfers
Control exchange cycles

All Main Bus transfers are priority sequenced, where the priority bus coordinates the usage of the other buses. When an AFU desires to use the Main Bus, it raises it priority line and simultaneously checks to see if there are any higher priority requests pending; if there are none, it uses the bus on the following cycle. AFU to AFU cycles, used only between sections of the Central Processor, are also controlled by the priority bus: the Central Processor assumes the Main Bus is available for a private "sneak" cycle if no priority lines are raised. Control exchange cycles are used to communicate control information between the System Supervisor and the other AFU's. During a control cycle, the Main Bus lines have preassigned uses, with certain lines used to start and stop each AFU, others to indicate the completion of an AFU task, etc.; during a given

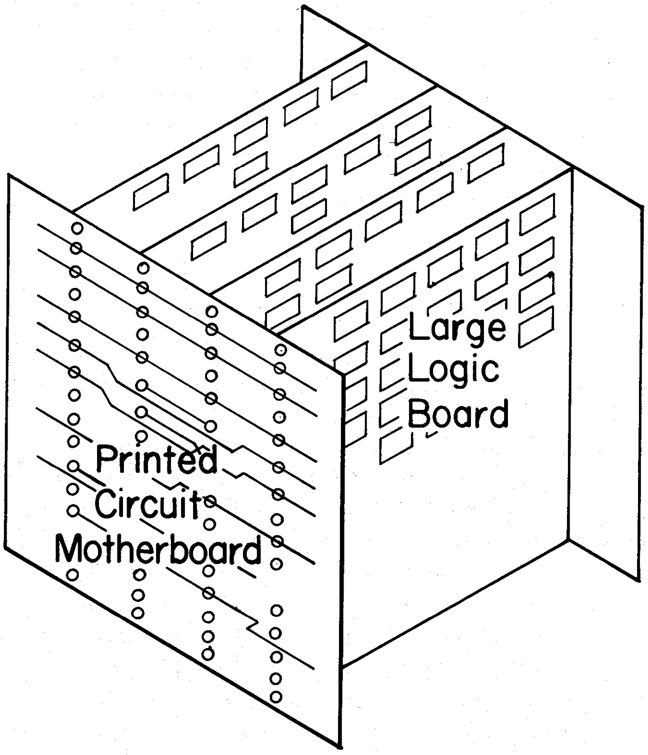

Figure 2—Physical organization of SYMBOL illustrating placement of large logic boards between parallel printed circuit motherboards

cycle, any combination of the paths can be used simultaneously.

SYMBOL DEBUGGING

The testing operations required in the development of a large system can be divided naturally into several fairly specific stages. The test functions vary as the system progresses from the research and development stage, to the prototype stage, to the production stage, and finally to the customer support stage. The emphasis on testing during these stages shifts from one in which strong support is given to engineering design checkout, to one which gives strong support to bad-part identification. System development within each stage requires component, board, AFU, and system testing functions; these functions are not always clearly distinct, but they can be considered separately for convenience. The discussion which follows illustrates the major requirements for testing in a research and development environment, with other aspects of testing discussed to a lesser extent.

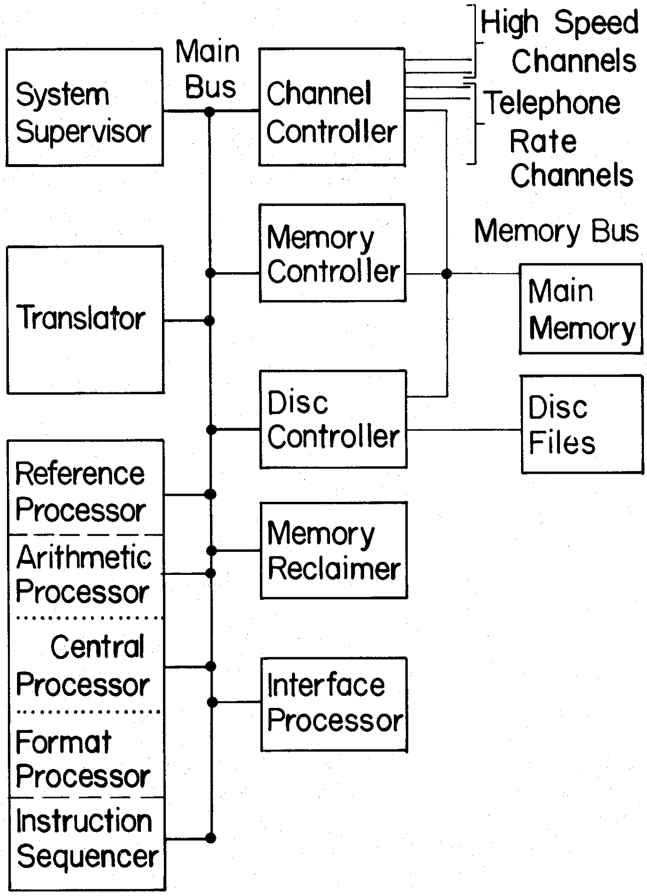

Figure 3—Block diagram of the SYMBOL system showing the original eleven autonomous functional units all connecting to the main bus

Component testing

Component testing is normally an incoming inspection operation. The integrated circuit devices used in SYMBOL were checked both statically and dynamically upon receipt for two main reasons: (1) The devices often had a long lead time for procurement, and an incoming inspection allowed immediate replacement orders to be made for bad devices. (2) The environment in which the devices were used (printed circuit boards) is one which has a high time (and therefore cost) penalty for replacing a device that should not have been installed in the first place.

The tests included a static check of the logic the device was supposed to implement, the on/off delay times from threshold to threshold, a check on the ringing tendencies, operation of the device when driven by a minimum clock pulse (where applicable), and the operation of the device under minimum and maximum power supply limits. These tests were made on a breadboarded device tester which, while adequate, was not very efficient, especially from a human factors viewpoint. In particular, the tester was capable of making only one class of measurements at a time; if a device required two classes of measurements, it had to be retested in a second pass. This resulted in a low throughput rate since about half of the time required to test a device was spent in manually transferring it from the source bin to the tester and from the tester to the "accept" or "reject" bin. Fortunately, better component testers are now available with good human factors design and automatic device transporters for quick and efficient incoming inspection.

Except for perhaps 100 devices received in the last few weeks of the project, all 18,000 integrated circuits in SYMBOL were given a thorough incoming inspection. It is safe to say that these last 100 devices caused more trouble during debugging than the first 18,000. This was sufficient proof of the absolute necessity for complete incoming component testing for future projects.

Board testing

Two major kinds of errors should be detected and corrected through board testing before a board is placed into a system. As in most system development, construction errors of various kinds will be discovered.

These errors will include fabrication errors such as drawing mistakes, missing or misplaced holes in the printed circuit, solder bridges, and misplaced components, to name just a few. In addition, there will also be system design errors ("oversights"?) which must be found and corrected. The scope of this problem was extremely large for SYMBOL boards because of their great number (110), their size (maximum of 220 integrated circuits), and their limited number of signal contact points (250). Considerable development is still necessary before automatic computer test generation is economically feasible for this size of board: current programs might require two hours to generate complete tests for about one-fifth of the logic on a board, and the difficulty of the task increases considerably with increasing size. Such costs could not be justified for this prototype system. If the problem were altered from an exhaustive test of all of the logic on a board to a test of all the used states of the logic, it might very well prove economically feasible. In particular, in a production environment, the cost of such test generation could be amortized over many systems since the same test sequence would be used over and over again. However, even though the isolation and correction of fabrication errors before system checkout began would have allowed more efficient debugging, it was felt that the amount of effort required for a thorough precheck could not be justified for this one-of-a-kind system. Thus, after a relatively cursory examination of each board for obvious errors (such as solder bridges) by experienced technical help, the board was returned to the designer for simple logic verification in a manual test station before proceeding to AFU or system test. This board test station has been described elsewhere.[4]

Subsystem and system test

Subsystem testing was the process of debugging a complete Autonomous Functional Unit as a unit. Each AFU performs, by itself, some function in the complete system, and, in a sense, is a stand-alone unit. Except for the Memory Reclaimer, a two-board AFU which was extensively (but not completely, as it turned out) simulated using the FAIRSIM* system, most AFU's were too large to allow simulation as a unit; therefore, subsystem test was the first time at which all of the boards in an AFU were run together. By this time most of the fabrication errors had been detected through board testing, although there were always a few left to find.

Subsystem testing could take many forms and could be performed in many different ways. An extension of the board test station was conceived where all boards of an AFU could be inserted into one module and a manual test performed. This sort of testing might have been useful in some limited areas such as verifying the basic cycling of control logic or the basic register transfers within an AFU, but, in general, a complete AFU test in this sort of test station would be very difficult, inefficient, and time consuming. Recognizing, then, that a thorough job of AFU testing was not desirable or even practical, subsystem and system testing were combined into the same operation and were essentially carried on simultaneously.

System testing was quite a prolonged process and involved a wide spectrum of activities from the initial startup of each of the AFU's on through to the final operation of the full system. The debugging of SYMBOL encountered many unique problems analogous to trying to test both a central processing unit and an operating system simultaneously on a more conventional computer. Unfortunately, self-diagnostics were impractical until late in the project because the construction schedule was such that Input/Output equipment was one of the last items to become operational. Some way of automatically exercising and/or monitoring various AFU's and portions of the system and of recording the results of these tests was absolutely necessary; in response to these needs, the first System Tester was developed.

SYSTEM TESTER

The System Tester consisted of three major elements: a programmable minicomputer, a logic interface and bus multiplexer between the minicomputer and SYMBOL, and a comprehensive set of computer programs which could control (and be controlled by) events

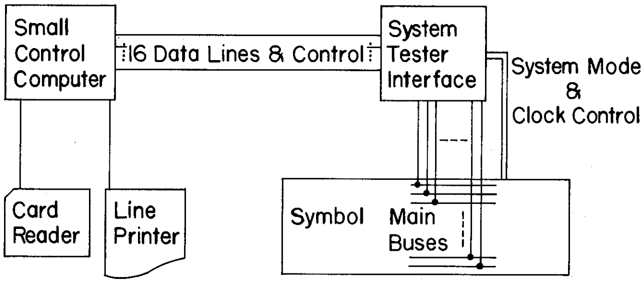

Figure 4—Block diagram illustrating connection of the programmable control computer to SYMBOL through the system tester interface

* Fairchild Digital Simulation program for Computer Aided Design.

occurring on the Main Bus. The configuration is schematically represented in Figure 4.

The minicomputer was an IBM 1130 with an 8192 word, 16 bits per word, memory (3.6 microsecond cycle time), a removable disc, a console keyboard and typewriter, a card reader/punch, a Data Products 80-column high-speed line printer, and a Storage Access Channel. The standard software supplied with the system (Disk Monitor Version II, Level 3) was used throughout the project.

The hardware interface consisted of four large logic boards between a pair of short motherboards mounted in a small separate enclosure (along with the necessary power supplies, cooling fans, etc.), placed adjacent to one end of the SYMBOL main frame. Short cables were used to connect the Main Bus to the interface, and a somewhat longer and thinner cable connected the interface to the control computer. The interface to the line printer was located on a fifth board in this same module.

The System Tester interface logic was divided into four basic sections. The first was a fairly small one which consisted of a number of TTμL inverters which were the logic level buffers between the control computer and the CTμL logic in the rest of the system. Second was a set of control interface registers and Input/Output logic which communicated with the control computer. The third section was another set of data registers which could be loaded and unloaded by commands from the control computer and which were used to transfer data to and from the Main Bus. The last section was the control logic which obeyed the priority rules of the Main Bus and included system reset and clock controls.

In addition to the 111 Main Bus lines, four extra lines were allocated to a System Test Mode which was distributed throughout the system and decoded by certain AFU's to provide additional control of several of the more complex operations. Different test modes, for example, could completely turn off a particular AFU or could force serial instead of parallel operation of all the AFU's. The discrepancy between the speed of the control computer's 16-bit data channel and the considerably larger Main Bus was resolved by allowing the interface to turn off the SYMBOL clock momentarily each time data was transferred to or from the interface buffer registers. Although control of the clock in this manner significantly lowered the execution speed of SYMBOL, all logic sequences were still executed in the same order with respect to each other, except for real-time peripheral devices, no matter what the actual clock speed.

The third major element of the System Tester was a language called DEBUG (what else!) and a set of programs which interpretively executed this language to control the interface as directed by input from the user; details of the language are given below. The actual interface and interrupt-servicing subroutines were written in assembly language while the majority of the remaining programs were written in FORTRAN. However, as new features were added to the system during the development period, the limited memory of the control computer was exhausted several times; each time, another routine was converted from FORTRAN to assembly language in order to free additional space. Notwithstanding this severe memory limitation, only rarely was a language feature removed, and then only after assurances from all users that the feature really was not being used.

In addition to the specific language features described below, many specialized programs were written (normally in FORTRAN) to provide formatted memory dumps, save-restore capability between the removable disc and SYMBOL memory, and other convenient features.

DEBUG LANGUAGE

The following sections describe the DEBUG language and the operation of the System Tester in some detail and especially attempt to convey some of the flavor of the system. The past tense is used because the System Tester was replaced by a special-purpose AFU, the Maintenance Unit (to be described later) and thus no longer exists.

The interpretive DEBUG processor accepted commands from punched cards. Each command consisted of an instruction element followed by a list of zero or more data elements. The format was relatively free form, with all blanks (spaces) ignored except in a string data element. Each element was separated from the preceding one by a comma or an equal sign. The last element was terminated by a period. Comments or other information following the period were ignored (a comment card was one whose first non-blank character was a period). Blank cards could be included in the deck for readability.

Extensive error checking was performed by the DEBUG processor, although very little error recovery was attempted because of the paucity of memory. When a mistake was discovered, the main response was an indication on the output listing of its nature. The system's action after an error was not predicted. In addition to a listing of the input commands and error messages, other messages of an informative nature and

TABLE I—List and Description of Programmed Register and Interface Hardware Register Mnemonics Recognized by the DEBUG Processor

Programmed Register Mnemonics

COMB—Address last formed by a COMBINE command
COUNT—Number of Main Bus transfers monitored in tracing
SPLTG—Group-link word address from a SPLIT command
SPLTP—Page address from a SPLIT command
SPLTW—Word address from a SPLIT command
ZERO—Infinite source of *zeros*

Interface Hardware Register Mnemonics

MP—Monitored SYMBOL priority bus lines
OP—Memory operation code last transmitted or error code last received
PL—Page-list currently specified (the mnemonic PAGE LIST could also be used)
PRIOR—Priority of the System Tester (any of the AFU's could be simulated)
RADR—Address last returned from SYMBOL
RCVX—Patchable register last received from SYMBOL
RDATA—Data last returned from SYMBOL
TN—Terminal number currently in use (TERMINAL NUMBER could also be used)
XADR—Address last transmitted to SYMBOL
XDATA—Data last transmitted to SYMBOL
XMTX—Patchable register last transmitted

the results of any action taken could be obtained on the line printer.

Data elements

A data element could have one of the following forms:

1. A hexadecimal constant formed by the character "/" followed by zero or more hexadecimal digits. Only the last 16 were retained. A typical example is /0079 004F C0 02D63B, where blanks have been included for readability. If fewer than 16 digits were entered, the result was right-justified. For left-justification ("contraction" is a good mnemonic) the last digit could be followed by an apostrophe and a character to designate the "fill" digit. Examples are /FF'O, where the leftmost byte is all *ones* and the rest are *zeros*, and /'A, a word of alternating *ones* and *zeros*.
2. A positive decimal number formed by zero or more decimal digits. Two examples are 0 (zero) and 18 446 744 073 709 551 615, the largest possible 64-bit number.
3. An alphanumeric string formed by a string-start indicator (an apostrophe) followed by zero to eight characters. To allow for character codes not represented on a keypunch, triplets composed of an escape character (the @) followed by a two-hex-digit coding of the desired character could be included in the alphanumeric string.
4. A data element could also be a register mnemonic formed by a single letter "A" through "Z" or a word chosen from a list of programmed registers or interface hardware registers which had specific predefined uses. The single-letter programmed registers were for temporary storage of data, addresses, etc., as the user desired. They could be initialized, cleared, etc., only by DEBUG commands or by being explicitly named in a Memory Control or System Supervisor command. A list and description of the multi-letter register mnemonics is given in Table I. Programmed registers A through Z and ZERO and hardware registers XDATA and RDATA were eight-byte (64 bit) registers. To refer to fewer than eight bytes, the mnemonics could be followed by a subscript from 0 through 7 enclosed in parentheses. Subscripts 3, 4, 6, and 7 implicitly referenced a single-byte datum. Subscripts 0 and 2 referred to a two-byte page address, and subscripts 1 and 5 referenced three-byte word addresses. No subscript implied context-dependent use of some or all of the full 64-bit register.
5. And finally, a data element could be empty or null if it were formed by two consecutive terminators or two terminators separated only by blanks.

The System Tester was a combination hardware/software system. To execute each command, the DEBUG processor transferred the contents of the indicated programmed registers to the appropriate hardware registers in the interface and initiated the proper operation. Although a data element could be left unspecified, the corresponding hardware interface register still participated in the operation; its contents were simply the value remaining from the previous operation. These registers could be initialized, set, cleared, etc., by DEBUG commands or by implicit side effects of various Memory Controller or System Supervisor operations.

Instruction elements

An instruction element was a mnemonic chosen from a predefined list; only the first five characters of mnemonics containing more than five characters were used

TABLE II—List of All DEBUG Main Bus Transfer Commands with Data Elements Explicitly Identified by the Corresponding Default Hardware Interface Register Mnemonic

Command	Function	Side Effects
AG, XADR, RADR.	Assign group	RDATA=0
AG00, RADR.		XADR=RDATA=0=PL
AG01, RADR.		XADR=RDATA=0
AG10, XADR, RADR.		RDATA=0=PL
DE, XADR.	Delete end of group	RADR=RDATA=0
DS, XADR.	Delete string	RADR=RDATA=0
DL, XADR.	Delete page list	RADR=RDATA=0
FD, XADR, RADR, RDATA.	Fetch direct	
FF, XADR, RADR, RDATA.	Fetch and follow	
FL, XADR, RADR, RDATA.	Follow and fetch	
FR, XADR, RADR, RDATA.	Reverse follow and fetch	
IG, XADR, RADR.	Insert Group	RDATA=0
RG, XADR, RDATA.	Reclaim group	RADR=0
RG0, RDATA.		XADR=RADR=0
SA, XADR, RADR, XDATA.	Store and assign	RDATA=0
SD, XADR, RADR, XDATA.	Store direct	RDATA=0

SO, XADR, RADR, XDATA.	Store only	RDATA=0
SS, XDATA, XADR, OP, RDATA.	Control exchange cycle	

for recognition. Most commands were order dependent, and data elements had to be listed in the exact order shown (or not listed at all). Data elements to the right of the last one of interest to the user did not need to be indicated. An example of each Main Bus command, with data elements explicitly identified by the default hardware interface register mnemonic, is given in Table II.

In addition to the simple Main Bus commands, there were 38 other commands available to the user to provide for explicit control of the System Tester environment; control of the hardware interface registers; maintenance of the files stored on the control computer's disc; loading, reading, writing, and testing of SYMBOL's memory; monitoring of SYMBOL; and decision making within DEBUG. These commands are summarized in Table III, where reserved mnemonics are shown in capital letters, and parameters and explanatory notes are given in lower case letters.

MAINTENANCE UNIT

To provide an independent maintenance and debugging capability, the System Tester was replaced by another AFU, the Maintenance Unit. Figure 5 schematically illustrates the final system configuration as delivered to Iowa State University. Input/Output equipment, controlled by a logic switch, is shared between the Maintenance Unit and a high-speed batch

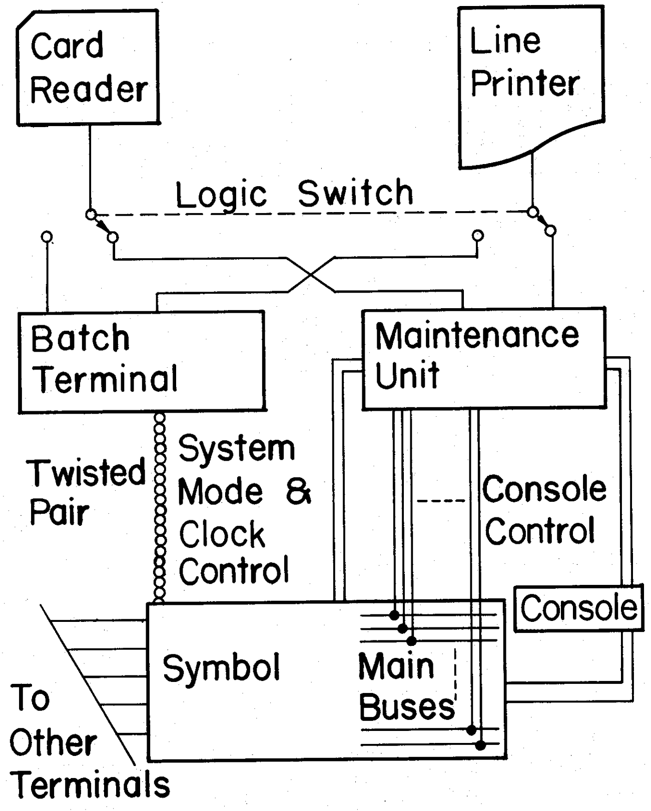

Figure 5—Schematic representation of the final system including the maintenance unit and a high-speed terminal sharing common input/output peripherals

TABLE III—DEBUG Macros and Commands for Controlling the System Tester

Control of the general test environment	
CLEAR TO ZERO, unordered list of registers.	
COMBINE, page number, group number, word number, COMB.	Address generator
EJECT.	Skipped output listing to a new page
END.	Signaled end of a testing session
EQUATE, old mnemonic = new mnemonic.	Corrected simple keypunch errors
HELLO, user's identification.	Identified beginning of a test session
LIST ALL.	Permitted printing of everything
LIST ERRORS ONLY.	Only error messages were printed
MOVE, destination = source.	Register-to-register transfers
PAUSE, number of milliseconds.	A timed delay.
PRINT, unordered list of registers.	
REGISTER STATUS.	Printed contents of interface registers
REPEAT LAST MEMORY COMMAND, number of times.	With XADR = RADR each time
SET, register = value.	Register initialization
SPLIT, source, SPLTP, SPLTG, SPLTW.	Address decomposer
STOP.	Press "START" on console to continue
WATCH, unordered list of hardware interface register mnemonics.	
Control of the hardware interface	
LOAD BUS AND STEP CLOCK, XDATA, XADR, OP.	Single-step bus control
START CLOCK.	Let SYMBOL free-run
STEP CLOCK AND PRINT CONTENTS OF MAIN BUS, number of times.	
STOP CLOCK.	Force SYMBOL to halt
SYSOFF.	Ccntraction of "system off"
SYSON.	Contraction of "system on"
Maintenance of files stored on control computer's disc	
DELETE, FILE n.	Deleted a previously saved file
FILE STATUS.	Gave status of all files on disc
RESTORE, FILE n.	Loaded SYMBOL memory and DEBUG status
SAVE, FILE n.	Stored SYMBOL memory and DEBUG status
Loading, reading, writing, and testing of SYMBOL memory	
FIND, beginning address, ending address, data, mask.	Searched for data
INITIALIZE, first address, last address, datum.	Loaded memory with datum
LIST, beginning address, ending address.	Dumped memory on line printer
LOAD, beginning address, ending address, ordered list of data elements.	
TEST CORE, XDATA, number of times.	High-speed repetive memory test
ZERO CORE.	Cleared SYMBOL memory to all *zeros*
Monitoring of SYMBOL	
PREPARE TO TRACE, unordered list of AFU names.	Set up for trace mode.
TRACE, XDATA, XADR, OP, unordered list of conditions for exiting.	
Decision making within DEBUG	
GO TO, label.	Skipped cards until label was found
IF, data, mask, condition, skip flag, number of cards.	Decision maker
LABEL, user-chosen label.	Provided target for a GO TO command

terminal. The Maintenance Unit console, with START, STOP, INHIBIT LIST, and RESET switches, is integrated into the SYMBOL console. A simple punched card input, easily produced at a keypunch or through another processor called SUPERBUG (written in FORTRAN for an IBM System /360) is used to direct the hardwired Maintenance Unit. To preserve the results of all prior testing, all DEBUG card decks were converted to equivalent SUPERBUG decks through a modified version of DEBUG which used the System Tester and SYMBOL in the translation process. The essential features of this control language are given below in hopes that they will provoke additional ideas.

The Maintenance Unit is a card-driven character processor where each card contains one or more commands. The command format is space independent, but parameters are order dependent. The first non-blank character on a card is the command code. Parameters (if any) are separated from each other by a dash (minus sign). Two consecutive dashes (with zero or more intervening spaces) indicate an (optional) missing parameter, in which case the register contents remaining from the previous command are used. The first semicolon on a card terminates processing of further characters from the card (i.e., human-readable comments, sequence numbers, etc., may follow a semicolon) and the command is executed with parameters received before the semicolon (a semicolon is automatically generated at the end of a card if none were previously found). Because of minimized decoding logic, the only valid characters before a semicolon are the hex digits 0 through F, the dash, and the (ignored) space.

Maintenance unit hardware

Table IV describes the hardware registers contained in the Maintenance Unit. In the table and in the following descriptions, each upper case character in a register mnemonic represents a single card column.

During operation, XXXXXX and Q are cleared to *zeros* before each new command is read. RRRRRR, RC, and DDDDDDDDDDDDDDDD are preserved from one instruction to another unless changed by a memory command. M is preserved until a new value is loaded or until a system reset is performed, after which M=0. XMP, CCCCCC, Ø, P, and TN are preserved from command to command unless specifically changed.

TABLE IV—Description of Registers in the Maintenance Unit

CCCCCC—	Address compared during trace (24 bits)
DDDDDDDDDDDDDDDD—	Transmitted or received data (64 bits)
M—	System test mode (4 bits)
Ø—	Operation code (4 bits)
P—	Page list (2 bits)
Q—	Disc quadrant code (4 bits)
RC—	Memory Controller return code (6 bits)
RMP—	Priority seen during trace (12 bits)
RRRRRR—	Returned address (24 bits)
TN—	Terminal number (5 bits)
XMP—	Priority watched for trace (12 bits)
XXXXXX—	Transmitted address (24 bits)

Note that P, TN, Ø, Q, XMP, and CCCCCC are treated as a single ordered parameter when loaded from a card. P and TN may be changed without affecting Ø by following TN with a dash or semicolon (or by leaving the remainder of the card blank). Other than these registers, the Maintenance Unit contains no memory; card commands are processed "on the fly" without benefit of additional storage.

SUPERBUG commands

The thirteen valid operation codes are summarized in Table V, where typical cards and variations are shown. Explanatory notes are again written in lower case letters. Unused command codes 0, 1, 2, 6, and - are simply ignored.

DEBUGGING TECHNIQUES

Although the command and control languages for the System Tester and the Maintenance Unit differed somewhat (with the Maintenance Unit having a considerably smaller repertoire), debugging using the two systems was essentially the same. Both systems allowed the full range of Main Bus transfers to be initiated. This meant, for example, that the Memory Controller (the central hub for most information transfers) could be thoroughly and exhaustively checked without having any other AFU functioning. Control exchange cycles enabled the starting and stopping of any AFU or groups of AFU's. The environmental commands and the macros, such as ZERO CORE, provided a good human interface with the system and permitted easy setup of initial conditions in preparation for a test. And last, and definitely *most* important, was the ability of both testers to monitor or "trace" the operation of SYMBOL as it operated under its own steam.

In the System Tester, monitoring was accomplished by a PREPARE TO TRACE card (which set the interface into a trace mode) followed by a TRACE command with parameters to start the proper AFU(s) and to establish stopping conditions. A single card combining both setup and startup commands was used with the Maintenance Unit. In either case, once the monitoring process was begun, all (or any subset) of the events occurring on the Main Bus (plus several "patchable" lines used to assist in observing internal AFU operations) could be printed on the high-speed line printer. At the option of the user, printing could be suppressed and the results of the trace could be stored "round robin" in a small temporary buffer (on disc with the System Tester or in SYMBOL core with the Maintenance Unit) for later playback only if something crashed. The buffer in the System Tester held

TABLE V—Examples of SUPERBUG Commands which Control the Maintenance Unit

```
; THIS IS A COMMENT CARD AND DOES NOT AFFECT THE MAINTENANCE UNIT IN ANY WAY
3; Pause. Press "START" on console to continue processing.
4; Enable printing of results on the line printer
5; Inhibit printing for greater test throughput
7; Skip the line printer to the top of a new page
8 00XXXX-DDDDDDDDDDDDDDDD-DDDDDDDDDDDDDDDD-etc.,   Load core with data
8 00XXXX-DDDDDDDDDDDDDDDD----------------------------------------etc.,   Load successive core locations with datum
8 -FFFFFFFFFFFFFFFF-1-4-30--AAAAAAAAAA00; Load beginning at address zero
9 00XXXX; Dump non-zero contents of memory on line printer
9;           Dump non-zero memory beginning at address zero
A 00XXXX-DDDDDDDDDDDDDDDD-DDDDDDDDDDDDDDDD-etc.,   Compare core with data
A -FFFFFFFFFFFFFFFF-1-4-30--AAAAAAAAAA00; Compare beginning at zero
B; Test core with all ones and all zeros, in that order
C XXXXXX-DDDDDDDDDDDDDDDD-P TN Ø; Memory cycle without check of results
C XXXXXX-DDDDDDDDDDDDDDDD-P TN Ø-RRRRRR-DDDDDDDDDDDDDDDD-RC TN; With check
D; System reset. Equivalent to pressing "RESET" on the console
E XXXXXX-DDDDDDDDDDDDDDDD-P TN; System Supervisor transmit without trace
E XXXXXX-DDDDDDDDDDDDDDDD-P TN 0 Q; Disc-synchronized System Supervisor transmit
E XXXXXX-DDDDDDDDDDDDDDDD-P TN 0 0 XMP CCCCCC; Trace after System Supervisor transmit
F M; Set new system test mode
```

the last 1600 operations whereas the Maintenance Unit's buffer held but the last 64; usually the most recent 10 to 20 were sufficient to analyze whatever problem caused the crash. As might be expected, this "instant reverse playback" feature gained heavy use since testing without the real-time printing of results speeded things up manyfold; only the last cycles which caused failure needed to be printed.

SUMMARY

The full-scale running SYMBOL system has demonstrated that:

1. A very high-level, general-purpose, procedural language and a multi-processing, multi-programming operating system can be implemented directly in hardware.
2. Design and construction techniques using only large two-layer printed circuit boards for all system interconnections, together with a functionally factored system result in an economical, serviceable, reliable, and "debuggable" system.
3. Effective testing techniques that connect an operating processor to an unproven system which has a bus-organized architecture can be developed to enhance and greatly simplify the debugging process

ACKNOWLEDGMENTS

The author wishes to acknowledge the help of the past and present members of the Digital Systems Research Department at Fairchild Camera and Instrument Corporation who contributed to the testing phase of SYMBOL. Steve Lundstrom designed the original System Tester and contributed to the development of the DEBUG language. Tom Cook assisted with the implementation of the Maintenance Unit. Eric Palmer wrote the SUPERBUG processor. The guiding hands of Rex Rice and William R. Smith were present throughout the entire project. And, of course, the hard work and enthusiasm of the other members of the department made the project succeed.

The Rice Research Computer—A tagged architecture*

by E. A. FEUSTEL

Rice University
Houston, Texas

INTRODUCTION

In this paper we report on a new computer with several novel features. These features are applications of the concept of tagged architecture, and although some of them are not unique to the Rice Research Computer (R-2), they focus our attention on this radical design form, its advantages and disadvantages. Since the work is still in progress, we limit this report to a discussion of the architecture and a few of its ramifications.

History of tagged architecture

The R-2 computer is an adaptation of a design of the Basic Language Machine (BLM)[1] of Iliffe. In his book and paper[2] he presents an argument for the utilization of a fraction of each memory word as tag bits. These tag bits are to be interpreted by the hardware as information about the data found in the referenced location, or its status with respect to the program or operating system.

The basic concept of tag bits is not new. Almost all computers employ a parity bit which the hardware uses to detect memory failure. In addition, many computers utilize a lock byte which limits access to an area of storage to the operating system or to those who have a key byte that opens the locked area.

Early machines also employed bits which were of special significance to the hardware. The Burroughs B5500 employed a flag bit to inform the hardware that the word at the location addressed possessed a non-numeric value which must be interpreted by the operating system.[3] The Rice Computer (R-1),[4] circa 1959, employed two bits for every word which could be set by the operating system or the programmer. These bits were used in an extensive debugging system wherein tracing, monitoring, or other procedures were carried out when a tagged data word or instruction was encountered.

Today the EAI8400 employs two tag bits for similar purposes. The Telefunken TR4 and TR440[5] employ two tag bits to denote the numeric type of data at an addressed location. The Burroughs B6700[6,7,8] and B7700 which were developed concurrently and independently of the R-2 employ three tag bits to identify types of numeric operands and special information used by the operating system.

What is new about Iliffe's concept is that it represents a rejection of the classical von Neumann machine in favor of something which may be better. In the von Neumann machine program and data are equivalent in the sense that the data which the program operates on may be the program itself. The loop which modifies its own addresses or changes its own instructions is an example of this. While this practice may be permissible in a minicomputer with a single user, it constitutes gross negligence in the case of a multi-user machine where sharing of code and/or data is to be encouraged.

Instead, Iliffe presents a different conjecture. All information which the algorithm needs to know about the data ought to be contained indivisibly in the data itself. For example, an algorithm to perform a *for*-loop on arrays ought to be the same whether the array is of length ten or length 100. Rather than record this information in a variable and use a loop with an index, Iliffe proposes to record the length of the array with the pointer to the array itself, as in Figure 1.

Rather than have several different algorithms for *add integer*, *add floating*, *add double precision*, and *add complex*, he proposes to make the data self-representing. An integer can only be used as an integer, a floating quantity as a floating quantity, etc. This idea is the fundamental difference between the class of machines represented by the BLM, the R-2, and the Burroughs B6700 on the one hand, and by those of more conventional architecture on the other.

Once the fundamental decision has been made to

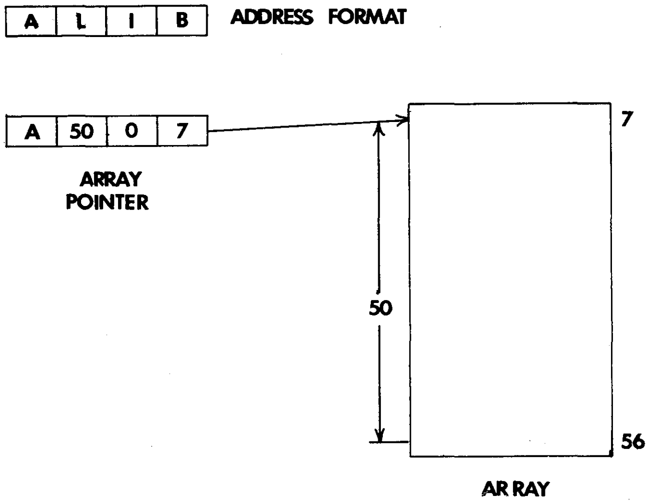

Figure 1—A typical array pointer and its array

adopt this goal in hardware, and the commitment to the use of memory bits for tags has been made, a great many benefits result. One of the most important is that the hardware, once informed of what each piece of data is, can perform run-time checks for consistency of data and algorithms, e g., bounds checking and type conversion.

General structure of the R-2

We now turn to the general structure of the R-2 as shown in Figure 2, which represents only a minor modification from the original design which began in January 1969. The system consists of three major asynchronous subsystems: a memory system of 24K 64-bit words of core memory, a Digital Equipment Corporation PDP-11 I-O controller, and the CPU complex. While the details of the first and second subsystem are of interest, we will not be concerned with them in this paper.

The CPU complex consists of a set of 64 16-bit scratch-pad memory circuits organized as 64-bit registers (designated XØ through X15), whose cycle time is approximately 40 nanoseconds, an arithmetic unit and a CPU. The latter two units are built from RCA ECL integrated circuits with typical delays of from 3 to 5 nanoseconds. This results in a typical add time for two 54-bit floating quantities on the order of 50-200 nanoseconds, and a multiply consisting of additions and shifts typically requiring 3 microseconds.

The address calculator in the CPU is one of the most important features of the system. It functions as an automatic base-bounds calculator and is responsible for the high security of the system programs. For every fetch from memory the address calculator is given four quantities, a base address B of 20 bits, an initial index I of 14 bits, a length L of 14 bits, and the element selector D of 14 bits. In 150 to 200 nanoseconds the calculator performs the following algorithm:

```
Temp:=D-I;
if Temp<0 then Low__error__1;
if Temp≥L then High__error__1;
Actual__address:=B+Temp;
```

I is a number between $-(2^{13}-1)$ and $(2^{13}-1)$ in one's complement form. D has a maximum value of $2^{14}-1$ and this is the largest segment which one can practically use. This should be sufficient for all but the largest one-dimensional arrays of data. The base address B is of sufficient size for any program (or memory) that we can currently foresee, on the order of 1 million words.

Data formats

Before we can discuss the operation of the CPU we must understand the various data formats which the R-2 can deal with. These formats are given in Figure 3. Each word currently consists of 62 bits of information. A two bit field in every word contains a parity bit Z and a write lock bit L. The remaining 60 bits may be divided into four classes of words: numeric words, control words, address words (or partition words), and instruction words. The first three classes contain six bits used for tags as Iliffe suggested. Four bits are used to distinguish types and two may be set by the programmer to generate interrupts. The type codes are listed in Table I.

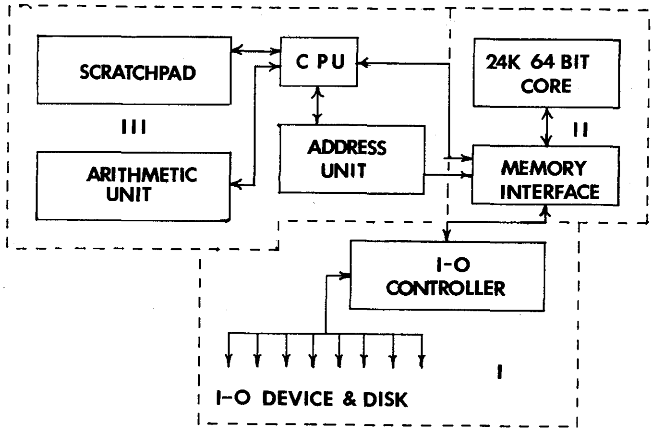

Figure 2—Subsystems of the R-2 Computer

The format of the various numeric types is of little interest. They are the same as those found in the original Rice Computer.[4] See Table I.

We should take greater note of the formats for address words. In addition to containing a base field (B), an initial index field (I) and a length field (L), each address word also contains an indirect reference field which indicates the type of the object in the block described by the address word. Two more bits are used. One indicates whether the block which is described is in core memory or in secondary storage (P). The other indicates whether the block may be relocated (Q).

Control words are an innovation. They are the only method of intersegment communication. They contain a 21-bit halfword pointer to an instruction (R-2 instructions are packed two per word). A mode field of 11 bits indicates the operating state of the computer at the time a jump to a subroutine is made. A two-bit condition code at the time the jump is made is stored in field C. Since the routine may be disk resident, a P field is provided to signal the routine's presence or absence in core memory. A chain field is provided in each control word. This field may be used to link together control words which are on the stack or are in a common linkage segment. Rather than scan storage linearly to find the previous control word, one merely follows the chain of links. Finally, a four-bit mark field may be used to indicate the level of the subroutine or the level of the subtask in the operating system. These marks are especially useful when employed with the control stack for exiting blocks and reestablishing an appropriate environment.

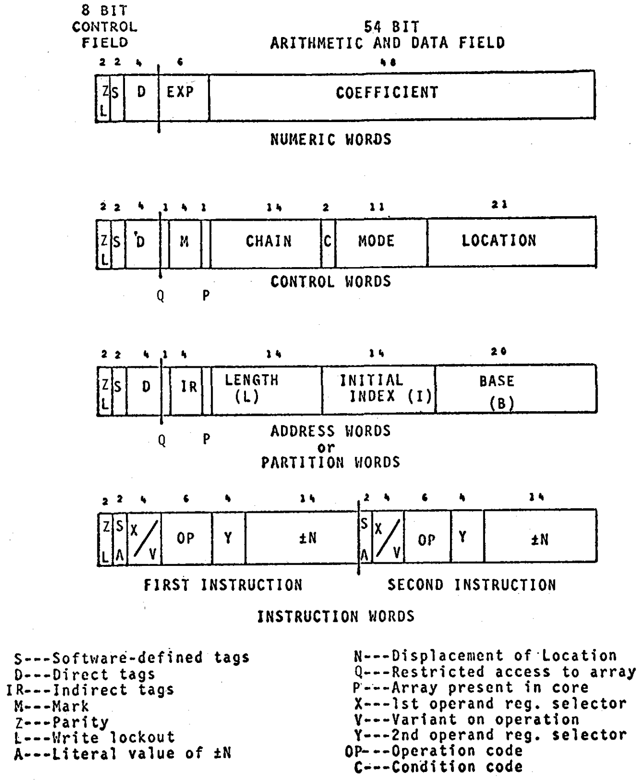

Figure 3—Diagram of R-2 word formats

TABLE I—Data Tag Assignment

TAG Number	*Meaning*
0000	MIXED OR UNTAGGED
0001	(unassigned)
0010	(unassigned)
0011	(unassigned)
0100	REAL, SINGLE PRECISION
0101	54 BIT BINARY STRING OR INTEGER
0110	DOUBLE PRECISION (real, fl. pt.)
0111	COMPLEX (two single precision fl. pt. words)
1000	UNDEFINED FOR NORMAL OPERATIONS
1001	PARTITION WORD
1010	RELATIVE CONTROL WORD
1011	ABSOLUTE CONTROL WORD
1100	RELATIVE ADDRESS, UNCHAINED
1101	ABSOLUTE ADDRESS, UNCHAINED
1110	RELATIVE ADDRESS, CHAINED
1111	ABSOLUTE ADDRESS, CHAINED

Processor facilities

Two major resources are available for use by the instruction unit. The first is the hardware stack and stacking mechanism. The second is the register set (previously described). The stack is maintained in memory and utilizes an address word held in register XØ as a stack pointer and bound. In order to utilize the address calculator in a consistent manner, the top of the stack is the location addressed by the base field of the address word and the bottom of the (accessible) stack is determined using the length field. Special words called partition words are stored by the operating system to denote the absolute beginning and end of the stack region or to point to a continuation of the stack in another segment (see Figure 4). Any word of the accessible stack within $2^{14}-1$ of the top may be accessed by an instruction. Partition words cannot be overwritten by normal stacking and unstacking operations.

Two hardware registers U and R constitute X1, the double length accumulator for arithmetic and logical operations. If X1 is loaded with an item of double precision or complex data, the second word is held in the R register. Special instructions are available to address the R register independently of U.

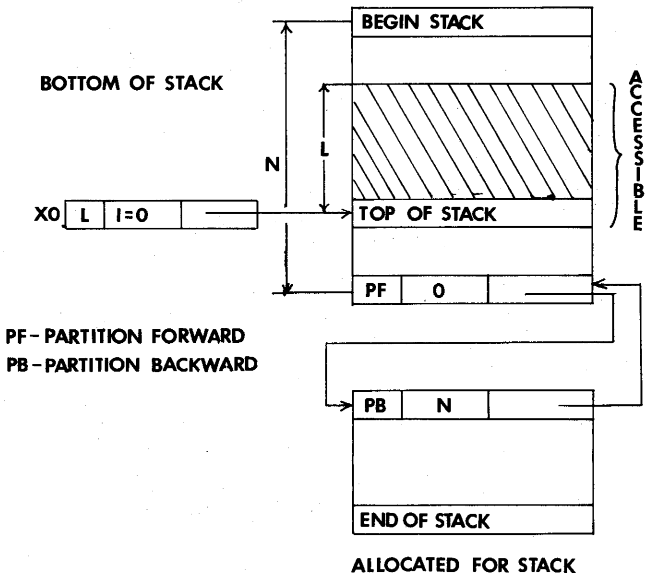

Figure 4—The stack pointer and stack layout

Registers X2 through X15 are implemented with the scratchpad memory integrated circuits mentioned previously, and a reserved, fixed core memory location is associated with each register to hold the second word of double word data when it appears. By recognizing the data tags "complex" and "double precision," the hardware automatically performs the appropriate double word transfers and storage so that no special programming is required. Thus, to the programmer X1 through X15 appear to be a set of general purpose double word registers. Since XØ is always used as the stack pointer, the hardware rejects (by interrupt) any attempt to store a word into XØ unless it is tagged as an address word.

All of the other registers except X15 may be used for temporary storage of numbers, addresses, or control words. X15 must contain an address word which describes where the interrupt vector is located. All interrupts transfer relative to this address. In the event of a catastrophe when there might not be an address word in X15, interrupts transfer to locations relative to absolute address 0.

Instruction formats

Every instruction contains a one bit software tag denoted by S and six bit function code field labeled OP in Figure 3. Each instruction also features an immediate bit labeled A, a numeric offset labeled N which may be plus or minus, and a register field Y. The remaining four bits labeled X/V in Figure 3 are interpreted differently in two classes of instructions. The first features a four bit result register field X. The second uses this field as a variant code for the operation, and for this class (which includes arithmetic and logic) the first operand is implicitly X1, which also contains the result.

Instructions are customarily written in the form S A X OP Y ± N or S A OP Y ± N where the function is to perform X OP $Y_{eff} \rightarrow X$. The first operand X is either stated explicitly or is implicit in the instruction. Y_{eff} depends on the contents of Y, the number N and the immediate bit A.

Rather than describe the operation of the addressing algorithm for Y_{eff} exhaustively by flow diagrams, we will describe instruction sequences for short algorithms. This will show the effect of Iliffe's conjecture, as well as illustrating the machine design.

EXAMPLE PROGRAMS

Example 1—Accessing vector elements

All elements must be accessed through an address word. Address words can be constructed by the operating system in a manner to be described in a following example. Suppose we have an address word in X2 which points to a vector in the manner of Figure 1, and suppose we wish to add the element with index ten of the array to a numeric quantity in X1. We could use the following instruction:

ADD X2.10 // Select the element of X2 indexed by 10 and add to X1. Suppose the initial index of X2, I(X2) is −4, the length 15, and the base address 1000. The sequence of computations would proceed as follows. The computer would check X2 and determine that it contained an address. It would issue B=1000, I=−4, L=15, and D=10 to the address calculator. The calculator would compute D-I (10−(−4)) or 14 which is greater than −1 and less than L. Since the element is within the vector, an address of 1014 would be generated and the element would be brought to the arithmetic unit. If the element is an integer it would be immediately added to the integer in X1 and the condition code would be set to reflect whether the result was less than, greater than, or equal to zero. If the element is real (fixed or floating point fraction), the computer would convert X1 to floating point form and perform the addition. If the element is anything but a numeric type, an exception occurs and an interrupt to a fixed location relative to the address in X15 takes place. If the instruction also invokes the auto-store option, denoted ADD→X2.10, the result would be stored back into 1014.

Example 2—Accessing array elements

On the R-2 we usually represent arrays in a tree structure. The first index is used to determine an element in a vector composed of address words. The second index is used with this address element to select an element from a second vector which is an address word and so on until the last index which is used to select the desired element. This kind of an array is illustrated in Figure 5. Because of the fact that each address word carries with it the length of the vector it addresses, such arrays may be uniform or nonuniform as desired. They may also be so large that only one vector of data will fit in core memory at any time.

Two different methods of addressing such arrays can be used. These methods are considerably more efficient than that used on the Burroughs 6700 because of the scratchpad registers X2-X14 which are available. One method involves element selection as in the first example. It is generally used when we wish to select only $X_{i,j,k}$th element of an array rather than to deal with every element. The following sequence of instructions indicates how this may be accomplished.

Suppose X2 contains the address word pointing to the vector and we desire to select $Z_{3,1,5}$ and assume that the initial indices are 0. Then we could use:

X2 DOT = 3 // Replaces the contents of X2 with the third element of first level tree.
X2 DOT = 1 // Replaces of the contents of X2 with the first element of second level.
X2 MOD = 5 // Generates the address of $Z_{3,1,5}$ in X2.
ADD → X2 // Adds (X1) to $Z_{3,1,5}$ and autostores back into the array.

This set uses the immediate address form of the instruction.

An alternative form might employ a vector of subscripts. Suppose that X3 contains the address word of a vector of subscripts to be applied to Z, i.e. (3, 1, 5). The following sequence indicates how this may be done.

X2 DOT X3.1 // Obtains the third element of first level.
X2 DOT X3.2 // Obtains the first element of second level.
X2 MOD X3.3 // Generates a pointer to $Z_{3,1,5}$.
ADD →X2 // Adds (X1) to $Z_{3,1,5}$. and autostores.

This sequence of computations is as follows. The first element of X3 (since I(X3) = 0) is selected and brought to the CPU. It has the value 3. If X3 had contained a number originally, 1 would have been added to that number and the resultant would have been used. This value is then used to obtain the third element of Z's first level subtree (denoted $Z_{3,*,*}$). This is left in X2. The next operation obtains an address word which is the first element of Z's second level tree of the third branch ($Z_{3,1,*}$). The next operation indexes this address to make its location field point to the desired element. This element is presumably a number (integer, real, complex, or double precision). It is added to the contents of the U register (X1), and the result placed in X1 and in $Z_{3,1,5}$, thus smoothly implementing the ALGOL 68 statement: Z[3, 1,5]+: = V; where V was the contents of X1. If the value of (X3.1), (X3.2), or (X3.2) had not been a number then an exception would have occurred.

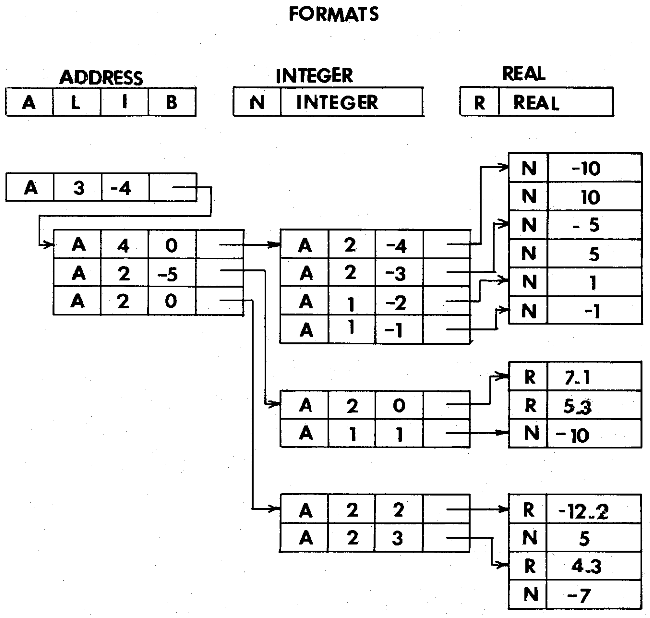

Figure 5—A nonuniform three dimensional array

Example 3—Array processing

In some cases vector processing is desired. For this purpose a different kind of access is desired. In this mode one systematically examines all the elements of an array or vector in turn, and performs some operation on them. For example, to sum a vector pointed to by an address word in register X2, one might use the following sequence of instructions. Assume (I(X2)) equals 0.

```
         X3 LOAD    4    // To sum five elements of
                            vector X2
         X1 LOAD    0    // Initialize X1 to Zero
AGAIN       ADD X2.0     // Add first element of
                            vector
         X2 MOD   =1     // Adjust X2 to point to
                            the next element
         X3 JGE AGAIN    // Continue to CONT if
                            X3 is zero or negative
CONT                     // Decrement and jump to
                            AGAIN otherwise.
```

This sequence loads X3 with the number 4 and X1 with the number 0. The next instruction causes the number pointed to by the B field of X2 to be added to the number in X1. If the length field is set to −1, an exception will occur. The next instruction uses the literal 1 to decrement the L field of the address in X2 and simultaneously increase the B field by 1. If L is less than zero an exception will occur. The next instruction examines X3. If it is a number less than or equal to 0, the next sequential instruction is taken. Otherwise the number is decremented by one and control passes to AGAIN. Using this sequence the first five elements of the vector pointed to by X2 are summed. If there are fewer than six elements in this vector, an exception occurs. If there are exactly five elements in the vector when the program gets to CONT, L(X2) equals zero. An attempt to do X2 MOD=1 again will cause an error exception. Otherwise the new L(X2) is five less than before and the new B(X2) is five more than previously.

A shorter sequence may be used if it is desired to sum all the elements of the vector. Here the programmer need not even know how long the vector is.

```
         X1 LOAD  =0     // Set X1 to zero
AGAIN       ADD  X2.0    // Add elements to X1
         X2 JNL  AGAIN   // See the discussion below
```

The last instruction checks to see if L(X2) is greater than 0. If it is it performs X2 MOD=1 and transfers control to AGAIN. If it is not, control passess to the next instruction.

As a final example of the power of this approach, assume that we have three arrays A, B^T, and C and that we desire to compute

$$C_{i,k}=\sum_{j=0}^{n} A_{i,j}B_{k,j}{}^{T}.$$

This can be calculated simply in the following routine assuming X2 is an address word pointing to A, X4 is an address word pointng to B^T, and X6 is an address word pointing to C.

```
INIT     X9 COPY   X4      // Copies (X4) to X9
BEGIN    X7 LOAD   X6      // Get ith subtree of
                              C
FIRST    X3 LOAD   X2      // Get ith subtree of
                              A
         X5 LOAD   X4      // Get kth subtree of
                              $B^T$
            ZERO   X7.0    // Put zero in $C_{i,k}$
SECOND   X1 LOAD   X3.0    // Get $A_{i,j}$
            MUL    X5.0    // Multiply by $B_{k,j}{}^T$
            ADD→   X7.0    // Add and autostore
                              to $C_{i,k}$
         X5 MOD    =1      // Next consider
                              $B_{k,j+1}{}^T$
         X3 JNL SECOND     // Next consider
                              $A_{i,j+1}$
CONT                       // if no more j con-
                              tinue here
         X4 MOD    =1      // Next consider
                              $B_{k+1,j}{}^T$
         X7 JNL FIRST      // Consider $C_{i,k+1}$ if
                              any left
         X6 MOD    =1      // Consider $C_{i+1,k}$
         X4 COPY   X9      // Start over with
                              $B_{0,0}$
         X2 JNL BEGIN      // Consider $A_{i+1,j}$ if
                              any left.
```

This routine destroys pointers located in X2, X4, and X6. The steps

```
            MUL    X5.0
         X5 MOD=1
```

may be combined into MUL! X5 which uses a variant option for the arithmetic operation code to modify the address word in X5 after the element has been fetched.

Example 5—Use of the stack

The stack may be used for intermediate storage in the following manner. It is first necessary to get the operand in a scratchpad register. Suppose we wish to stack X5. Then we write X5 STORE XØ. The contents of X5 is pushed onto the stack. On the other hand, X5 STORE XØ.7 stores the contents of X5 in the seventh location of the stack without altering other elements. If there are less than seven elements on the accessible stack an exception occurs. The top element of the stack may be changed without pushing by the use of X5 STORE XØ.1.

Elements are removed from the stack in an analogous manner. For example, ADD XØ adds the top element of the stack to the accumulator and pops the top element. ADD XØ.1 adds the top element of the stack but does not pop it; ADD XØ.7 adds the seventh element of the stack without affecting the stack.

This stack arrangement affords many conveniences in arithmetic operations. An example of this is the instruction save and fetch. Take as an example X2 SVF X3.12. This instruction gets the twelfth element of the array pointed to by X3, after saving the old value of X2 on the stack, and places the new value in X2. In compiling, the instruction X1 SVF Xi.N will occur frequently. Intermediate results can be saved on the stack for later use. Alternatively, when the value is to be used many times they can be stored in a register using COPY.

The stack is also useful in control actions. The instruction JUMP AND SET MARK, e.g., 4 JSM LABEL, causes a control word to be made up pointing to the next sequential instruction. This control word contains the current mode, the current condition code, and the mark specified by the JSM instruction, in this case 4. The chain field is loaded with the current value of L(XØ). The resulting control word is pushed on the stack. XØ is then updated to reflect a new stack regime. L(XØ) is set to 0 and B is set to the location that is one less than that occupied by the control word. This stack regime is completely disconnected from the prior one; there is no way save through the registers or memory constants to reach any of the members of the previous stack regime (see Figure 6). One can return to the previous environment by the use of the return instruction: RET 4. The previous control word is found by examining the address B(XØ)+L(XØ)+1. This address contains the last control word or a partition word pointing to another section of the stack regime or a partition word marking the absolute beginning of the stack. If a control word occupies this position, B(XØ) is set to point to this address. The chain field of the control word is copied into L(XØ), the mode field to the mode register, the condition code to the condition code register, and the 21 bit address to the program counter. If the mark field is less than the literal used with the return instruction, the computer resumes processing. Otherwise the process described above is repeated until a partition word marking the absolute beginning of stack is encountered. If the beginning of stack is encountered, an error exception will result. This form of return has the advantage that it is efficient and can be used to return several levels in a block structured language.

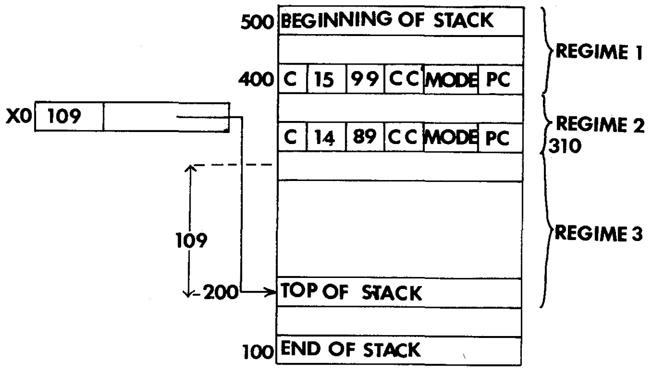

Figure 6—The use of the stack in programming systems

Relative addressing

In an earlier section we stated that all addressing was done via an address word. In fact this is not quite true. Addresses may be relative to the program counter or to the location in which the address word or control word is stored. One may then jump minus five halfword instructions. This feature was available on the R-1 in 1959 and made possible the development of very efficient relocatable code. It is frequently found on machines today. One can also access fullword data in the same manner so that constants can be stored with the code.

In the same way relative codewords and addresswords can be used to address other quantities. The address of the location in which the address or control word is stored must be determinable by the computer. An offset relative to this address is used to point to the jump location or to the data. This feature makes possible relocation of large blocks of data in a very efficient manner and minimizes the number of address words which contain absolute addresses. This is important because it drastically reduces overhead in the reorganization of storage. Only a few locations need to be modified to relocate all programs and their data.

Chained Addressing

A second kind of addressing is also provided. Chained addressing provides for efficient parameter passing mechanisms, particularly of the call by reference variety. The addressing algorithm is modified to include indirection. When a chained address or control word is encountered the machine causes an indirect reference through the address or control word to the next quantity. A counter is employed to assure that chaining beyond 32 levels is not allowed. Special instructions are employed to defeat chaining for loading and storing. These instructions allow complete control of the addressing mechanism.

Miscellaneous instructions

The R-2 is designed to be used with compilers rather than assemblers. It has many useful miscellaneous instructions including reverse divide, variants of pre- and post-complemented addition and logical operations, and integer and floating multiplication and division. Various instructions allow extraction and replacement of the predefined data and instruction fields. A large number of shift, bit count, and test instructions complement the arithmetic and logical set of instructions, thus facilitating the development of operating systems and compilers.

Ramifications of tagged architecture in the R-2

The use of tagged architecture has many ramifications. In a future paper we will discuss them more fully. Here we will comment on a few of interest to those who write or use compilers and operating systems or who must debug programs.

Compilers can be made simple and more efficient. Since tags indicate what each numeric quantity is and since the hardware will correctly perform the appropriate operation on all legal combinations of data, the compiler need not deal with semantic operations referring to basic types of identifiers. This is now handled conveniently at run-time. The problem of temporary storage is largely solved by the stack whose implementation is greatly facilitated by the address calculator and the tagged address type. The tagged registers allow simple manipulation and mechanization of vector and array operations and allow dynamic variables much more freedom than do previous machines. They also permit the optimum calculation of expressions of type *address* and type *numeric.* Finally, tagged addresses and numbers greatly simplify the problems of run-time systems for use with particular compilers; note that even undefined quantities have a distinct representation.

Operating system design is facilitated by tagging. The difference between a label and an address can be determined at run-time. This means that one cannot jump through an address word or a number but only to approved points in a subroutine via a control word. Attempting to do otherwise produces an interrupt.

Secondly, addresses can only be manipulated by means of a special set of instructions. The more powerful instructions may be denied to the user and he may be given the use of MOD, TAG, and LIM. TAG is an instruction with an immediate operand. The compiler monitors all TAG instructions assuring that no unauthorized user can construct illegal address or control words. Any user may employ MOD or LIM. They modify an address to point to a subset of the elements in an addressed space. Since an unprivileged user may never generate an address outside the initial space to which he has been given access, protection of user programs is enhanced if not insured. This protection mechanism appears to be exactly what is required for recursively defined operating systems.

The design and use of debugging systems is greatly simplified. A program can be written to dump core memory using the type of each datum. This means that complex, double precision, floating, integer, and undefined types can be used to interpret the data contained in the cells. This can be used in the analysis of dumps. Addresses and labels are also distinct in this scheme; the fact that they are not in other systems has been a recurring problem for those who must debug.

Dynamic debugging is also easily implemented. By the use of symbolic locations, relative locations, or absolute locations, data or instructions may be tagged with software tags. Whenever such tagged data is encountered, an interrupt occurs. The programmer may supply his own programs to analyze or monitor the data values which are encountered. The software tag in each of the instructions may also be set to cause interrupts related to tracing any or all control actions. Again the user may write a program to analyze the results. Finally since the tag bits may be set either at compile time by the compiler, or arbitrarily at run-time by the user through the operating system, code which is verified as being correct need not be recompiled, thus simplifying and expediting the process of debugging.

SUMMARY

This paper has reported the state of the Rice Research Computer in its development. It has emphasized the features of the R-2 which arise from accepting the principle of tagged architecture. For a particular implementation, we have shown by example the power of tagged architecture in application to compilers, operating systems, and debugging systems.

ACKNOWLEDGMENTS

I would like to acknowledge the work of the designers of R-2 including John Iliffe, I.C.L. (London, England), Walter Orvedahl (Colorado State University), Dr. Sigsby Rusk (Rice University), Douglass DeLong (Graduate Student, Rice University), Dr. Ernest Sibert (Syracuse University), and Dr. Robert C. Minnick (Rice University). Also, I owe thanks to Dr. J. Robert Jump and the graduate and undergraduate students at the Rice University Laboratory for Computer Science and Engineering who have made and are making the machine a reality.

A generative CAI tutor for computer science concepts*

by ELLIOT B. KOFFMAN

University of Connecticut
Storrs, Connecticut

INTRODUCTION

Limited progress has been made in software for computer-assisted instruction. Frame-oriented CAI systems have dominated the field. These systems function as mechanized programmed texts and utilize the computational power of the computer to a minimal extent. In addition, they are difficult to modify and tend to provide a fairly fixed instructional sequence.

The conventional frame-oriented CAI system is organized as a series of frames. A frame may present a piece of information and/or ask a question. The questions are normally objective and often are of the multiple-choice type. The frames are usually linked in a sequential fashion and a student will cycle through them one at a time. Frames may be presented on a teletype, a graphical display, a slide projector, via an audio track, or any combination of the above.

There are severe problems inherent in systems of this type. All questions must be specified by the course-author as well as a set of anticipated student responses to each question. If branching is to occur, explicit instructions must be given indicating the performance criteria for a branch and the new continuation point in the program.

Since everything must be specified in advance, extensive time must be spent in preparing course material for presentation. Furthermore, once programmed this material has very little flexibility. Modifying the set of questions to be asked of the student or the material to be presented is a major undertaking and much reprogramming must be done.

This type of system is not very useful in teaching quantitative courses. Subject areas such as engineering or the physical sciences are concerned with teaching techniques of problem solving. Problem solving competence is often acquired through a process of "learning by doing." Consequently, it is essential that the CAI system be capable of presenting a wide variety of problems and solutions to the student. Reprogramming each problem and its solution in a manner suitable for presentation by CAI would be extremely inefficient.

It is precisely for these reasons that generative CAI systems have recently become of great interest. Generative systems are capable of generating a series of questions (and answers to these questions) as a function of the student interaction. These systems can be divided into two classes. Those which are oriented toward the "soft-sciences" and textual material and those which are more concerned with numerical manipulations and quantitative material.

Carbonell[1] and Wexler[2] have designed generative CAI systems which have been used to teach concepts in geography. These systems are organized around an information structure or network. Carbonell uses the semantic network developed by Quillian.[3]

Once the information network has been specified, these systems are capable of generating a sequence of questions for a student. As each question is generated, the answer is retrieved for comparison with the student's response. If the student is incorrect, Wexler's system is capable of providing individualized remedial comments. This would consist of either a correct and relevant statement using the student's incorrect answer or a systematic presentation of the steps performed by the system in deriving the correct solution. Both these systems allow the student to interrupt and pursue topics which interest him at greater depth.

The potential for incorporating generative CAI in the "hard sciences" is extensive. Algorithms for solution of classes of problems could be incorporated into CAI systems. In some cases, solution techniques might be sufficiently complex that heuristic programs would be necessary. Examples of the latter case would be teaching symbolic integration or proving theorems. In

* This research is sponsored by the Connecticut Research Commission under Grant RSA-71-7.

any event, CAI systems organized around a set of algorithms would have the capability to generate and solve a wide range of problems.

An extensive project in the subject area of analytical geometry has been described by Uttal.[4] His system is capable of generating twelve problem types which are representative of the problems found in an analytical geometry course. These problems usually involve an expression or graphical representation of a particular conic section. The expression is obtained from the general quadratic equation: $AX^2+BY^2+CX+DY+E=0$.

The required expression is obtained by setting certain coefficients to 0 and selecting the others at random. The complexity of the equation generated depends on the constraints imposed on the coefficients. For example, to generate circles centered at the origin, $A=B$ and $C=D=0$.

Associated with each of the twelve problem types is an answer routine. The routine which determines if a randomly generated point (x,y) falls on the locus represented by a randomly generated equation simply plugs this point into the equation. The expression generator itself is used as the answer routine when the student is asked to supply the equation for a conic section with given standard characteristics.

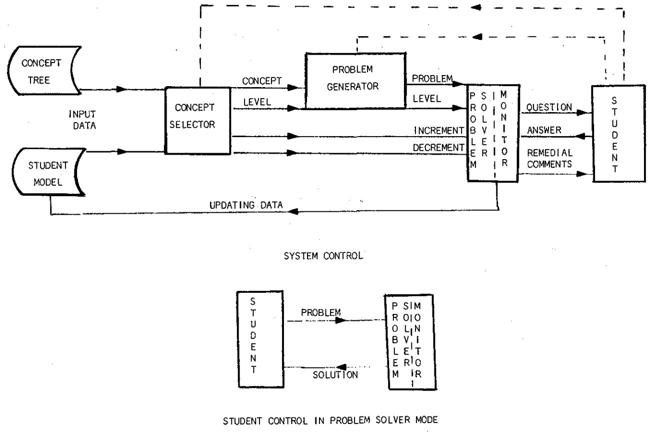
The following sections will describe a generative tutor that has been used in an introductory computer science course. It has been used to teach concepts of digital circuit design as well as to introduce students to machine language programming. Because of the large number of concepts covered, an intelligent "concept selector" has been designed which attempts to tailor the current instruction each student receives to fit his past performance record.

GENERATIVE CAI IN DIGITAL SYSTEMS

The system is designed to be extremely flexible in that it can completely control the progress of a student through the course, selecting concepts for study on an individual basis and generating problems. Alternatively, the student can assume the initiative and determine his own areas of study and/or supply his own problems.

In addition, the system also operates in a "problem-solver" mode. In this mode, the student specifies the concept area and his problem, and the system will crank out the solution without further interaction. It is anticipated that students in later courses and the digital laboratory will utilize this mode for solving complex minimization problems and determining the relative merits of different state assignments.

Figure 1 is a block diagram of the system functions. Subsequent sections of this paper will describe how these functions are accomplished. As has been mentioned, the student can assume the initiative and bypass the Concept Selector and/or Problem Generator (indicated by dashed lines from Student box). The bottom part of Figure 1 shows the student exercising full control in the problem-solver mode.



SYSTEM CONTROL

STUDENT CONTROL IN PROBLEM SOLVER MODE

Figure 1—System block diagram

When the system is in control of the interaction, it attempts to individualize the depth and pace of instruction presented to each student. A model of each student is kept which summarizes his past performance in each of the course concepts. Table I shows the contents of a student record.

In addition, the system is supplied with a concept tree which indicates the degree of complexity (plateau) of a concept and its relationship with other concepts in the course. A sample tree for the concepts currently covered is shown in Figure 2. This, of course, represents the author's interpretation of the relationship between course concepts. There are alternate interpretations which are just as valid.

The system uses each student's record to determine how quickly he should progress through the tree of concepts, the particular path which should be followed, the degree of difficulty of the problem to be generated, and the depth of monitoring and explanation of the problem solution.

Figure 3 is a flow-chart of the overall operation of the system.

PROBLEM-SOLVER/MONITOR

The course is organized as a set of solution algorithms. Normally there is a single algorithm for each major concept of the course. The algorithms solve the problems much as a student would, breaking each problem

TABLE I—Student Record

A B CONCEPT A IS A PREREQUISITE OF CONCEPT B.
A B CONCEPT A IS A PREREQUISITE OF CONCEPT B; CONCEPT A MAY BE USED AS A SUB-CONCEPT BY B.

Note: The relation "is a prerequisite of" is transitive (A is a prerequisite of B, B is a prerequisite of C, implies A is a prerequisite of C)

Figure 2—Concept tree

If the student is questioned, then his answer is compared with the system's solution. If the student is correct, his level is increased; if he is incorrect, he will receive a remedial comment explaining the correct solution procedure and his level for that concept will be decreased. The higher a student's level, the fewer questions he will be asked. When the student reaches a level of 3 in a concept, the system will solve subsequent problems dealing with this concept for him.

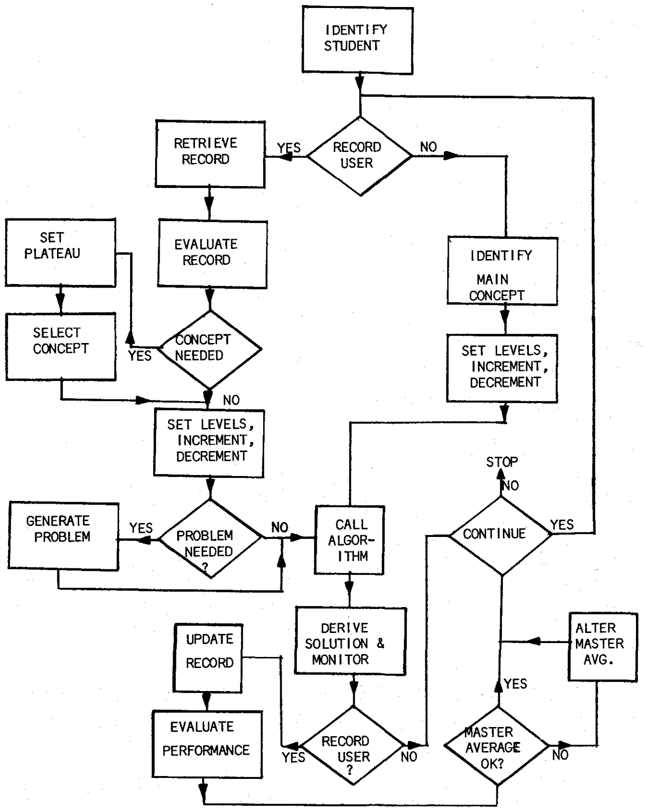

Figure 3—System flow chart

Table II presents examples of different degrees of interaction with a student in an octal addition problem. The first character of all student inputs is underscored. A single algorithm solves binary, octal, and hexadecimal addition problems. The decimal sum of each pair of digits and old carry is first calculated. The corresponding new carry and sum digits in the problem base is then determined.

A student with level less than 1 is quizzed on all details of this algorithm; while, the initial decimal calculation is skipped for students with level between 1 and 2. The student with level between 2 and 3 is asked only for his final result; whereas, the final result is generated for a student with level equal to 3. The

TABLE II—Different Degrees of Interaction

Problem: Form the sum of 75.3, 2.7 in the base 8.

LEVEL RANGE 0-1
Modify 2.7 for addition to 75.3
02.7
Correct. The rightmost digit is digit #1.
What is the decimal sum of digit #1
of 75.3 and digit #1 of 02.7?
8
No. Their decimal sum is 3+7 or 10.
What is digit #1 of the sum in the base 8?
1
No. The decimal number 10 is equivalent to 12 in the base 8. Digit #1 is 2.
What is the carry to digit #2?
1
Correct. What is the decimal sum of digit #2 of 75.3 and digit #2 of 02.7 and the carry from digit #1?
⋮
LEVEL RANGE 1-2
The rightmost digit is digit #1.
What is digit #1 of the sum in the base 8?
2
Correct. What is the carry to digit #2?
0
No. 3+7=12 in the base 8.
The carry to digit #2 is 1.
What is digit #2 of the sum in the base 8?
⋮
LEVEL RANGE 2-3
What is the complete sum of 75.3, 02.7 in the base 8?
77.2
No. The sum of 75.3, 02.7 is 100.2 in the base 8.
LEVEL RANGE≥3
The sum of 75.3, 02.7 is 100.2 in the base 8.

amount of interaction a student receives will vary as the problem solution progresses and his level changes from one range to the next.

In this manner, the amount of monitoring is dynamically adapted to fit a student's current level of achievement. Often a solution algorithm will utilize an algorithm dealing with another course concept as a subroutine. When this happens, the student's level in the sub-concept will control the depth of instruction. If he has mastered the sub-concept (level ≥ 3), this portion of the solution will be provided for him.

When a student response is incorrect, he receives an individualized remedial comment which explains the system's derived answer. For example, in a problem utilizing the Flip-Flop Design algorithm, the student would be given the current state and desired next state and asked to supply the required values of the Flip-Flop excitations. Table III presents some of the alternative forms of feedback which might be presented depending on a student's level and his answer.

The correct solution in this case is derived through a table lookup. System response *A* is automatically generated if one of the excitations match and the correct answer for the non-matching excitation is "*D*" (a don't care). System response *B* is presented for all other types of errors. The additional information presented to students with level <1 is obtained by calling the Flip-Flop analysis algorithm in the problem-solver mode. This algorithm determines the next state which would result from the current state if the student's values of the Flip-Flop excitations were applied.

The magnitudes of the increment and decrement for correct and incorrect answers respectively are also individualized to fit the student's past performance. They are calculated for the particular concept which has been selected as follows:

$$\text{Increment} = K2 \cdot K1$$

$$\text{Decrement} = K2/K1$$

where

$$K1^2 = 1 + W_N + \Delta L \text{ and } .5 \leq K1^2 \leq 2, \; K2 = 1 - .5R$$

$\Delta L =$ last change in level

$W_N =$ weighted average level change for N uses of a concept

$$W_N = \frac{(N-1) \cdot W_{N-1} + 2 \cdot \Delta L}{N+1}$$

$$R = (\text{Number of uses of concept at present level range})/N \qquad (1)$$

If the student's level in a concept has been consistently increasing, W_N and ΔL will be positive and $K1^2$ will tend to be large. $K1^2$ represents the ratio of Increment to Decrement. Consequently, a student who has been performing well in a concept will be rewarded more for a correct answer than he is penalized for an incorrect one. Thus, he is receiving the benefit of the doubt for an occasional incorrect answer and progresses more rapidly to the problem-solver mode for that concept. The opposite is true for a student who has been performing poorly. This will enable him to drop quickly to a lower level at which he will receive further monitoring and instruction if he continues to answer incorrectly.

R represents the stability of the current level for the concept in question. *K*2 assumes values between .5 and 1.0, the higher values representing a greater degree of instability. Consequently, when the current level is in a relatively unused or unstable level range, the Increment and Decrement will both tend to be larger than when the current level appears to be a stable one. This makes it easier for a student to move out of a new level range; whereas, he must answer more questions correctly (or incorrectly) if he is to move out of a level

TABLE III

QUESTION

The current state of JK Flip-Flop 1 is 0.
The next state should be 1.
What are the values of $J1$, $K1$?

STUDENT ANSWER: $J1=1$, $K1=1$

SYSTEM RESPONSE A: Your answer is correct, however, a better answer would be $J1=1$, $K1=D$.
(D symbolizes a "don't care" condition)

The remedial feedback generated for a wrong answer to the above question follows:

STUDENT ANSWER: $J1=D$, $K1=1$

SYSTEM RESPONSE B: Wrong. To bring a JK Flip-Flop from the 0 to 1 state, set $J=1$ and $K=D$.

ADDITIONAL RESPONSE FOR LEVEL<1: Your Flip-Flop excitations would cause the next state to be indeterminate.

range which has become established as typical of him for a particular concept.

The values of Increment and Decrement calculated in this manner will have a minimum of .35 and a maximum of 1.4. These are multiplied by a fraction associated with each question. A typical value of this fraction is .2 which means the magnitude of the change in level per question is normally between .07 and .28.

The entry level of a student during his initial use of a concept is set equal to $.5+2-M$, where M is his master average. The significance of a student's master average will be discussed in the next section.

CONCEPT SELECTOR

Since there are a large number of concepts available for study, the system attempts to select the next concept in such a way as to make optimal use of the student's time. The goal is to pace the student through the concepts quickly enough so that he does not become bored or unmotivated and yet not so fast that he becomes unduly confused.

There is no set order in which the concepts are selected nor is there a set level of achievement which every student must exceed in order to advance. The algorithm attempts to individualize concept selection through examination of the student's performance record.

Each student is assigned a master average when he first logs onto the CAI system. This could be a function of his I. Q. or class standing. (In the past, each student has been arbitrarily assigned an initial master average of 2.) This value changes as the system gains experience with a student.

A student's master average controls the speed with which he jumps from one plateau of the concept tree to the next. In order to jump to the next higher plateau, the average of his levels of achievement in all concepts at and below the current plateau must exceed his master average. Consequently, the lower a student's master average, the faster he will progress.

Each student's master average is updated after the completion of a problem as follows:

$$\Delta M = -K(\Delta L + W_N)(1.1-R) \qquad (2)$$

where ΔL, W_N, and R have been defined previously. (See Equation 1.)

$K=1$ if the concept is from the student's current plateau

$K=2$ if the concept resides at a higher plateau and $\Delta L>0$.

$K=2$ if the concept resides at a lower plateau and $\Delta L<0$.

$K=0$ for all other cases.

Since R cannot be >1, ΔM and $(\Delta L+W_N)$ will be opposite in sign.

If the system selects the concept from the student's current plateau, K will be 1. If the student's level increases and W_N is also positive, his master average will decrease. If the student has selected the concept from a higher plateau and $\Delta L>0$, the magnitude of the decrease is doubled as this indicates the student is ready to progress more quickly. If the concept is above his current plateau and he does poorly ($\Delta L<0$), he is not penalized by an increase in his master average ($K=0$). However, if the concept is a remedial one (below his current plateau) and $(\Delta L+W_N)$ is negative, the increase in his master average is twice what it would be for the same performance in a concept from his current plateau.

The effect of the term $(1.1-R)$ is to cause those changes, which occur when in a relatively new level range, to have a greater influence on the master average. This is reasonable since a student who performs

TABLE IV—Sample Problems Generated

1. Convert the decimal number 65.75 to the base 8.
2. Calculate 75.3−24.56 in the base 8 using 8's complement subtraction.
3. Derive the truth table for $((P \vee (\neg Q)) \uparrow (\neg (R \wedge Q)))$
4. Design a combinational circuit such that:
   Input word A is 2 bits long. Input word B is 2 bits long.
   The output X=A+B. The output Y=1 if A<B.
5. Minimize a function which has 0, 1, 3, 4, 5, 10, 11 as minterms and 2, 8, 14 as don't cares using the Karnaugh Map Method.
6. Minimize a function which has 2, 4, 5, 10, 11 as minterms using the tabular method.
7. Find the excitation equations for a JK Flip-Flop such that:
   Input word A has maximum value 7.
   The Flip Flop is in state 1 if A=0, 2, 4, 6.

well after reaching a new level range is indicating that he is not disturbed by the decrease in interaction and is ready to advance at a faster pace. While a student who does poorly may be in over his head and might prefer it if the pace were slowed down. In any event, the magnitude of the change in master average may not exceed .2.

After the master average is updated, the student's plateau is determined by comparing his new master average with the average level of all concepts at and below his current plateau. If this average level exceeds his master average his plateau is increased by one and the comparison is repeated.

Once the student's plateau has been determined, the system selects a set of candidate concepts from this plateau and those below it if necessary. In order to qualify as a candidate concept, the average of the student's levels of achievement in all prerequisites for this concept (as determined from the concept tree) must exceed his master average. If this is not the case, the prerequisite concept in which the student has the lowest level is selected as a candidate in its place. This provides for automatic review of selected concepts at lower plateaus.

The system then chooses one concept from among the candidates. Each concept is evaluated based on a number of factors such as the time elapsed since its last use, the "stability" of its current level, the sign and magnitude of its most recent level change (negative changes are weighted more heavily), and its relevance to other concepts as determined by the number of branches of the tree connected to it. The highest scoring concept is selected for presentation to the student.

The student always has the option of vetoing this selection and choosing his own concept or accepting the system's second best choice. The selection process is described more formally in the Appendix.

PROBLEM GENERATION

After a concept has been decided upon, the system must generate a problem within this concept area unless the student prefers to supply one. The system attempts to tailor the problem difficulty to suit the student's level in that concept. Table IV gives some sample problems generated by the system.

As an example of the problem generating procedure, the algorithm used to form logical expressions for teaching about truth tables (see problem 3 in Table IV) will be presented in some detail. The basis of this algorithm is the probabilistic grammar shown in Table V which produces expressions utilizing binary operators with P, Q, R, S as variables. A probabilistic grammar is a formal language in which each rewrite rule is assigned a probability of being applied.

The first decision to be made is the number of variables in the final logical expression. As currently implemented, the probability of two variables is .5 for $0 \leq \text{level} \leq 1$ and decreases to 0 for level>1. The probability of 3 variables is .5 for $0 \leq \text{level} \leq 2$ and increases to 1 for level>2. The probability of 4 variables is .5 for $1 \leq \text{level} \leq 2$ and 0 elsewhere.

The incomplete logical expression is scanned from left to right for non-terminals. When the non-terminal symbol A is found (P_a+P_b) represents the probability of increasing the length of the expression where:

$$P_a(t)=P_b(t)=.75\,c/(n(t)+1.5c-1.5) \qquad (3)$$

where $n(t)$ is the current length and c is the number of variables in the expression $(c \geq 2)$

Since (P_a+P_b) is inversely proportional to the current length, the logical expressions do not become unwieldy. If the random number generated indicates that the

expression should not be extended, one of the variables P, Q, R, S replaces A.

If the non-terminal symbol is *, one of the five binary operators is selected. P_e increases with level, while, P_d decreases. Hence, the more difficult operators are more likely in expressions generated for the students at higher levels of achievement.

Modifications of this technique are used to generate problems for combinational design and sequential design concepts. For the earlier number system manipulations, it is necessary to select a base for the number system and concatenate a set of valid digits from that base. As might be expected, the hexadecimal base appears more frequently at higher levels and the numbers to be manipulated are somewhat larger than those generated for lower levels.

IMPLEMENTATION

The system has been implemented on the IBM 360/65 at the University of Connecticut. It is programmed in the **C**onversational **P**rogramming **S**ystem (CPS).[5] CPS is a dialect of PL/I and includes some string processing features which have been extremely useful in programming this system.

There are forty IBM 2741 terminals connected to the main computer. CPS operates in low-speed core and each user is allowed a maximum of 12 pages of core (48 *K* bytes). Currently, space is reserved for fifty student records on disk. There is room for thirty concepts on the tree. There is an instructor mode which permits easy modification of the concept tree. Student records can also be printed out while in the instructor mode.

Students can log onto the system any time from 9 A.M. to 11 P.M. The average student session is about an hour in length. The student's record is automatically updated every 15 minutes so that the results of a complete session will not be lost in the event of a system failure.

The course coverage includes familiarizing the students with the binary, octal, and hexadecimal number systems. The students also learn how to use truth tables to represent logical functions. They learn techniques of combinational design and how to minimize the logic elements needed for a design problem. They are introduced to Flip-Flops and the design of sequential circuits. They also learn about machine-language programming by analyzing short program segments and indicating the changes incurred in various registers as these segments are executed.

Reaction from the students using the system has been very favorable to date. It has been used as a supplement to the regular lectures and homework assignments covering the material up through plateau four of the concept tree (Figure 2). The problem generation capability was not fully implemented which required students to insert their own problem parameters as they were requested by the problem solution algorithms. The major complaint of the students was the slowness of the system. This has been alleviated considerably now that problems are generated for all system concepts.

The system responds to a student input typically in 5 seconds or less. In a couple of the more complex solution algorithms (tabular minimization for example), a student working in the problem-solver mode may have to wait up to three minutes for a problem solution. Students at lower levels very rarely have to wait more than thirty seconds as the solution algorithms are executed in a piecemeal fashion. This, of course, could be improved substantially if compiled code (CPS is an interpretive system) and high-speed core were available.

During the current semester, a student group is using the CAI system in lieu of regular homework assignments. The complete tree of concepts is available. Table VI is an example of the dialogue that occurs between the system executive and the student. The system's messages are capitalized. All student inputs are preceded by a "—." Table VII presents examples of the interaction that takes place during a problem solution.

CONCLUSIONS AND FUTURE WORK

A generative system for teaching digital computer concepts has been described. This system includes an intelligent concept selection routine which attempts to individualize the path taken by each student through the tree of course concepts. In addition, the instruction and monitoring provided by each solution algorithm is dynamically adapted to suit a student's current level of knowledge. The system can also operate as a problem-solver and will provide portions of the solution process which have already been mastered by a student.

Expansion of the CAI system is continuing. The majority of the portion which teaches logical design has been completed. Students have also been exposed to an on-line simulator of the Digital Equipment Corporation PDP-8 which teaches machine-language programming.

Future efforts in this area will lead to a generative system which produces programming problems. As the problem is generated, a sequence of sub-tasks similar to a flow chart will also be produced. This will be used as the basis for teaching machine language programming and testing students' solutions. As before, portions of the program will be generated for the student and he will be required to supply the rest. The amount required from him will decrease as his level increases.

It is also anticipated that there will be further improvement of the concept selection algorithm. It is likely that performance can be improved by incorporating additional parameters into the algorithm as well as by adjusting the weights of the parameters currently used.

The techniques discussed in this paper could readily be applied to other courses which teach techniques of solving problems. In fact, several courses could be administered simultaneously by the concept selection routine. A concept tree would have to be specified for each course together with the algorithms necessary for generating and solving problems.

The initial burden on the course designer is, perhaps, greater than in a frame-oriented system as he must program general solution algorithms rather than a representative set of questions and anticipated replies.

It is possible that a "canned" solution program (such as ECAP for circuit analysis) could be converted into a teaching program by first segmenting it into course concepts. Each concept would be modified by inserting

requests for student answers after the completion of each step in the solution process as well as remedial statements explaining the correct procedure to be followed for each step in the solution. In addition, a program statement would have to be included which would allow this question to be skipped by students above a specified level of proficiency.

It is felt that the extra effort required to program an algorithm based CAI system is worthwhile as the end product is a very versatile and flexible teaching tool.

APPENDIX—CONCEPT SELECTION

C_{ij} is the jth concept at Plateau i
L_{ij} is the level of C_{ij} where $0 \leq L_{ij} \leq 3$
n_i is the number of concepts at Plateau i
L_i is the average level of concepts at Plateau i, where

$$L_i = \frac{1}{n_i} \sum_{j=1}^{n_i} L_{ij}$$

If I is the current plateau, calculate L, where $L = I^{-1} \sum_{i=1}{}^{I} L_i$ and L is the average of all concepts at and below plateau I.

If $L \geq M$, where M is the Master average, then increase I by 1; otherwise, I does not change.

Now select the set of candidate concepts $K = \{k_1, k_2, \ldots, k_{nI}\}$ as follows:

Let $S_j = \{L_{xy} \mid (x \leq I) \Lambda (y \leq n_x) \Lambda (C_{xy}$ is a prerequisite of $C_{Ij})\}$ for $1 \leq j \leq n_I$

Calculate $\bar{S}_j$, the mean of S_j

If $\bar{S}_j \geq M$, then $k_j = C_{Ij}$, otherwise, $k_j = C_{ab}$ where C_{ab} is the prerequisite concept whose level, L_{ab}, is the smallest element in S_j.

Given the set of candidate concepts, K, the candidacy value, V_j, of each concept must be calculated. The concept, k_j, which has the highest candidacy value for this student is selected.

$$V_j = \sum_{i=1}^{5} w_i F_{ij}$$

$$F_{1j} = (2\Delta L_{Ij})^2 \qquad \text{(A1)}$$

$$w_1 = 1 \quad \text{if } \Delta L_{Ij} < 0$$

$$w_1 = 0 \quad \text{if } \Delta L_{Ij} \geq 0$$

Factor 1 tends to favor repetition of concepts for which previous usage led to a large negative change in level. The student is experiencing difficulty with this concept and its reuse with more interaction and monitoring occurring may prove beneficial

$$F_{2j} = \frac{(Q - Q_j)}{Q}, \qquad \text{(A2)}$$

where Q is the current sequence number and Q_j was the sequence number at the time concept k_j was last called. (Q increases by 1 each time a new concept is selected.)

$w_2 = 1$ if $Q_j > 0$

$w_2 = 3$ if $Q_j = 0$ (Indicates concept k_j has not been selected for this student.)

Factor 2 favors the recall of concepts which have not been used recently.

$$F_{3j} = R_j \qquad \text{(A3)}$$

where R_j is the stability of concept k_j as defined previously.

$$w_3 = -1$$

Factor 3 inhibits the use of a concept whose level is in a relatively stable range.

$$F_{4j} = \frac{|\Delta L_{Ij}|}{L_{Ij}} \qquad \text{(A4)}$$

$$w_4 = 1$$

Factor 4 is the percentage charge in level during the last usage of k_j. Factors 3 and 4 bias the selection toward concepts whose levels seem most likely to change during an interaction

$$F_{5j} = 2 \cdot D_j + E_j \qquad \text{(A5)}$$

$$w_5 = .1$$

Factor 5 calculates the number of prerequisites for concept k_j. Those prerequisite concepts which may be called as subroutines are counted twice. This factor gives emphasis to concepts which are more likely to result in the review of other concepts.

Preliminary thoughts about a UNIversal TEAching Machine (UNITEAM)

by JOE K. CLEMA, R. L. DIDDAY and M. WESSLER

Colorado State University
Fort Collins, Colorado

INTRODUCTION

Computer Aided Instruction (C. A. I.) promises to make practical the goal of enabling each student to receive highly individualized instruction at some point in his educational career. C. A. I. has evolved over the last fifteen years from programmed instruction which itself has had a relatively short history as an educational procedure.

Programmed instruction has not changed dramatically since the time of Pressey,[1] who in 1926 used it as a means of reinforcement in the educational process. Thirty years later Skinner[2] saw the need for incorporating stimulus materials into a framework of instructional aids in order to provide education without a live teacher. However, the ultimate goal of a universal teaching machine which provides instruction to individuals in arbitrary fields has not yet been achieved.

We consider a universal teaching machine to be one which may be converted to teach any subject by simply changing the program data base and which can adapt the instruction to the needs of each individual student. It is desirable that the transformation from the natural language of the subject to the machine language of the data base be somehow simple.

TEACHING MACHINES AS QUESTION-ANSWERERS

For us the problems faced by a general teaching machine are similar to those faced by question-answering systems. A question-answering system is one which accepts information and uses it to answer questions. Question-answering systems are attempts to construct and manipulate data bases which are represented as associations among symbols which have meaning when humans see them. Newer systems are based on theorem provers,[3] and when given some input question must choose efficiently from an infinity of possible deductions in order to arrive at an answer. At present the limiting factor in their usefulness is the difficulty in selecting an appropriate sequence of deductions in a reasonable length of time.

A question-answering system does not store as such all information which is available to the user. Instead, it maintains a compressed data base of compactly coded facts.[3,4,5] The facts may reside in data structures[3,4,6] such as lists or binary trees. There are many methods for deducing answers which have not been explicitly stored in memory. These include:

1. A set of prewritten programs, one for each class of question. These programs are a permanent part of the system and do not change from their initial state.
2. A translator which creates a subprogram each time a question is input to the system. This subprogram exists only as long as it is needed to answer the question.
3. A formal theorem prover using some subset of current known facts as axioms.

The problem with prewritten subprograms is when questions arise that require interaction among existing classes. Either the interaction must be anticipated or new subprograms must be written. In No. 3 the inference mechanism must be general enough to answer questions of a variety of types.

An important characteristic of all question-answering systems is the set of languages programmed into them. At the most sophisticated level are the dialogue languages[3] which include:

1. A language for introducing facts into the system;
2. A query language to be employed by the user;
3. An answer language to be employed by the system.

In the process of answering questions the system may require additional information from the user. Thus it is necessary that a query language be employed by the user and an answer language be employed by the system.[7]

Question-answering systems also consist of one or more internal languages. These are machine languages which are used as intermediate steps in translation[8] or for calculation and manipulation of data.

The problem of representing data may be derived into three parts:[7,10]

1. Determining the semantic content of the data;
2. Choosing a language to represent the semantic content;
3. Choosing an internal representation of the language chosen above.

For example, the sentence "GASP is FØRTRAN based." may be expressed by the binary relation "is" as applied to the subject "GASP" and the predicate "FØRTRAN based." In choosing a language to express semantic content we might use the notation of symbolic logic, and in choosing an internal representation we might express a series of binary operations as a binary tree structure.[9,11]

OUR APPROACH

A teaching program can be structured so that the burden of finding a path through the data, i.e., from question to answer, is placed on the student. To put it another way, we can generate proofs at random. Of course we will not know what theorem we have proven (what question we have answered) until we are through, but this seems to be the way that human teachers operate anyway.

Currently we plan to represent a topic as an ordered set of information units called *concepts.* A concept consists of an ordered triple (a production), a string of symbols called the *question format,* a list of concept labels called the *error list,* and an integer weight which serves as a measure of how well the student knows the concept.

In operation the system will be able to access a subset of concepts, namely those it has introduced so far. Associated with each student is a vector, the elements of which serve as the *weights* of each concept in the topic when he is using the system. When the student is asked a question, the system selects a concept with a probability skewed by his weight vector.[13,14,15,16] This involves Monte Carlo methods and techniques for generating pseudorandom numbers. A certain number of deductions are then made, again chosen according to the weighted distribution. As each deduction is performed, the question format of each successive concept is taken into account so as to generate a reasonably well-stated question. At some point in the random deduction process a deduction is not made according to the production associated with the current concept. Instead, an alternate concept is chosen from the error list, and its production is carried out next. This allows the use of "what is wrong with . . .?" type questions which we will demonstrate later.

When a student's error vector fits certain criteria, a new concept will then be introduced and used (with high probability) in the question generation process. It is our basic assumption that if a student can answer arbitrary questions which result from associations among a basic collection of concepts, he has learned the topic. It is in this respect that we call our programs *teaching programs.*

Where do concepts come from? Unlike the designers of question-answering systems, we make no effort to find an elegant or concise representation. We believe that concepts should be the embodiment of a global model of the topic encoded in "symbology" which is as close to the natural language as possible. We further envision that such a program could be developed in the following way.

Experts in a field such as mathematics, programming, etc., will be engaged to extract from their topic a set of concepts which describe it. By "describe" we mean that the concepts they provide can potentially lead to the derivation of all facts that they are trying to teach in their subject area. We can think of the topic as a vector space and the concepts as a set of basic vectors which describe it. We imagine that the process of extraction will be done on-line, i.e., at any point the designer can interrogate the concepts he has previously defined in order to see what, in fact, can be derived from them. Thus he can refine concepts which lead to false deductions.

It has been implicitly assumed that we can embody everything necessary about a topic within a reasonable number of concepts. Also, the usefulness of this technique depends on its efficient implementation so that a large number of students can interact with the program simultaneously and economically. The former requirement dictates that the productions associated with each concept be potentially powerful. The latter requirement dictates that they be easily manipulated. A similar problem is faced by those who write the software for computer languages. ALGOL is represented as a "context-free" (Chomsky Type 2) set of productions, as opposed to Chomsky Type 1 which is "context sensitive," which are easy to manipulate but which do not completely specify the language. Context sensitive aspects of the language such as the requirement that array sizes be explicitly declared have been shelved away in symbol manipulation routines, etc.

This solution is one we cannot take. Our goal is to expose all aspects of the subject within the framework of these concepts. We apparently will be forced to use a context sensitive scheme in every interesting case.

COMPLETED WORK

In order to test our approach, we have chosen to design a program, UNITEAM, which teaches the simple programming language BASIC. We have further simplified our immediate goal, choosing to divide the teaching into three phases. We hope that those phases can eventually be included in one general framework which will be applied to a broad range of topics. Phase 1 we term "motivational" in that we are trying to relate the new words "computer", "memory", "word", "I/O", etc., both to things with which the student is already familiar and to each other.

In Phase 2 the syntax of the language and its semantics with respect to the concepts of Phase 1 are introduced. In Phase 3 the semantics in terms of the world and more global techniques of programming are emphasized. The following reports our work in Phase 2, mentioning our approach to the other two phases only in passing.

Sample productions belonging to concepts which will be stressed in Phase 1 are things like:

COMPUTER HAS-AS-PART MEMORY
COMPUTER HAS-AS-PART CONTROLLER
COMPUTER HAS-FUNCTION PERFORM
  OPERATION
etc.

Sample questions might be something like:

WHAT PART OF COMPUTER HAS-
  FUNCTION PERFORM OPERATION?
etc.

There is much work to be done on this phase which is the most general phase. For example, we must understand what effect allowing various verbs (second element of the production) has on the system. In Phase 2 we deal almost exclusively with productions which have the same verb.

In Phase 2 we are currently using techniques similar to those used in compilers for languages expressed as context free grammars (Chomsky Type 2). Since there are also global (context sensitive) features, we make a slight addition. A typical production is

/line/ IS UNIQUE (/statement number/0/
  statement/CR

which would appear in traditional Backus-Naur form[17] as

/line/ ::= /statement number/statement/CR,

and says that a /line/ consists of a /statement number/, a /statement/, and a carriage return. It is a global feature not expressed in the second form above that no two lines may have the same statement number. In our system the expression "UNIQUE( )" will reference a subprogram which insures that any statement number that is generated through this production is unique. There will be an additional concept with the production

UNIQUE( ) HAS-FUNCTION EACH LINE
  HAS A UNIQUE /statement number/

which summarizes the operation of the hidden subprogram for the student.

A second difference is that, unlike compilers, we will proceed from left to right which requires the rewriting of a few productions from their more commonly seen forms.

With this brief introduction let us sketch the operation of the system as it would proceed in generating a question. For this example we will generate a statement as it would appear in BASIC[18] except for one error. We will not write all the productions which are necessary, but suppose that concept 23 has been chosen. Concept 23 looks like this:

C_{23}→./assignment/ IS LET / variable /
  = / arithmetic expression /
  .QUESTION FORMAT = ...
  .ERROR LIST = $\wedge$ (null)
  .WEIGHT = ...

We will have three push-down stacks:[19,20] One stores the concepts in order of application, one stores that part of the final string we have completed, and one stores the parts we are still working on. We call these the C stack, T stack, and W stack respectively.

So far the stacks look like this:

C Stack	W Stack	T Stack
C_{23}	LET	LET
⋮	/variable/	⋮
	=	
	/arithmetic expression/	
	⋮	

Next we choose a concept which has a production that tells us something about the top-most (non-terminal) element of the W stack. Suppose we choose

C_{35}→./variable/ IS / identifier/

.

.

.etc.

Then the stacks would look like:

C Stack	W Stack	T Stack
C_{35}	/identifier/	LET
C_{23}	=	⋮
⋮	/arithmetic expression/	
	⋮	

At some point in the processing the student will encounter a concept which has a relatively high weight, meaning that the student has had trouble with it before. Instead of copying the right side of that concept's production onto the W stack, the program copies the right side of a production belonging to one of the concepts in the current concept's error list. This fact is noted on the C stack.

Suppose that later in the processing the top of the W stack contained/arithmetic primary/, and instead of an appropriate match we choose from the appropriate error list

C_{24}→/logical expression/ IS /arithmetic primary/ /relation/ /arithmetic primary/.

The stacks would end up looking like this:

C Stack	W Stack	T Stack
C_{24} ERROR	/arithmetic primary/	=
C_{28}	/relation/	B4
C_{25}	/arithmetic primary/	LET
C_{37}	⋮	
C_{35}		
C_{23}		

Imagine that finally we had:

C Stack	W Stack	T Stack
C_{35}		7
C_{31}		<
C_{41}	⋮	A2
C_{35}		=
C_{31}		B4
C_{24} ERROR		LET
C_{28}		⋮
C_{25}		
C_{37}		
C_{35}		
C_{23}		

The system prints

WHAT IS WRONG WITH THIS /assignment/?
LET B40 = A20 < 7.

Note that /assignment/ is the left side of the production of the bottom concept in the C Stack (C_{23}).*

If the student's answer looks something like

/logical expresion/ SHOULD HAVE BEEN / arithmetic expression/,

i.e., if it names expressions which pinpoint where the error was made, the program accepts it. If the student's answer includes expressions found *higher* in the C Stack than the ERROR flag, for example, /relation/ SHOULDN'T BE THERE, the program responds:

YES, BUT CAN YOU BE MORE SPECIFIC?

Otherwise the program limits the productions which caused the error and any others in the C Stack that the student might want to see.

We have not yet settled on the best way to locate an error nor on the best way to update the weights of those concepts used in generating a question.

Phase 3 is dedicated to teaching the student how to write small, meaningful programs. It will begin with concepts which describe how the various BASIC statements alter the variables referenced within them. The next batch of concepts will introduce bits of programs such as "short routine", "sum an array", etc. Finally, the highest concepts will be oriented toward a canonical representation of a few simple programs. Thus, if all goes well, at the end of his relationship with the system the student will be asked questions about what specific, complete programs do.

CONCLUSION

We have outlined our initial approach to the problem of creating a universal teaching program. The fundamental ideas are similar to the theorem proving approach, i.e., the technique used by question-answering systems, but runs "backwards," generating questions which test the student's ability to manipulate the basic concepts of the topic he is to learn. We have given an example which, while extremely simplified from the general case, demonstrates a sophisticated capability when compared to present day teaching programs. It remains to be seen if the techniques we devise can be generalized sufficiently to accept concepts derived from diverse topics.

The parameters used to evaluate such a system are access time, CP (Central Processor) time, IØ (Input/Output) time for Control Data Corporation 6000 machines, mass storage, and core requirements. We believe that all four can be cut drastically by utilizing the random access capability of the Control Data Corporation 6400 on which our program is being implemented. That is to say that the system will be maintained on disc. Since the selection of concepts is inherently random, this approach seems intuitively correct. The elimination of chaining, i.e., searching for data sequentially, will minimize access time, and CP time will be reduced by holding data manipulation to an absolute minimum. Since the system will reside on mass storage units, core capability will be greatly enhanced.

The principal advantage of UNITEAM over other systems (PLANIT, PLATO, ETC.) is that UNITEAM is the most adaptive program yet devised. Certainly the ultimate C. A. I. will include verbal communication and pictures, as does PLATO. PLANIT can recognize responses in a number of ways which UNITEAM at its present stage of development cannot.

PLANIT can derive data from several sources in order to provide a basis for making instructional decisions. This examination of various sources of data and records is incorporated into UNITEAM to formulate the weights (UTILES) of the value of various topics to be presented to the student.

1. Student performance on a question;
2. Cumulative student performance;
3. Student entry characteristics;
4. Student preference.

Student performance includes accuracy of response, time of response, etc. Student entry characteristics include the ability and educational background. It is felt that UNITEAM should make use of the prior knowledge of an individual, including such things as grades, IQ, interests, teacher ratings, etc.

Feedback is a major factor in determining which material and at what depth that material should be presented next, thus enabling the program to adapt to the needs of the individual. All previous feedback including the most recent information in one sense is reevaluated at each step since UNITEAM is based on stochastic methods. Although UNITEAM bears some Markov chain similarities, it is more complex, and thus final evaluation will rest with performance of students rather than mathematical analysis. Thus, total examination of feedback determines to a large degree which direction one next proceeds.

* The concept numbers correspond to a list we have used but which is not included in this paper.

At the present time feedback consists of:

1. Student records;
2. Evaluation of performance;
3. Number of prompts, hints, cues needed;
4. Elaboration on a student's response as a means of reinforcing a concept.

Unlike other C. A. I., UNITEAM employs Monte Carlo methods in addition to a weighting scheme associated with topics, concepts, etc. This system provides a completely non-linear capability and innumerable paths of deductions as UNITEAM develops necessary logic at each stage or step in the question-answering process. UNITEAM is capable of providing an almost unlimited number of pathways through the instruction because its responses are dependent upon each individual student who is making his own decisions, and it is very unlikely that any two students would choose the same path through UNITEAM.

APPLICATION OF UNITEAM

The system design of UNITEAM envisions the following to be provided by the instructor:

1. Text or subject material (data) to be punched on cards;
2. List of key words which students are to know;
3. Table of weights (utiles) for various topics and concepts;
4. Table of yes-no and true-false questions.

Instructors are not required to know anything about programming or how UNITEAM works. They must know how to present material, and if they wish, UNITEAM will handle the weights of all topics and concepts equally by default. The table of key words provides ready access to the determination of important concepts.

At the current stage of UNITEAM's development, response time is not a problem. This, of course, is because at its present stage of development, the question-answering is one of essentially true-false or yes-no. Development is centering on multiple choice responses, and definitions at this time, and the response time problem is appreciated as the question-answering becomes of a more complex nature. Disc storage rapidly becomes a problem, as we envision the capability of UNITEAM to essentially control access to all knowledge about a particular course being taught that an instructor might like to include. For the controlling system (UNITEAM) disc storage is not a problem, but the course material (data) rapidly can become unwieldy. With the development of such hardware as Precision Instrument Company's trillion-bit laser mass memory, one might hope that this problem will soon be eliminated or at least greatly reduced.

Mainline CAI, necessary but not oppressive*

by C. VICTOR BUNDERSON

University of Texas
Austin, Texas

Two years ago the term "mainline instruction" was introduced as a referent to a carefully designed, total instructional system to replace complete courses with a far less labor-intensive mixture of men and machines.[2,3] This mode was contrasted with the adjunctive use of the computer by faculty members who are happy to work within the system and merely want to use the computer to improve their instruction. The two NSF-sponsored conferences on Computers in the Undergraduate Curriculum[11,6] have illustrated and stimulated the adjunctive approach.

The term "mainline instruction" is not fully descriptive of the concept it designates. It serves as a shorthand term for *individualized instructional systems of major scope, using the computer as a tool for instructional management and information transmission, developed according to a design science approach and used as a less costly alternative to conventional instruction.* The ends to which computer uses are directed in this mode are necessarily controversial for: (1) mainline instructional systems revise the role of the teacher substantially, (2) mainline systems imply the emergence of a new profession of "courseware design" backed by instructional scientists who develop the instructional theorems used by the courseware designers, and (3) it is feared by some that the transformation of education from labor-intensive to technology-intensive systems might be accomplished only at the sacrifice of certain values of our liberal education tradition.

Advocates of the adjunctive use of computers in education point out that their approach bypasses these controversial aspects of the more radical mainline approach. By leaving the teacher firmly in control they minimize the threat to members of that profession, and more easily avoid charges of "dehumanization." By pointing out that no generally accepted theory of instruction exists, nor ready translations of learning psychology to instruction, they keep the teacher in control of program development and put off the problem of standards for evaluating programs. Because of the merits of the adjunctive mode in opening instruction to more student-oriented, problem-solving approaches, they can argue that adjunctive computer use in instruction not only preserves important values of our liberal tradition, but enhances them.

Arthur Luehrmann has been one of the more articulate and positive advocates of the adjunctive approach. Among the values to be sought through this mode are the following:

(1) to bring about a qualitative restructuring of the curriculum toward algorithmic and problem-solving approaches, and
(2) to encourage independent, self-motivated learning, and investigation using the computer as a tool.[7]

A third value should be added to this list, for Luehrmann and his colleagues at Dartmouth have been leaders in this effort for years—

(3) to bring about widespread and flexible access to computer use in higher education nationally consonant with the recommendations of the Pierce report.[8]

My intention in writing this paper is not to challenge these values, for I share them. It is not to argue that the adjunctive approach is not a good way to seek the three goals listed above, for I believe it is and that it will be the more visible way to achieve them for the next few years, touching many more students than will mainline CAI. My purpose in this paper rather is to present data and rationale supporting the propositions that:

(1) mainline systems are necessary for the widespread dissemination of computers throughout the educational establishment; and

* Research reported in this paper has been supported by NSF Grant GJ 509 X. TICCIT courseware development is supported by NSF Grant GJ 28095 and a MITRE Corporation subcontract.

(2) that contrary to stereotypes built up through comparison with earlier attempts at tutorial CAI, mainline systems can lead to the first two goals listed above and need not detract from other important values of liberal education.

THAT MAINLINE SYSTEMS ARE NECESSARY

The Pierce report recommends that steps be taken to provide all college and university students needing such services with adequate computing services. It does not specify how this is to be done. A direct investment of the Federal Government to support the free and relatively unstructured use of computers in the adjunct mode would represent a staggering capital investment. The government has not risen to this challenge. To examine some reasons for their reluctance to do so, the need for computers must be put in context with other problems being faced by education in this country which also demand additional capital. Some of these problems are accompanied by compelling arguments for higher priority than the Pierce report recommendations.

Colleges and universities are facing serious financial problems and social pressures which call for rapid and dramatic change. Consider the following facts. During the past ten years, the gross national product increased 93 percent. During the same period, the cost of higher education increased 266 percent. An ever-increasing percentage of this rise was attributable to faculty salaries. Instructional outlays accounted for 45 percent of the costs of higher education in 1945. In 1971, they accounted for 65 percent. Approximately 90 percent of instructional costs are attributable to faculty salaries.

While salaries have been increasing, productivity, as expressed by teacher-pupil ratios, has been decreasing. In 1959-60, the ratio was one teacher to 26 students in higher education. In 1969-70, it was 1 to 20.

In an analysis of population trends for the 100 largest standard metropolitan areas, the Academy for Educational Development[10] projected that the population of 18-24 year olds will increase from 12.5 million to 15.7 million between 1968 and 1990 (26 percent). During this same period of time, however, collegiate level enrollment was projected to increase from 4.1 to 8.2 million, or 100 percent. This increase reflects increasing numbers of disadvantaged youth entering college, increases in married women returning to school, more employees upgrading skills, more technical and vocational education, and more leisure time due to automation. The cost estimate for this greatly increased body of students is $24 billion in 1990, up 200 percent from the $8 billion cost in 1968. This estimate covers operating costs alone. It does not reflect capital construction nor athletics.

Legislatures, state and federal, are refusing to support these trends. In an attempt to help beleaguered college presidents meet the resulting cost squeeze, the Academy for Educational Development listed 115 ways to decrease the costs of higher education. First on the list was reducing the number of non-tenured faculty, adjunct or part-time faculty, consultants, and research and teaching assistants. Another suggestion was to cut computer costs or postpone the acquisition of new hardware. However, if CAI could be shown to be a cost-effective alternative to more labor-intensive methods, college presidents would have many more options, including, in some cases, the option to increase enrollment and effectiveness simultaneously.

Clearly, radically different approaches to education are needed. It will not be possible economically to continue the teacher/classroom model indefinitely as the prime method in higher education. Peter Drucker[4] has expressed this thought as follows:

> *The educators still talk of minor changes, of adjustments and improvements. Few of them see much reason for radical changes. Yet education will in all likelihood be transformed within the next decades by giant forces from without.*
>
> *It will be changed, first, because it is headed straight into a major economic crisis. It is not that we cannot afford the high costs of education; we cannot afford its low productivity. We must get results from the tremendous investment we are making . . . .*
>
> *Teaching is where agriculture was around 1750, when it took some 200 men on the farm to feed one nonfarmer in the town. We have to make the teacher more productive, have to multiply his impact, have to increase greatly the harvest from his or her skill, knowledge, dedication, and effort. Otherwise we shall run out of teachers—even if we do not run out of money for education.*

It is difficult to see how adjunctive CAI can meet the requirements implied by Drucker for educational reform. The philosophy of adjunctive CAI accepts without question the central role of the classroom teacher. Materials are prepared with teachers in mind to provide the context and motivation for the usage of computer packages. This assures that computer use will represent an add-on cost to existing costs for labor, overhead, and physical plant. It also makes it difficult to disseminate the package widely, for a teacher training project of some kind is necessary to enable the new user to adapt the inductive approach to instruction usually implied, provide the necessary context and motivation, and operate the program skillfully.

Because of its systematic development and "total system" approach, mainline CAI systems have by design provision for context, motivation, sequencing and correct utilization of each system component. Training programs are obviously required for the teachers and others who will still be involved in the system, but with a mainline system the student to teacher ratio is greatly increased, and the costs of the development and operation of retraining programs are spread over a much broader base.

These factors lead any economist to predict much greater potential for mainline CAI than for adjunctive to produce mass dissemination of computers in education, assuming the demonstrated solution to problems of hardware, software, and educational effectiveness. Wide availability of multi-terminal computer systems for administering these programs, if properly configured, will also provide a resource for enormously expanded activity of the adjunctive variety. Minicomputer systems designed for mainline courseware could also provide computer power for running small student jobs, e.g., in BASIC. They would have to be tied to larger systems to permit large data base simulations and other powerful adjunctive applications. It is most important that students and teachers have access to adjunctive computer resources, for such activity does lead to qualitative improvement of aspects of the curriculum; creative ideas which can be implemented more broadly, both by packaging within mainline systems and by easy transfer to compatible systems.

ENHANCING IMPORTANT EDUCATIONAL VALUES IN THE DESIGN OF MAINLINE INSTRUCTION

Early attempts at tutorial CAI, or other forms of programmed, packaged instruction designed to carry a substantial burden, have been criticized for being plodding, inflexible, unimaginative, and stultifying to the intellectually able and creative student. Too often these criticisms have been justified. But to judge the potential of any system involving considerable tutorial CAI by these examples is equivalent to judging the potential of motion pictures, having never seen a modern movie, on the basis of a few amateur home movies.

Consider the two values stressed by Luehrmann.[7] The first is that it is desirable to bring about a qualitative restructuring of the curriculum through computer use. The use of algorithmic and information-processing approaches to representing and illustrating concepts in new and powerful ways is an important contribution of the computer. Programs which make such a contribution can be used either by a teacher in the adjunctive mode or within a mainline system. In addition to this, the systematic analysis of a block of knowledge in mainline program design can lead to another form of qualitative restructuring, also powerful and effective in its educational consequences. This systematic behavioral analysis forms an essential part of any large-scale courseware development project. It involves the specification of measurable performance objectives in relation to broader course goals and the construction of a "learning hierarchy" which relates the major objectives and enabling objectives to one another by means of a kind of flowchart which shows prerequisite relationships and other dependencies. Such an analysis usually cuts away numerous topics which for years have been taught because of tradition rather than instructional merit. It simplifies and streamlines the structure of a course and acts as a theory for the steps a novice must take to attain the performance capabilities of a competent graduate. Such an analysis may reveal fuzzy concepts and suggest new research. It results in a representation of the course of study and its criteria for success which is more comprehensible to both students and teachers than outlines or syllabi.

An example of the effectiveness of this approach is found in an analysis of that portion of beginning Arabic dealing with the writing and sound system.[1] In class it takes 6 weeks, 6 periods per week to teach this complex non-Latin script and its phonetics. Our CAI program takes students from 5 to 9 hours at the terminal, augmented by 4 hours with an instructor. Comparison studies have shown that the students' performance surpasses by far that of groups learning in classroom or language laboratory. Only a part of this gain can logically be attributed to the computer. The behavioral analysis and specification of appropriate practice for each objective was the key, and classroom work could be greatly enhanced by its adoption regardless of the existence of a computer.

Another goal discussed by Luehrmann[7] was to encourage independent, self-motivated learning and investigation using the computer as a tool. It is quite as possible to seek this goal in the design of mainline courseware as through adjunctive approaches. The National Science Foundation has funded two major demonstrations of computer-assisted instruction: the PLATO system, under development by The University of Illinois, and the TICCIT system, under development by the MITRE Corporation. Under subcontract to the MITRE Corporation, a group of instructional psychologists at The University of Texas and at Brigham

Young University are developing the courseware for the TICCIT system. This courseware may be described as a set of mainline systems in the areas of freshman mathematics, freshman English composition, remedial English, and remedial mathematics. The target is the junior colleges of this nation. The four mainline systems are designed to replace up to 20 percent of the classroom instruction in the typical junior colleges at less than $1.00 per student hour (instead of the existing $1.50 for instruction, or $3.20 for total costs now extant).

In the development of courseware for the TICCIT junior college project, we are designing novel systems which will enable students to achieve on each of four major kinds of objectives, each measured by special scoring systems implemented in the courseware. These are:

(1) All students will achieve mastery at either A, B, or C level (student contracts for the level) on the lesson and unit tests that make up the measurement system for mastery.

(2) All students will develop a more positive attitude toward the subject matter and mode of instruction as measured by increases in their tendencies to approach voluntarily optional work related to the subject matter. More precisely, we provide opportunities within the course for optional work, use a variety of techniques to encourage approach responses, and measure our success. In some ways, we feel that approach is the master criterion, for it determines the student's future relationships with the subject matter. We can teach him to hate it and avoid it in the future or to like it and approach it in the future. This criterion seems especially important at the junior college level.

(3) All students should develop improved strategies for learning relative to the subject matter and the TICCIT system implementation. Strategies are operationally defined in our courseware as a vector of integers referring to items on one or more menus presented to the student. The order of the integers describes a sequence through the items on a particular menu. Menus exist at the course level, unit level, and lesson level, and serve as hierarchically organized points of control. A strategy may be entered in any of two different modes: survey or instruction. Provision for review is also available.

We will measure our success in improving strategies by changes in efficiency scores (mastery ÷ time) and by reference to strategies found to be effective for certain outcomes by certain classes of students, especially the more effective students. A high-level advisor program will exist to encourage and help students in the selection of good strategies.

(4) We wish students to develop a sense of responsibility for their own learning. We want them to feel that education is their choice and that both the positive and negative consequences of it are to be chosen or rejected by them alone. What we wish to convey to the student is that he is not just the recipient of orders but a participant in decisions that shape his life. He will be given the opportunity to choose a grade level, try various strategies, choose to take optional extra work or not, and choose among various "fun options" (games, films, computation and plotting programs, etc.). From the instructional system and the humans who manage it, the student should get the clear message:

> "We provide effective, efficient, and palatable instructional resources and a way of measuring your progress toward your goals. Choosing among alternate goals is your responsibility. Working effectively is your responsibility. If you fall below your potential we provide sympathy and advice. If necessary, we provide automatic control for a time, always encouraging the independence that assures you of control over your own destiny."

Measurement of changes in responsible behavior in the use of learner control options and commands is a complex process and will initially be done only at a gross level. These gross scores will locate the student somewhere between yielding control completely to the program and permitting him to push control buttons wildly or to jump about within the course without making progress on mastery and efficiency.

Such an ambitious scheme can only be attempted within the context of large mainline instructional systems. We estimate that the average student will sit at the terminal for at least 50 hours for five hours of semester credit. The mechanisms we have and are designing to achieve each of these objectives cannot be described in this short paper, but some flavor can be given. Briefly, we seek to achieve these objectives through three major sets of novel approaches which have never been used before, to our knowledge, in any CAI program. These are: (1) new control structures, to facilitate both learner control with program control options, (2) the construction of a high-level "advisor program," (3) the use of a variety of motivational techniques.

CONTROL STRUCTURES AND LEARNER CONTROL

Three years ago The University of Texas CAI Laboratory developed a modestly sized mainline CAI system to teach mathematics prerequisite to freshman science courses.[9] This program employed learner control of sequence, amount of practice, and testing very extensively. Hierarchical index structures, menus, and a separate control program were implemented. A series of research studies was conducted to analyze the effects of various control options (e.g., Judd, Bunderson, and Bessent).[5] These studies were inconclusive regarding the effects of learner control vs. program control on mastery and speed criteria. Though equivocal, the results indicated that little might be lost through the use of learner control in CAI on mastery and speed. It later occurred to us that much might be gained, and that learner control was more likely to be related to measures of approach, strategy, and responsibility than to mastery. Gambling that evaluation will prove us right, but that if it doesn't the program control options can take over, the control structures developed in the MathS course were revised and improved, and are being implemented in the TICCIT courseware.

Methods of control differ somewhat from course to course and among levels within courses. A number of the important concepts are illustrated in Figures 1 and 2. Figure 1 represents the components of a lesson menu from the precalculus mathematics course. The objectives section tells the students about the structure of the lesson. Those students who opt for this material learn that there are two major supporting objectives, corresponding to the two instructional sequences (items 5 and 6). Section 5 provides structured instruction to enable the student to achieve the objective: Given a second degree polynomial function in standard form, perfect square form, and factored form, identify and plot the extreme point, zeros (if any) and y intercept. Section 6 teaches algorithms for transforming functions from one form to another, and for finding zeros. Within both of these instructional sequences various control options and paradigms derived from recent research and theory in instructional psychology are used. The "Review Tips" section discusses the prerequisites (concept of zero, domain, range, function, etc.), provides brief review material, and references earlier lessons. The "So what?" file contains information on why a junior college student should bother to learn these objectives. The mini-lesson is a quick survey of the entire lesson. Definitions are provided for the important concepts in the lesson, including second degree polynomial and the three forms of the function. The mastery test is diagnostic. If the student fails parts of it he is given advice which is designed to help him go back to the lesson menu, or to review, before taking the test another time.

Lesson Menu

Second Degree Polynomial Functions

1. Objectives
2. Review tips
3. So what?
4. Mini-lesson
5. Definitions
6. Instruction: zeros, extreme point, y intercept, graphing
7. Instruction: algorithms
8. Mastery test

Figure 1—Sample menu for lesson on second degree polynomial functions

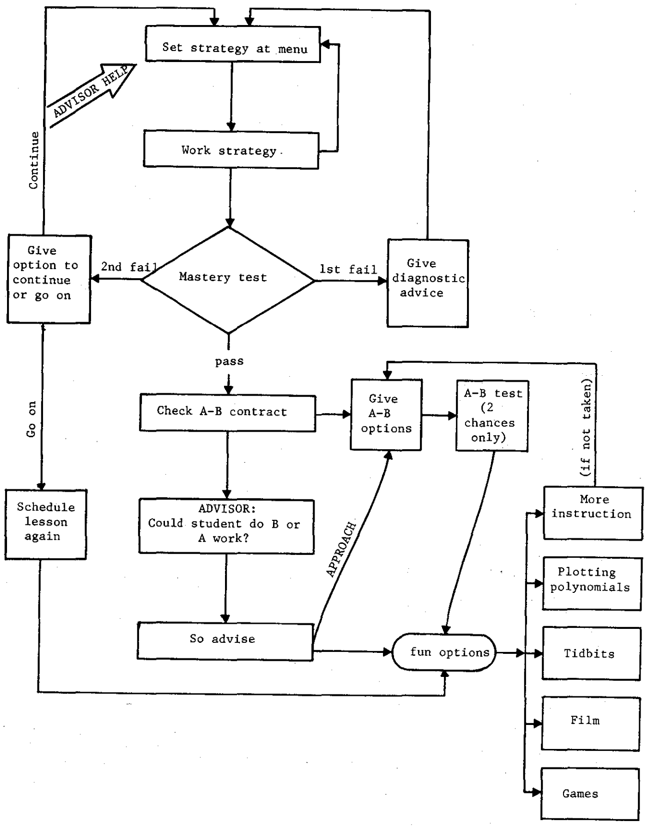

Figure 2—Generalized flow within a lesson

Figure 2 is a nondeterministic flowchart in which the overall pattern for most lessons is revealed. Students may try several strategies before taking the mastery test, and after failing it the first time. The advisor program may be called by the student for a discussion of various strategies used by fast, slow, and average students, or the advisor program may interject commentary under certain conditions.

A student is not required to attempt a mastery test more than twice in close succesion, but may elect to come back to the lesson at a later time. Under this condition the lesson is automatically rescheduled. The student may request "status" from the advisor program at any time to see what lessons he has completed.

Once the mastery test has been passed, if there is additional instruction at the A and B level, then the student contract is checked, and if he has elected a B or A, additional instruction is given, along with the A-B test. If he has not elected a B or A, a calculation is made to predict what he would probably get on the A-B test. If he is an underachiever who could get a B or A, he is provided with friendly advice and scored for approach if he takes it. He then has a chance to select among the "fun options" which might include such items as "More on that Topic" (which gives him A and B items not seen), a computational plotting program, a game film or a short film (videotapes can be shown on the TICCIT terminal). TIDBITS are historical vignettes, anecdotes, etc., related to the lesson topic, and are scored as approach. The student pays for fun options, using points earned through earlier achievement. The advisor may "advertise" certain options when the student arrives at the fun options menu. If he arrives at the fun options menu without having passed the mastery test, his choices are restricted and his bank account of points is low.

THE ADVISOR PROGRAM

The advisor is simply a set of routines which are either called by the student by depressing an interrupt key and typing a code word, or which are called by the course program at certain points. Four of the functions have been discussed above: strategy advice, status report, A-B advice, and "advertising." Other functions deal with setting and changing the grade contract, with scheduling reviews, and with keeping track of the "bank account" income and expenses.

MOTIVATIONAL TECHNIQUES

The reader will have observed a number of motivational techniques in the previous discussion. The whole concept of learner control, with emphasis on responsibility and skill in the use of strategies, has the potential of being very motivating to many students. The "So what?" file, the "fun options," and the point system used to earn fun options are designed to enhance motivation as well as to develop approach. In addition to these techniques, humor, cartoons, graphics, color, and audio are used throughout in an attempt to introduce the light and clever touches which have been used so well in the TV programs developed by Children's Television Workshop. Professional writers and TV scriptors are a part of the courseware teams. The intimate mixture of short videotapes and CAI sequences is a powerful new mechanism of expression for creative authoring talent, and we hope to learn to use it to the fullest to provide instruction that is palatable and fun as well as effective and efficient.

ON FREEDOM AND PRIVACY

The philosophy of learner choice and the respect for the individual implicit in our courseware design assure individual freedom. An individual is free even to remain antagonistic toward mathematics, or to resist attempts to accept responsibility, for our interactions are all persuasive rather than coercive.

On the issue of privacy, we plan to keep scores on mastery, speed and accuracy, learning strategies, voluntary approach, and the responsible use of control options. These scores are necessary both for the advisor program and for the human advisors to help each student achieve his objectives, and to improve the system for later students. The data are analogous to a combination of a grade transcript and a set of aptitude scores now found in students' files in registrars' offices at any college, but these data are more precise and detailed. They could presumably be misused in the same manner as could the registrars' files if security were lost. IQ scores have been misused and restrictions set up against their distribution. Presumably, appropriate restrictions must also be established to protect the misuse of our courseware scores. Indeed, it is possible to permit the individual to contract for the courseware to attempt to influence strategies, attitude, and responsibility as well as mastery. Such an agreement between the student and the system would be a positive and constructive substitute for the "privacy warning" now given to Dartmouth students whenever a record is kept of certain of their transactions at a terminal.

SUMMARY

Because of increasing cost problems in higher education, and the need to find more cost-effective approaches to traditional instruction, mainline instructional systems were proposed as a desirable alternative. The first reason discussed was economic. Mainline instructional systems, as defined in this paper, replace important subsystems within an educational institution with a less labor-intensive, potentially more cost-effective technology. Any proposal which uses technology as an adjunct to a classroom teacher, representing an add-on cost, is unlikely to represent a viable alternative in the years ahead unless somehow incorporated within a more radical restructuring of education.

That systematically designed mainline courseware can lead to the qualitative restructuring of curricula, and, in particular, can enhance independent, self-motivated learning and other important values was discussed. An example was taken from the TICCIT courseware development project in freshman mathematics to illustrate this discussion.

Should the computer teach the student, or vice versa?

by ARTHUR W. LUEHRMANN

Dartmouth College
Hanover, New Hampshire

This sermon begins with a parable.

Once upon a time in the ancient past there was a nation in which writing and reading had not yet been invented. Society was as advanced as possible, considering that it had no mechanism for recording the letter of the law or of writing agreements, contracts, or debts. Nor was there a way of recording the heritage of information and knowledge that had to be passed on from generation to generation.

As a result, a great fraction of the total effort of the society was spent in oral transmission of information. Master teachers, who themselves had been taught by older master teachers, lectured before children and young people of the society. Training a master teacher was a long and expensive process, and so the society could not afford many. For reasons of economy the curriculum was quite rigid and lectures were on a fixed schedule. Teaching, obviously, was a labor-intensive industry based on skilled, expensive talent. Education, per force, was a luxury that could be afforded by the elite classes only.

Then, one day, writing and reading were invented. Not surprisingly, the first application of this new technology was to business and government. Money was printed; laws were encoded; treaties were signed. In response to these needs, a reading and writing industry grew up. Within a few years it was able to offer a broad range of reading and writing services to its customers. The customers found this to be a convenient arrangement, since hiring readers and writers from service vendors eliminated the need for each customer to invest in an expensive R&D effort of its own. The customers remained illiterate.

At first the situation was somewhat chaotic. Each vendor of reading and writing service tended to develop its own favorite language and its own technique for encoding information, leading to incompatibilities that impeded the spread of the new technology. After a winnowing-out period, however, the number of competing systems settled down to a few and major difficulties were handled by translators—though inevitably something seemed to be lost in the process.

Always looking for new markets, the vendors of reading and writing service began to examine the area of education. In view of its elitist role in the society it had been dismissed at first as too limited a market. A few, more imaginative people, however, argued that the application of reading and writing technology could turn education into a mass market. They proposed the following plan of attack. Reading and writing specialists and master teachers would work as a team. The master teachers would deliver their best, most carefully prepared lectures to the reading and writing experts, who would write them carefully *verbatim* into books. The books would then be copied many times, and each copy would be made available to a new type of educational functionary—the *reader*. His only job would be to assemble groups of students and to read aloud to them the recorded lectures of the master teachers. In view of the fact that training such a reader would be far less expensive than the education of a master teacher, the on-going cost of such a program would be far less than that of the conventional lecture method. The new method came to be called Writing Assisted Instruction, frequently abbreviated to WAI.

Needless to say, WAI had its opponents. Established master teachers expressed doubt whether a less skilled reader would be able to communicate subtleties of inflection, and they were certain that a mere reader could not process student responses with skill or intelligence. WAI proponents counter-charged that the master teachers were merely expressing their vested interest in the present educational establishment, and, indeed, that they ought to be fearful because the superiority of WAI would ultimately drive out the conventional practitioners. Even within the education establishment some younger members became WAI supporters on the grounds that the new method was a boon to education research. Until then, teaching had been something of a black art, shrouded in the privacy of the classroom. To compare one teacher with another was impossible. But in the future, they said, the written record of the lectures of master teachers would make the teaching experience explicit and subject to analysis, comparison and improvement. It was high time, the young Turks exclaimed, that the teaching profession act with accountability to the public it served.

Unfortunately, such controversy remained for many years on a hypothetical plane. The number of actual WAI efforts was very small and their results were not striking. There was also a credibility problem. Many of the most outspoken advocates of WAI, especially in the legislature and in business and on local school boards, were themselves almost totally illiterate in the new reading and writing skills. How could they evaluate a new technology if they had not mastered it themselves?

Finally, government, business and some members of the education establishment decided to mount two or three large-scale demonstrations of WAI in order to show publicly the advantages of the new educational technology. For a period of several years curriculum experts collected information on a few key courses of lectures by assorted master teachers. The reading and writing experts wrote down the best series and read them aloud to the curriculum experts, who would criticize them and make improvements. The reading and writing experts would then incorporate the improvements in the next draft. Then came the field test. Readers began to read the drafts aloud to actual classes of students, and this led to further revision by the curriculum experts and rewriting by the reading and writing experts. At the end of a few more years a summative evaluation of the projects was undertaken by an independent, reputable educational testing organization, whose mission was to compare the cost and effectiveness of WAI with conventional education.

The parable is nearing its conclusion now. Actually it has two alternate endings, one happy and one sad. The sad ending, which follows now, is brief.

The educational testing organization reported that the projects were a complete vindication of Writing Assisted Instruction. It found that students taught by WAI performed even better on standardized tests than students taught by the average master teacher, that the students liked WAI better, and that the total cost of WAI was about a fourth that of conventional instruction. These pilot projects were imitated on a grand scale and education was revolutionized. Special institutes turned out vast numbers of readers and within ten years they were reading courses of lectures aloud to masses of people who could never have been educated before the new instructional technology arrived. The nation grew and prospered and thanked the day that the reading and writing industry was founded.

That is the sad ending. The happy ending is somewhat longer and more complicated. Here it is:

The educational testing organization found that WAI was neither measurably worse than conventional instruction, nor better. It found that costs were somewhat higher than anticipated, mainly because the market demand for people with reading and writing skills had driven their wages up near those of master teachers.

But this lukewarm finding was anticlimactic when it came, for the impact of reading and writing on education had taken a new turn during the intervening years. Here is how it happened.

At first a few master teachers had themselves found it necessary in pursuing their own research to spend the enormous effort required to master the skills of reading and writing. As they became more and more competent readers and writers, they began to see clearly the power of the written word within their own disciplines. Naturally enough the humanists were the first to apply this new intellectual tool to their fields of interest. Literature specialists collected stories, wrote them down, exchanged them with each other and began to develop literary criticism to a new height. Language specialists compiled lists of grammatical rules, which became writing manuals. Scientists were slower in becoming literate, with mathematicians leading the way, since they grasped the possibility of writing mathematical concepts in abstract notation. Nevertheless, for many years scientists continued to remain in verbal darkness.

While reading and writing had its primary impact on scholarly research, at the same time many master teachers across the land began to wonder whether it might not be beneficial to introduce elementary uses of reading and writing to students in their courses. A few language teachers began to show students how to write phrases and sentences, and the more venturesome teachers even asked students to write sentences of their own. Such experience, they claimed, greatly enhanced a student's understanding of syntax and rules of grammar. Even in subject areas far removed from language, to which reading and writing have a natural affinity, teachers began to report pedagogical gains due to having students carry out elementary reading and writing tasks as an adjunct to conventional instruction.

One obstacle to student use of reading and writing was the awkwardness of the main systems of notation, which had been developed mainly for research and business applications. The most popular such system was particularly difficult to format, since its characters all had to be positioned accurately in a fixed number of columns. Occasionally there were rumors that a group of teachers in a remote province near the northern frontier had developed a simpler writing system and all their students were using it daily. Such rumors were hard to verify; only a few people ever voyaged that far north, and, in any case, experts in the reading and writing industry seemed confident that anything that made the current system simpler would also take away its power and elegance. So most teachers adhered to it.

Within a few years teachers began to hold national meetings to tell one another how their students used reading and writing within their courses. Advocates of this type of use, which came to be called *adjunctive*, insisted that it be distinguished clearly from WAI. Writing Assisted Instruction, they charged, was nothing more than an improvement in the technology of delivering instruction. Adjunctive use of reading and writing by the student, on the other hand, represented a change in the intellectual content of instruction. They argued from the following philosophical premise:

> Reading and writing constitute a new and fundamental intellectual resource. To use that resource as a mere delivery system for instruction, but not to give a student instruction in how he might use the resource himself, was the chief failure of the WAI effort, they said. What a loss of opportunity, they exclaimed, if the skill of reading and writing were to be harnessed for the purpose of turning out masses of students who were unable to read and write!

WAI advocates responded that it was well and good that a few elitist schools teach their students the difficult skill of reading and writing; it was enough that WAI teach lesser skills to masses that might otherwise remain uneducated and unemployable.

How much longer, asked the WAI opponents in rebuttal, will an illiterate person be considered educated? How long will he be employable and for what jobs if elitist schools are turning out competent readers and writers by the hundreds?

The more visionary advocates of mass literacy told of foreseeing the day when students would spend more hours of the day reading and writing than listening to lectures. Small research libraries had indeed sprung up at some schools, but they were expensive operations limited to a few specialists who had to raise funds to pay for their use. Such people were particularly incredulous at the suggestion that every school ought to adopt as an educational goal the establishment of a significant library open freely to all students. School administrators were at first appalled at the idea that the library should not be on a pay-as-you-go basis but should be budgeted as part of the general institutional overhead costs.

But as time went on and even school administrators became competent and imaginative users of the skill of reading and writing, all schools gradually accepted as a mission the bringing of literacy to all students. Accreditation agencies examined the quality of libraries before approving schools. Books began to appear all over and finally even in people's homes. WAI did not die out altogether, but continued as a cost-effective alternative to the lecture. But as books reduced dependence on lectures, students made less use of both WAI and lectures and spent more time on their own reading and writing projects. The nation grew and prospered and wrote poems in praise of the day that reading and writing were discovered and made available to all people.

End of parable.

It is a perilous strategy, bordering on bad taste, to tell a joke and then for several pages explain why it was supposed to be funny. However, this allegorical tale has been told here not merely for entertainment but mainly for the moral lesson it carries. To compare reading and writing with computing might be dismissed as an amusing frivolity; but that would be wrong. Our fundamental philosophical premise here is that, like reading and writing,

> "[computing] constitutes a new and fundamental intellectual resource. To use that resource as a mere delivery system for instruction, but not to give a student instruction in how he might use the resource himself, has been the chief failure of the [C]AI effort. What a loss of opportunity if the skill of [computing] were to be harnessed for the purpose of turning out masses of students who were unable to [use computing]!"

As this example shows, it is a trivial editing task to go through the entire reading and writing fable and turn it into a story about computing and its uses in education. In fairness, the author admits that the story really *is* about computing and that reverse editing was done in the original telling so that it would seem to be about reading and writing. Yet, as a story about reading and writing it has considerable plausibility, doesn't it? The Writing Assisted Instruction program outlined in the story is not a totally absurd idea for putting reading and writing to use in education. One cannot argue against claims that committing lectures to writing would make education available to more people, would invite critical comparisons and a consequent improvement in subsequent revisions of written materials, and would be an asset to the study of the learning process itself. What does appear absurd, however, is the failure of these mythical WAI proponents to recognize that the best educational use of reading and writing is the teaching of reading and writing itself to everyone. Mass literacy is an educational mission about which few of us have doubts today.

Yet that consensus among us seems to vanish when one substitutes "computing" for "reading and writing" and "CAI" for "WAI". Mass computing literacy is not an agreed-upon educational goal. Today very few courses at any educational level show students how to use computing as an intellectual tool with applications to the subject matter being taught. Oh, there are a few isolated, subject-matter-free courses in computer programming; but their market is largely restricted to vocational-education students, at one end of the spectrum, and future computer professionals at the other. It is true that most schools consider it prestigious to have a large and powerful computer facility; but the fact of the matter is that such computers are usually the captives of research and administrative interests and operate on a pay-as-you-go basis. Ironically, it is in the most prestigious universities that students are least likely to be permitted to use those prestigious computers. It is a rare secondary school, college, or university that budgets and operates its computer facility in the same way that it budgets and operates its library. (There is a persistent rumor of an exceptional example in some remote province near the northern frontier, but so few people ever travel that way that the report is hard to verify.) In the main, literacy in computing simply is not an educational goal at many schools. Most educators seem to find bizarre the suggestion that accreditation agencies examine schools for the quality of their educational computing facilities, just as they now do with libraries.

The distressing truth today is that educators, local school boards and federal policy-makers are far more receptive to the plans of CAI proponents for using the technology of computing as a cost-effective delivery system for instruction in math or remedial English than they are to making computing itself a part of education. This statement should not be taken as a blast against CAI. On the contrary, CAI advocates are to be commended for their desire to reduce the cost of instruction, to tailor it to the different learning styles of students, to develop systems that encourage closer examination of what is being taught and systems for improving instruction, and to hold teachers and schools accountable to their clientele. With enough developmental work on CAI, it is likely that students will perceive the computer as a very superior teacher. Above all, CAI promises to make education a less labor-intensive industry and so to enable masses of people to become better educated. This is certainly a goal worth working for.

But there is a higher goal. If the computer is so powerful a resource that it can be programmed to simulate the instructional process, shouldn't we be teaching our students mastery of this powerful intellectual tool? Is it enough that a student be the subject of computer administered instruction—the end-user of a new technology? Or should his education also include learning to use the computer (1) to get information in the social sciences from a large data-base inquiry system, or (2) to simulate an ecological system, or (3) to solve problems by using algorithms, or (4) to acquire laboratory data and analyze it, or (5) to represent textual information for editing and analysis, or (6) to represent musical information for analysis, or (7) to create and process graphical information? These uses of computers in education cause students to become masters of computing, not merely its subjects.

It will be countered that such an educational mission is well and good for a few elitist schools, where students are willing to learn the difficult skill of computing; but it is enough that CAI teach lesser skills to masses of students that might otherwise remain uneducated and unemployable.

In response we ask, how much longer will a computer illiterate be considered educated? How long will he be employable and for what jobs if elitist schools are turning out competent computer users by the thousands?

The true story about computing and education is at its midpoint. Like the reading and writing parable, it has a sad ending and a happy ending. Which one actually occurs will be determined by you—teachers, school administrators, computer professionals, and government policy-makers.

Performance evaluation—A structured approach*

by STEPHEN R. KIMBLETON

University of Michigan
Ann Arbor, Michigan

INTRODUCTION

Computer systems are expensive in terms of development, acquisition and maintenance. The efficient and effective system appears to be the exception rather than the rule. Concern for system improvement is voiced by almost every computer-related management or technical support group. The types and amounts of data which can be gathered through hardware and software monitors appear to be ever increasing. A bewildering array of papers and proceedings are published every year and the problems of analyzing computer systems are described with loving detail.

In spite of the effort implicit in the activities described above, the author has rarely visited an installation at which the systems analysts were reasonably familiar with literature available in the technical journals on modeling computer systems. The most common approach to system improvement appears to be one of incremental enhancement coupled with a 'cut and try' approach. The absence of a basic underlying approach for a problem of such significance is difficult to believe.

MODELING SYSTEMS

In order to study large-scale complex systems efficiently, one normally proceeds via the development of suitable models. Effective tools for modeling have been developed by generations of operations research analysts. Unfortunately, mere knowledge of modeling tools does not guarantee the production of a good model of a system. Something akin to an O.R. viewpoint is also required. This viewpoint is normally opposed to that which seems reasonable to programmers and computing center managers by virtue of their training and natural inclinations. Consequently, a communication barrier is created between the O.R. analyst and those engaged in making decisions regarding the selection, evaluation and enhancement of computer systems.

This communication gap has two primary sources, the first being the difference in viewpoint. Most managers of computing centers have a reasonably thorough knowledge of the problems inherent in writing programs for currently existing large-scale computer systems. In particular, they are well aware that a meticulous concern for detail is necessary for the successful production of programs within acceptable time limits. Consequently, the forest of computing is viewed as a collection of individually interesting trees. This viewpoint produces a natural propensity toward simulation models of computer systems whose basic level of detail is in the sub-millisecond range.

A careful analysis of well-regarded models for other large-scale systems[1] demonstrates that the major prerequisite for successful modeling of complex systems is the identification of a reasonably small number of key variables. A corollary of this identification process is the omission of as many other variables as possible. Once the identification of the key variables driving the system has been performed, the basic methodologies of operations research, e.g., mathematical programming, queueing analysis, scheduling theory, etc., can be invoked. Clearly, the resulting model will appear incomplete to the casual observer knowledgable in the process being modeled. However, the acid test of the model is neither its complexity nor its apparent completeness; rather, it is the capability of the model for providing information of use by a decision-maker.

The resolution of the difference in viewpoints between the computing center manager and the O.R. analyst can only be achieved through construction by the latter of models which provide information of use to the former. This requires that the model relate the input variables to the performance of the system as a whole.

* This research was partially supported by the Office of Naval Research, Information Systems Program under Contract N000-14-67-0181-A-0036 (NR 049-311).

Unfortunately, most of the models existing in the literature are for components of a computer system. In particular, a large number of models exist for: (i) CPU scheduling algorithms,[2,3,4] (ii) memory management models[5,7,6] (iii) I/O models[8,9,10] and (iv) miscellaneous models of use in studying storage contention[11] the effects of buffering,[12] etc. A few attempts at building models which provide information on throughput have been made. In particular, the papers by Gaver[13] and Hanssmann, Kistler and Schultz[14] are noteworthy.

Before attempting to develop a model, it is natural to seek guidelines for the properties which it should possess if it is intended to be of use to a computing center manager. The tradeoff between the effort involved in building the model and the information obtained from it must be carefully considered. Consequently, an absolute formulation of guidelines cannot be made. However, extensive studies have been made of the categories of information required by a decision-maker in order to apply the formal techniques of decision analysis. In particular one must have:[15]

(1) a list of variables to be considered is making a decision, viz., the input variables and the output variables,
(2) a model showing the interaction between the input variables and the output variables,
(3) a list of constraints which the chosen solution must satisfy,
(4) a means for evaluating various alternative combinations of input and output variables.

As an example, the performance of a computer system is often measured in terms of:[16] (a) throughput, (b) turnaround time and (c) availability. Throughput is normally measured in jobs processed per week or month, availability is measured in terms of idle time per shift, and turnaround time is measured in terms of elapsed time from submission of a job until its output is available, Thus, it might be determined that a given system should possess the capability for processing 4000 jobs/month, with an average turnaround time of one hour and an availability of one hour/shift. In considering systems which meet this requirement, it is also desirable that some attention be given to the stability of various solutions. That is, given two systems which meet the requirements, one would normally choose the less expensive of the two. However, if a large increase in potential performance can be obtained at only a modest increase in cost, the more expensive system could be chosen.

Clearly, a model which effectively incorporates all of these factors constitutes a difficult objective. However, as a first cut at building a model of interest to a computing center manager, one might seek to relate the attributes of the programs which are to be run on the system (measured in some suitable manner) to the performance of the system as a whole (measured in terms of the three primary variables). In the following such an approach is described for a somewhat restricted class of programs.

THE SYSTEM PROCESS MODEL

A model for describing the performance of a computer system (hardware plus operating system) must possess the following two capabilities: (i) the activity of a process must be characterized in terms of some basic collection of descriptors, and (ii) the interaction of the collection of processes in the system must be characterized.

In modeling the activity of a process in a computer system, we observe with Denning[17] that at any given instant in time a job or process is in one of three states:

(i) active, i.e., currently being serviced by the CPU,
(ii) blocked, i.e., halted pending completion of some event and incapable of being serviced by the CPU,
(iii) ready, i.e., awaiting the CPU.

The lifetime of a job consists of an alternating sequence of active, blocked and ready intervals, which may have length zero. The utility of this observation does not appear to have been previously noted. Perhaps, this is because of observed variations in the lengths of these intervals, the relative times at which they occur and their number. That is, the activity of a process is not deterministically reproducible when its evolution is viewed as an alternating sequence of such intervals. Fortunately, the activity of the process is statistically reproducible.

The interactions of the collection of concurrently executing processes are assumed to behave in the following manner:

(i) all jobs are statistically identical,
(ii) all processes cycle through the active, blocked and ready states in the same order, i.e., processes do not pass each other, and an exit from the active state results in an entrance into the blocked state,
(iii) the amount of time spent in any given state is exponentially distributed.

Although these assumptions are a simplification of the manner in which a computer system operates, some available evidence[19] seems to indicate that estimates for the performance of a real system which can be obtained through the use of this model are reasonable. In the following, we shall refer to this model of the activity of a computer system as the System Process Model (SPM).

The preceding assumptions are made in order to obtain an analytically tractable model. Results similar to those described later in the paper can be obtained for non-statistically identical processes. However, statement of the results becomes significantly more complex. The assumption that processes do not pass each other is clearly not satisfied by the operation of a real system. However, the effects of passing appear to be local in nature and, consequently, this assumption does not appear to be unduly restrictive. The exponential assumptions for the time spent in the active, blocked and ready states are only tenuously satisfied by some available data.[19] Thus, this assumption does not appear to be unduly restrictive on the range of applicability of this approach.

For the SPM, mathematical expressions for the CPU utilization, the average number of active intervals, the average length of a ready interval and the average system residence time of a process can be derived. In obtaining these results, the average length of an active interval, the average length of a blocked interval and the total amount of CPU time are assumed to be known. The results obtained can then be used as estimators for the corresponding quantities of a real system. In order to clearly distinguish between quantities which are obtained for the SPM and those which are assumed to be obtained through the use of monitors from a real system, we adopt the following notation:

(a) $\hat{U}(K)$ denotes the SPM estimate for $U(K)$, the CPU utilization given K concurrently executing jobs in the system,

(b) $\hat{N}$ denotes the SPM predictor for $\bar{N}$, the average number of active intervals,

(c) $\hat{R}(K)$ denotes the SPM estimate for $\bar{R}$, the average ready interval,

(d) $\hat{S}(K)$ denotes the SPM estimate for $\bar{S}$, the average system residence time of a job, i.e., the elapsed time from initiation of the first active interval until termination of the last active interval.

The following theorem has been obtained elsewhere.[18,19]

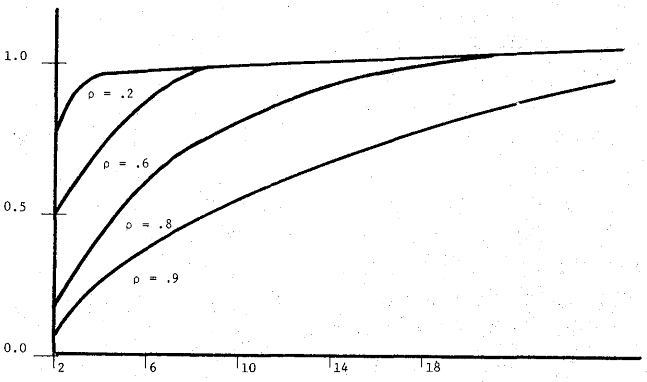

Figure 1—CPO utilization estimate

Theorem:

Let A_Σ denote the total amount of CPU time required by a given process. Let $\bar{A}$ and $\bar{B}$ denote the average length of the active and blocked intervals of the process. For the System Process Model with K concurrently execution processes:

(i) $\hat{N} = A_\Sigma/\bar{A}$,

(ii) $\hat{U}(K) \geq 1 - \rho^{K-1}$

(iii) $\hat{R}(K) = (K - E[I(K)])\, \bar{A}\, \hat{U}(K)$,

(iv) $\hat{S}(K) = \hat{N}(\bar{A} + \bar{B} + \hat{R}(K))$.

where $\rho = \bar{B}/(\bar{A}+\bar{B})$ and $I(K)$ denotes the number of active intervals which can be initiated during a blocked interval.

The behavior of $\hat{U}(K)$ is described in Figure 1. We note that the effect of increasing the number of concurrently executing processes in the system is to increase $\hat{R}(K)$ in a nearly linear manner, provided the CPU utilization is near one. We further observe that since A_Σ represents the total amount of CPU time required by a job, variations in A_Σ with different injections of the same job will reflect the effects of system overhead and should be nearly negligible.

Throughput is a subject of much interest at most computer installations. Unfortunately, since it is normally computed in terms of jobs per day, week or month, it is difficult to examine the impact of a single job on the throughput at an installation. However, throughput is simply the rate at which jobs are processed. An expression for this quantity can be obtained through the use of our model. Indeed, by using well-known arguments from renewal theory,[20] it follows that the rate at which one job is completed is $1/\hat{S}$. Since there are K distinct jobs in the system, the rate at which these jobs are completed is $K/\bar{S}$. Thus, under the assumptions of our model, the throughput is $K/\bar{S}$. It should be observed that this expression is consistent with the definition of throughput. Over a time interval of length S, precisely $K/\bar{S} \times \bar{S} = K$ jobs will have been completed.

It is appropriate to inquire as to the stability of decisions achieved through reasoning in the preceding manner. Fortunately, the available evidence seems to indicate that process behavior is statistically reproducible, provided the system is large enough so that no single job dominates it. Indeed, measurements made on the University of Michigan's MTS Computer System (a twin-processor 360/67 with three 2301 paging drums, three eight-drive 2314 disks, two data cells, 100 terminals, plus assorted other peripheral devices) through the use of the embedded software monitor[21] have shown that the probability distributions obtained for the lengths of the active, blocked and ready intervals vary in a very predictable manner as a function of the CPU load. (The MTS System is a processor bound system; hence it is reasonable that the CPU load should be the controlling influence on the variation in the distributions of the lengths of these intervals.) Similar arguments would appear to hold for other systems in which there exists a well-defined limiting resource other than the CPU.[19] If there is no limiting resource, the system is lightly loaded and the estimates described here may not be valid since processes can 'chase' each other.

EXTENSIONS AND APPLICATIONS

The preceding results are of use in studying the effects of different job mixes for a computer system in which the hardware and operating system are assumed fixed. If one wishes to study the effects of varying either the number, type or arrangement of I/O devices, it is useful to have a means of estimating $\bar{B}$. In addition, if one wishes to study the effect of changes in the CPU and/or operating system, it would also be desirable to have a method for estimating $\bar{A}$. Some considerations relevant to obtaining such estimators will now be described.

Estimation of $\bar{A}$

Both the 'power' of the CPU and the impact of the operating system are reflected in $\bar{A}$. Consequently, of the four basic approaches to gathering information about a computer system, i.e., (a) benchmarks, (b) hardware and software monitors, (c) simulation models and (d) analytic models, the use of analytic models would seem least likely to succeed. This stems from the difficulty of treating dependent relationships with analytic models. Attempting to predict $\bar{A}$ as a function of the hardware and operating system characteristics through the use of a simulation model could probably be done. However, a rather fine level of detail might have to be incorporated in order to achieve a reasonable estimator. Since one is normally interested in making a large number of comparisons, this might render the cost of a simulation approach prohibitive. It should be noted, however, that it would be of independent interest to study the minimal amount of detail which must be incorporated in a simulation model in order to yield consistent estimators for $\bar{A}$. Such a study might provide some information on the level of detail which should be incorporated in a simulation model of a computer system—a subject on which little appears to be known.

Perhaps the most suitable approach to this problem would be through the use of hardware or software monitors applied to suitably chosen benchmarks. Unfortunately, the difficulties encountered in identifying the process responsible for a particular event being measured with a hardware monitor appears to make their use somewhat difficult. A software monitor capable of tracing the activities of an individual process such as the event driven software monitor embedded in the MTS System[21] would appear to be ideal. However, most of the commercially available software monitors operate on a sampling basis which necessitates a certain amount of guesstimating in determining $\bar{A}$, although these monitors are useful for determining fractional CPU utilization.

Estimation of $\bar{B}$

Estimating $\bar{B}$ appears to be rather simpler than estimating $\bar{A}$. Data described elsewhere[19] indicate that variations in the length of $\bar{B}$ are rather small (at least for a system in which the CPU is the limiting resource) over a fairly large CPU load range. A simulation[22] of a single channel eight drive IBM 2314 indicates that the distribution of arriving requests by module is the most significant single factor in achieving a satisfactory channel utilization. In particular, given a suitable distribution of requests by module, the delay time of a request appears to be rather insensitive to the particular disk scheduling policy being used, e.g., FCFS (first come first served), SCAN,[10] or SSTF.[23]

This result would seem to indicate that in estimating $\bar{B}$ as a function of the collection of I/O devices in the system, the level of detail which must be incorporated is not excessive. In particular, in addition to knowledge of the hardware characteristics of the devices, the most important variables appear to be: (a) arrival rate by device, (b) distribution of arrival requests by cylinder for disks, (c) device-channel arrangement and (d) degree of buffering. Given this information one may write:

$$\bar{B} = \sum p_i \bar{B}_i.$$

In this expression p_i is the fraction of blocked intervals which occur for a device of type i, $\bar{B}_i$ denotes the average length of a blocked interval for such a device and the sum is computed over all I/O devices in the system. Estimation of $\bar{B}_i$ is straightforward for dedicated peripherals if the distribution of arrivals to the device and the amount of information to be transmitted in each request is known. For drums and disks, comments made earlier would seem to indicate that rather simple simulation models can be employed. Alternatively, somewhat less accurate estimates could be obtained through the use of analytic models described in the literature.

Block times less than those indicated through the use of these models are indicative of either a good arrangement of data sets on devices or an effective use of buffers. Indeed, the appropriate depth of buffering might be examined by observing the extent to which modifications in this depth affect the observed blocked interval. An observed value of the average blocked interval greater than that indicated by the device models may indicate poor data set organization for a given job, contention between jobs for data sets stored on the same device, channel contention, etc. Although this approach does not pinpoint the exact source of delay, it can be used as an indicator for the presence of potential problems. Further, comparison of the values observed with those predicted by the models provide insight into the size of the anticipated reward which might be achieved through further investigation.

SUMMARY

We have obtained a model which yields estimates for turnaround time, CPU availability and throughput rate for a collection of statistically identical processes characterized in terms of the total amount of CPU time required and the average lengths of the active and blocked intervals. Consequently, the effects of varying the number of users in the system upon the three primary measures of system performance can be investigated. In turn, this allows one to apply the techniques of formal decision analysis to the selection, evaluation and comparison of computer systems. Such an application requires an expression of the means to be used in judging various alternatives and the decision to be made.

Protection—Principles and practice*

by G. SCOTT GRAHAM and PETER J. DENNING

Princeton University
Princeton, New Jersey

INTRODUCTION

The protection mechanisms of computer systems control the access to objects, especially information objects. The range of responsibilities of these mechanisms includes at one extreme completely isolating executing programs from each other, and at the other extreme permitting complete cooperation and shared access among executing programs. Within this range one can identify at least seven levels at which protection mechanisms can be conceived as being required, each level being more difficult than its predecessor to implement:

1. No sharing at all (complete isolation).
2. Sharing copies of programs or data files.
3. Sharing originals of programs or data files.
4. Sharing programming systems or subsystems.
5. Permitting the cooperation of mutually suspicious subsystems—e.g., as with debugging or proprietary subsystems.
6. Providing "memoryless" subsystems—i.e., systems which, having performed their tasks, are guaranteed to have kept no secret record of the task performed (an income-tax computing service, for example, must be allowed to keep billing information on its use by customers but not to store information secretly on customers' incomes).
7. Providing "certified" subsystems—i.e., those whose correctness has been completely validated and is guaranteed *a priori*.

We shall consider here the protection mechanisms required for level 5, but not those required for levels 6 or 7. We do this because we are interested in specifying the structure of protection mechanisms that work irrespective of considerations of internal program structure; levels 6 and 7 in general require control over internal program structure. Moreover, little is known about the mechanisms for levels 6 and 7, whereas much is known about the mechanisms for levels 1 to 5.

Much has been written about the legal and social implications of protection and privacy (see, for example Reference 10). We deal exclusively with the technical aspects of protection—i.e., the procedures governing the access of executing programs (processes) to various resources in the system. This is because little has been written about the technical side of the problem. It is also because the technical approach, when balanced with the legal approach, is useful in clarifying the inadequacies of both approaches and in understanding how they can complement one another. For example, without a technically sound protection system, a user might find it possible to perform malicious acts undetected, rendering certain laws unenforceable. Even with a sound protection system, however, certain aspects of protection can be dealt with only by laws, e.g., the problem of false identification.

The first step in the design of a protection system is the specification of the main parties and their interactions. That is, the entities to be protected and the entities to be protected against are identified, and rules by which the latter may access the former are formulated. For this, common sense and examples of existing protection systems can be used to guide our thinking in the development of the elements and principles of a protection system. We formalize these principles as a model (theory) of protection, based on one developed by Lampson.*[16] Perhaps the most important aspect of

* Work reported herein was supported in part by NASA Grant NGR-31-001-170 and by National Research Council of Canada Grant A7146.

* Approximately half our development here is an exposition and reformulation of the elements of Lampson's model. The remainder extends Lampson's in several important ways. We have investigated the problems of establishing the correctness of a protection system, of creating and deleting objects, of implementing cooperation among mutually suspicious subsystems, and of identifying the existence or absence of the elements of the model in contemporary systems.

the model is the notion that each process has a unique identification number which is attached by the system to each access attempted by the process. As will be seen, this will make it impossible for a process to disguise its identity and will allow us to establish the correctness of the model with respect to implementing protection at level 5.

The implications of the protection model with respect to operating system structure and hardware architecture will be considered. Although the model is abstracted from examples of existing systems, we shall see that few current commercial systems meet the requirements of a complete (secure) protection system. We shall identify a few existing systems which do meet the completeness requirement of our model.

A THEORY OF PROTECTION

In current systems, protection takes many forms. The IBM System/360 uses a "key-lock" approach to memory protection.[12] A "ring" protection mechanism is used in Multics.[9,18] The Hitac 5020 Time-Sharing System uses a key-lock-ring mechanism.[17] There are many other examples. As Lampson has pointed out, the myriad of implementations forces us, as observers, to take an abstract approach to the subject of protection;[16] otherwise, we might never make sense out of the seemingly endless variety of solutions to protection problems.

Elements of the model

A protection system comprises three parts, which will be reflected as components of our model. The first component is a set of *objects*, an object being an entity to which access must be controlled. Examples of objects are pages of main memory, files, programs, auxiliary memory devices, and instructions. Associated with each object X is a unique *identification number* which is assinged to the object when it is created in the operating system. Identification numbers might, for example, be derived from a clock which measures time in microseconds since the system was first built; the time-of-day clock on the IBM System/370, being a 52-bit counter, could allow a new object name every microsecond for approximately 143 years.[13] We shall use the symbol X interchangeably for an object's name and number.

The second component of the protection model is a set of *subjects*, a subject being an active entity whose access to objects must be controlled. A subject may be regarded as a pair (process, domain), in which a process is a program in execution and a domain is the protection environment (context) in which the process is operating. Examples of domains include supervisor/problem-program states in IBM System/360,[12] the 15 user environments in IBM's OS/360-MVT,[11] or the file directories and rings in Multics.[1] Other terms which have been used to denote the idea of domain are "sphere of protection" [4] and "ring." [9,18] Since subjects must be protected, they too are objects, and each has a unique identification number.

The third component of a protection system is the rules which govern the accessing of objects by subjects. We shall describe a particular choice of rules shortly. These rules are the heart of the protection system. The rules must be simple, allowing users to gain an immediate understanding of their scope and use. They must be complete, not allowing a subject to gain unauthorized access to an object. They must be flexible, providing mechanisms which easily allow the desired degree of authorized sharing of objects among subjects.

An important property of our model is: each and every attempted access by a subject to an object is validated. This is necessary in order to permit cooperation among mutually suspicious subjects, for it cannot otherwise be guaranteed that a previously well-behaved subject which suddenly turned malicious or went awry will be denied access when authorization is lacking.

The choice of the subjects, objects, and rules of a protection system is at the discretion of the system designer and will be made to meet the protection and sharing requirements of the given system. We return later to the problems of choosing subjects and objects.

It is convenient to regard all the information specifying the types of access subjects have to objects as constituting a "protection state" of the system. There are three distinct problems to be solved: representing the protection state, causing subjects to access objects only as permitted by the protection state, and allowing

		OBJECTS						
		subjects			files		devices	
		S_1	S_2	S_3	F_1	F_2	D_1	D_2
SUBJECTS	S_1		block wakeup		read write		seek	
	S_2			stop		update		seek
	S_3				delete	execute		

Figure 1—Portion of an access matrix

subjects to alter the protection state in certain ways. With respect to the first, we may represent the protection state of the system as an *access matrix* A, with subjects identifying the rows and objects the columns (see Figure 1). The entry $A[S, X]$ contains strings, called *access attributes*, specifying the access privileges held by subject S to object X. If string α appears in $A[S, X]$, we say "S has α access to X." For example, in Figure 1, subject S_1 may read file F_1, since 'read' appears in $A[S_1, F_1]$; or, S_2 may stop S_3. Figure 2 shows that an alternative representation of the protection state is a directed graph, which is in one-to-one correspondence with the access matrix.

Associated with each type of object is a *monitor*, through which all access to objects of that type must pass to be validated. Examples of monitors are the file system for files, the hardware for instruction execution and memory addressing, and the protection system for subjects. An access proceeds as follows:

1. S initiates access to X in manner α.
2. The computer system supplies the triple (S, α, X) to the monitor of X.
3. The monitor of X interrogates the access matrix to determine if α is in $A[S, X]$; if it is, access is permitted, otherwise, it is denied and a protection violation occurs.

Note that access attributes are interpreted by object monitors at the times accesses are attempted. Figure 3 shows the organization of the protection system. The mechanisms between the dashed lines of that diagram are invisible to subjects—subjects direct their references to objects, these references being intercepted and validated by the monitors of the protection system.

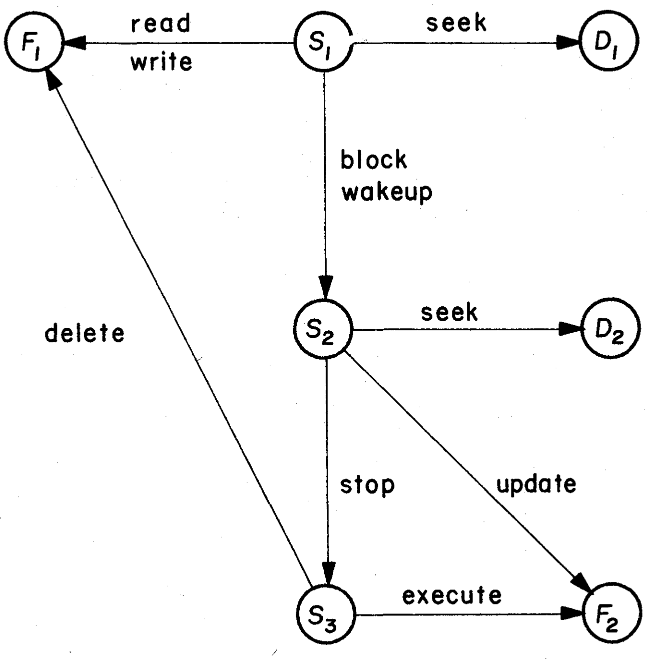

Figure 2—Access diagram

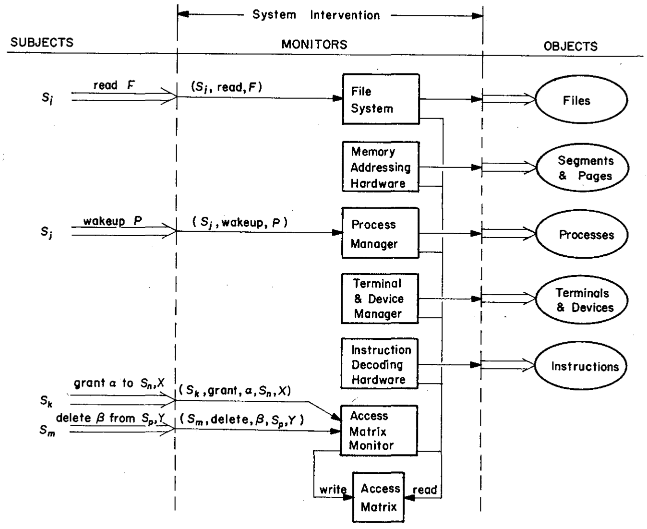

Figure 3—Organization of protection system

It is important to note that the identification number of a subject is system-provided in rule 2 above, and cannot be forged by S. That is, even if every subject knows the identification number of every other subject, there is no way for S to alter the fact that its identification number is presented to the monitor in rule 2; hence the monitor cannot be "tricked" into interrogating the wrong entry of A. Since no subject may access A, it is on this basis that we can develop proofs concerning the correctness of the protection system. The correctness of the protection system can be reduced to the correctness of the monitors.

The foregoing rules govern the use, by monitors, of the access matrix, once it has been specified. We require rules for changing the access matrix itself. These rules will be enforced by the monitor of the access matrix. Unlike the monitors of system objects, the access matrix monitor may modify the access matrix. In particular, it may transfer, grant, or delete access attributes on command of subjects and only on appropriate authorization. For this purpose, we introduce the access attributes 'owner' and 'control,' and the notion of a *copy flag* (denoted by asterisk), and the rules R1-R3 of Table I to be implemented by the access matrix monitor.

TABLE I—Protection System Commands

Rule	Command (by S_o)	Authorization	Operation
R1	**transfer** $\begin{Bmatrix}\alpha^*\\ \alpha\end{Bmatrix}$ **to** S, X	'α*' in $A[S_o, X]$	store $\begin{Bmatrix}\alpha^*\\ \alpha\end{Bmatrix}$ in $A[S, X]$
R2	**grant** $\begin{Bmatrix}\alpha^*\\ \alpha\end{Bmatrix}$ **to** S, X	'owner' in $A[S_o, X]$	store $\begin{Bmatrix}\alpha^*\\ \alpha\end{Bmatrix}$ in $A[S, X]$
R3	**delete** α **from** S, X	'control' in $A[S_o, S]$ or 'owner' in $A[S_o, X]$	delete α from $A[S, X]$
R4	ω:= **read** S, X	'control' in $A[S_o, S]$ or 'owner' in $A[S_o, X]$	copy $A[S, X]$ into ω
R5	**create object** X	none	add column for X to A; store 'owner' in $A[S_o, X]$
R6	**destroy object** X	'owner' in $A[S_o, X]$	delete column for X from A
R7	**create subject** S	none	add row for S to A; execute **create object** S; store 'control' in $A[S, S]$
R8	**destroy subject** S	'owner' in $A[S_o, S]$	delete row for S from A; execute **destroy object** S

Rule 1 permits a subject to transfer any access attribute it holds for an object to any other subject, provided the copy flag of the attribute is set, and it may specify whether the copy flag of the transferred attribute is to be set; in Figure 4, for example, S_1 may place 'read*' in $A[S_2, F_1]$ or 'write' in $A[S_3, F_1]$, but it may not transfer its ability to block S_2 to any other subject. The purpose of the copy flag is preventing an untrustworthy subject from wantonly giving away access to objects. Rule R2 permits a subject to grant to any subject access attributes for an object it owns; in Figure 4, for example, S_1 can grant any type of access for S_2 to any subject, or any type of access to device D_2 to any subject. Rule R3 permits a subject to delete any access attribute (or copy flag) from the column of an object it owns, or the row of a subject it controls; in Figure 4, for example, S_1 can delete any entry from columns S_2 or S_3, or from row S_3. In order to facilitate these rules, we require that 'control' be in $A[S, S]$ for every subject S and we include rule R4, which permits a subject to read that portion of the access matrix which it owns or controls. Rules R5-R8, which govern the creation and deletion of subjects and objects, will be discussed shortly.

It should be noted that a subject may hold 'owner' access to any object, but 'control' access only to subjects. For reasons to be discussed shortly, we shall assume each subject is owned or controlled by at most one other subject, though other multiply-owned non-subject objects are allowable. If a subject has 'owner' access to another subject, the former can grant itself 'control' access to the latter, so that 'control' is implied by 'owner.' It is undesirable for a subject to be 'owner' of itself, for then (by Rule R3) it can delete other subjects' access to itself.

The rules R1-R4 and access attributes shown in Figures 1 and 4 should be interpreted as examples of rules which can be provided for the purposes intended. One might, for example, introduce a "transfer-only"

	S_1	S_2	S_3	F_1	F_2	D_1	D_2
S_1	control	owner block wakeup	owner control	read* write*		seek	owner
S_2		control	stop	owner	update	owner	seek*
S_3			control	delete	owner execute		

Figure 4—Extended access matrix

mode by postulating a "transfer-only copy flag"; if this flag is denoted by the symbol •, then in R1 the command to transfer α (or α•) from S_0 to S for object X would be authorized if α• were in $A[S_0, X]$ and would cause α • to be deleted from $A[S_0, X]$ and α (or α•) be placed in $A[S, X]$. This is useful if one wants to limit the number of outstanding access attributes to a given object—e.g., if it is required that each subject be owned by at most one other subject, or that a given object be accessible to a limited number of subjects. One can also define "limited-use" access attributes, of the form (α, k); access in manner α is permitted only if $k>0$, and each use of this attribute decreases k by one.

Creation and deletion of subjects and objects

The creation of a non-subject object, e.g., a file, is straightforward, consisting of adding a new column to the access matrix. The creator subject executes a command (rule R5 of Table I) and is given 'owner' access to the newly created object; it then may grant access attributes to other subjects for the object according to rule R2. The destruction of an object, permitted only to its owner, corresponds to deleting the column from the access matrix (rule R6).

Creating a subject consists of creating a row and column for the new subject in the access matrix, giving the creator 'owner' access to the new subject, and giving the new subject 'control' access to itself (rule R7). The destruction of a subject, permitted only to its 'owner,' corresponds to deleting both the row and the column from the access matrix (rule R8).

According to our definition of subject as a pair (process, domain), there are two ways a subject can come into existence: a given process switches from one domain to another, or a new process is created in some domain. (Similarly, there are two ways a subject can go out of existence.) With respect to the former problem, a process must have authorization to switch domains since domain-switching entails a gain or loss of access attributes. Specifically, if process P wishes to switch from domain D_1 to domain D_2, subjects $S_1=(P, D_1)$ and $S_2=(P, D_2)$ would exist in the system; the switch by P from D_1 to D_2 is permitted only if authorization (e.g., access attribute 'switch') is in $A[S_1, S_2]$. In practice, it would be more efficient to regard a subject as being dormant (rather than nonexistent) when its process is operating in another domain—i.e., if P switches from D_1 to D_2, subject (P, D_1) becomes dormant and subject (P, D_2) becomes active, but the switch neither creates a new subject nor destroys an old one. (The idea is very much like that of transferring control between coroutines.) In practice, therefore, rules R7 and R8 would be invoked only when a process is created or destroyed.

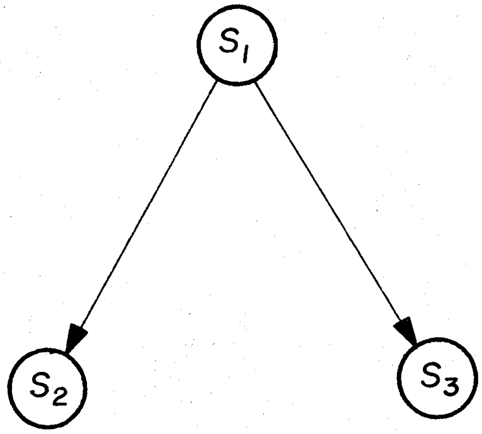

Figure 5—Ownership diagram

We suppose that the system enforces the requirement that each subject be owned by at most one other subject—i.e., an owner may not grant 'owner,' and 'owner' is either untransferable or is transfer-only. In this case the relation 'owner' defines naturally a tree hierarchy of subjects. Figure 5 shows the subject tree for the access matrix of Figure 4. If S_1 is 'owner' of S_2, S_2 is *subordinate* to S_1. By rule R1, a subject can transfer only a subset of its access attributes to a subordinate; by rule R2, it can grant any access for a subordinate to any other subject; by rule R3, it can delete any access attribute from a subordinate; and by rule R4, it can discover what access attributes a subordinate has. We have carefully avoided including any provision for a subject to acquire for itself (copy) an access attribute it does not have but which a subordinate has obtained. This can be incorporated, if desired, as an extension to the model.

It is not overly restrictive to require that subjects be members of a hierarchy, the utility of hierarchies having been demonstrated adequately in practice. This mechanism can be used to ensure that a subordinate, upon creation, has no more privileges than its creator. It can be used to define a protocol for reporting protection violations (and indeed any other fault condition), for the violation can be reported to the immediate superior of the subject generating it. It can be used as an aid in resource allocation and accounting, for a subordinate can be granted only a subset of the resources held by its creator. Considerations such as these motivated the design of the RC4000 system.[2] Our subject

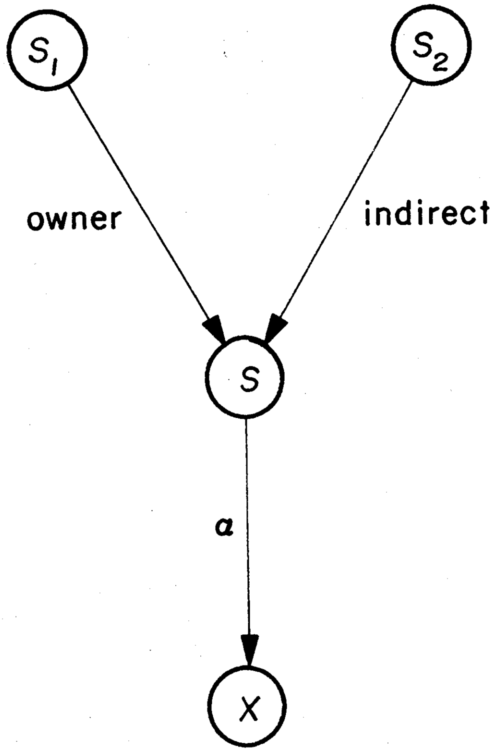

Figure 6—Sharing an untrustworthy subsystem

hierarchy is in fact the same as the sphere-of-protection hierarchy proposed by Dennis and Van Horn,[4] or the domain hierarchy used by Lampson.[15] If one regards a process operating in the context of a file directory as a subject, then the directory hierarchy of Multics defines another example of a subject hierarchy.[1] As will be seen, the rings of Multics also define a subject hierarchy.[9,18]

A subject in a hierarchy without an owner is called a *universal subject.* For convenience, we assume there is only one universal subject, and it has every possible access attribute to every object. When a user wishes to sign on the system, he communicates with the universal subject. Having convinced itself of the user's identity, the universal subject will create a subordinate subject for the user, and will initialize the row of the access matrix corresponding to that subject with attributes derived from some data file private to the universal subject.

Sharing untrustworthy subsystems

It is clear from the above that, if subject S_1 wishes to share an object X with subject S_2, it may do so without risk of S_2 acquiring access to any other of its objects. But if X is a subject, we must ensure that S_2 is allowed access to objects X can access and that X, if an active entity, cannot access objects of S_2 without authorization.

Suppose subject S_1 owns a subsystem S which it wishes to share with subject S_2. However, S_2 does not trust S, and S_1 may wish to revoke S_2's access to S at any time. We introduce the access attribute 'indirect' for use among subjects: if one subject has 'indirect' access to another, the former may access objects in the same manner as the latter, and it may read but not acquire for itself access attributes of the latter; the subject which owns the latter may (rule R3) revoke the former's 'indirect' access at any time. The sharing of S among S_1 and S_2 according to this idea is illustrated in Figure 6. The rules of operation of object monitors must be modified slightly to allow for indirect access:

1. S_2 initiates indirect access to X through S in manner α;
2. The system supplies (S_2, α, S-X) to the monitor of X;
3. The monitor of X interrogates the access matrix to determine if 'indirect' is in $A[S_2, S]$ and α is in $A[S, X]$; if so access is permitted, otherwise it is denied and a protection violation occurs.

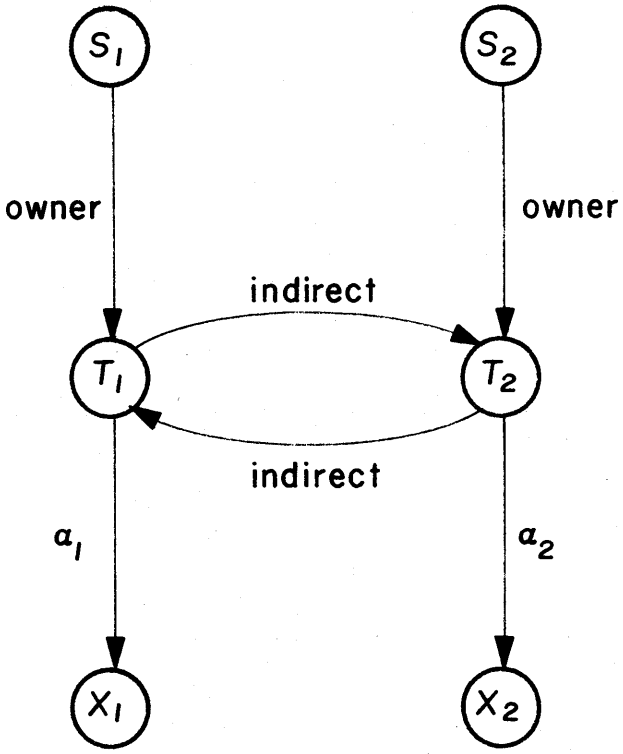

Figure 7—Cooperation between mutually suspicious subsystems

An example of the type of sharing in Figure 6 is the "debugging problem," in which S_1 wishes S_2 to debug S. Here S_2 needs complete access to all objects accessible to S, but S must be denied access to S_2 or its other objects. Another example of the same type of sharing is the "grading program" problem, where S_1 corresponds to a student who is submitting a program S to an instructor-program S_2 for grading.

A more complicated example involves mutually suspicious subsystems. Suppose S_1 and S_2 own respectively subsystems T_1 and T_2; T_1 and T_2 are to cooperate, but neither trusts the other. For example, T_1 might be a proprietary subroutine which S_1 wants executed, but not read, by others; and T_2 might be a data management system which accesses certain files owned by S_2. Figure 7 shows how the cooperation can be arranged. Observe that T_1 may access only the objects of S_2 (such as X_2) which are accessible to T_2, but no others, and that S_2 may revoke T_1's access to T_2 at any time. (The converse is true for T_2 and S_1.) Observe that T_1 can only use, but not acquire for itself, access attributes of T_2.

We have now developed the necessary basis for a protection theory, allowing us to view the protection state of a system as being defined dynamically by its access matrix. We have shown how this model allows for protection at the fifth level discussed in the introduction. The utility of the abstractions, both in understanding current protection systems and in formulating future "ideal" protection systems will be discussed shortly, after we have considered the notion of correctness of a protection system.

CORRECTNESS, SHARING, AND TRUST

To prove that a protection model, or an implementation of it, is correct, one must show that a subject can never access an object except in an authorized manner. Two things must be proved: any action by a subject which does not change the protection state cannot be an unauthorized access; and any action by a subject which does change the protection state cannot lead to a new protection state in which some subject has unauthorized access to some object.

With respect to the first, given the correctness of each monitor, it follows that the attachment by the system of the identification number of a calling subject to each reference makes it impossible for a subject to gain unauthorized access to an object. The most important requirement in the argument is thus the assumption that the system attaches a nonforgeable identification number to each attempted access. It is necessary to prove that the operating system attaches the identification number correctly, the monitors interrogate the correct entry in the access matrix, and no monitor (except the access matrix monitor) alters the contents of the access matrix.

With respect to the second, it is clear that each application of rules R1-R8 produces a new protection state in the manner specified, assuming the correctness of the access matrix monitor. There are, however, various aspects of trust implicit in rules R1-R8. Specifically, if the owner of a given object is not careful, it is possible for untrustworthy subjects, acting singly or in collusion, to grant some subject access to that object, access not intended by the object's owner. Since the model cannot deal satisfactorily with problems relating to trust, this will demonstrate the need for external regulations or laws to complement the technical solution implemented by the model. We shall explore this point in the paragraphs following.

Consider the transferring and granting rules (R1 and R2). Suppose subject S_1 has created an object X and granted various types of access for X to subjects $S_2, \ldots, S_n$. Suppose further that S_1 intends that, under no circumstances, should S_0 gain access to X. He can do this by avoiding granting any access attributes to S_0, but he must also grant attributes with the copy flags off to any subject among $S_2, \ldots, S_n$ who he feels might violate trust and grant access for X to S_0 indirectly. In other words, an understanding must exist between S_1 and subjects receiving access to X that S_0 is not to receive, either directly or indirectly, any access to X. Only when these considerations are understood and the requisite trust is present should S_1 be willing to pass a copyable attribute. With this, rules R1 and R2 are correct.

On the basis of the foregoing argument, we conclude that the protection system is correct and will operate exactly as intended among *trustworthy* subjects. Untrustworthy subjects cannot be dealt with completely by mechanisms of the protection system. External regulation, together with a system for detecting and reporting violations, is required.

Consider the subject creation rule (R7). The correctness of the environment of the created subject is founded on the assumption that the creator's environment is correct, since a subordinate subject cannot be initialized with any access attribute not held by its creator. Thus the correctness of any subject's environment derives ultimately from the universal subject's having created a correct environment for a user when he signs on the system. Here is where the problem of false identification enters. An arbitrarily complicated question-and-answer procedure can be developed to

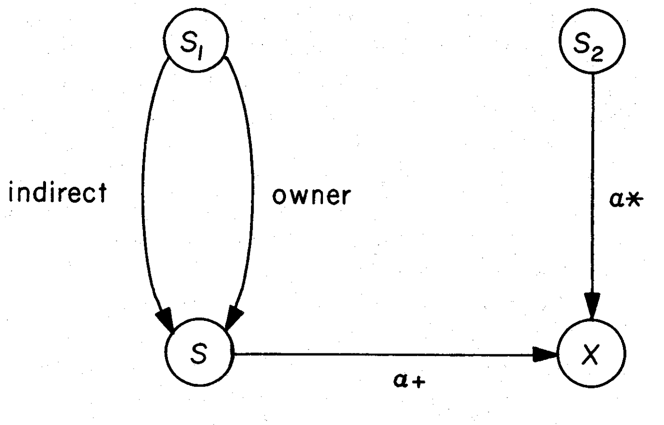

Figure 8—Preventing unwanted indirect access

establish the identity of a user to within any reasonable doubt, but it cannot be done absolutely. Again, a system for detecting and reporting violations of this type is required, and external regulations must deal with offenders.

As further illustration of the role of trust in the model, we consider four instances of trust's being implicit in the interpretation of access attributes themselves. First, consider the 'read' attribute. Reading is an unusually powerful operation, as it implies, for example, the ability to read and copy a file. It is then possible for one subject to distribute access attributes for the copy freely to other subjects, even to subjects who were not authorized to read the original. In this sense, the 'read' attribute is equivalent to the 'read*' attribute.

Second, consider the 'indirect' attribute, and refer to Figure 8. Subject S_2 has α^* access to X and wishes to transfer α to S. However, the owner S_1 of S may grant itself 'indirect' access to S and so gain α access to X, even though this may not have been intended by S_2. There are several ways to solve this:

(1) Define an access mode, denoted by the symbol '+,' which cannot be used in an indirect manner; thus $\alpha+$ is not only nontransferable, but it is usable only by the subject to whom it was granted.† This is shown in Figure 8.

(2) Do not allow an owner to grant itself 'indirect' access to a subordinate subject.

(3) Make α a "limited-use" attribute so that the exposure of X to the owner of S is of limited duration. It is not clear that (2) or (3) are viable solutions.

Third, consider the 'owner' attribute. A subject creating an object is given 'owner' access to that object, indicating that it may grant access attributes for that object to other subjects. It is possible in our model for the 'owner' attribute of a nonsubject object to be transferred, and thus multiple ownership may arise. Prior arrangements must exist among the owners, else contradictory actions may result—e.g., one owner grants access the others do not want granted. Such difficulties can be avoided by allowing only one owner, e.g., 'owner' is either untransferable or transfer-only but it is not clear whether this is a desirable or useful solution.

Fourth, consider rule R3, which permits the owner of an object to revoke arbitrarily any access held by any nonsubordinate subject to that object. This ability is open to question. Vanderbilt argues that no such ability is warranted as, in effect, the owner of an object and those to whom access has been granted have entered a contract[19]—i.e., the nonowners presumably have used the object in their programs and depend on its presence. Lampson, on the other hand, argues that, for the proper implementation of cooperation among mutually suspicious subsystems, absolute power of revocation is warranted.[16] The latter view is reflected in our model.

These considerations illustrate that trust is a distinctly nontechnical concept. They reemphasize an earlier point, viz., the complete solution to the protection problem must strike a balance between technical and nontechnical issues. More research is required on both issues, especially on methods of detecting and reporting violations and on coordinating external regulations with internal protection mechanisms.

Two other ways of breaching the security of protection systems exist, but do not fall in the province of the model. First is the "wire-tapping" issue. We consider this a solved problem, since coding techniques exist that render it essentially impossib!e for anyone tapping a data line to decode what he finds there. Second is the "system-error" issue. What if a system error changes the access matrix or the identification number of a subject or other object? Can a subject gain access it did not have before the error? The problem can be solved by appropriate use of coding techniques for subject and object identification numbers and for access attributes; in particular, it is possible to use error-correcting codes, and to arrange that the probability of an identification number (or access attribute) being changed to another valid identification number (or access attribute) is arbitrarily small.

† We have defined altogether four modes for access attributes: α^*, $\alpha\cdot$, α, and α^+, where α^+ is the most restricted mode of α and α^* the least.

SYSTEM IMPLICATIONS

The protection model presented above does not resemble any particular system with which the reader is familiar, although it likely contains concepts with which he is. By considering implementations of the access matrix, one can show that many protection systems are practical examples of the theory.

Storing the access matrix

Since the access matrix is likely to be sparse, it would be impractical to implement it directly as a two-dimensional matrix. A more efficient implementation could store the access matrix as a table of triples $(S, X, A[S, X])$—i.e., the nonempty entries of A. Since most subjects and objects would not be active at any given time, it would be unnecessary to store all the triples in fast memory at once. Moreover, it is often necessary in practice to be able to determine what object a given subject can access (or what subject can access a given object); a simple table of triples has too little structure to permit efficient search procedures to be implemented. Therefore, this method is unlikely to be practical, especially when the number of subjects and objects is large.

There are, however, at least three practical implementations. The first uses the idea of storing the access matrix A by rows, i.e., with each subject S is associated a list of pairs $(X, A[S, X])$, each pair being called a *capability* and the list a *capability list* (C-list).[4] A C-list represents all the objects that a subject can access, together with the authorized modes of access. Following this approach, one may regard a C-list as defining the environment (domain) of a process, a subject as a pair (process, C-list), and the operation of switching domains as switching to a new C-list.[4,16] Because the protection system allows only authorized operations on C-lists, possession of a capability by a process is *prima facie* proof that the process has access to an object.[15]

A second approach uses the idea of storing the access matrix by columns, i.e., with each object X is associated a list of pairs $(S, A[S, X])$. In Multics, such a list is called an *access control list* when the objects are segments;[1,18] in the Cambridge multiple-access system, it is called an *authority list.*[20]

A third approach represents a compromise between the C-list and the access-control list implementations. Suppose a set of subjects desires access to a certain set of objects. In the C-list of each subject will appear entries (X, K) where X is an object name and K a *key.* Associated with the set of objects is a *lock list* containing entries of the form (L, α) where L is a *lock* and α an access attribute. The monitor of the set of objects, upon detecting that S is attempting to access X in manner β, will obtain an (X, K)-pair from the C-list of X; it then will search the lock list and permit the access only if it finds an (L, α)-pair for which $K=L$ and $\alpha=\beta$ (i.e., the key fits a lock that, when opened, releases the desired access attribute). In this system, the owner of an object X can distribute α access to X simply by granting (X, K) pairs to various subjects and placing (K, α) in the lock list. He can revoke this instance of α access to X simply by deleting (K, α) from the lock list (i.e., changing the lock); in this case the outstanding (X, K) pairs will be invalidated. It is possible for an owner to create various keys and locks for the same access attribute α—e.g., he can grant (X, K_1) to some subjects and (X, K_2) to others, placing both (K_1, α) and (K_2, α) in the lock list. This resembles the system of "storage keys" used in IBM System/360[12] with one important difference—viz., there is no concept of a C-list and it is possible for certain subjects to forge storage keys.

Efficiency

The viability of the model in practice will depend on the efficiency of its implementation. With respect to this, a few observations can be made. (1) Access attributes would not be represented as strings. An entry $A[S, X]$ of the access matrix might be represented as a binary word whose ith bit is 1 if and only if the ith access attribute is present. A corresponding binary word could be used to store the copy flags. (2) According to the rules, there is nothing to prevent one subject from granting another unwanted or unusable access attributes. Although this does not alter the correctness of the model, a practical implementation may require some mechanism to limit this effect. (3) The identification number of a subject can be stored in a protected processor register where it is quickly accessible to object monitors. (4) The implementation of the rules for creating and deleting columns and rows of the access matrix must be tailored to the manner in which the matrix is stored. In the C-list implementation (storage by rows), for example, deleting a row corresponds to deleting a C-list, but deleting a column would imply a search of all C-lists. In this case, it would be simpler to invalidate the name of the object whose column is deleted and use a garbage collection scheme to remove invalid capabilities from C-lists. (5) The C-list implementation is inherently more efficient than the access control list implementation because a C-list must be stored in fast-access memory whenever a subject is active whereas an object may not be active often enough to warrant keeping its access control list in fast-access memory at all times.

It is worth a special note that the mapping tables of a virtual memory system are a highly efficient form of the C-list implementation for memory protection. A separate table is associated with each process, and each entry of such a table is of the form (X, Y, α) where X is the name of a segment or page, Y is its location in main memory, and α specifies the types of access permitted to X (typically, α is some combination of 'read,' 'write' and 'execute'). In fact, the C-list proposal by Dennis and Van Horn[4] was motivated by generalizing the idea of mapping tables to include entries for objects other than segments. The point is: the same techniques used to make virtual memory efficient can be generalized to make the C-list implementation efficient. The requisite hardware has been described by Fabry[6] and Wilkes.[20] It is interesting to note that Multics, even though it centers on the access control list implementation, uses a form of the C-list implementation (the "descriptor segment") as well, the appropriate entries of the access control list being copied into the descriptor segment as needed.[1]

Choosing subjects and objects

The model assumes that an access attribute applies uniformly to an object and all its components, but allows components of objects to be objects themselves. It is possible, for example, to regard a file as an object and some of its records as objects too. Thus the designer has great flexibility in the choice of objects.

By taking a subject to be a (process, domain) pair, the model forces all components of a process to have identical access privileges to objects. Thus, whenever it is necessary to grant components of a process differing access privileges, it is necessary to define different subjects for each component. To illustrate this point, suppose a process P operating in domain D consists of subprocesses $P_1, \ldots, P_n$ which must be accorded differing access powers. Since the domain defines the access powers of a process, the subjects $(P_1, D), \ldots, (P_n, D)$ would have identical access privileges. Instead, the system would have to allow the definition of subjects $(P, D_1), \ldots, (P, D_n)$ where domain D_i is effective while subprocess P_i is executing; only then can the subprocess P_i of P be accorded differing access privileges.

As further illustration of the latter problem, consider a system implementing segmentation, in which a process P is uniquely and permanently associated with a name space described by a segment table T; i.e., each subject is a pair (P, T). Suppose $T=[(s_1, \alpha_1), \ldots, (s_n, \alpha_n)]$ where s_i is the ith segment and α_i defines the access P has to s_i. If now we want to debug a new segment s_{n+1}, there is no way to change P's access power when it enters segment s_{n+1}. In terms of Figure 6, it is not possible in this system to put the segment being debugged at a subordinate level. One solution would be to place s_{n+1} in its own name space with segment table T' and process P', so that the subject (P', T') being debugged is subordinated to the debugger (P, T). This cannot be done very efficiently, as software-implemented message-transmitting facilities would have to be used for communicating between the processes P and P'. The problem could have been avoided in the first place if it were possible to define a series of domains $T_i=[(s_i, \alpha_i)]$ and subjects $S_i=(P, T_i)$ so that S_{n+1} can be made subordinate to $S_1, \ldots, S_n$. This is the approach suggested by Evans and Leclerc.[5]

Existing systems

We examine now several important systems in the light of the model. For each system we will identify the elements of the model, points of inefficiency, and points of insecurity (if they exist).

One of the most common systems in use is IBM's OS/360.[11] In this system, objects typically are files, tasks, and instructions. The domains correspond to pairs (mode, block) where "mode" refers to the supervisor/problem-program machine states and "block" refers to a block of the multiprogramming partition of main memory. A subject is then a triple (task, mode, block). One of the principal elements of the model is not present, viz., the idea of attaching a subject identifier to each attempted access; the storage-key mechanism in effect does this for access to objects in memory, but there is no such notion associated with attempts to switch domains or to reference files. It is possible for a task to guess a supervisor call number and issue a supervisor call (SVC) with that number, thereby gaining unauthorized access to the supervisor domain. It is also possible for a user to guess a file name and access it through the job control language.

OS/360 is representative of many current commercial systems in the lack of an adequate protection system and underlying protection theory. The limitations above indicate the OS/360 does not even provide protection at the lowest level mentioned in the Introduction, i.e., it cannot guarantee absolutely that each user is protected from the ravages of other users. The two systems described below (RC4000 and Multics) do embrace the concepts of the model, concepts which must be embraced widely in the commercial systems before they will be capable of providing protection at the level required for sharing mutually suspicious subsystems. There are, of course, other systems which embrace the concepts of the model, but which cannot be discussed here for lack of space; these include the CAL system at Berkeley,[14] the capability hardware proposed by Fabry at Chicago[6] and Wilkes,[20] Project SUE at the University of Toronto,[8] and the IDA system.[7]

The RC4000 system is one example of a commercial system having a protection system incorporating all the elements of the model.[2] The objects of this system include the usual repertoire of files, devices, instructions, and processes. In this system, each process defines a domain (i.e., subjects are identical to processes), and a "father-son" relation defines a hierarchy of processes. Each object is associated with exactly one domain; therefore each process has exclusive control over certain objects, and it must request other processes to access other objects on its behalf. (In this sense, each process is the monitor of its objects.) For this purpose, the system implements a message-transmission facility and associates with each process a message buffer in which are collected all messages from other processes. A process P wishing to send message α to process P' uses a system call

send message (α, P'),

the effect of which is to place the pair (P, α) in the message buffer of P'. Note that this is precisely the notion of attaching the identification number of a subject to an attempted access, if we take the view that each process is an object monitor and a message is an attempted access to some object controlled by the monitor. This system provides a great deal of flexibility: each process plays the role of a monitor; the number of monitors is variable; the definition of an object can be dynamic since the programming of a process can be used to implement "virtual objects" which are accessible to other processes via the message-transmission facility; and each process can determine the authenticity of each message it finds in its message buffer. The limitations of this system include: the message facility, being implemented in software, is of limited efficiency; there is no way to stop a runaway process, as the system cannot force a process to look in its message buffer; and a possibly elaborate system of conventions may need to be adopted in order that receivers can learn the identification numbers of senders. Further discussions of these points are found in References 3 and 15.

The Multics system at MIT is an example of a noncommercial system which implements the elements of the protection model. Typical objects are segments and processes. The virtual memory is the monitor of the segments and the traffic-controller the monitor of the processes. The domains of this system are defined by pairs (ring, base) where "ring" refers to integers 0, 1, 2, ... and "base" is a pointer to the descriptor segment (segment table) of the name space. Each process is associated with exactly one name space so the base can be used as its identification number. Each segment s has associated with it a ring number n_s; if process P is executing instructions from segment s in name space with base b, the subject is the triple (P, n_s, b). Observe that a control transfer from segment s to segment t for which $n_s \neq n_t$ defines a change of subject. The access privileges of a subject are considered to diminish as its ring number increases; in other words, for given P and b, the ring numbers 0, 1, 2, ... define a linear hierarchy of subjects $(P, 0, b)$, $(P, 1, b)$, $(P, 2, b)$, ... Associated with segment s are three pairs of integers

(r_1, r_2)—the read bracket, $r_1 \leq r_2$

(w_1, w_2)—the write bracket, $w_1 \leq w_2$

(e_1, e_2)—the execute bracket, $e_1 \leq e_2$

(These numbers can be stored in the segment table along with flags indicating whether each type of access is permitted at all. In Multics, only three of the seven integers associated with a segment are distinct, so only three integers need be stored to represent the three access brackets and ring number.) In terms of a subject hierarchy, the notion of an access bracket for access attribute α of an object means simply, for a certain range of levels above and below the owner of the given object, a superior or subordinate subject within the range is automatically granted α access to the object. It is an extension of the concept of access attribute. The access matrix is stored statically in the form of access control lists associated with objects (segments). This information is copied dynamically into the descriptor segment as segments are referenced for the first time, so that the descriptor segment is a form of a capability list. A subject (P, n_s, b) may access in any manner any segment t listed in the descriptor segment when $n_t > n_s$; furthermore, if $n_t \leq n_s$ it may read, write, or execute (transfer control to) t if n_s falls in the proper attribute access bracket of segment t. If it wishes to transfer control to a segment t whose execute bracket is (e_1, e_2) but $e_2 < n_s$, it may do so by transferring to a "gate" (protected entry point) of segment t; the attempt to do so generates an interrupt which invokes a "gatekeeper" that permits transfers only to gates. A full description of the mechanism as outlined above can be found in References 9 and 18.

CONCLUSIONS

We have carefully tried to limit the complexity of the model, omitting from its basic structure any feature which is either controversial or not completely understood. It is possible to extend the model in any or all of the following ways. (1) A subject which creates an object can specify that the object is permanent, so that the universal subject can make that object available for future reincarnations of that subject. Alternatively, a subject can specify that, if it dies, ownership of objects it owns can revert to a superior subject. (2) In a subject hierarchy, superior subjects can be regarded as dormant when their processes are not executing, so that subordinates can send messages which, for example, request additional access attributes. (3) Since a subordinate subject may acquire access attributes not held by its superiors, rules may be required specifying when superiors can acquire such attributes for themselves; Lampson allows for this.[15] (4) Given the possibility of multiply-owned objects, rules may be required to permit owners to guard their access attributes from deletion by other owners. (5) If one adopts the view that a subject and all its subordinates constitute a "family," [2] one can make a case for allowing a subject to transfer an access attribute to a subordinate even if the copy flag is not set.

The considerations of the section on System Implications indicate that most current commercial systems do not implement a complete protection mechanism, even at the lowest level described in the Introduction. The most serious defect is the lack of completeness when a process changes protection environments. Although the incompleteness of these systems could be rectified by (probably extensive) software modifications, a complete protection system cannot hope to be efficient unless the basic elements of the model are implemented in hardware. The requisite hardware has been described in many forms—by Fabry,[6] by Schroeder and Saltzer,[18] and by Wilkes[20]—and is in fact quite straightforward.

It can be noted that the "average" user, who employs only system compilers and library routines, is unlikely to break the security of the system if only because compilers and library routines will not cause the loopholes to be exercised. This does not mean attention should not be paid to structuring the hardware so that even the most enterprising and malicious user cannot break security. It takes only one such user to compromise another's privacy which, once lost, may be irrecoverable. On this basis, the cost of hardware and software development required to achieve efficient implementations of protection is of the utmost value.

We began the paper with the statement that the technical approach to protection had not been treated adequately to date in the literature. Hopefully, the discussion here has shown that it is possible to state the problem on an abstract level where the elements of protection can be isolated, where methods of proving the correctness of a protection system can be formulated, where drastically different physical implementations of the one model can be compared and evaluated, and where the nontechnical issues required to complement the technical ones can be identified. The discussion here has been intended as an example of what is possible in a model; we are under no delusions that this is the only model or that this is the best model. Our preliminary work has indicated that the abstractions formed in the modeling process are useful in themselves and that the model provides a framework in which to formulate precisely previously vague questions. We hope that this discussion will motivate others to undertake additional research in this area. Much needs to be done.

ACKNOWLEDGMENTS

We are indebted to Michael Schroeder for pointing out the seven levels of sharing mentioned in the Introduction, and to Richard Holt, Butler Lampson, Richard Muntz, and Dennis Tsichritzis for many helpful discussions and insights.

PRIME—A modular architecture for terminal-oriented systems*

by HERBERT B. BASKIN, BARRY R. BORGERSON and ROGER ROBERTS

University of California
Berkeley, California

INTRODUCTION

The architecture of most interactive systems is based on the general strategy that suitable terminal service can be provided by a central processor that is time-multiplexed among all the active terminals. In order to achieve adequate response time in an interactive environment, the CPU is usually time sliced. Other major system facilities such as I/O channels and secondary storage units are also shared among the users, and multiprogramming techniques are employed to keep all the major system resources as fully utilized as possible. An operating system is usually developed which performs these functions as well as supervising the terminal communications, implementing a system-wide filing subsystem, handling user commands, etc. The result of combining these and other functions into a time-sharing operating system is a highly complex software system which transforms what is basically a batch processing computer structure into a multi-terminal system with significant limitations that are an outgrowth of this strategy. While a failure can occur in any section of the hardware or software, we know that hardware failures are more likely to occur in the electromechanical and core memory sectors than in solid state logic, and that software failures tend to be concentrated in the more complex areas of code. Failures of hardware components may require modification of the operating system in order to regain operational status since the allocation strategies may need more than parametric modification when system resources are affected.

The main attribute of a computing facility that will serve many users simultaneously is that it provide continuous service. By this we mean the ability to service as many users as possible even when a failure has occurred within the system. Failures must be considered normal occurrences which can co-exist with a full range of other normal operations such as resource allocation, interpreting user commands, etc. However, conventional time-sharing systems cannot cope with these failures, and hence cannot offer continuous availability, since large and complex portions of both hardware and software are concentrated in unique units of the system. While it may appear on the surface that further development and refinement of the basic strategy will bring one closer to the goal of continuous availability, we feel this is a false evolutionary path. Instead the approach we have taken is to begin with a totally different architecture which achieves these goals at the very outset.

All of the above considerations are no less true when several processing units are employed as scheduling processors, communications processors, file control processors, etc. The basic problem is that such organizations are all predicated upon the notion that the normal mode of operation of the overall system is when no failures exist. In any practical utility, such as a telephone system or power system, it is always assumed that failures exist as a normal occurrence and must be treated while continuing as near normal operation as possible. This assumption is one of the basic cornerstones of the architecture described in this paper.

Another motivation behind our approach is to provide the ability for any user to continue undisturbed with his use of the system even though it is undergoing considerable change. In a conventional architecture, all user programs run under system-wide software which, if changed, may require the user to update his programs. Even when a considerable effort is made to

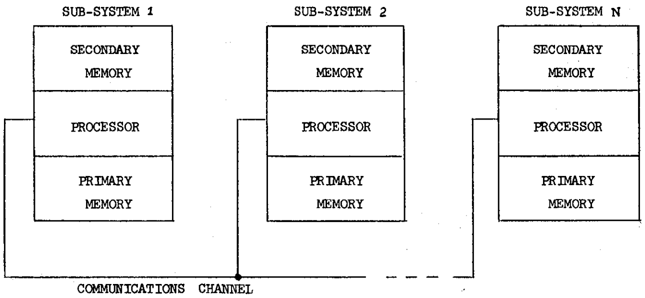

Figure 1—Canonical system

avoid such situations, they do occur, and represent a fundamental flaw in the design. In the PRIME system, the only requirement is that user software be compatible with the processor instruction set.

A user who wishes to have a local operating system supplied to him may avail himself of a currently available version, use a colleague's system, or supply his own. As a result of this new degree of freedom the user may elect to continue using a version of an operating system which has been superseded, thus insuring that his programs, which have been running in a satisfactory manner, will continue to do so. This is of considerable importance in a commercial environment.

SYSTEM ARCHITECTURE

The PRIME system structure is highly *modular* in that it is composed of a small set of different functional units, each of which is replicated many times. The major functional units include primary memory modules, secondary storage modules, and processing modules, which are so interconnected that larger functional units are obtained, each a replication of another. An understanding of this architecture can best be gained by examining the structure and properties of a conceptual system which we call the *canonical system.* As can be seen from Figure 1, the canonical system is composed of a number of subsystems, each independent of the others, which can communicate with each other through a communications channel. Since a subsystem is composed of a processor, primary memory, and secondary storage, it is completely self-contained and able to function independently. The communications channel is used to facilitate data transfers between subsystems. It can be used only in a very specific manner, in that both the sender and the receiver of the data must agree to set up the communications path, and is present mainly for data base sharing operations among users.

This canonical system consists of n identical subsystems which can process n independent jobs with an extremely high degree of protection from each other. Software faults within a subsystem, whether in the user software or in the local operating system (within each subsystem) cannot affect the other subsystems. In addition, hardware failures for the most part only affect the faulty subsystem. There are, however, some possibilities that certain hardware failures (in the communications channel) can cause erroneous interconnections between the subsystems. In these cases, which are strictly non-electromechanical, fault detection schemes can be provided which would guarantee the integrity of the communications channel. System availability with this approach is therefore very high since a failure (hardware or software) usually affects very few of the subsystems.

The canonical system, as was shown above, could provide us with a highly secure and available system. However, in order to achieve more efficient and useful system operation, it is necessary to have methods for allocating the system resources among a large number of users. This must be accomplished without degrading the security or availability characteristics of the canonical system. Accordingly, three additions are made to the canonical system structure just described. The first addition is to place a memory switching unit in each path from a processing module to its primary memory modules, and to allow each memory switching unit to connect to a large number of primary memory modules. This allows processing modules, and therefore basic subsystems, to share primary memory modules and therefore allows for variable primary memory resource sharing. The second addition is to place a switching unit in each path from a processing module to its secondary storage modules. This modification, together with the previous one, allows for extensive resource sharing within the system. The third addition which is necessary to manage allocation of system components is a controlling process, called the *control monitor.*

The resultant system now has facilities for extensive resource allocation, but still retains the security and availability properties of the basic canonical system. This is because, at any instant in time, PRIME is configured to be n subsystems, each consisting of a processor, primary memory, and secondary storage. Each of these subsystems can be considered to be logically and electrically distinct, and as such, compose a system which is essentially similar in structure to the canonical system. The effect of the additions was merely to allow the specific partitioning of the configurations to vary over time. In order to achieve the capability to allocate and repartition the system we use one subsystem to implement the control monitor.

Its processor is designated the *control processor* while the remaining processors are called *problem processors.* Since the assignment of roles of the processors is completely arbitrary, it can vary on a dynamic basis. The functions of the control monitor include job scheduling, terminal buffer management, secondary storage allocation, primary memory allocation, low-level accounting, system diagnosis and problem processor monitoring. The problem processors, on the other hand, have as their main responsibility that of executing user jobs. In order to accomplish user service functions, each problem processor contains a *local monitor,* whose functions include user program file transfers, user program trap routines, and general program I/O.

Each of the subsystems is completely self-contained in that each processing module is composed of a number of functional units which allow it to fully complete a processing cycle. By this we mean that once a subsystem composition is formed and a user process has been activated, no further interaction between that process and the control monitor is necessary until the completion of the job step. Additionally, each processing module contains functional units, inaccessible to user processes, which are used for system-wide functions and control. The particular functional units implemented in each processing module are:

(1) target machine
(2) disk control
(3) memory access
(4) terminal control
(5) communications channel
(6) control monitor extension

where the first three are for user process execution and the last three are system functions.

The target machine functional unit executes machine language instructions and is the interface between user software and the system. A complete description of it would be beyond the scope of this paper.[2]

The memory access and disk control functional units allow the processing module to access, in a secure manner, primary memory modules and secondary storage modules. Each is composed of machinery restricting these accesses to allocated modules. This latter machinery is in the form of maps, which translate user virtual addresses into system absolute addresses. The contents of the maps are set by the control monitor, in a manner described below, at the inception of a job step, when the control monitor allocates primary memory and secondary storage modules to the process just starting up.

The terminal control functional unit in each processing module is connected to a subset of all the terminals connected to the system, and transfers characters between them and the control monitor. With this organization, we have obviated the need for a unique multiplexor, with its attendant reliability problems, and have distributed the terminal control throughout the system. It should be noted that there is no direct relationship between the terminals connected to a processing module and the user processes executing on it.

The information flow between the control monitor and processing modules, as discussed above, is accomplished through the agency of the communications channel functional unit in each processing module. This unit allows for data to be exchanged between the control processor and any of the problem processors.

At the heart of each processing module, managing the activities of the previously discussed functional units, is the control monitor extension functional unit. Each ECM (extended control monitor) is actually a part of the control monitor, performing local actions on its behalf within each subsystem. These actions include setting and reading the map entries of the memory access and disk control functional units, saving and restoring the state of user processes, managing the swapping of user processes, interfacing between the control monitor and user processes, and implementing local error checking and diagnostic algorithms. It should again be noted that the ECM is not implemented in software, executing on the target machine functional unit, but is a distinct functional unit completely inaccessible to and independent of user programs.

The combination of the control monitor executing on the control processor, and each of the ECMs contained within problem processors provides for a rational distribution of responsibility and a concomitant decrease in complexity. Global allocation of primary memory modules and secondary storage modules to processes, and processes to processors is performed by the control monitor, while local allocation of virtual addresses to absolute addresses and local process control is performed by each ECM. Similarly, global error checking and diagnosis are performed by the control monitor, while local error and consistency checks are performed by each ECM.

The main result of this organization is that system functions are completely shielded from user programs in that the control monitor and user processes are never executed on the same processor. There is a physical barrier, brought about by the structure of the system, between those system operations which must remain secure from interference by potentially harmful user software. The allocation of the system between system functions and user functions is not time-multiplexed, as in most conventional organizations, but rather distributed in space. This has many implications relating to system security. The two most important are that since the control monitor is always executing, it is able to continuously monitor the state of the system and that a failure, either in hardware or software, does not cause a breach in the barrier between the system and a user. The decrease in complexity of the control monitor which accrues from the fact that it runs on an independent processor and is involved with each active process only at its initiation also contributes to system security and availability. With a less complex monitor, it is considerably easier to prove that the system software, as it relates to security functions, is operating correctly. Additionally, since the control monitor is responsible for only a subset of the system functions, and hence maintains only a few of the system state tables, it is decidedly easier to recover from a control processor failure.

The processing modules, as described, consist of six independent functional units. In the first implementation of PRIME, however, these processing modules will be constructed from microprocessors and a modest amount of special hardware, with the separate functional units being micro-code subroutines. We feel that this organization is desirable since we are developing a system with which we can conduct experiments with different operating procedures and system organizations. We consider the first implementation of the PRIME system to be a laboratory within which we can experimentally implement a variety of different systems that have in common a number of the architectural features described above.

The decision to employ microprocessors was made to allow for maximum flexibility of the system for such experimentation. An alternate implementation choice would be to construct each processor module from a number of very small inexpensive processors. In addition to the flexibility advantage, the microprocessor choice currently has a cost advantage. However, this situation is expected to radically reverse itself in the next few years. The PRIME architecture will allow us to keep up with the trend toward low cost LSI processors without any architectural changes to the system since later expansion would be with additional modules that are functionally similar to the microprocessor modules, but are internally implemented using several LSI processing units.

SYSTEM COMPONENTS AND OPERATION

The components of the PRIME system are interconnected in the manner illustrated in Figure 2. The processing modules are general-purpose micro-programmable processors which operate on 16-bit operands with a cycle time of approximately 100ns. The control storage for these processors is arranged in 32-bit words, which is also the instruction width. When fetching operands from control store, only half of the word is used. The processor has 2048 words (32-bit wide) of control store and 32 directly addressable 16-bit registers. The data processing logic consists of an arithmetic/logical unit which processes data received from two source buses (A and B buses) and stores the result into the destination register via a third bus (D-bus) after passing the data through a shifter unit. The processor we use which has these characteristics is the META 4 microprocessor units supplied by Digital Scientific Corp.

The processing element uses 21 double bus accumulators and eight general-purpose I/O registers. Five of the I/O registers are used to drive the primary memory system. Of these, two are for transferring data, one for the operand address, one for the instruction address, and one for the memory status. In each processor, the remaining three I/O registers drive the I/O bus which is used for all communications between that processor and external devices. This includes devices attached to the I/O terminals, the real-time clock, the time-of-day clock, the memory map, fault detection messages, and the external access network which will be described below.

The primary memory system for each processing module consists of the five I/O registers, a memory interface which controls memory traffic and contains a memory map, and a memory bus. As shown in Figure

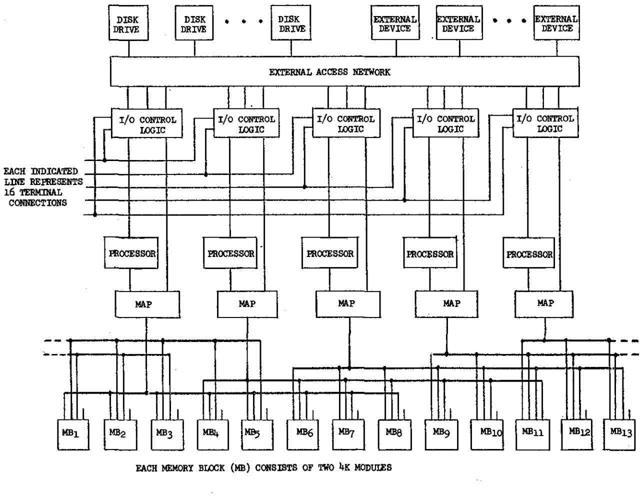

Figure 2—A block diagram of the PRIME system

3 each memory block consists of a four-by-two switching matrix and two 4k × 33 bit memory modules, each of which is partitioned into four 1k word pages.[3] There are five memory buses in the system, each of which connects a processor to eight memory blocks. Thus each processor connects to 16 of the 26 4k memory modules in the system.

Since 64k words of memory is substantially greater than the size of the working sets we anticipate encountering, the allocation of memory modules will be simple and straightforward. In addition, the possibility of being unable to schedule a process due to insufficient free memory modules will be remote. The use of the four-port memory switching units not only provides a distributed memory switch which contributes to the high availability of the system, but also allows for experimentation with different memory/processor connection algorithms.

With the exception of fault reporting and map loading and reading, the memory interface is independent of the I/O bus. The conflicts between the processor and the disks for the use of a memory bus are resolved in the memory control and switching unit shown in Figure 4. This unit also buffers a single word requested by the instruction address register, thus allowing instruction prefetches. In addition to translating logical pages into real pages, the memory map contains bits that specify whether a page is writable, readable, or executable. The use of separate operand and instruction address registers allows the hardware to determine the difference between an operand fetch and an instruction fetch and thus to easily detect when any reference violation has occurred. Other bits in the map include a dirty-page bit, a use bit, and a parity bit.

The memory is constructed from 1k bit MOS devices instead of the traditional core storage technology. Each 4k × 33 bit memory module is made up from 132 such chips. The memory modules have 400ns access and 550ns cycle times. Refresh is performed automatically within the module, using one cycle every 100 microseconds.

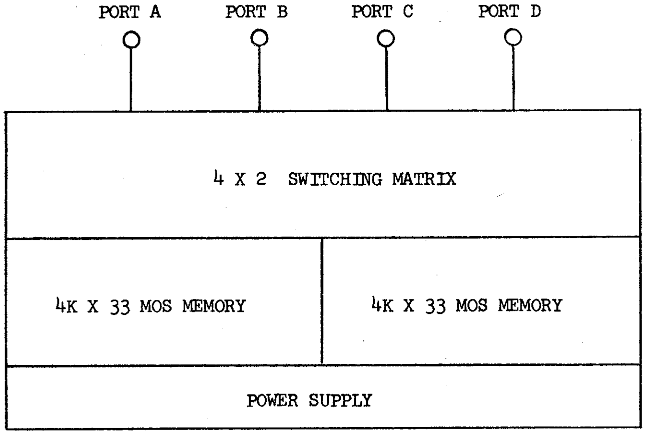

Figure 3—Memory block

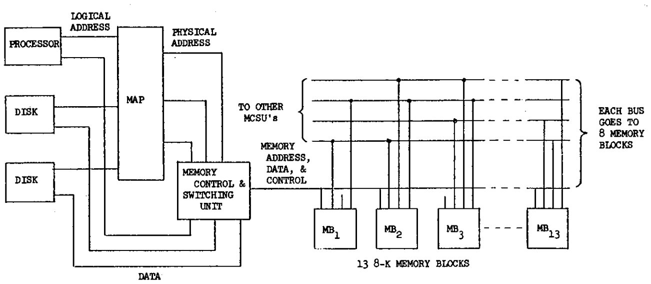

Figure 4—PRIME memory system

In the PRIME system, swapping space, secondary storage, and third level storage all reside on a single type of storage unit. This gives us another level of modularity and interchangeability which in turn contributes to the continuous availability of the system. The unique feature of the PRIME architecture which provides that each active process has its own processor and secondary storage unit makes possible this use of a single device for all of these functions. For this purpose we have chosen a commercially available high-performance moving-head disk drive, and have modified it to transfer data at twice its normal rate. This drive is a modified Model 213 unit supplied by Century Data. The basic Model 213 has 11 platters, 20 heads, 400 tracks, a capacity of approximately 60 million bytes, an average access time of 32 milliseconds, a latency of 12.5 milliseconds, and a transfer rate of 2.5 MHz. We have modified the units to read two heads in parallel so that at the interface it appears to have 10 heads and a transfer rate of 5MHz. Using two heads in parallel with moving head disks drives results in a deskewing problem which is especially acute when one tries to read data from a disk pack written on another drive. Rather than attempt to provide enough buffering to handle the worst possible case of head skewing, we chose to deskew the data by reading words from each head into every other memory location. That is, words assembled from one head are written into odd memory locations, and those from the other head into even memory locations. Thus if one head gets ahead of the other, the controller will simply wait for the last head to finish reading before proceeding. With this scheme we can roll in an 18k working set in under 200 milliseconds.

Each processor in the system can simultaneously connect to any two of the disk drives through the External Access Network as shown in Figure 2. One of these disk paths will normally be used for user file operations, and the other will be used for overlap swapping. Hence, if all ten disk drive paths are transferring simultaneously, the total transfer rate between secondary and primary memory will be 50 MHz or better than 6 million bytes per second. This is indeed a very high rate obtained from such inexpensive devices (approximately $.00003 per bit including modifications and controller). This type of high performance file capability is particularly important to interactive users as well as those who are data-base oriented. Such users tend to require turnaround times of ½ to 2 seconds within which they need only several tens of milliseconds of processing time. In the PRIME system, a process can be continuously active for up to several hundred milliseconds during which user paging activity could take place directly between a problem processor and its dedicated secondary storage unit. In such an environment, the amount of primary memory needed to efficiently execute a process is substantially less than that required in previous system structures.

With the exception of the terminals, all I/O between the PRIME system and external devices takes place via the External Access Network (EAN). This unit allows any processor to connect itself to any external device or to any other processor. Each processing module has three paths to the EAN. Each path contains a parallel interface which is 40 bits wide and transfers data asynchronously at a rate of about 100k words per second. On the processor end the data are routed directly to and from the processor by the I/O controller. In addition to the 40-bit path that communicates directly with the processor, each path through the EAN contains two lines that assemble data from the disk and transfer them directly to memory. These two bits are used only by the disk data paths. All other I/O, including that of the remote end of the disk controllers, takes place through the standard 40-bit path. Actually, the internal switching unit that is part of the EAN is only four bits wide in each direction. The 40 bits are always disassembled, transmitted through the switch, and then reassembled at the other end. However, these are internal details within the EAN and are not apparent at any of its ports. The cost of the switch within the EAN is a function of the product of the number of processors and external devices and also is proportional to the width of its internal data path. These considerations together with our bandwidth requirements have led us to the selection of a four-bit internal switching path. A more complete discussion of the design considerations of the EAN is presented in another paper in these proceedings.[4]

Each processing module is connected to an equal number of terminals, thereby achieving a distributed input/output capability. Each terminal is connected to two processors so it can continue to run in the presence of a failure of a processing module. This provides back-up at minimum cost since the connections to the processors consist simply of level shifting circuits. All assembly and disassembly of characters is done by the microprocessor on a bit by bit basis. As soon as a character is assembled by a processor, it is sent to the control processor where line editing and buffering takes place.

Interprocessor communication takes place via the External Access Network. Direct communication between problem processors is not allowed. Rather, all interprocessor communication is initiated by the control processor connecting itself to a problem processor through the EAN.

The External Access Network treats all of the processor ports in a symmetrical manner. However, at any point in time one processor port is designated as the controlling port and as such has the capability to establish a link between any other processor port (addressing port) and an addressable port to which external devices may be connected. Thus we not only achieve the above mentioned ability for a control processor to communicate with other processors and for any processor to connect to any external device, but by redesignating the controlling port, we can make any of the processors in the system the control processor. We have developed techniques for the redesignation of the control processor that would allow for continuous operation of the PRIME system in the presence of a hardware failure anywhere in the system. These techniques will be described in a later paper.

SUMMARY

We have described a system which is currently being constructed by the Computer Systems Research Project at the University of California at Berkeley with the support of the Advanced Research Projects Agency. Our principal goals are to open up new architectural avenues that will lead to simpler, more reliable, and secure terminal oriented systems. The architecture we have described here provides the user with a target machine having an exceptionally high bandwidth to secondary storage and a powerful medium scale computer on a dedicated basis during the period that he needs processing. The technique of having a bank of components to draw from to construct such a user subsystem allows for nearly continuous operation without having to use redundant components.

Computer graphics terminals—A backward look

by CARL MACHOVER

Information Displays, Inc.
Mt. Kisco, New York

INTRODUCTION

Five years ago, the price of admission into Interactive Computer Graphics was spending about $50,000 or more for the Graphics Terminal and associated hardware, plus writing almost all of the applications software, as well as much of the basic software. And, only about a dozen suppliers offered commercial equipment.

Today, the price of admission has dropped dramatically. Graphics Terminals can be purchased for less than $10,000. Some turnkey applications software packages are available. And the buyer can choose from among more than 35 hardware and system suppliers, offering over 60 different models.

Some aspects of graphics terminal performance have not changed materially over the past five years. For example, maximum screen data content (number of flicker-free points, characters and lines) has remained almost constant for refresh displays. However, there have been significant advances in other areas, such as intelligent (minicomputer-based) terminals, low cost terminals, color displays, specialized hardware function devices, graphic tablets, and the use of storage tubes and digital TV to increase screen content.

SUPPLIERS

In my FJCC Paper about five years ago,[1] I listed sixteen manufacturers of commercially available CRT graphic terminals. A comparison between that list and an updated version compiled from Computer Display Review,[2] and Modern Data Systems,[3] is given in Table I.

The number of suppliers has more than doubled in the past five years. During the past five years, several companies, such as Adage, IBM, and IDI, have offered upgraded versions of earlier systems. Probably the most widely used graphic terminals over the past five years were the IBM 2250 Series units. Originally introduced in Spring 1964 with the IBM 360 Series comupter, three additional versions were subsequently offered.

Two companies (Stromberg Carlson and Philco-Ford) have essentially withdrawn from the commercial field. Several companies do not appear in either list, because either they introduced and then withdrew products in the intervening years, or they introduced products and were then merged into another company. For example, Corning Data Systems and Graphics Display Ltd (England) both introduced low cost graphic terminals several years ago and then either formally, or informally, withdrew them from the market a year or so later. Computer Displays, Inc. introduced the first low cost graphic terminal (using a storage tube) about four years ago, and then merged into Adage about a year ago, losing its corporate identity.

I will not be surprised if there are other changes by the time this is published in May 1972 . . . new products and suppliers, mergers, or product withdrawals. For example, plasma panels and liquid crystal panels with associated displays are just now becoming commercially available from Owens-Illinois and Optel, respectively.

I estimate that the companies listed have each spent in the range of $250,000 to $3,000,000 to bring these commercial products into the market place. Perhaps, then, some $50,000,000 has been invested in these terminals, whose current installed value is about equal to that investment. Certainly, graphic terminal business is not a "get-rich-quick" scheme!

TERMINAL CONFIGURATIONS

Intelligent terminal

Five years ago, most terminals consisted of a display generator (with digital logic and some analog function generators) and a refreshed CRT. Only one system used a storage tube (the BBN Teleputer System), and only two systems included their own computers (DEC

and Bunker-Ramo). The other units used either non-programmable mass memories (such as core or drum) to refresh the display, or were refreshed from the core of the host computer.

In the past five years, the spectrum of configurations has significantly increased. Because of the sharp break in commercially available minicomputer prices, many more intelligent terminals[4] are now offered. A comment from the 1966 Computer Display Review[5] emphasizes the minicomputer price decline.

> "In fact, the DEC 338 has a general-purpose PDP-8 satellite computer which operates independently of the display controller. While the DEC display may seem expensive, the PDP-8 alone is worth $18,000."

Versions of the PDP-8 are now available for less than *one-third* of the 1966 price. Software supported intelligent terminals (which include their own commercial mini or midi GP computers) are now offered by Adage, Bunker-Ramo, CDC, DEC, IDI, IBM, Sanders and SEL. Conograph, Imlac and System Concepts furnish software supported intelligent terminals which use their own designed minicomputers.

Almost all other commercial graphic terminal suppliers are prepared to, or have interfaced their units to a variety of mini or other large scale host computers.

The 1966 Computer Display Review[5] could comment quite legitimately that:

> "There are presently no generally accepted standards or methods for evaluating line-drawing equipment."

In an effort to remedy the situation, the Computer Display Review developed a series of quantitative measures for refreshed displays, based on the manufacturers data. Figure 1 shows the range of price and performance for the displays included in the 1966 Review, compared to the 1971 Review. Note that although the data content characteristics have not changed significantly (the range of flicker-free points, lines, characters and frames), the minimum cost per function has in general been greatly reduced.

Low cost graphics terminals

Storage tubes have introduced one of the major changes in terminal configurations. Until about four years ago, essentially all graphic terminals used refreshed CRT's, with tube sizes ranging from 16″ round to 23″ round . . . resulting in usable display areas of about 10″ × 10″ up to about 14″ × 14″. After Tektronix introduced the Model 611 X-Y Storage Tube Unit with a 6″ × 8″ usable area, several companies including Computer Displays (now Adage), Computek, Tektronix, DEC, and Conograph, began to market interactive terminals based on the Model 611. These storage tube terminals marked the beginning of low cost CRT graphics . . . originally introduced in the $12,000 to $15,000 range, the units are now selling for about $8000. In late October 1971, Tektronix introduced a limited graphic storage terminal selling for less than $4000.

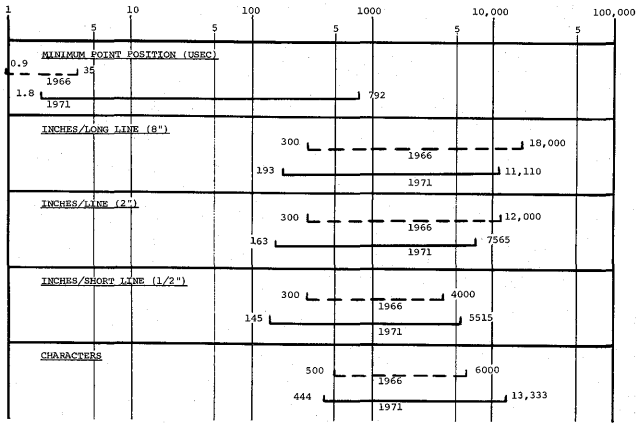

Figure 1a—Flicker free graphic functions

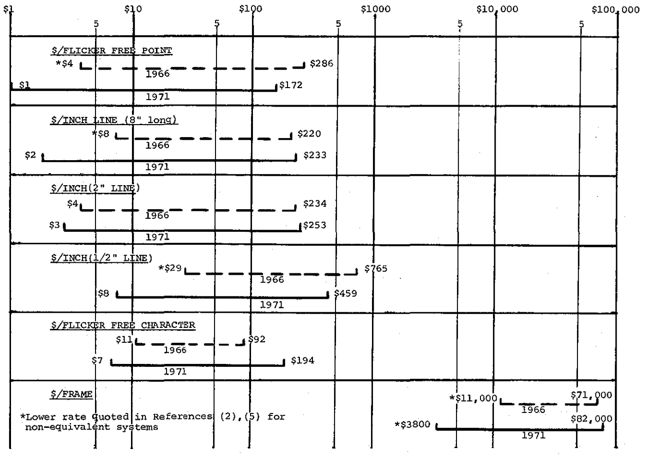

Figure 1b—Cost per graphic function

Within the past two years, several other low cost terminals (under $10,000), using either refreshed displays or some form of TV (either scan conversion or digital TV), have been introduced. Included are refresh displays from Imlac and IDI, scan converter displays from Princeton Electronics, and digital TV displays from Data Disc.

Generally, these low cost units are available with varying levels of software support.

Typically, the low cost graphics terminals involve some compromise in terminal performance . . . such as small picture area, low contrast, restricted dynamic motion, poorer picture quality (lower resolution and some line drawing limitations), and no gray levels. However, for many applications, these are acceptable compromises.

Long persistence phosphors

In order to increase the flicker-free data content of refreshed displays, many terminals now use long-persistence phosphor CRT's. Until about three years ago, the only satisfactory long persistence phosphor was the P7 . . . a combination P19 phosphor for persistence and P4 for fast response (in order to use a light pen). This phosphor couples reasonable burn resistance with satisfactory performance in the 30 frame per second refresh range.

TABLE II—3-D Picture Manipulation
Software vs. Hardware Comparison

(Adapted from Reference 30)

	SOFTWARE	HARDWARE	
ITEM		ANALOG	DIGITAL
1. Number of lines which can be rotated flicker-free.	Independent of rotation method. Depends only upon display techniques.		May bef unction of picture composition if average line drawing time less than matrix multiply time. Line content then determined by matrix multiply time.
2. Time to calculate constant data. Assumes approximately 600 machine cycles per calculation.	Independent of rotation method. Approximately 0.5 millisecond per new angular position.		
3. Time to calculate rotated point (line). (For Software, assumes approximately 170 machine cycles per calculation.)	130 USEC	1–6 USEC, due to transformation array settling time.	5–10 USEC
4. Resident program size.	Approx. 650 decimal words	Approximately 300 decimal words.	
5. Display list buffer size (including 3D and 2D display files), where *W* is number of words required to store 3D display file.	2.3W	W	W
6. Number of lines that can be *smoothly* dynamically rotated (without apparent jump from frame to frame).			
a. Maximum rate (180°/sec) beyond which eye gives "strobe" effect at 30 cps refresh, P31 phosphor.	250 lines	Limited by vector drawing time: number of vectors drawn @ 30 f/s.	
b. At 1°/second	2000 lines		
c. At 2°/second	1000 lines		
d. At 4°/second	500 lines		
7. Perspective	Yes, incl. in routines	No, can be simulated by Z dependent intensity modulation for depth cueing	Yes
8. Hidden Line	Yes, special cases processed in real-time.	No, requires software.	No, requires software.
9. Delta cost (approximate)	$5000 Assumes additional 4K memory increment required. (3D program 650 words; 2D display File #1 1675 words; 2D display File #2 1675 words.) However this increment can be used in other programs as well.	$15,000 $40,000	$70,000

TABLE III—Cost per Console Hour
(From Reference 7)

TYPE	CAPABILITY	INPUT	OUTPUT	EXAMPLE	COST PER HOUR
I Non-graphic teletype	alphanumerics only	keyboard	keyboard	ASR 33	$10
II Non-graphic refresher CRT	alphanumerics only	keyboard	display	IBM 2260	$15
III Graphic Storage Tube	alphanumerics and vector generation	keyboard	display	ARDS and Computek without tablet	$20
IV Graphic Storage Tube	alphanumerics & vector I/O	keyboard & tablet	display	ARDS and Computek with tablet	$30
V Graphic Refresher CRT	alphanumerics & vector I/O	keyboard, light pen, & function buttons	display	IBM 2250 CDC 274	$80 to $150

Recently, doped P39 phosphors, and the Ferranti L4 phosphor, have offered the same burn resistance with acceptable performance in the 16–25 frame per second refresh range.

Hardware function generators

Hardware vs. software trade-offs were continuously modified over the past five years. Most early systems included hardware line and character generation, some included circle generators, but picture manipulation and curve generation were done in software.

While this is still the predominant situation, some terminals including those manufactured by Adage, Conograph, Evans & Sutherland, Lundy, Sanders, and Vector General, offer 2-D and 3-D rotation hardware. Others, including those offered by Conograph, Lundy, and Sanders, offer some form of arbitrary curve generation hardware. Like most trade-offs, choosing hardware vs. software for these functions involve a clear understanding of the application in order to decide if the additional cost is warranted. Factors involved in such a trade-off study are illustrated in Table II.

Operator input devices

Over the past five years, the light pen and keyboard have persisted as the predominant operator input devices for graphic terminals. Joysticks and trackballs are used occasionally, and there has been continuing, although not large, interest in the SRI MOUSE.[6]

Rapidly assuming a major role as an operator input device is the Graphic Tablet. Until the advent of the storage tube display, the Graphic Tablet was viewed simply as direct competition to the light pen. Early versions, such as the Rand Tablet (supplied by BBN), were relatively expensive, (about $10,000 to $15,000), but there evolved a number of devoted users. Sylvania entered the market with an analog version, the price level came down somewhat (about $7000), but the lower priced light pen (about $1500) continued to dominate.

However, the light pen could not be used with storage tube systems, and much attention became directed to the development of a lower cost graphic tablet. Currently, at least two, under $3000, units are available; one from Science Accessories (the Graf Pen, using an acoustic principle) and the other from Computek (using a resistance technique). Undoubtedly others will be marketed.

Color displays

Five years ago, color displays could be most readily obtained with TV techniques, using the commercial, color mask tube. Although there were some isolated usage of the color mask tube in random (non-TV) systems, the systems were costly, and relatively difficult to keep satisfactorily aligned. TV was not widely used for Computer Graphics.

Several years ago, a new color tube, the Penetron, was introduced by several tube manufacturers, including Thomas, Sylvania and GE. The Penetron uses a dual phosphor, and color changes (over the range from red, through orange, to green) are obtained by switching the anode potential, usually over a range from 6000 to 12,000 volts. Switching times are currently in the order of 150 USEC/color, and the tube seems best used in a non-synchronous field sequential mode. Penetron systems offer essentially the same resolution as convention monochromatic random positioned systems (as compared to the lower resolution of commercial TV). At least one manufacturer (IDI) now offers the Penetron as an optional output display for both its low cost terminal (IDIgraf) and its higher cost intelligent terminal (IDIIOM), at a cost premium of about $8000 per display.

Deflection systems

Five years ago, most displays were magnetically deflected. In the terminals featuring fast hardware character generation (in the order of 10 USEC/character, or faster), the display usually included a second high speed deflection channel, either magnetic or electrostatic.

Currently, however, because of better deflection yoke design and improved transistor drivers, newer terminals, such as those supplied by IDI and Sanders, feature a single, wide bandwidth, magnetic deflection channel, capable of full screen deflection in 10 USEC, and capable of responding to characters written in about 3 USEC.

Improved tube and transistor design have also revived interest in electrostatically deflected displays. Storage tube systems use electrostatic deflection, but because of storage requirements, the writing speeds are relatively low. However, a new series of electrostatic, solid state, X-Y displays offered by Hewlett-Packard, feature fast deflection (1 USEC full screen), wide video bandwidth (5 MHz), good spot size (20 MIL), relatively large screen (up to 19″ rectangular), and low price (about $3000).

A terminal manufacturer can now also buy "off-the-shelf" magnetically deflected X-Y displays from suppliers such as Kratos and Optomation. Five years ago, Fairchild and ITT offered similar units, but they no longer market a commercial product.

APPLICATIONS

Five years ago, commercial usage of graphic terminals was limited almost exclusively to Computer Aided Design and Simulation. Many other applications were being investigated, but each investigator was essentially a pioneer. Except for the software supplied by a computer manufacturer to support his terminal (such as CDC and IBM), each user had to "start from scratch."

Today, the situation is considerably improved (although there is much more that can be done). Most intelligent terminal suppliers furnish some graphic software, including graphic subroutines, operating systems and higher level languages. Some offer complete application packages for free-standing versions of their systems (such as the IDI Automatic Drafting System, IDADS). Others (such as CDC and IDI) offer emulator packages that permit their terminals to appear like the IBM Series 2250 displays, and hence are capable of utilizing IBM, or IBM user, developed software. A number of systems organizations, such as Applicon and Computer Vision, also offer turnkey graphic terminal-based systems. These systems permit the user to use computer graphics for making PC boards and IC masks, without any further software investment. In fact, it appears now that most IC manufacturers are using terminal-based computer graphics.

Computer-Aided Design (CAD) remains a major application area, although reported usage is still concentrated in the Aerospace and Automotive industries. However, there appears to be increasing use in Architecture, Shipbuilding, and Civil Engineering.

Over the past five years, the use of graphic terminals in Utility Control has been accelerating. I estimate that about 10 percent of all investor owned utilities are now using or are planning to install graphic terminals for this purpose.

Enough commercial experience has been gained over the past few years to allow meaningful cost justifications to be prepared. The results of one survey giving console costs per hour billed to users for various types of consoles[7] are given in Table III. Five years ago, much justification for computer graphics was based on faith!

PUBLICATIONS, COURSES AND SEMINARS

Certainly, one measure of growth (or at least interest) in a field is the amount published, or the number of related discussions. In the past five years, several engineering level display and computer graphics texts, relating to computer displays, have been published[8,9,10,11] and numerous national and international meetings have been held. References 12–16 list several representative meetings. Several universities, including the University of California, the University of Michigan, Stanford, the University of Wisconsin, and Brooklyn Polytechnic, have sponsored short courses oriented to displays and computer graphics. ACM organized a special interest group for graphics (SIGGRAPH), and the Society for Information Display continues to flourish. Annual or periodic graphic terminal equipment surveys have become common like those published by Keydata* Corporation,[2,5] Modern Data Systems,[3] Auerbach Corporation,[17] Data Product News,[18] Computer Design,[19] and Computer Decisions.[20] Even the American Management Association,[21] the Harvard Business Review,[22] Scientific American,[23] Newsweek,[24] and the Jewish Museum[25] have

* In late 1971, Keydata Corporation sold its publishing business to GML Corporation.

taken note of computer graphics. Computer graphics terminals were featured on several national TV shows, like the David Frost Show and San Francisco Airport.

A few of the Seminars were concerned with "breast beating". It became increasingly popular in 1969 and 1970 to ask the question, "Why hasn't computer graphics lived up to its initial promise . . . a terminal in every home and office?"[26,27] Early predictions of a $200,000,000 market by 1970[28] were not being fulfilled. As a participant in many of these sessions, I felt that the question was being "begged". Some of the applications predicted for graphic terminals were being effectively handled by A/N CRT terminals (of which there are now estimated to be some 75,000 units installed).

The growth in other applications depended on a consolidation and analysis of results from the previous year's efforts. Still others couldn't be exploited until appropriate software, or less expensive hardware became available. And, 1970 was a miserable business year, anyway!

During these sessions, my position was, and continues to be, that although some early predictions were overly optimistic, conditions now exist for attractive growth. A number of market surveys, and projections have been published in the last five years . . . but the future is the province of another speaker in this session. Some review of the past five years might provide a useful bridge, however. For commercial applications, the consensus is that there are currently about 1200 high cost graphic terminals and about 700 low cost graphic terminals installed.[29] Five years ago, there were probably (my guesstimate) about 300 high cost graphic terminals installed. There were no low cost graphic terminals.

WHAT DIDN'T QUITE MAKE IT

As shown in Table I, almost all suppliers from five years ago are still offering commercial equipment. Several products and concepts which seemed promising during the period didn't quite make it though. For example, about four years ago, a British company, Graphic Displays Ltd, had an interesting idea for a low cost graphic terminal. The ETOM 2000 coupled an inexpensive drum memory to a long persistent phosphor display. Operator input was achieved with an X-Y mechanical table arrangement. Apparently technical problems and limited customer acceptance scuttled the project.

Corning Data Systems exploited a photochromic storage technique in their Corning 904 terminal. For about $20,000, the customer was offered a storage display with hard copy output, and extensive software support. But Corning couldn't find a large enough market and withdrew the product. All was not lost, however, because they were able to sell the software package to Tektronix.

Ported CRT's seemed to be a promising techn'que five years ago. However, the added cost and complexity limited the use to selected military applications, and there is little current commercial interest in the configuration.

Many practitioners expected (or at least hoped) that there would be a universal higher level graphics language by now . . . but that didn't quite make it, either!

SUMMARY

It was an exciting five years!

New suppliers, new products, and new applications surfaced during this period. Because of lower cost terminals and turnkey software/hardware systems, the use of graphic terminals began to spread beyond the Fortune 500 . . . beyond the Aerospace and Automotive Industries.

Generally, terminal performance was maintained, while prices were lowered. This was a reasonable trend since most applications were not hardware limited.

Of necessity, a survey paper like this tends to be superficial. For every example cited, several more may exist. But the purpose has been to give the sense of movement over the past five years, perhaps at the expense of some detail.

Usually, this kind of paper ends with a forecast . . . a prediction of things to come. Fortunately (since predictions have a habit of coming back to haunt), the seer's mantle has been placed firmly on another speaker's shoulders!

The future of computer graphics

by THOMAS G. HAGAN and ROBERT H. STOTZ

Adage Inc.
Boston, Massachusetts

Predicting the future is a hazardous enterprise—especially in high technology where seers tend to be too optimistic in the short run (3-5 years) and overcautious in the long run (10-20 years). In computer graphics, the forecasts started about 10 years ago, and so far almost all seem to have been too optimistic. But the pace now quickens, and the next 10 years' developments may at last outstrip the visions of 10 years ago. At least, so it seems now to us, and so we join the optimists, even though to date they've all been wrong.

The optimists (i.e., almost everyone in the field) have been disappointed because they failed to recognize at the outset the level of completeness necessary in a graphics system to do a useful job. They consequently either tried to work with incomplete systems, producing negligible results, or, in achieving completeness, encountered higher than expected costs for both development and subsequent production use. The realists, on the other hand, *knew* that achievement of successful on-line graphics applications would at first be a slow and costly process, and planned accordingly. They concentrated on applications areas where the high initial costs could be justified, and where the available hardware and software technology was sufficient for the job. They have achieved some significant successes. Based upon those achievements, we believe that computer graphics is entering a new phase which will be characterized by rapid growth.

We can summarize our conclusions for the future by saying that the technical feasibility of graphics applications has now been demonstrated in many areas, that economic feasibility has been established in a few areas, that costs will come down by a factor of 10 in 10 years, and that graphics systems will therefore proliferate, first in areas where the economics are already favorable, then into new ones as they become so.

Areas where growth can be expected on the basis of already proven economics include situation display, data analysis, and simulation. The economic turning point has just been reached for computer-aided engineering design (except for exotic cases which have been economic for several years) and for some forms of drafting. In the future lie still broader drafting applications, publishing industry applications for editing and page layout, architectural design, routine use for film and video tape animation and editing, management information systems, hospital information systems, and computer-aided instruction. We shall discuss each of these applications areas in turn, but first let us examine the technological prospects for computer graphics: the display hardware itself and the computer systems technology behind it.

DISPLAY HARDWARE TECHNOLOGY

Only five years ago, the random-access refreshed CRT was the only serious graphic display technology. Today, we have a plethora of new techniques. Interestingly, all of this new technology has been directed toward the image storage approach to graphic display. That is, the picture is stored in its two-dimensional form or in some one-to-one map of that form (e.g., video disk). Therefore, one cannot meaningfully discuss display technique without including the memory for retaining images.

In the next 10 years, it is reasonable to expect the bistable direct view storage tube (DVST), the video scan converter tube and the video disk each to mature and to find particular application in areas where its advantages will be realized. A long life for each approach can be expected, although, particularly for the DVST, new hardware will probably succeed present equipment.

One new direct view storage technique is the plasma panel, which appears to be nearing commercial application. The plasma panel performs functionally like the bistable DVST; that is, it retains images for direct view once it has been written. But it has some interesting advantages. It is fundamentally flat and reasonably transparent, which makes rear projection of static data easy. It should be more rugged than a CRT and it is digitally addressed, thereby eliminating all analog circuitry. But its most interesting feature may be its price. The cost of this panel has been projected by authoritative sources to be as low as a few hundred dollars for a panel with drivers. At any price below $1000, the plasma panel will certainly be a popular device.

Several other DVST techniques have been introduced, but we do not foresee major impact from any of them. Photochromic storage systems are slow and too expensive and, in fact, the one commercial entry utilizing a photochromic system has been withdrawn from the market. The cathodochromic direct view storage tube is viewed by reflected light, which is an advantage in a high ambient light environment. However, its slow erase property will limit its utility.

The random-access CRT does not have much competition today where dynamic performance is required. There will be a shift toward raster displays, however, possibly for even the most dynamic pictures. The flexibility of TV video format for remote transmission, large screen display, and image mixing, particularly with non-computer generated pictures, argues for this, as does system cost. In the past, the scan conversion cost was prohibitive, but as digital logic cost drops further and its speed improves, the cost will become more competitive.

The move toward video format will encourage the work being done on display of solid figures. However, applications for solid figure display (limited more by computer systems technology than display hardware) will probably continue to be limited, even in 10 years.

Quite likely, too, by the early 1980's, several new display techniques will be with us that we are not even aware of today. It is hard to project the impact of currently unknown techniques, but, as has been the case in the past five years, they will probably be directed more at cost reduction than at performance improvement. In fact, in the next decade, it may be that *all* the significant technological developments in display devices will result in cost reduction rather than in performance improvement.

COMPUTER SYSTEMS TECHNOLOGY

The factor that has limited the utility, and therefore the market growth, of interactive computer graphics systems has not been the display hardware technology (CRT's have worked fine for years) but the computer systems technology behind the display. By this we refer to the whole system for providing enough on-line processing power, sufficiently responsive, with enough memory to be effective, with adequate programming support, and with communications adequate to get the data to the user at the necessary speed, all at a low enough cost.

Interactive graphics systems are by definition conversational. In order to be truly interactive, they must provide responses within a few seconds for many or most of the actions taken by the user at the console. Cost for graphics systems has always seemed high to users, and attention has often been focused on the cost of the display terminal itself as an obvious target for reduction. But compared to keyboard-only conversational systems, conversational graphics entails manipulation of relatively large data files, with consequently much longer messages between terminal and mass memory. Concentration on cost of the display device often has led to overlooking the cost of the processor hardware and the mass memory necessary to support the terminal device with the levels of performance needed for a conversational graphics environment. In the past, some systems disappointed users because of the large amount of core memory needed in the system to support each terminal, or the high cost of the communications facilities necessary to provide the link to the CRT, or the lack of enough fast mass memory to support a reasonably complete application. Proliferation of graphics systems, therefore, depends not only upon reducing cost of the display itself, but also upon reducing the cost of the processor hardware and the mass memory needed to support the display. Numerous users have concluded that each graphics console requires in the range of 10 million to one hundred million bits of mass memory with access time well below 1 second. Communications costs are significant whenever this mass memory and the processing hardware are remote from the console. Even though present digital communications costs are expected to be reduced dramatically, we believe that many or most graphics systems will incorporate local processing power, and some form of local mass memory. The communications burden then reduces to one of occasionally shifting data from individual consoles or clusters of consoles through communications lines to a central repository accessible to many users.

The need for sufficient processing power, core memory, and mass memory behind the tube is the reason that useful interactive graphics systems today cost $100,000, and up, per console. We believe that 10 years will see a 10:1 reduction in these costs, permitting complete, useful systems with the equivalent of today's functional performance for $10,000. Cost per console hour will therefore drop from today's $25.00 to $50.00 range to about $2.50, permitting significant growth of current applications, and penetration of computer graphics techniques into many areas currently untouchable. Here are our thoughts on prospects for a number of different present and future applications.

APPLICATIONS

Many people assume that Interactive Graphics = Computer Aided Design (CAD). It is true that CAD is an important applications area for computer graphics and the one that most easily captures the imagination, but there are many other application areas, including some that have achieved a higher degree of maturity (i.e., proven economic effectiveness) than CAD. We shall discuss a series of application areas in turn, roughly in the order of their currently demonstrated effectiveness. (We are specifically not discussing them in the order of present or potential market sizes, which cover a wide range, although clearly areas where economic effectiveness is established soonest generally achieve earliest penetration of the available potential market.)

Situation display

About $100 million has already been committed by the FAA for computer graphics systems for air traffic control situation displays. The next 10 years should see computer graphics firmly established for real-time situation displays in many areas. Other forms of traffic will be brought under control of systems which will include computer graphics for overall situation display: rail, transit, harbors, shipping lanes. Computers will be inserted between the antennae and CRT's of almost all radar systems, converting them into computer graphics systems capable of much more comprehensive situation display than current "simple" radars. Thus, specialized computer graphics systems will eventually be found aboard all airliners and all ships as part of the navigation and piloting systems—if not by 1982, then by 2001, just as we were informed by Stanley Kubrick's film.

The few computer graphics systems now installed for monitoring and control of chemical processes and utility distribution systems presage what we believe will be widespread use of computer graphics for situation display in these areas, possibly replacing completely the walls full of panel meters and recorders that have come to typify the industrial process control room.

As discrete manufacturing operations become more automatic, situation displays will begin to be used for monitoring material flow and inventory levels. In other words, for supervisory control, somewhat analogous to that practiced in continuous flow chemical manufacturing processes.

Computer graphics systems are already being used as situation displays for monitoring tests and experiments conducted with the use of expensive test facilities, and frequently for assisting with control of the facility. Aircraft flight test, wind tunnel test, and Van de Graaf generator experiments are all today being conducted with computer graphics systems used for real-time display and control. Achievement of even a small increment of increased utilization (or enhanced safety) of a very expensive test facility can justify a computer graphics situation display system at today's costs. As costs come down, such display systems will proliferate, finding use in conjunction with larger numbers of gradually less expensive test facilities.

Data analysis

Any operation involving the collection of large quantities of data for subsequent human interpretation constitutes a potential application area for computer graphics. Today's successful applications (in the military, electronic intelligence data analysis; in industry, oil exploration data analysis) can be expected to continue growing and should lead to applications in similar areas: semi-automatic map-making (photogrammetry), weather data reporting and forecasting, and other forms of mineralogical survey data analysis besides oil exploration. Increased use of automatic sensors to collect data should lead to increased use of computer graphics as an aid to analysis of that data. In addition, some data sets built up by keyboard source data entry (census data, for example) have become large enough to be candidates for analysis via computer graphics.

Simulation

This is an area that has used computers in an on-line, interactive mode right from the start, and usually with some form of graphic output—strip charts or X-Y plots. Analog computers were used almost exclusively at first, then hybrids took over, and now much simulation is done on purely digital machines. Simulation models have grown more and more complex so that systems behavior can be studied *in toto* rather than piecemeal. Flexible dynamic display has become more and more necessary, either to achieve "picture-out-the-window" verisimilitude in the case of vehicular simulations, or to achieve an over-all "situation display" for the simulation model—with the same general requirements (plus flexibility) required for the "real world" situation displays discussed above.

To date, engineering simulation has been highly mathematical and quantitative, even where the object was to get the "feel" of sensitivity to parameter variations. The display flexibility of computer graphics will permit a more qualitative kind of simulation, still based upon an underlying mathematical model, but where there is less a "numerical" and more a "graphical" sense of the model. In short, simulation will be used for what we think of as styling as well as for what we think of as engineering design. The distinction between the two, already blurred, may gradually disappear. In the future, dynamic aspects will be "styled," as static aspects now are.

Computer aided design

Meanwhile, there is CAD. After a long slow start, great strides are being made and numerous on-line applications are felt by their users to be cost-effective today. However, the dream of an integrated design system which takes a large design task from concept to final production drawing (or microfilm or magnetic tape) will be realized in only a few areas even in 10 years. Clearly one such area is the layout and design of electronic circuits. In 10 years, virtually all circuits will be designed with the aid of the computer. Circuit and logic designs will be synthesized and tested by computer, and test specifications for completed circuits will be an automatic by-product. Almost all of this kind of design work will be done with on-line interaction via graphic terminals.

One consequence, in this and other areas, will be a change in the economics of short-run production. By cutting design costs, CAD will make the production of "custom" circuits more practical.*

Interactive graphics are being used successfully today in several dozen places for performing various kinds of engineering analyses that form a part of the design process. Success has come quickest where a pre-existing and already proven applications package developed for batch operation has been adapted to be made available on a conversational basis via interactive graphics. The usual main result is a dramatic shortening of the cycle time for the part of the design job converted to graphics—a job involving many iterations that used to take six weeks under batch being finished in one two-hour console session, etc. There is also often the feeling (hard to prove) that a better design job was done. The high cost of graphics systems and applications programming today restricts these applications to a few critical points in the design process. As costs come down and confidence increases, use is spreading to less critical design jobs: from today's computation-intensive jobs (stress analysis, heat flow, vibration analysis) to geometry-intensive jobs (complex layouts, clearance analysis, pipe routing, numerically-controlled machine tool tape generation and verification) and finally to drafting/clerical intensive jobs (detailed drafting).

Some forms of detailed drafting are already cost-effective using computer graphics, in particular the preparation, editing, revision and file maintenance for drawings made up from a set of standard symbols. (Circuit diagram, logic diagrams, flow charts, block diagrams, etc.) Especially where revision is frequent and fast turn-around is important, as in the preparation and revision of system maintenance drawings, computer graphics is now ready to compete with traditional drafting and technical illustration methods.

The design function is a social activity. Design tasks are usually undertaken by groups of people, with the overall design job in one way or another divided among members of the group. It is easy to think of CAD as a means for helping an individual designer with his task, and to overlook the implications of CAD with regard to communications within the design group. In thinking about the long run, it is important to visualize teams of designers using on-line interactive devices to communicate with a data base containing both the design constraints they are working with (specifications, costs, catalogs of available parts) and the results to date of their joint effort. Much of their communication with one another will be via the design itself as it exists in storage. What will happen when (and if) 10, 100, 1000 designers are interconnected on line? The airlines reservations systems constitute the closest current model to such a situation—and the detailed total reservation schedules the thousands of clerks at CRT terminals are constantly building up is a kind of "design"—but the constraints they work with are few and fairly simple.

Architecture

We think the introduction of computer graphics here will be relatively slow because of the diffuse nature of

* Similarly, wherever the high cost of processing information "by hand," for either the design or the manufacturing portion of the production process, has resulted in a large cost differential between "custom" and "mass" production, CAD, with computer graphics playing a significant role, may redress the balance, and much of our industrial output may return to the "one-of-a-kind" production typical of pre-industrial times. If so, computers will have (in this respect at least) an effect upon the quality of our lives quite opposite from that expected by those who see them only as a threatening source of increased standardization and regimentation.

the business structure, with many small independent firms, most without the resources for investment in hardware and development of software. City and regional planning may be an exception if government money is used to fund the necessary development. Emphasis upon the creation of presentation drawings is misplaced. The cost of renderings and models for client presentations represents a small part of the total architectural cost, the bulk consisting, as in other design activities, of the creation of working drawings. Therefore architecture may benefit mostly from progress made elsewhere with generalized drafting: the creation of dimensional drawings with materials lists.

Publishing

Computer graphics has promise as a publishing tool, and we expect substantial progress in this area in the next 10 years. Preparation and editing of text and graphics source material, and page layout, are the functions that graphics systems can help with. Automatic typesetting has gone as far as it can go without the front end of the publishing process being automated. Cost reduction and shortening of the cycle time are again the primary benefits. By 1982, it will no longer be necessary to submit SJCC papers "in final form suitable for printing" seven months prior to publication of the Proceedings, as it now is. But, in order for graphics to see widespread use for this function, it is clear that console time must first get most of the way down to that $2.50 per hour.

Film and video tape production

There is an obvious role for computer graphics for producing and editing visuals (as they are called in the trade) for television and motion pictures. Entertainment programs, commercials and educational programs have all been produced on a limited but already commercial scale. The first full length feature movie shot and edited solely on video tape, then transferred to standard 35 mm color film, has been produced and distributed. We expect to see increased use of computer graphics as combined animation stand and editing console, both for creating "computer generated pictures"—i.e., computer animation—and also for editing live-action film or VTR footage.

Computer aided instruction

The current high-priced applications such as trainers for airplane pilots and astronauts are of course already economic, but normal classroom use of computer graphics as a standard teaching tool, which is what most people mean when they talk about CAI, clearly requires system costs in the range of $2.50 per hour and down, and therefore we do not believe that the next 10 years will see massive proliferation. On the other hand, small computer graphics systems will become standard lecture/demonstration tools in many areas of education, both for "live" use and for creating simple low- or no-budget teaching films or tapes—i.e., canning lectures.

Management information systems

Of course every organization has *some* kind of management information system—partly verbal, partly a manual paper system, and in most large organizations these days, at least partly computerized. But the computer part is batch, not on-line, so it isn't what people mean who talk about MIS. So far it's been mostly talk, with not much in the way of results. Maybe because on-line MIS isn't needed—top management really doesn't care what goes on minute by minute, and counts itself lucky to get reliable reports weekly or monthly. But down in the infra-structure, there *is* a need to know minute by minute about material location, tool availability, stockroom levels, etc. If on-line computer systems begin to get applied for these functions, then MIS as commonly envisioned will be a by-product, and computer graphics will be a popular tool for analyzing the data contained in such systems.

Hospital information systems

Many people seem to believe that Hospital Information Systems, as distinct from other types of computerized management information systems, are needed, feasible, and about to happen. If so, there will be a role for graphics, since so much patient care data are graphical in nature. The need will be for low cost inquiry stations capable of displaying static charts, graphs, and possibly even line drawings abstracted from X-rays. These would be terminals connected into an overall integrated information system primarily concerned with record keeping.

On the other hand, there will be another use for computer graphics in the form of higher cost, more dynamic systems used for patient monitoring in operating rooms and intensive care wards. Use of these systems will not depend upon creation of an integrated HIS.

CONCLUSIONS

In interactive computer graphics, we are at the end of the beginning. About $50 million has been invested to develop the products now on the market. Users and government sponsors have invested an additional $20 to $40 million in software development to tell us what we now know can and can't be done working in front of a CRT. In keeping with the New Accounting, almost all of these development costs have been written off as losses by the various organizations that have made investments to get started in graphics. Now computer graphics has entered a new phase. Most of the systems currently installed (about $100 million worth of hardware, by our estimate) were ordered as interesting but risky and somewhat daring experiments—many of which failed; but in the last year, graphics systems began to be ordered to do specific jobs, with reasonable certainty that they would be effective in those jobs. Thus we believe that an important corner has been turned.

Two ingredients are necessary for the field of computer graphics to experience growth—the availability of systems complete enough in hardware and software to do a variety of useful jobs, and a pattern of decreasing costs to end users. Both of these ingredients are now present, and we therefore believe that the period of significant growth for computer graphics, long anticipated, has now begun, and will be sustained throughout the coming decade.

A versatile computer driven display system for the classroom

by J. W. WILLHIDE

Boston University
Boston, Massachusetts

INTRODUCTION

The last two decades have seen education in the sciences, mathematics and engineering move from a practical base to the teaching of highly sophisticated abstract principles. The changes have been rapid and radical. Generally, they have affected subject matter only and for the most part this new material is being taught by traditional methods. The changes in subject matter are proper, but they must be accompanied by changes in pedagogy. The use of display-based, highly interactive computer simulations represents one approach toward building the required new pedagogy.

The educational system in this country is almost totally classroom based—one teacher interacting with a class of students on a regularly scheduled basis. This unanimity of approach implies that most administrators feel this is the most cost-effective approach to teaching *available today* that lies within their financial resources. In a similar fashion, one of the most cost-effective ways to implement a model-oriented pedagogy *today* is through the use of a computer-driven display system in the classroom. Other approaches to a model-oriented pedagogy such as individual student terminals supported by a CAI (Computer-Aided Instruction) system may at some point in the future challenge the classroom system on a cost-effective basis. However, it will be some time until such an approach will become the rule rather than the exception. One must bear in mind that even if CAI systems offered a cost-effective advantage over the classroom system today, many schools could not afford such a system because of the large initial investment and relatively long pay-back period.

At Boston University, the College of Engineering has implemented a versatile computer-driven classroom display system known as the AID System. The AID System is unique in its emphasis on real-time dynamic graphics, i.e., computer generated animation. AID allows the user to animate, in real-time, iconic representations of physical systems in a highly interactive environment. The user can change parameters and immediately observe the effect of the change on a CRT display. In addition to its real-time dynamic graphics capabilities, the system also makes use of the more conventional static information transmittal modes such as alphanumeric text, graphs and symbolic diagrams.

The AID System is structured around a PDP-9/AD-40 hybrid computer. The AD-40 analog computer is used to simulate the system under study or serve as a signal processor for experimentally derived data. Animation is produced by dynamically manipulating a set of geometric figures generated on the PDP-9 digital computer as functions of the time-varying signals sampled from the analog computer. These animation sequences can be accompanied by graphs which unfold in time synchronism with the animation. For cases where animation does not make sense, graphs of selected simulation variables can be displayed.

A high-level language, the AID Language, is under development to support the system. This language can be easily learned by a highly motivated sophomore engineering student. It is not intended, however, for the professional animator or casual user of the system, since some background in analog and digital computation is assumed. A film illustrating some of the attributes of the AID System and produced on the system itself using the AID Language will be shown.

ROLE OF THE SYSTEM

The system serves a dual role in the classroom. First, it can be used to assist the student in grasping difficult concepts through the use of iconic and graphical presentations. Second, since the system is computer-based, it can be used to illustrate the role of simulation and computation in engineering design. The above

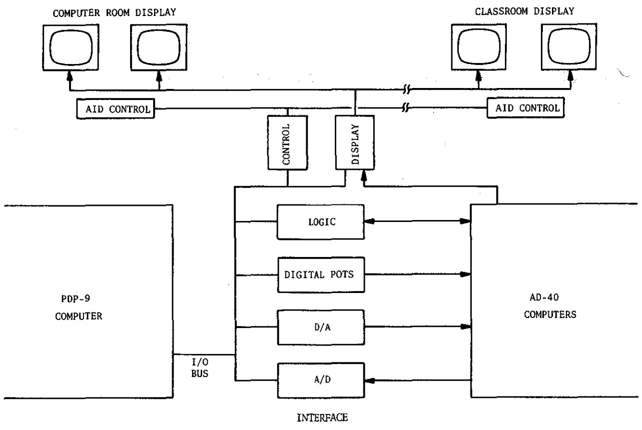

Figure 1—AID system

dichotomy is not always clear in many classroom situations. However, it does serve to focus attention on the two fundamentally different roles of the computer in the system—as an invisible "helper" and as a visible computer performing calculations and other tasks that a student thinks a computer should do.

The classroom-oriented display system can also serve several useful functions outside the classroom. First, since a duplicate display system is also located in the computer room, highly inquisitive or troubled students can interact with a preprogrammed simulation sequence on an individual basis and often answer their own questions. Meaningful interaction can be achieved with minimal programmed support because the student has been introduced to the simulation sequence in the classroom. A second function of the system outside the classroom is with student use of the system hardware and supporting software to add a new dimension to their project work. As an example, a group of sophomore-level students programmed, as an extracurricular activity, an animation of a pendulum swinging in an accelerating railroad car to accompany a project in their Dynamics course. The third function the system can perform outside the classroom is in conjunction with the laboratory exercises associated with our introductory analog computer course. In these exercises the students animate, in real-time, a pictorial representation of the physical system they are studying by signals generated in their analog computer simulation. The resulting iconic communication mode helps students bridge the gap between the typical "squiggly-line" output of the analog computer and the physical system which they are simulating. In addition, it has been found that the introduction of computer animation into an undergraduate course brings with it a fresh new breath of life—a level of excitement and motivation rarely seen today.

The system, with its dynamic systems simulation and graphics capabilities is ideal for generating demonstrations in a wide variety of undergraduate engineering disciplines. We hope to add interest to lectures while clarifying points which are difficult to perceive in terms of verbal descriptions or blackboard sketches. The demonstration examples will in some cases precede the lecture material to motivate and prepare the student for the abstract material. In other cases, the demonstrations will follow the presentation of a concept to validate and reinforce that concept. In both cases it is expected that the real-time interaction offered by the system will considerably heighten the sense of discovery and intellectual curiosity of the students in the classroom.

SYSTEM CONFIGURATION

The classroom display system at Boston University is depicted in Figure 1. From the figure it can be noted that the bulk of the system is a typical hybrid computer configuration consisting of a Digital Equipment Corp. PDP-9 digital computer, two Applied Dynamics AD-40 analog computers and a custom designed interface. Thus, the step from a hybrid computer to an interactive classroom display system is a relatively small one—consisting of adding a Control Interface with remote control units, a Display Interface and large screen CRT displays.

A hybrid computer was chosen to drive the system to gain the complementary attributes of its constituent analog and digital computers. The analog computer offers a convenient means to simulate the dynamic systems used in most classroom presentations. The digital computer is used to give the user a simple and yet effective interaction with the simulation through the use of a special control box located in the classroom. Through its graphics abilities, it also gives the system alphanumerics for giving instructions to the user and displaying parameter values, and line graphics for static and dynamic pictorial presentations.

Two independent large screen CRT displays placed side-by-side are used in the classroom. This provides the system with what the author believes is the visual channel capacity required for a flexible and effective computer-driven interactive classroom display system. For example, in demonstrating the response of an electric circuit to some excitation, one display would present the schematic diagram of the circuit complete with parameter values while the other display would present the excitation and circuit response. Once given a dual display system, it seems that almost all demonstrations require such a system for effective presentations. This may either be a corollary to Parkinson's Law, or, as the author interprets it, an indication that two independent displays are essential.

DISPLAY SUBSYSTEM

Of the two displays in the AID System, one is primarily used for the presentation of static or slowly changing images such as alphanumeric text, pictorial diagrams and graphs. This display, the left-hand one of the pair, is a large screen TV monitor. It is driven by a Tektronix 4501 Scan Converter, a device which accepts $x-y$ inputs and produces a video output signal. The scan converter is based on the use of a bistable storage CRT. Hence, this display functions as a stored type display. It need only be written once and it will retain the stored image until erased. When driven by a digital computer, the stored type display places considerably less burden on the computer than a refreshed type display. The stored type display is also convenient to have for many analog computer generated displays. For example, a simulation may be running in the repetitive operation mode with one value of a particular variable being generated during each run. A storage type display is required to present a plot of this variable versus time in the classroom.

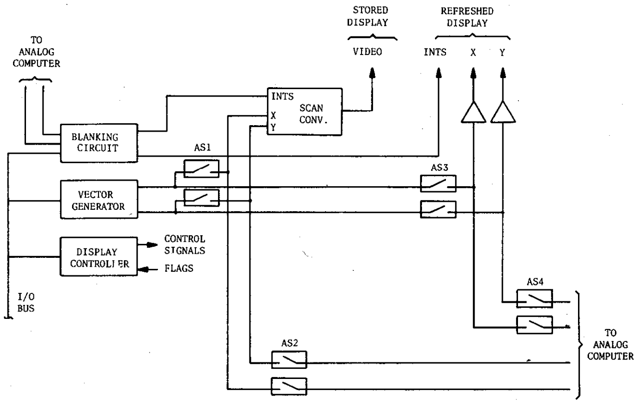

Figure 2—Functional diagram of display interface

The other display of the system is used primarily for the presentation of dynamic graphics such as animated iconic models (e.g., a pictorial spring-mass system which looks and behaves like a real spring-mass system) and curves generated by the analog computer in the repetitive operation mode. This display is a large screen $x-y$ CRT which functions as a refreshed display. It is driven directly by analog signals from either the analog computer or the digital computer display interface.

					Display Assignment	
Configuration	AS1	AS2	AS3	AS4	Stored	Refreshed
1	closed	open	closed	open	DIGITAL	DIGITAL
2	closed	open	open	closed	DIGITAL	ANALOG
3	open	closed	closed	open	ANALOG	DIGITAL
4	open	closed	open	closed	ANALOG	ANALOG

Figure 3—Source/display combinations

A functional diagram of the AID Display Interface is given in Figure 2. Analog switches which are under program control are used to set the system configuration to suit the particular problem being solved. Figure 3 presents the various combinations between driving sources and displays. When both displays are driven from the digital computer, the programmer selects the display he wishes to write through the use of an appropriate display command. Both displays receive the same $x-y$ inputs. However, only the one being written receives an intensify pulse. This allows the programmer to switch back and forth between the displays. When the displays are driven by the analog computer, display selection is achieved through trunkline patching.

CLASSROOM CONTROL UNIT

A remote control unit is used in the classroom to give real-time interactive control to the system user. A pictorial representation of this unit is given in Figure 4. It was designed to fill the dual objective of presenting to the user an extremely simple and yet versatile interface with the system while at the same time minimizing the hardware and software needed to support the unit. The AID Interactive Control Unit allows the user to:

(1) Set and change parameters.
(2) Set initial conditions.

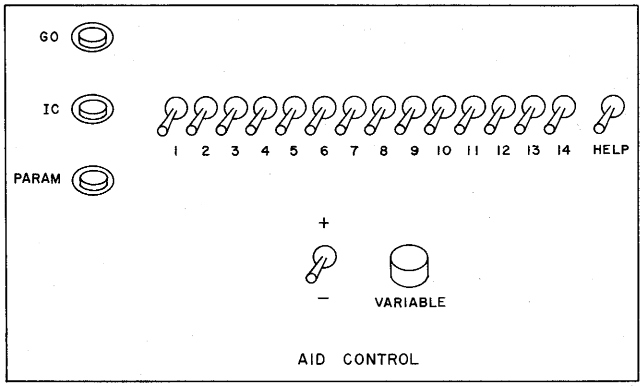

Figure 4—AID interactive control unit

(3) Choose a preprogrammed presentation mode, i.e., what variables will be displayed, what parameter will be variable, etc.

(4) Request HELP messages, e.g., switch assignments, presentation modes available and how to use them, etc.

A more detailed look at the classroom use of the AID Interactive Control Unit will be given in the following section.

All interactive parameter and initial condition values are entered into the system via a single potentiometer on the control unit. The analog signal from this potentiometer is read into the PDP-9 computer through a channel of the A/D converter in the hybrid computer interface. The digital computer then either sets the appropriate digital pot on the analog computer or changes a program variable. It also presents the classroom user with a "digital voltmeter" type display on one of the display units so that he can set the variable to the desired value. This visual feedback technique not only compensates for resistive voltage drop in the long lines to the computer room but also couples the class in with "the action" and visually indicates to the students the current value of the parameter being changed.

When a user initiated response is requested by depressing one of the three pushbuttons, a serial data stream containing information on the pushbutton depressed and states of the switches is transmitted over a single line to the Control Unit Interface in the computer room. When the complete message has been received, a program interrupt request to the PDP-9 computer is initiated. The computer responds to this interrupt and branches to an appropriate point in the AID program to carry out the requested response.

AN ILLUSTRATIVE EXAMPLE

Several segments from a presentation developed on coupled oscillators will be used to illustrate the type of typical interactive classroom use which can be made of the system. When first initiated, the system presents a title, a "what to do" message and then awaits further commands from the classroom control unit. For the example we are considering, the left-hand display would present "MASS-SPRING SYSTEM . . . FOR NORMAL SEQUENCING HIT 'GO' AT THE END OF EACH STEP . . . OTHERWISE USE 'HELP' SWITCH IN CONJUNCTION WITH 'GO' FOR DIRECTIONS." In normal sequencing, the first depression of the GO button takes the system to the parameter mode. In this mode the user can change any of the parameter values from those nominally entered. He does this by setting the appropriate switch, hitting the PARAM pushbutton and then adjusting the potentiometer on the control unit for the desired value while watching the "digital voltmeter" on the display. This is illustrated by the top display pair of Figure 5. The user is in the process of changing K3 from the nominally entered value of 1.0 to a new value of 0.100. The numbers in the ⟨ ⟩'s are the switch assignments for the parameters. Other parameter changes are made by repeating the above sequence. The next depression of the GO button takes the system to the initial condition mode. For this particular example, the user does not set any values for initial conditions but simply chooses the perturbations to be made on the mass-spring system. When the IC pushbutton is depressed, the masses are gently nudged to their initial condition position by AID's "helpful little computer hands." The middle display pair of Figure 5 illustrates the initial condition mode—it can be thought of as a snapshot of the displays as the hands are in the process of moving the masses to their initial condition positions (down for M1 and zero for M2). Subsequent depressions of the GO button take the system through various run modes such as the one illustrated in the bottom display pair of Figure 5. For the case shown, an animation of the bobbing mass-spring system is on one display while the corresponding displacement of each mass from equilibrium position is plotted on the other display. Other run sequences plot various combinations of accelerations, velocities and energies.

The above example illustrated the user following normal sequencing by repeated depressions of the GO button. By using the switches in conjunction with the GO button, the user can break the normal sequence and branch to any particular desired segment of the presentation. Through use of the PARAM and IC pushbuttons, parameters and initial conditions can be changed at any time during a presentation.

COMPUTER ROOM CONSOLE

A special console is used by the programmer in developing AID programs. It features dual displays whose characteristics are identical to those in the classroom, an AID Interactive Control Unit, and a Computek GT50/10 graphic tablet. Thus, all phases of program development ranging from initial image generation to final debugging and checkout can be done at the console.

The console, in conjunction with the AID Language, will not only make the programming of AID presentations convenient and easy but will also provide a stimulating environment in which to work. We are de-

pending on the latter attribute coupled with the drive for relevance and accomplishment on the part of today's students to supply a manpower pool to assist the instructional staff in developing AID presentations.

SOFTWARE SUPPORT

The AID Language under development to support the system is in an experimental phase and might best be described as a pseudo high-level language at this point in time. It has many of the appearances and attributes of a high-level language but has no compiler or interpreter. In its present form it is simply a collection of subroutines and symbol definitions that are used in conjunction with the PDP-9 assembly language programming system. This approach allows for changes to be quickly and easily implemented—an important consideration during the early experimental stages of developing a language. Its chief disadvantages are a slight awkwardness in the association of control variables with their commands—they must follow in a vertical string underneath the command—and the use of an octal rather than a decimal number system base. However, even in this experimental form the language is easy enough to use such that sophomore students can write program sequences.

The language provides commands for:

(1) Servicing the interactive control unit.
(2) Controlling the analog computer.
(3) Generating static and dynamic graphical displays.

It features an on-line mode which allows the program developer to perform the following functions interactively while sitting at the computer room console:

(1) Write his program in a conversational mode.
(2) Enter graphical images via a graphic tablet.
(3) Scale, move and synthesize graphical images.
(4) Generate, scale and move alphanumeric text displays.
(5) Tune up timing used in sequencing.

To illustrate the basic structure of the AID Language, an example AID program is given in Figure 6. This example shows how the top support, spring, and mass of the MASS-SPRING SYSTEM discussed earlier are generated. The analog computer is solving the differential equations governing the system in real-time. From these system variables, the analog computer generates the dynamic animation variables used to animate the static images stored in the PDP-9 computer. The dynamic animation variables are read into the digital computer on each pass through the program by the SAMPLE commands.

In order to avoid becoming prematurely display-bound in a system designed for real-time dynamic graphics it is essential that a continuous stream of data flow to the display. Compound images must not be constructed in memory and then displayed. They must be displayed as they are constructed. This philosophy is inherent in the instruction pair TRANSFER/CONTINUE. One point at a time is transferred from a source table to a specified destination—usually a display. During this transfer of the image from the source table, any of the AID manipulative commands placed between the TRANSFER and CONTINUE command operate on the image being transferred. All images which are to be dynamically displayed are stored centered around the origin of the coordinate system used for the displays. This system has its origin located in the center of the display area. Such an approach simplifies the definition and generation of the dynamic animation variables.

In the example of Figure 6 the image SPRING, which consists only of the zig-zag lines, was dynamically scaled in the x and y directions to convey the illusion of a spring being alternately stretched and then compressed. The invariant vertical segments of the spring were associated with the images TOP and MASS. Another, and even better approach, is to use the command ANIMATE in conjunction with two key frames stored in memory. In this case, the invariant vertical segments of the spring could be associated with the stored images of the spring rather than the mass and top support. The number of control variables would be reduced from three to two—one for translation and one to govern the amount of linear interpolation between the key frames specified by the ANIMATE command.

The header statement VIEW runs the program in real-time for direct viewing in the classroom or computer room. When making a film, this mode allows for previewing a sequence before it is actually recorded on film. Once a satisfactory sequence has been obtained, the statement CAMERA is substituted for VIEW and the system is ready for filming. The header statement CAMERA automatically slows the system timing down for filming at four frames per second and synchronizes the computer to the movie camera.

FUTURE PLANS

We view the AID System configuration of Figure 1 only as a starting point in our endeavor to couple the computer effectively into the classroom. For example,

```
LINE Ø/     NEW                  Initializes the system for a new run from t = 0

LINE 1/     VIEW                 Sets up timing, synchronization, etc. for real-
                                 time viewing

LINE 2/     CONFIGURATION DD     Sets up Configuration 1 - both displays driven
                                 by digital computer

LINE 3/     SAMPLE Ø             Sample A/D channel Ø and assign the value to the
LINE 4/     S1L                  variable S1L (Spring 1 Length Scale Factor)

LINE 5/     SAMPLE 1             Sample A/D channel 1 and assign the value to the
LINE 6/     S1W                  variable S1W (Spring 1 Width Scale Factor)

LINE 7/     SAMPLE 2             Sample A/D channel 2 and assign the value to the
LINE 10/    S1V                  variable S1V (Spring 1 Vertical Displacement)

LINE 11/    SAMPLE 3             Sample A/D channel 3 and assign the value to the
LINE 12/    M1V                  variable M1V (Mass 1 Vertical Displacement)

LINE 13/    TRANSFER             Transfer one point of the image from the source
LINE 14/    TOP                  table named TOP to the refreshed display and
LINE 15/    DISPLAY 2V           display in the vector mode

LINE 16/    CONTINUE             Continue the above initiated transfer until
                                 completed

LINE 17/    TRANSFER             Transfer one point of the image from the source
LINE 20/    MASS                 table named MASS to the refreshed display
LINE 21/    DISPLAY 2V           and display in the vector mode

LINE 22/    MOVE                 During the above initiated transfer, move the
LINE 23/    ZERO                 image in the X direction per the variable ZERO
LINE 24/    M1V                  (which has a value of Ø) and in the Y direction
                                 per M1V

LINE 25/    CONTINUE             Continue the above initiated transfer until
                                 completed

LINE 26/    TRANSFER             Transfer one point of the image from the source
LINE 27/    SPRING               table named SPRING to the refreshed display
LINE 30/    DISPLAY 2V           and display in the vector mode

LINE 31/    SCALE                During the above initiated transfer, scale the
LINE 32/    S1W                  image in the X direction per the variable S1W
LINE 33/    S1L                  and in the Y direction per S1L

LINE 34/    MOVE                 During the above initiated transfer, move the
LINE 35/    ZERO                 image in the X direction per the variable ZERO
LINE 36/    S1V                  and in the Y direction per S1V

LINE 37/    CONTINUE             Continue the above initiated transfer until
              .                  completed
              .
              .
            GOTO LINE 1
```

Figure 6—Illustrative example of AID programming

interest has been expressed by a group of students in tying the College's two wind tunnels into the PDP-9 for on-line control and data reduction. Once this has been accomplished it is but a small step to bring the thrill of direct on-line real-time experimentation into the classroom through use of the AID System. Another area of expansion under active consideration is a link to the IBM 360/50 at our computer center. This would open up new areas of application in which the problems are best cast in general or problem-oriented high-level languages such as FORTRAN, GPSS, NASAP, etc. In this mode of operation the classroom control unit would most likely be a typewriter-like keyboard. Still yet another area of expansion is in application programs resident in the PDP-9 itself. Work is under way in this area with program packages for deterministic and stochastic signal analysis (e.g., FFT algorithms, random number generators, etc.). In this as well as in the above cases, the structure of the AID Language will allow for efficient integration of the expansions into the AID System.

GOLD—A Graphical On-Line Design System

by L. J. FRENCH and A. H. TEGER

RCA Laboratories
Princeton, New Jersey

INTRODUCTION

Computer programs do not "design." They blindly follow procedures that the computer programmer thought should solve a given class of problems. However, the methods of solution for many design problems are not *a priori* known. Actively inserting the human in the design process can add the elements of experience, insight, and creativity to the computer's ability to perform rote design procedures and repeated checking operations.

Graphic displays are ideally suited to this combination of computer power and human intellect if, and we must emphasize only if, the application deals with large quantities of data that must be absorbed or modified graphically. Teletypes or text displays are inadequate to deal with these pictorial problems. Full graphic displays are the only practical mechanism to provide rapid creation of a complex picture that can be quickly understood by the designer.

We have developed a general system for Graphical On-Line Design that operates stand-alone on a small computer, and yet supports a large, powerful data structure partitioned for local disc storage. The data structure, described in more detail later, is capable of storing relationships needed for computer-aided design, including non-graphic as well as graphic information.

The GOLD system has been applied to the design of integrated circuit masks. IC masks, especially for large arrays, contain huge amounts of graphical data that cannot be checked by the human designer without some display or plot. Furthermore, attempting to correct the artwork for these masks from a file of text plotting statements is an error-prone and time-consuming process. The interactive graphical editing possible with GOLD is alleviating these problems.

We designed GOLD to be a user-oriented interface between the computer and the designer. As such, the graphical language used to modify the artwork has to be easy to understand and to use by an integrated circuit designer; it must correspond to the natural thinking process that the designer would use to make corrections by hand. Yet the graphical language must also be general enough to apply to other application areas, and to deal with a hierarchical data structure smoothly enough so that the user can take advantage of its power without needing to understand how the structure is organized.

Perhaps the two most significant contributions of the work described herein are the creation of an efficient, hierarchical data structure, and of general graphical editing techniques that incorporate application dependent parts within the confines of a small stand-alone computer. General purpose graphical systems and graphical editing systems for IC masks exist, some of which are listed in the references, but the GOLD system represents an attempt to achieve the generality of large graphical systems and the practicality of smaller IC mask design systems on a small stand-alone computer.

The data structure described herein is ring type and hence similar to that of McCarthy,[8] Sutherland,[1] and Wiseman[2] yet is different in design in that it is specifically partitioned for secondary storage and is efficient in core utilization both in storage of the data structure and of the data structure functions themselves. The SELECT and LOCK editing functions are new and represent attempts at overcoming refresh display hardware limitations (flicker) and providing convenient techniques for rapidly protecting and interacting with various hierarchical levels in the data structure.

SYSTEM DESCRIPTION

GOLD hardware system

The large capital investment and operating costs for large computers and the advent of inexpensive, relatively powerful mini-computers convinced us to utilize

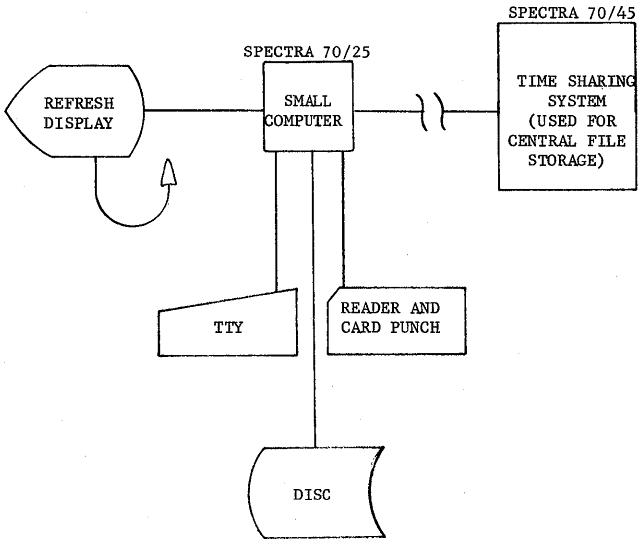

Figure 1—GOLD hardware system

a small computer in our interactive graphical design system. If such a system can perform a useful task, it might then be, and present evidence suggests that it is, economically justifiable.

The advantages of convenient and rapid interaction influenced our decision to utilize a refresh type display. A block diagram of the GOLD system is shown in Figure 1. The display is a refresh type, custom made by Information Displays, Inc. and is refreshed via a Spectra 70/25 computer having 32K bytes of memory with a 1.5 μsec cycle time. The input/output devices are a light pen, typewriter, card reader/punch, and a remote time sharing system. The disc is a single, 7¼ million byte capacity RCA 70/564 drive.

The philosophy of the GOLD system is that the fast secondary storage medium (disc unit in this case) can be utilized to provide access rates fast enough for rapid on-line interaction with a very large data base. The small computer can operate on a stand-alone basis, not simply as a display controller.

Computer-aided design system for integrated circuit masks

The GOLD system is compatible with other techniques for creating and editing integrated circuit artwork that have been developed at the RCA Solid State Division in Somerville, New Jersey. Two of these techniques are a digitizer system and a user-oriented mask description language, called PLOTS. The digitizer system captures a mask description by physically tracing a drawing point by point. The mask description obtained is stored in central files of a time sharing system. These files can be accessed by GOLD, where they can rapidly be displayed, edited, and stored either locally, or returned to the time sharing system.

PLOTS, also developed at RCA Solid State Division, is an artwork language used to describe drawings interactively on the time sharing system via a teletype. The files of PLOTS statements can similarly be accessed by GOLD for interactive graphical manipulation with the option of returning the modified files to the time shared system. An output program can convert either PLOTS or digitizer files to drive high accuracy plotters to obtain finished artwork. The compatibility that GOLD has with these two artwork systems gives a mask designer the flexibility of being able to select the best editing system for any part of a mask design.

GOLD software system

A block diagram of the GOLD software system is shown in Figure 2. Mask descriptions can be entered via the on-line typewriter, light pen, cards, or from a time sharing file. The mask description is processed by the input language compiler which checks syntax and produces object code for the Data Structure Compiler (DSC). The DSC builds a partitioned hierarchical data structure using a ring type language and a set of subroutines which provide techniques of creating and traversing partitioned ring type data structures. Figure 2—GOLD software system

partitioned data structure contains the accurate and hierarchical description of the application being undertaken and provides a general interface for all data manipulations.

The Picture Compiler (PC) is a recursive program that traverses the partitioned data structure and creates a binary display file within the confines of the user supplied specifications (see the display function in the third section). The binary display file is contained in part of main memory and is used to refresh the display to produce a picture. The picture compiler inserts into the binary display file markers that provide the hierarchical connection between the binary picture representation and its corresponding description in the data structure.

The light pen aids in graphical interaction by detecting light and interrupting the processor. The light pen interrupt is processed via the Identification Program which blinks the identified entity and provides the link to the actual representation of the entity in the data structure. The Graphical Editing Functions use the information supplied by the Identification Program to gain access to the data structure and all editing is performed on the data structure using the PRSP language and corresponding functions. Finally, the output programs traverse the data structure, again using PRSP, and provide an output mask description on either cards or in a time sharing file.

The data structure and data structure language

The data structure that has been designed and implemented within the GOLD system is a partitioned ring type data structure. It has the capability of containing 500K bytes of data which is partitioned into 128 segments in secondary storage. The data structure provides the capability of storing graphical information and hierarchical relationships. All mask coordinates are stored in a floating point notation created specifically for the Spectra 7Ø/25 and all floating point operations are performed via software due to the absence of hardware. Any graphical entity can be edited and entities can be combined into higher ordered entities within the data structure.

Any entity can be locked or selected, which in the data structure simply corresponds to a few bits being set in the proper entity. If an entity has been locked, editing will not be permitted on that entity. If an entity that is locked is pointed to by the light pen, the identification program automatically identifies the next higher unlocked entity. Thus, the lock function provides the graphics user the capability of controlling what can be edited and on what hierarchical level identification should initially occur. Each entity in the data structure has a bit which can be set to indicate that the entity has been selected. Presently this general data structure function has been employed only in displaying entities as discussed in the third section. Select is a general function which allows a user to select a class of data structure entities for any desired operation.

The data structure language (PRSP) provides a general language for creating and traversing partitioned ring type data structures. It is a new language based primarily on the work of Wiseman and Hiles of the University of Cambridge in England. PRSP is a macro language that expands into subroutine calls on 32 different data structure functions to provide full data manipulation capability with a common but well specified interface. Perhaps most noteworthy of all is that the data structure subroutines and the file management program occupy only $1ØØØ_{16}$ bytes of core. Core is at a premium in a small computer and the size of any program must be weighed very carefully against the power the program adds to the overall system. Each function in PRSP has been designed to provide the greatest capability in the least amount of core storage. In PRSP the programmer has the capability of partitioning his data structure on secondary storage to suit his particular circumstances. For the GOLD system a partitioning algorithm was selected to minimize disc I/O for operations on a specific mask level.

The file management routines in conjunction with PRSP provide rapid access to secondary storage for program overlays as well as for data structure operations. If a small computer is to handle 500K bytes of data structure and all the programs to provide a stand-alone system, the secondary storage retrieval time is crucial to the success or failure of such a system. In the GOLD system the average access time per segment (4120 bytes of information) is about 55 msec. This is fast considering that the disc rotation time for the raw information is 31 msec. PRSP can handle any number of data structure segments in core. However, present core size has limited this to two data structure segments. The file management routines calculate a "success factor" for each data structure segment in core. Whenever a data structure function requests a segment that is presently in core, the success factor is incremented by one. Whenever a segment is requested that is not in core, the least successful segment is overwritten by the new segment. In the fourth section the results of two file management algorithms are discussed.

Picture compilation

In the GOLD system the picture compiler compiles a picture as constrained by the user. Since the amount

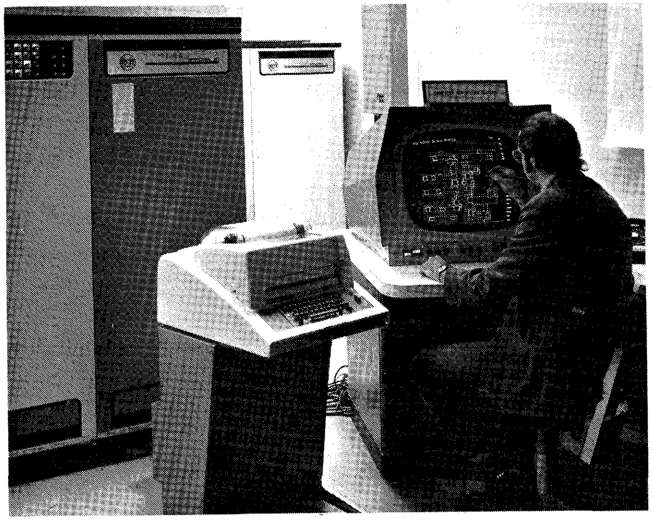

Figure 3—Display hardware layout

of data involved in a mask description may be roughly ½ million bytes, it is impossible to maintain the entire mask description in a display file in core. Thus, the user specifies what part of the mask he wishes to see and the picture compiler provides that specific display file by traversing the data structure. One of the functions the picture compiler performs is zoom (windowing). While our display does not have hardware zoom, software zoom would be required to provide a reasonably sized display file. The speed of the picture compiler is the most critical of all programs since it affects the interaction time of the system. An evaluation of the picture compiler program is contained in the fourth section.

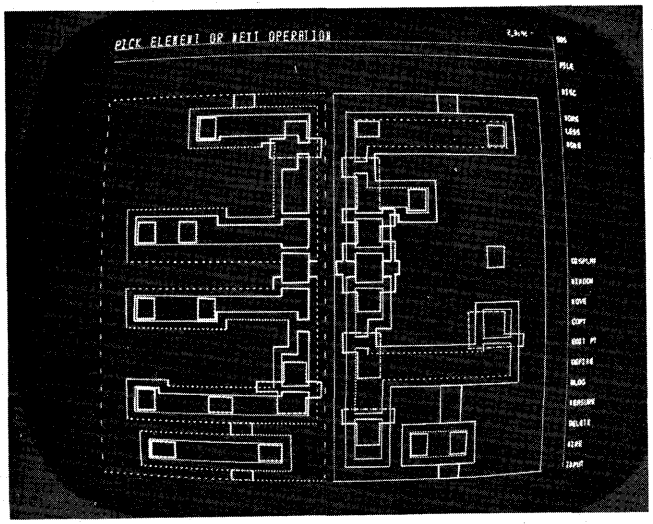

Figure 4—Display screen showning an IC design with 3 mask levels superimposed. There is no display flicker

GRAPHICAL CAPABILITIES

A user of the GOLD system wants to modify the artwork for a given set of masks by making additions or corrections to it. He therefore needs to access the files containing the artwork description, choose the portion to be displayed, and then be able to do the actual editing operations. GOLD provides a set of graphical tools to perform these functions. The light pen is used to pick operations, identify parts of the drawing, and perform many of the manipulations. The user inputs lengthy text messages such as personal file names or identification with the on-line typewriter. Figures 3, 4 and 5 show examples of display usage.

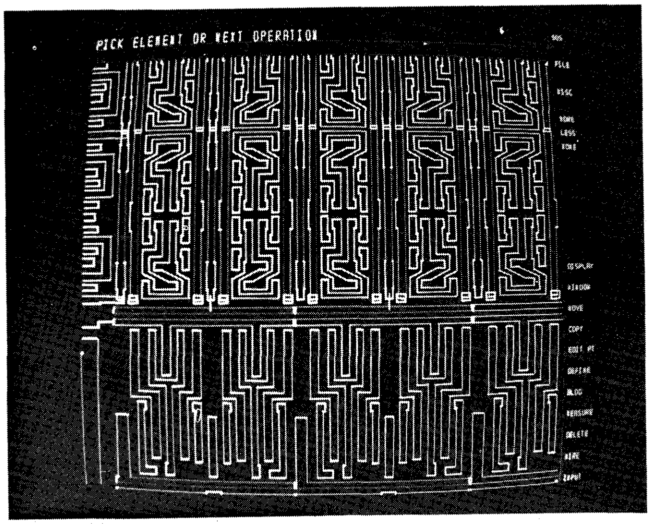

Figure 5—Display of part of a complex mask (zoom used). Flicker is evident

The display screen is divided into three functional areas. On the right side of the display, the menu of command choices is shown. These choices change as the user performs a given function so as to guarantee that only legal commands can be picked at any step in the process, and to provide detailed commands for each general function requested. At the top of the screen, system messages are displayed to guide the user in choosing the correct sequence of operations, and to issue error messages when needed. Error messages are blinked to attract the user's immediate attention; normal requests to indicate the next step are not blinked.

Beneath the message line is a line that can contain temporary information for the user, such as x,y data, and in which the user composes various light pen responses for the system. The third and largest functional area, occupying the central portion of the screen, displays the picture requested by the user. The actual editing changes are seen here.

File access

By pointing the light pen at the command FILE, the user has a choice of retrieving artwork files in various formats. For example, PLOTS files, consisting of "English-like" plotting statements, can be accessed via the local card reader or from remote files on the time sharing system. The system allows the user to define and repeatedly call graphical subroutines of any degree of complexity. These calls may be nested up to 10 levels deep in PLOTS, however, the nesting is unlimited in the data structure used by GOLD.

Another input format is the data structure itself. The user may store files on the local disc or on cards with all the structural information added during the graphical design session, and then retrieve the files for later enhancement.

Display creation

Having read in a file, a user has several tools for creating the desired display. He can specify which mask level should be shown, or request a combination of any number of mask levels. The line structure for each mask level can be individually chosen as either solid, dotted, dashed, or dot-dashed. Thus, he can check alignment of entities between mask levels, and still distinguish, by the line structures, which level each shape is on.

The WINDOW function permits a user to zoom in or out on any section of the artwork. To zoom in, he uses the light pen to position a tracking mark at the origin of the desired window. The absolute x,y value in mils of this coordinate is displayed as a numeric check. He draws a square with the light pen indicating the area he is interested in. When satisfied, he points to an OFF button attached to the tracking mark, and the area within the square is enlarged to full screen. Whichever mask levels and line structures were displayed before are retained after the windowing operation. The zoom feature permits a user to work on large drawings to whatever precision he desires by magnifying that section of the artwork and consequently overcoming the inherent inaccuracies of any graphical display. The zoom operation is performed on the data structure so that full precision is maintained in the display file. At any time, the user may point to a light button requesting full artwork size. This gives in effect a quick zoom out to display the full artwork.

The major problem in the GOLD system is display flicker, that is, the amount of information that can be displayed. Presently the system has memory space to display 2000 vectors while flicker occurs at about 800 vectors. The fact that new display hardware currently available is a factor of 2 or 3 faster than our display would aid in this problem but certainly would not solve it. The functions WINDOW and SELECT (described under Editing techniques) in some cases solve the problem by allowing the user to remove unnecessary parts of the drawing from the screen in order to eliminate confusing detail and reduce flicker. However, in other cases the user cannot eliminate parts (or enough parts) of the picture and needs to display 4000 to 5000 vectors without flicker. Some of the users who originally thought they could do little, if any, editing without seeing large quantities of the picture at a time, have since learned to think about mask design in a different fashion and have found they can do a great deal of work in a piecewise manner.

Editing techniques

All the graphical functions can operate on any entity displayed on the screen. The lowest level (atomic) entities are lines, simple polygons and orthogonal polygons. The system will treat a light pen hit on any vector on the screen as though the entire entity had been identified and will blink that entity. For example, a hit on a side of a complicated polygon will cause the entire polygon to blink, and the user, having visually verified that he does mean that polygon, can now modify the polygon via one of the graphic functions.

The general editing functions encompassed by the system are building block, move, copy, delete, rotate, measure, input and select.

1. BUILDING BLOCK

The power of graphical interaction lies in being able to create and operate on more complicated entities. The user, by pointing at the words BLDG BLOCK (a light button in the menu), can designate any number of atomic entities and previously defined building blocks as a new building block. The entities may be connected or unconnected, and may be from several different mask levels. The new building block is placed in the data structure to indicate its relationship to the rest of the artwork. Building blocks may be nested to any desired degree.

In order to use these building blocks, the light buttons MORE, LESS and NONE are part of the menu. On a light pen hit, the lowest level non-locked entity will blink on the screen. Pointing at MORE tells the system to move up to the next level of complexity in the data structure, i.e., the next higher building block. This can be repeated till the most complex building block, of which the original vector is a part, is blinking. Whatever is blinking at a given time can be operated on by any one of the graphical functions. LESS steps downward in complexity through the building blocks, and NONE stops everything from blinking.

2. MOVE

Any blinking entity (entity and building block will be used synonymously from this point on) can be moved using the light pen. A tracking mark appears on the reference point of the entity. By pointing at the tracking mark, the user moves the entire entity across the screen. The x,y location of the tracking mark in mils is shown at the top of the screen as a numeric check. The user can constrain the motion to x only, or y only, at any time. When the light pen is released, the entity "jumps" to the nearest user-defined grid location. This grid, which can be changed whenever desired, permits smooth tracking of entities, and yet precise positioning to any degree of coarseness. The user can also step the entity in increments of this grid horizontally or vertically.

The user may specify the absolute x,y position where the entity should be moved or he may give a numerical increment (up, down, right or left). In these cases the entity jumps to the new position and the absolute x,y location is again displayed on the screen.

When satisfied, the user points to 'OK' to finalize the change.

3. COPY

Any degree of complexity of building blocks may be copied. The user identifies the desired entity, checks that it is blinking, and requests a copy. The copy is drawn, slightly displaced from the original, and MOVE automatically called to operate on the copy.

4. ROTATE

The user may rotate certain entities in increments of 90°, and may mirror them about the x or y axis. All eight possibilities of mirroring and rotation are available.

5. DELETE

Any identified (blinking) entity may be deleted.

6. MEASURE

The tracking mark provides a numeric check on any x,y location on the screen. The optional imposed grid and x only, or y only, tracking constraints are the same as those described in MOVE.

7. INPUT

This function allows the user to create new atomic entities, namely lines, simple polygons or orthogonal polygons. The user specifies which mask level the new entity is to appear on, and a desired width if the entity is a line. Lines are drawn as a center line representation to reduce clutter on the screen, and can have an optional orthogonality constraint applied. Simple polygons may have sides at any angle, although the tracking mark can be used to make any given segment horizontal or vertical. The system will guarantee closure of both simple and orthogonal polygons, or give an error message if not possible. The special case of rectangles is handled by allowing the user to fix one corner of the new rectangle with the tracking mark, and then move the diagonally opposite corner (via the tracking mark) to draw in one motion all four sides. All x,y values are continually displayed at the top of the screen while these entities are being drawn.

8. SELECT

In order to reduce clutter and to minimize flicker on the display, the user can select any number of entities with the light pen. He then can choose to display *only* the selected entities, to blank *only* the selected entities, or to display all entities. The system reminds him of how many entities are selected at any given time. This feature permits work on complicated artwork at full size without destroying the sanity of the user.

File storage

During a design session, the entire data structure may be stored temporarily in any of four work areas on the disc. This allows the user to try different modifications of the job, and still be able to back up to any of these previous check points if desired.

After editing is complete, the file may be stored locally in data structure form, or converted back to PLOTS and stored on the time sharing system or cards. From the time sharing system, the files may be plotted on either of two high accuracy flat bed plotters to produce the final artwork for the masks.

SYSTEM EVALUATION

All editing functions in the GOLD system are performed on the data structure using PRSP and require no more than at most a few seconds. As explained in the second section, the interaction rate of the system is critically dependent upon the picture compiler. The picture compiler program extracts entities on the user specified mask levels, handles the SELECT and LOCK functions, performs scaling, rotation, all windowing, and the creation of a binary display file with embedded data structure markers. The picture compilation time varies in a rather complicated fashion from a few seconds to a maximum of about 1½ minutes with the average being about ½ minute. As an example, to create a display file of 800 vectors, the picture compiler requires 15 seconds.

A memory array designed at RCA Laboratories by J. Meyer and N. Kudrajashev using the GOLD system has been used as a benchmark to evaluate the operation of the system. The circuit is a 256-bit random access CMOS/SOS memory chip which measures 144×173 mils. The description consists of 7 mask levels and approximately 17,ØØØ points. To evaluate where the picture compile time is spent, measurements were made on the picture compilation of all mask levels with everything inside the window. In the actual operation of the GOLD system this picture compilation would terminate abruptly when the display file core space was exhausted. To overcome this, the picture compiler was temporarily patched such that the actual binary display file words were discarded. *Thus, this compilation represents a situation that cannot exist in practice but does give a worse case evaluation that is an order of magnitude worse than actual conditions.*

Using a file management algorithm which handles only one piece of data structure in core at a time, the picture compilation required a total of twenty minutes. We must stress that this is not a real case. The amount of information here (all parts of all mask levels) is far more than the user could visually understand or work with on a refresh display, and more than could fit in any display file.

The picture compile time distributes as follows:

DISC I/O

TOTAL DISC TIME = 2.71 MINUTES
= 13.6 PERCENT OF TOTAL TIME

TOTAL # OF DISC I/O = 2937

FLOATING POINT OPERATIONS
(software subroutines)

# ADD'S = 157,984	(1.46 msec/ADD)
# MULT'S = 60,225	(1.36 msec/MULT)
TOTAL # = 218,209	

TOTAL FLOATING POINT TIME
= 5.22 MINUTES
= 26.1 PERCENT OF TOTAL TIME

DATA STRUCTURE OPERATIONS

TOTAL # OPERATIONS (FUNCTION CALLS)
= 393,339

TOTAL D.S. OPERATION TIME
= 7.0 MINUTES
= 35 PERCENT OF TOTAL TIME

OTHER COMPUTE TIME
(EXCLUDING ABOVE)

= 5.07 MINUTES
= 25.3 PERCENT OF TOTAL TIME

The entry labeled "OTHER TIME" accounts for the decision making time of the picture compiler. The average instruction execution time of the 70/25 is approximately 20 μsec. Thus, in twenty minutes this is about 2.4×10^9 executed instructions. These numbers show two significant things. First, the amount of information contained in integrated circuit artwork is enormous. Second, it is important to notice that the disc I/O time, even with the very simplest of file management algorithms as used in this measurement, is relatively small. This is impressive considering that the entire GOLD system operates on both the data structure and all programs in a partitioned (virtual memory) environment.

The same picture compilation was rerun using a file management algorithm that manipulates two data structure segments in core at a time. This algorithm reduced the number of *disc I/O's to 759 and a total disc time of .7 minutes.* This reduced the overall compile time to 18 minutes, such that the *disc I/O time was only 3.9 percent of the total compilation time.* While this algorithm reduces the disc I/O time significantly, the overall effect on the system time is small. The conclusion to be drawn from this is that the GOLD system is not disc limited as one might anticipate from a virtual memory system. Part of this is due to the design of the data structure, part to the design of the file management routines, part to the disc file organization, and part due to the fact that the 7Ø/25 is a moderate, if not slow, computer. To explain the latter point in more detail, it is possible that many of the modern mini-computers could decrease the average instruction execution time by roughly an order of magnitude. Some have hardware push down stacks which would significantly decrease the time, perhaps even more than the ten to one reduction in the faster instruction set. In any case a faster instruction speed would decrease the PRSP and OTHER TIME by a factor of ten but would have no effect on the disc I/O time. The times for the various items would then be as follows:

DISC I/O

# READS=759	UNCHANGED
TOTAL DISC TIME =.71 MINUTES=12.8 PERCENT	

FLOATING POINT OPERATIONS

# ADD'S=157,984	(1 msec/ADD)
# MULT'S= 60,225	(1 msec/MULT)

TOTAL #=218,209

TOTAL F.P. TIME
=3.62 MINUTES=65.3 PERCENT

PRSP FUNCTIONS

TOTAL # OPERATIONS=393,339

TOTAL TIME
=.7 MINUTES=12.8 PERCENT

OTHER TIME
=.51 MINUTES=9.1 PERCENT

TOTAL COMPILATION TIME
=5.54 MINUTES

These last figures show that if the computer was a modern mini-computer, the disc I/O time would become a somewhat more significant part of the system time but would still be relatively unimportant. Another way of viewing this is that if the system described above had infinite core, such that the disc I/O time was zero, it would only be 12.8 percent (disc I/O part) faster.

These figures also show the usefulness of floating point hardware. If the system described above had 10 μsec floating point hardware instructions, the total floating point time would be 2.18 seconds instead of the 3.62 minutes required by the software floating point operations. This would increase the overall speed of the system by approximately 65 percent and reduce the total compilation time to less than 2 minutes. Thus, a modern mini-computer with floating point hardware would have more impact than a mini-computer with a large memory capacity.

One of the problems generally encountered in the utilization of list type data structures is the large amount of overhead storage required due to pointers, etc. In the GOLD system significant effort has gone into creating an efficient data structure while maintaining the advantages of list type structures. In many list type data structures it is not uncommon for the data structure to require 10 times more storage than the raw data alone (canonical form). The GOLD data structure, for the benchmark integrated circuit previously described, requires 71,677 bytes of storage. The canonical raw data form (non-structured) requires 25,158 bytes of storage. This is a ratio of 2.8 to 1, which shows that the data structure is rather efficient in storage utilization. Recent work in this area has resulted in relatively simple techniques (simple in implementation) which will reduce the storage from 71,677 bytes to approximately 56,000 bytes, and would make the ratio 2.2 to 1. The size of data structures at this point presents little problem to the GOLD system. The mask description for the benchmark integrated circuit is one of the more complicated circuits being designed yet only uses about 15 percent of the available data structure storage.

SUMMARY

The GOLD system has been utilized on an experimental basis for about one year. Most users have found the system easy to learn, and to use. However, all users have required some training, to varying degrees, to utilize the system's more sophisticated capabilities.

We have overcome the basic inaccuracies of the display hardware by providing continual numeric checks, a quantized user grid, and zooming ability. The power of GOLD is illustrated by building block, which gives the ability to work with functional units as a whole, and to define new functional units dynamically. Thus, the user can, for example, apply all the graphical manipulations to a line or to the transistor it belongs to, or to the circuit the transistor belongs to, etc.

The system offers very rapid and convenient interaction and is compatible with all other parts of the overall CAD system for integrated circuit artwork. We believe the GOLD system proves that it is possible and economically desirable to utilize a small computer on a stand-alone basis to provide a large, sophisticated, hierarchical data structure and graphical system.

ACKNOWLEDGMENTS

The authors wish to express their appreciation for the programming contributions to GOLD made by M. Gilchrist, J. Grabowski, G. Held, F. Larkin, C. Neroth, G. Payor, and H. Schnitzler. N. Wiseman and J. Hiles of Cambridge University, England, aided in the original version of the data structure routines, and M. Lewin designed and debugged the computer-display hardware interface. The cooperation of J. Miller and D. Ressler contributed to making GOLD compatible with RCA Solid State Division's artwork systems. Finally the support of G. B. Herzog and B. Lechner of RCA Laboratories made this work possible.

Establishing lower bounds on algorithms—A survey

by E. M. REINGOLD

University of Illinois
Urbana, Illinois

INTRODUCTION

Algorithms for various computations have been known and studied for centuries, but it is only recently that much theoretical attention has been devoted to the analysis of algorithms. Turing machines and recursive functions were the first approaches, but these models, which provide much interesting mathematics, do not look at the problem from a practical standpoint. In "real" computing, no one uses Turing machines to evaluate polynomials or to multiply matrices, and little of practical significance is obtained from that approach. On the other hand, recent work has led to more realistic models and, correspondingly, to more practical results. Most of the results cannot be considered to be truly practical, but, all of them were motivated by practical considerations.

This survey is concerned with efforts to establish lower bounds on the number of operations required to solve various practically inspired problems; in particular we discuss the problems of sorting, searching, merging, root finding, polynomial evaluation, matrix multiplication, and many others. No theorems will be rigorously proved; for some the idea of the proof will be presented, and most will only be stated. The reader is urged to pursue in the literature the details of any topics which interest him.

In the establishment of lower bounds on algorithms we must consider the following questions:

- What function or class of functions is to be computed?
- What class of algorithms is allowed?
- With what are we measuring lower bounds?

The answers to the last two of these questions are inherently interwoven with the answer to the first question. In analyzing sorting we will consider different things important than in analyzing matrix multiplication, and so in each case we will allow different kinds of algorithms and we will measure their efficiency in different ways.

Even for a specific answer to the first question, how the efficiency of an algorithm should be measured is not obvious. Ideally, we would like to assign a realistic cost to every operation performed; such a model usually makes the establishment of lower bounds too difficult. To simplify the problem, we isolate the "key" operations and ignore all others. There are two ways to count the operations used by an algorithm: the number used on the worst case input or the expected number used on a random input, assuming some distribution of the inputs. An algorithm is *minimax optimal* or *worst case optimal* if no algorithm is more efficient in the worst case; an algorithm is *minimean optimal* or *average case optimal* if no algorithm is more efficient in the average case.

It should be noted that some of the results discussed here have never been formally published, but have become a part of the "folklore" of the area; in such cases the citation will be to the place they first found their way into print—usually a textbook. Moreover, this survey is not complete: to include every known result would give the paper undue length; in addition, many results undoubtedly remain unnoticed, buried in journals, technical reports, and unpublished manuscripts.

NOTATION

The floor and ceiling operations are defined as usual: $\lfloor x \rfloor$ is the greatest integer less than or equal to x, and $\lceil x \rceil$ is the least integer greater than or equal to x. We use the standard notation for the order of magnitude of a function: $f(n) = 0(g(n))$ if there is a constant $k > 0$ such that

$$\limsup_{n\to\infty} \frac{f(n)}{g(n)} = k.$$

If the limit

$$\lim_{n\to\infty} \frac{f(n)}{g(n)} = k$$

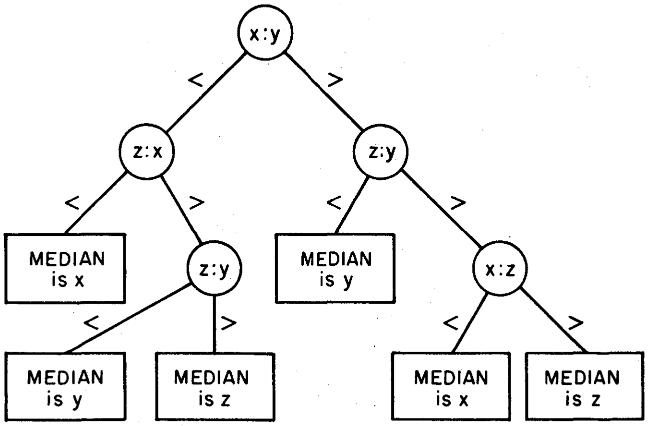

Figure 1—An extended binary tree representing the computation of the median of three numbers x, y, and z

exists and $k=1$, we say that $f(n)$ is asymptotic to $g(n)$, written $f(n) \sim g(n)$; if $k=0$ then we say that $f(n)=0(g(n))$.

The symbol "lg" is used to represent logarithms base 2, while "ln" is used for natural logarithms. We use "log" as the generic term when the base is unimportant.

COMBINATORIAL PROBLEMS

In studying the complexity of algorithms for combinatorial problems such as sorting, finding the median, merging, and others, we will allow algorithms to have only pairwise, errorless comparisons and no other operations. It is convenient to represent the algorithms as *extended binary trees* (like flowcharts), an example of which is shown in Figure 1. Each *internal node*, drawn as a circle, represents a comparison between two numbers (inputs or constants) and each *external node*, drawn as a rectangle, represents a possible outcome of the algorithm. Thus Figure 1 is the tree corresponding to an algorithm to find the median of three numbers x, y, and z.

The *height* of the tree corresponds to the number of comparisons used in the worst case. The *external path length* of a tree is defined as the sum of the distances from the root to each external node; thus if there are n external nodes, the external path length is n times the average number of compares, assuming all outcomes are equally probable. Both the worst case and the average case provide reasonable measures of efficiency. The following are useful:

Lemma 1:

The minimum external path length of an extended binary tree with n external nodes is $n\lceil \lg n \rceil + n - 2^{\lceil \lg n \rceil}$.

Lemma 2:

The minimum height of an extended binary tree with n external nodes is $\lceil \lg n \rceil$.

A complete discussion of most of the results discussed below can be found in Knuth.[Kn72]

Sorting

Suppose we are given a set $\{x_1, \ldots, x_n\}$; what is the minimum number of comparisons required to determine the permutation π so that $x_{\pi(1)} < x_{\pi(2)} < \cdots < x_{\pi(n)}$? Let $S(n)$ denote the minimum number of comparisons needed to rank n distinct inputs according to some ordering, then we have

Theorem 1:

$\lceil \lg n! \rceil \leq S(n) \leq 1 + n\lfloor \lg n \rfloor$ and thus using Stirling's approximation we have that $S(n) \sim n\lfloor \lg n \rfloor$.

The upper bound follows from some of the better algorithms for sorting, for example, the *binary insertion sort* first observed by Steinhaus[Stei50] before the advent of computer sorting. The lower bound is derived from Lemma 2 and the observation that each permutation of the n inputs must cause termination at a different external node of the tree. This is a "standard" information theoretic argument which says that given k outputs at least $\lceil \lg k \rceil$ binary decisions are required to distinguish between them. This argument appears to have been discovered independently by several authors but first appeared in Steinhaus.[Stei58]

There has been considerable work in refining the upper bound. Most notably, Ford and Johnson[Fo59] have developed a method of sorting which Hadian[Ha69a] showed required

$$\sum_{k=1}^{n} \left\lceil \lg \frac{3}{4} k \right\rceil$$

comparisons to sort n inputs in the worst case. Knuth[Kn72] has called this the *merge-insertion sort.* Comparing Hadian's result with Theorem 1 we find that the merge-insertion sort is optimal for $n \leq 11$ and $n=20, 21$ but that it requires more than $\lceil \lg n! \rceil$ comparisons for other values of n. Wells,[We65] using a computer, has shown that it is also optimal when $n=12$. Summarizing, we have

Theorem 2:

$$S(n) = \sum_{k=1}^{n} \left\lceil \lg \frac{3}{4} k \right\rceil \quad \text{for} \quad n \leq 12 \quad \text{and} \quad n=20, 21.$$

Define $\bar{S}(n)$ to be the minimum average number of comparisons required to sort n items. As before, we must have $n!$ external nodes and so by Lemma 1

$$\bar{S}(n) \geq \frac{1}{n}\,(n\lceil \lg n\rceil + n - 2^{\lceil \lg n\rceil}).$$

Letting $\lceil \lg n\rceil = \lg n + \theta$, $0 \leq \theta < 1$ this becomes

$$\bar{S}(n) \geq \lg n + 1 + \theta - 2^{\theta}, \qquad 0 \leq \theta < 1.$$

Since in $[0, 1]$ the function $1+\theta-2^{\theta}$ has a range of $[0, .08^{+}]$ we have

Theorem 3:

$$\bar{S}(n) \geq \lg n! + 0(1) = n \lg n - n/\ln 2 + 0(\log n).$$

Theorem 3 was first observed by Gleason[Gl56] and first published by Kislicyn.[Kis62,Kis63]

Searching

If we are given a sorted set $x_1 < x_2 < \cdots < x_n$, how difficult is it to determine in which of the $n+1$ ranges y lies? Let $s(n)$ be the minimum number of comparisons to do the searching. The binary search algorithm, first noted by Steinhaus[Stei50] requires $\lfloor \lg n\rfloor + 1$ comparisons. Applying Lemma 2, we see that $\lceil \lg(n+1)\rceil$ comparisons is a lower bound; since $\lceil \lg(n+1)\rceil = \lfloor \lg n\rfloor + 1$, we know that binary search is optimal in the worst case.

Sandelius[Sa61] noted that binary search is also optimal in the average case: applying Lemma 1 as before we see that the minimum possible average is $\lg(n+1)+0(1)$ and binary search achieves that bound.

A somewhat related problem is the discovery of the single counterfeit coin, either heavier or lighter, in a group of n coins; this problem is well known in the literature of recreational mathematics. One is usually allowed to use a balance scale and hence the comparisons are of linear functions, over $\{-1, 0, 1\}$, of the inputs rather than just pairwise comparisons. One optimality result for this problem is due to Smith[Sm47] and he has shown that when $n = (3^k - 1)/2$, k such comparisons are necessary and sufficient.

Merging

Given two sorted sets $A_1 < A_2 < \cdots < A_m$ and $B_1 < B_2 < \cdots < B_n$ (all distinct) what is the best way to merge these into a single sorted set $x_1 < x_2 < \cdots < x_{m+n}$? Since the $n+m$ elements are all distinct, there are $\binom{m+n}{m}$ ways the A's may appear among the B's. Thus by Lemma 2, if $M(n, m)$ is the minimum number of comparisons required to do the merging,

$$M(n, m) \geq \lceil \lg \tbinom{m+n}{m} \rceil.$$

A simple upper bound on $M(n, m)$ is $m+n-1$ since the "usual" merging algorithm outputs at least one element for each comparison; the last element requires no comparisons. Hwang and Lin[Kn72] have developed a much better merging algorithm which requires

$$m + \left\lfloor \frac{n}{2^t} \right\rfloor - 1 + tm \quad \text{where} \quad m \leq n \quad \text{and} \quad t = \left\lfloor \lg \frac{n}{m} \right\rfloor$$

since this is less than $\lceil \lg \binom{m+n}{m} \rceil + \min(m, n)$ we have

Theorem 4:

$$\lceil \lg \tbinom{m+n}{m} \rceil + \min(m, n) \geq M(n, m) \geq \lceil \lg \tbinom{m+n}{m} \rceil.$$

When $m = 1$, merging becomes a simple search and so

$$M(1, n) = \lceil \lg(n+1) \rceil.$$

When $m = 2$, the analysis of merging is quite difficult; Graham[Gr71] and Hwang and Lin[Hw71] have independently shown that

$$M(2, n) = \left\lceil \lg \frac{7}{12}\,(n+1) \right\rceil + \left\lceil \lg \frac{14}{17}\,(n+1) \right\rceil.$$

By the construction of what Knuth[Kn72] calls an *oracle*, Karp and Graham independently showed that

$$M(n, n) = 2n - 1.$$

An oracle is a hypothetical device which constructs a worst case for any possible algorithm; in other words, it acts as an adversary to the algorithm, forcing the algorithm to do the maximum possible work. The oracle in this case is $A_i < B_j$ if and only if $i < j$.

Selection

Suppose that there are n inputs and we want to know which is the k^{th} best in a ranking; Hadian and Sobel[Ha69b] have termed this the "selection problem." On the other hand, if we wish to know the k best and their ranking, they call this the "ordering problem."[Ha70] When $k=1$ and $k=2$, the ordering and selection problems coincide and a minimal solution for one is also a minimal solution for the other.

The case $k=1$ is trivial and a simple induction argument shows that $n-1$ comparisons are required. Rabin[Ra71] has shown that in the case $k=1$, that is, computing the maximum, $n-1$ comparisons are necessary even if comparisons may be made between any analytic functions of the inputs. For $k=2$, the problem of determining the minimal number of comparisons was first posed by Steinhaus in 1929. Schreier[Schr32] first stated the solution to this problem, but with an incorrect proof. Slupecki[Sl51] gave another incorrect proof. The first correct proof was given by Kislicyn[Kis64] by means of an oracle; he proved that

$n-2+\lceil \lg n \rceil$ comparisons were necessary and sufficient to find the second largest element in a set.

Recently, Blum, Floyd, Pratt, Rivest and Tarjan (personal communication) have developed a remarkable algorithm which finds the k^{th} largest element in a set of n elements in $0(n)$ comparisons in the worst case, regardless of k. Prior to the development of this algorithm it was commonly conjectured that the median of a set of n elements could not be computed in fewer than $0(n \log n)$ comparisons in the worst case. It was known[Van70] that it could be done by an algorithm in which the *expected* number of comparisons was $0(n)$; but in the worst case this algorithm requires more than $0(n)$ comparisons.

Summarizing these results, let $V_k(n)$ be the smallest number of comparisons required to find the kth of n elements, then we have

Theorem 5:

(a) $V_1(n)=n-1$
(b) $V_2(n)=n-2+\lceil \lg n \rceil$
(c) $V_k(n)=0(n)$ for all k.

Pohl[Po69] approached the selection problem in an entirely different way, showing that at least $\min(k, n-k+1)$ storage locations are required to determine the kth of n elements.

ALGEBRAIC PROBLEMS

In this section we will discuss the minimum number of arithmetic operations required to compute various functions. The arithmetic operations we will allow are addition, subtraction, multiplication, and division; no other operations (comparisons, exponentiation, etc.) will be allowed. To make an analysis, we need a precise definition of what algorithms are allowed.

Let $\circ$ denote any of the arithmetic operations addition, subtraction, multiplication or division. A *scheme* is defined as a sequence of operations

$$P_i = Q_i \circ R_i \qquad i=1,2,\ldots,m$$

where each Q_i and R_i is either a constant, an input value, or a P_j where $j<i$.

Polynomial evaluation

Suppose we are given a number x and asked to compute x^n for a fixed n, by a scheme as described above; what is the minimum number of steps required? Starting with a sufficiently large x, we can prove by induction that after k steps of a scheme the largest number obtainable is x^{2^k} which is computed by squaring x, squaring the result, and so on. Thus we must have

$$x^{2^k} \geq x^n$$

and hence

$$k \geq \lceil \lg n \rceil.$$

Thus at least $\lceil \lg n \rceil$ multiplications are required to compute x^n from x. Proving that this minimum is asymptotically achievable is more difficult. The following theorem is due to Brauer;[Br39,Kn69] Val'skii[Va159] arrived independently at the same result.

Theorem 6:

Let $m(n)$ be the least number of multiplications required to compute x^n for given values of x, then $m(n) \sim \lceil \lg n \rceil$.

This problem readily generalizes to: What is the smallest number of arithmetic operations needed to evaluate the n^{th} degree polynomial

$$f(x)=a_0+a_1x+\cdots+a_nx^n \qquad a_n \neq 0,$$

for given values of x? Ostrowski[Os54] was the first to suggest that this problem be analyzed, and he gave results for quadratic and cubic polynomials.

When it is known *a priori* that the values of x given will be equally spaced, a method using finite differences might be most convenient; however, we will assume that the values of x will be arbitrary. The method usually used is Horner's method:

$$f_0 = a_n$$
$$f_{r+1} = xf_r + a_{n-r-1} \qquad r=0,1,\ldots,n-1,$$

which requires n additions and n multiplications. Can this be improved? One can easily find specific polynomials for which there is a better method; for example

$$f(x)=1+x+2x^2+x^3+x^4$$

which can be evaluated in two multiplications and two additions by proceeding as follows:

$$x^2,\ x^2+1,\ (x^2+1)((x^2+1)+x).$$

However, we want a more general method, one which will work for all polynomials and for all values of x. Clearly Horner's method is a valid scheme for polynomial evaluation, and in fact, Horner's method is optimal, in the sense that it requires the fewest operations necessary in the type of scheme allowed, for we have:

Theorem 7:

Any scheme which can evaluate an arbitrary n^{th} degree polynomial has at least n additions/subtractions and n multiplications/divisions.

In this theorem, the necessity of the n additions/subtractions was shown by Belaga[Be58,Be61,Kn69] while the necessity of the n multiplications/divisions is due to Pan.[Pan66] Not only is Horner's method optimal, but it is uniquely optimal: Borodin[Bo71] has shown that any scheme using only those $2n$ operations is essentially Horner's method.

A different approach can be taken if a large number of values $P(x)$ are required. Consider the following example, due to Todd.[Tod55] We want to evaluate the polynomial

$$P=x^6+Ax^5+Bx^4+Cx^3+Dx^2+Ex+F.$$

Define the following polynomials

$$P_1=x^2+ax=x(a+x)$$

$$P_2=(P_1+x+b)(P_1+c)$$

$$P_3=(P_2+d)(P_1+e)$$

and determine a, b, c, d, e, and f such that $P=P_3+f$. This can be done by the solution of linear equations and a single quadratic equation. Once these equations have been solved, P can be evaluated using only three multiplications and seven additions using the sequence

$$P_1,\ P_2,\ P_3,\ P=P_3+f,$$

a savings of three multiplications at the expense of one addition and some "preconditioning" of the coefficients. Since multiplication is usually much slower than addition and since we sometimes want the same polynomial evaluated at many arbitrarily spaced points, the above method can represent a significant improvement over Horner's method.

A scheme with preconditioning is formally defined as a scheme in which the Q_i and R_i are, in addition, allowed to be any real functions of the coefficients of the polynomial to be evaluated. The scheme due to Todd above, is an example of such preconditioning. The idea of preconditioning is due to Motzkin[Mot55a] and he showed that if a scheme with preconditioning computes all n^{th} degree polynomials then it contains at least $\lfloor (n+1)/2 \rfloor$ multiplications.[Kn69] Combining this result with the full strength of the result of Belaga used in Theorem 7, we have

Theorem 8:

Any scheme with preconditioning which can evaluate an arbitrary n^{th} degree polynomial has at least $\lfloor (n+1)/2 \rfloor$ multiplications and at least n additions/subtractions.

Much effort has been spent to find a scheme with preconditioning which attains the lower bounds of Theorem 8. Early papers by Motzkin[Mot55a] and Knuth[Kn62] gave methods which evaluate polynomials of degrees four, five, and six in $\lfloor (n+1)/2 \rfloor+1$ multiplications and $n+1$ additions; Pan[Pan61,Pan65] has given similar methods for $n \leq 12$. In each of these cases, the methods are applicable only for a particular value of n. Pan[Pan61] gives a method valid for $n \geq 2$ which requires $\lfloor (n+1)/2 \rfloor+1$ multiplications and $n+2$ additions/subtractions and in Reference Pan59 he gives a method for $n \geq 5$ for which $\lfloor n/2 \rfloor+2$ multiplications and $n+1$ additions/subtractions are needed. For $n \geq 3$, Knuth[Kn62] gives a method using $n+1$ additions/subtractions and the number of multiplications varies between $\lfloor (n+1)/2 \rfloor+1$ and approximately $\frac{3}{4}n$. Belaga[Be61] proved that $\lfloor (n+1)/2 \rfloor+1$ multiplications and $n+1$ additions suffice to evaluate any nth degree polynomial, but these operations may involve complex numbers. Finally, Eve[Ev64] modified Knuth's method to give a method requiring $\lfloor n/2 \rfloor+2$ multiplications and n additions/subtractions, all of which involve only real numbers. The preconditioning in Eve's algorithm is, unfortunately, irrational; Rabin and Winograd (personal communication) have developed a method in which the preconditioning involves only rational operations, but his method then requires about $\lceil n/2+\lg n \rceil$ multiplications to evaluate a polynomial.

The best general algorithm for polynomial evaluation, Eve's, requires only the minimum number of additions/subtractions, however, it unfortunately requires one more than the minimum number of multiplications. It is known[Kn69] that when n is odd both of these lower bounds cannot be simultaneously achieved, and a similar result holds when $n = 4$ and $n = 6$. There is no known general algorithm using $\lfloor n/2 \rfloor+1$ multiplications when n—8, although such methods are known for $n=4$, 6, and 8, where the algorithms require one or two extra addition/subtraction operations.[Kn69,Pan62]

The above optimality theorems show that no one method will work for all polynomials of degree n unless it has a certain minimum number of operations, but there are some "special" polynomials which can be evaluated far more rapidly, for example, a x^{16} requires only five multiplications and no additions, instead of the minimums given by Theorems 7 and 8. There are "few" such polynomials for Belaga[Be61] has shown

Theorem 9:

The set of n^{th} degree polynomials which can be evaluated by schemes with preconditioning in fewer operations than specified in Theorem 7 has Lebesgue measure zero in the space of all nth degree polynomials.

Pan[Pan62] has proved a similar result for schemes without preconditioning.

Most of these results have been generalized to polynomials of many variables and to rational functions. In particular, such results are given in References Be58, Mot55b, Os54, and Pan62. Some of the results have also been obtained for the problem of simultaneously evaluating several polynomials in the same variable[Pan66] and for the specific case of the simultaneous evaluation of a polynomial and its first derivative.[Kn69, Mu71a]

Other activity in this area has concerned the analysis of polynomial evaluation when an arbitrary number of arithmetic operations can be performed in parallel; see, for example, References Ma71 and Mu71b. Also of interest is polynomial evaluation when the coefficients are rational; Paterson and Stockmeyer[Pat71] have shown that $0(\sqrt{n})$ operations are necessary and sufficient for the evaluation of an nth degree polynomial.

Linear algebra

By generalizing the notions in the above results to arbitrary fields, Winograd[Wi70] proved some very elegant theorems. Let F be a field and let $x_1, x_2, \ldots, x_n$ be a set of variables. The question then becomes, what is the minimum number of field operations needed to compute the m field elements

$$\Psi_i \in F(x_1, \ldots, x_n) \qquad i=1, \ldots, m.$$

Winograd gave a very general definition of a scheme without preconditioning, and considered only the number of multiplications/divisions. He showed:

Theorem 10:

Let Φ be an m by n matrix whose elements are in the field F, let ϕ be an m vector of elements in F, and let x denote the n column vector $(x_1, \ldots, x_n)$ so that

$$\Phi x + \phi \in F(x_1, \ldots, x_n)^m.$$

If there are u column vectors in Φ such that no nontrivial linear combination of them (over F) is in F^m, then any scheme, without preconditioning, computing $\Phi x+\phi$ requires at least u multiplications/divisions.

Pan's result on the number of multiplications needed for polynomial evaluation without preconditioning (part of Theorem 7) follows from this theorem as a corollary, for here Φ is the 1 by $n+1$ matrix

$$(1, x, x^2, \ldots, x^n)$$

and the columns of Φ are all linearly independent so that $u=n$.

We also have another corollary:

Theorem 11:

Let X be a p by q matrix and let y be a q column vector. Then to compute Xy requires at least pq multiplications/divisions and so the ordinary method of computing Xy minimizes the number of multiplications/divisions.

This follows from Theorem 10 by defining

$$\Phi_{ij} = \begin{cases} y_k \text{ if } j=iq+k & 1 \leq k \leq q \\ 0 \text{ otherwise} \end{cases}$$

and letting $x=(x_{11}, \ldots, x_{1q}, x_{21}, \ldots, x_{2q}, \ldots, x_{pq})$.

Fiduccia[Fid71] proved a theorem similar to Winograd's, but involving submatrices rather than columns:

Theorem 12:

Let Φ, ϕ, x and F be as in Theorem 10. If Φ has a u by v submatrix S such that there are no nontrivial vectors α, and β such that $\alpha S \beta$ is in zero, then at least $u+v-1$ multiplications/divisions are required to compute $\Phi x+\phi$.

Immediate corollaries to this theorem are that at least three real multiplications are required to compute the product of two complex numbers (also proved by Munro[Mu71a]) and that at least seven real multiplications are required to compute the product of two quaternions.

Winograd[Wi70] similarly generalized Motzkin's result (part of Theorem 8) on the number of multiplications when preconditioning is allowed:

Theorem 13:

Let Φ, ϕ, x and F be as in Theorem 10. If there are u column vectors in Φ such that no nontrivial linear combination of them (over F) is in F^m, then any scheme with preconditioning computing $\Phi x+\phi$ requires at least $\lfloor (u+1)/2 \rfloor$ multiplications/divisions.

Motzkin's result follows from this exactly as Pan's followed from Theorem 10, and we have a corollary similar to Theorem 11:

Theorem 14:

Let X and y be as in Theorem 11, then every algorithm for computing Xy requires at least $pq/2$ multiplications/divisions which do not depend only on the entries of X or only on the entries of y.

Winograd[Wi70] showed the possibility of approaching the lower bound given in Theorem 14, by giving an algorithm, which uses preconditioning, to compute Xy in $p\lceil q/2 \rceil + \lfloor q/2 \rfloor$ multiplications; this algorithm then leads to an algorithm to multiply two n by n matrices in $n^2\lceil n/2 \rceil + 2n\lfloor n/2 \rfloor$ or approximately $n^3/2$ multiplications; Winograd's result is somewhat surprising since the usual method of matrix multiplication, that is by the definition, requires n^3 multiplications, and it had not been thought that this could be diminished.

This work was soon followed by an astonishing result of Strassen,[Str69] who showed that two n by n matrices could be multiplied using only $4.7n^{\lg 7}$ (about $4.7n^{2.81}$) arithmetic operations. Strassen's method is based on a clever trick by which 2 by 2 matrices are multiplied using only seven scalar multiplications (instead of eight) and eighteen scalar additions:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix}\begin{pmatrix} w & x \\ y & z \end{pmatrix}=\begin{pmatrix} (a+d)(w+z)+(b-d)(y+z)+d(y-w)-(a+b)z & (a+b)z+a(x-z) \\ (c+d)w+d(y-w) & (a+d)(w+z)+a(x-z)-(c+d)w+(c-a)(w+x) \end{pmatrix}$$

Since this trick does not make use of commutivity of multiplication, it follows that the method generalizes to higher order matrices by decomposing them into blocks. Strassen goes on to apply his methods to matrix inversion, computing the determinant, and solving linear systems of equations and he shows that each of these can be done in $0(n^{\lg 7})$ arithmetic operations, provided certain submatrices are nonsingular.

It is not, in general, known whether or not Strassen's method is optimal. Hopcroft and Kerr[Hop71a] have worked on this problem and they give a generalization of Strassen's method for multiplying m by 2 times 2 by n matrices which requires $\lceil(3m+1)n/2\rceil$ multiplications. They then show that this number of multiplications is minimal for the cases $n=m=3$ and $m=2$, n arbitrary; the optimality of Strassen's method for 2 by 2 matrices follows immediately from their results.

Several years prior to the work of Strassen and Winograd, Kljuev and Kokovkin-Shcherbak[Kl65] had approached the problem of the solution of an n by n linear system in a different manner. Using a detailed examination of the number and placement of zeroes in the matrix, they proved

Theorem 15:

If only operations on entire rows are permitted then $\frac{1}{6}n(n-1)(2n-1)+n^2$ additions/subtractions and $\frac{1}{3}n(n^2+3n-1)$ multiplications/divisions are required to solve an n by n system of linear equations.

Since these are exactly the numbers of operations required by Gaussian elimination, we have as a corollary that Gaussian elimination is optimal, when one is restricted to operating on entire rows. Strassen's method is faster, but it uses operations on submatrices rather than on rows. In References Kl66, Kl67, Ko68, and Ko70 Kljuev and Kokovkin-Shcherbak extended their previous work and by similar methods established lower bounds for the number of arithmetic operations required for the transformation of matrices.

MISCELLANEOUS PROBLEMS

This section is devoted to a potpourri of results, which stand more or less alone, without a general frame of reference.

Nonlinear equations

Given a nonlinear equation, the problem is to approximate the solution to within a prescribed accuracy using arithmetic operations. Vashakmadze[Vas69] has established some lower bounds on the minimum number of operations necessary to approximate solutions to certain differential equations, and Emel'yanov and Il'in[Em67] studied the same question for certain integral equations.

Various results have been discovered concerning the optimality of iterative root finding methods such as the secant method or Newton's method. For example, Rissanen[Ri71] has shown that the secant method is, in a sense, optimal among all algorithms which use the "same amount of information" and which also satisfy a certain "smoothness" condition. Much work has also been done to find the best starting values for Newton's method applied to square roots; for example, References Mou67, Kin69, and Ster69. Recently, Paterson (personal communication), using the "standard" definition of the efficiency of an iterative scheme, has shown Newton's method to be optimal, for the calculation of square roots (in the sense that no rational scheme can have greater efficiency).

Scalar arithmetic

So far, we have been concerned only with how many operations need to be performed, not considering the time required for individual operations. The usual method for adding/subtracting two n digit numbers requires time proportional to n and the usual method of multiplication requires time proportional to n^2. Can either of these methods be improved upon? For addition/subtraction no substantial improvement is possible since the usual time is about n "cycles," and there are $2n$ inputs (digits) while on each cycle one can use at most two of the inputs. Multiplication, however, can be done more quickly than the usual method. Karatsuba and Ofman[Kara62] developed a method which requires time proportional to $n^{\lg 3} \approx n^{1.57}$. Toom[Too63] generalized this algorithm and proved that for all $\epsilon > 0$ there is a multiplication algorithm such that the time required to multiply two n digit numbers is $0(n^{1+\epsilon})$. Schonhage and Strassen[Scho71] devised a different algorithm which requires at most time $0(n \log n \log \log n)$; this is the most efficient algorithm known, but it has not been proved optimal.

The only non-trivial optimality result is due to Cook and Aanderaa[Co69] where they proved that on a bounded activity machine, an on-line "super" Turing machine, multiplication cannot be performed in less than time $0(n \log n / (\log \log n)^2)$.

Ofman[Of62] introduced the idea of studying the delay time of a circuit and the number of elements in a circuit which computes some given function, say addition. Toom[Too63] extended this work to multiplication and Winograd[Wi65,Wi67] and Spira[Sp69] derived lower bounds on the number of delays and elements required for various operations. Elementary discussions of some of this material appears in References Arb69 and Wi68. This work is not really germane to the present discussion since it deals with circuitry rather than computational schemes of a programmable nature.

Graphs

Other than information theory arguments, there is only one known technique for establishing lower bounds on graph algorithms: if the graph of n nodes is presented as an n by n binary connection matrix then $0(n^2)$ operations are needed to examine all of the arcs of a graph. Based on this observation, Holt and Reingold[Hol72] have shown that determining shortest paths, the existence of cycles, and connectedness requires $0(n^2)$ operations for graphs with n nodes. These results show that the "usual" $0(n^2)$ algorithms for these problems are optimal to within a multiplicative constant factor, when the graph is represented as a connection matrix.

Hopcroft and Tarjan[Hop71b] have devised an $0(n \log n)$ algorithm which determines whether or not an n node graph is planar; Tarjan[Ta71] has improved this to $0(n)$. These algorithms do not violate the lower bound of $0(n^2)$ since a planar graph of n nodes can contain at most $3n-2$ arcs; additionally, their algorithm requires that the graph be presented in a certain linked list format, rather than as a connection matrix.

Computing the transitive closure of a graph is another well-known problem in this area. Warshall[Wa62] gave an $0(n^3)$ algorithm for computing the transitive closure of a graph from its connection matrix. Furman[Fu70] applied Strassen's method of matrix multiplication to that same computation obtaining an $0[n^{\lg 7}(\log n)^{2+\epsilon}]$; Arlazarov, Dinic, Kronrod, and Faradzhev[Arl70] developed another $0(n^3)$ algorithm. Recently, it has been shown[Mu71c,Fis71] that the problems of doing Boolean matrix multiplication and of computing the transitive closure are equivalent to one another; that is, given an $0(f)$ algorithm to multiply Boolean matrices, we can derive an $0(f)$ algorithm for transitive closure, and vice versa. In connection with this result, an $0(n^{\lg 7}(\log n)^{1+\epsilon})$ algorithm is developed.

Harper and Savage (unpublished) have shown that the problem of matching bipartite graphs with n nodes is at least $0(n^3)$ in complexity when the computation is done by combinatorial switching network. In contrast with this, Hopcroft and Karp[Hop71c] have developed an $0(n^2\sqrt{n})$ algorithm, using a different model of computation.

Maximization of unimodal functions

A unimodal function of one variable is function f which has a unique maximum $\bar{x}$; it is characterized by

$$x < y < \bar{x} \Rightarrow f(x) < f(y)$$

$$x > y > \bar{x} \Rightarrow f(x) < f(y).$$

Suppose we want to locate, to within a unit interval, this unique maximum; what is the smallest number of function evaluations required? This question was first studied by Kiefer.[Kie53,Kie57] He showed that if we are to locate the maximum over an interval $[0, L]$ and $F_n \leq L < F_{n+1}$, where F_j is the jth Fibonacci number, then $n+1$ function evaluations are necessary and sufficient. Karp and Miranker[Karp68] characterized optimal strategies when parallel function evaluations are allowed.

Analysis of combinatory algorithms— A sample of current methodology

by W. D. FRAZER

IBM T. J. Watson Research Center
Yorktown Heights, New York

INTRODUCTION

The study of the computational efficiency and inherent limitations of algorithms for computer solution of problems drawn from classical continuous mathematics has been with us as long as general purpose computers themselves. Similar studies of algorithms of other kinds, however, have been sporadic and isolated until fairly recently. With the growing realization of the critical role played by combinatory algorithms in any instance in which the computer is employed as a logical decision maker, however, has come intensive and widespread interest in understanding such algorithms. Further, these studies have progressed to the point where patterns in analysis have begun to emerge and a summary seems in order. We shall focus our attention here on analytic approaches and methodology, rather than on the specifics of the results obtained. For a summary of the latter, the reader is referred to a companion paper elsewhere in this volume.[16]

To begin with, one might consider what constitutes a combinatory algorithm and what does not, but rather than restrict the nature of the analyses we shall consider, let us say merely that we shall not discuss problems in numerical analysis, in the theory of automata, or in arithmetic and leave it at that. We shall take it as our primary concern to try to summarize the kinds of information people have attempted to learn about various algorithms, and then indicate some of the tools and techniques they have employed. An effort will be made to point out common threads where possible, and to indicate potential directions for future development where this seems appropriate. As illustrative vehicles for the discussion we shall focus on some simple, but basic, examples. To the best of our knowledge, the analyses and proofs (as distinct from the results) are new except where noted.

Broadly speaking, analyses of combinatory algorithms can be classified in two "dimensions," viz.,

	Analysis of a Single Algorithm	Analysis of a Class of Algorithms
Analysis of a Single Case (usually worst or best)		
Analysis of a Probability Distribution of Cases		

The kinds of information sought through analysis are typically: (a) Does the algorithm(s) do what is desired? (b) How does it (or they) perform if all goes favorably or unfavorably? (c) How good is performance "on the average"?, and (much less frequently) (d) How average is average—i.e., what is the variance?

Of course, the study of algorithm performance presupposes a choice of a figure of merit for that performance. This choice is frequently quite difficult to make in a manner which reflects adequately the amount of real computation involved. In the case of algorithms for sorting, for example, a common figure of merit is the number of comparisons made. This measure is a valid indicator of actual program performance, however, only if comparisons constitute the bulk of the computation. An algorithm which performs address calculations based on record key values may perform few or even no compares; another, which does base its course of action on the outcomes of compares, may nevertheless access memory often to move items around without comparing them, and thus be greatly inferior in reality to one which makes a few more comparisons. It is primarily because of a lack of reasonably close correspondence with reality in the underlying models and measures of performance that almost all of the work on "computational complexity" in the literature of automata theory finds little or no use for our purposes.

In the course of our examination of the techniques of analysis of algorithms, we will observe repeatedly that there are two qualitative "depths" to which such an analysis is normally pursued. The first is a general level where all that is specified is the operations performed by the algorithm and the general form of the data structures it accesses. The second is the level of at least a source language implementation in which considerable attention must be paid to the implementation of these operations and data structures. An operation such as "find a circuit" of a linear graph, for example, is far more complex than "compare this item with that item," even in cases where the latter requires reference to a lexicography. Again, the data structures or accessing patterns required by the general specification of an algorithm may not be directly implementable or may incur excessive overhead in implementation.

With these caveats in mind, let us begin an examination of some of the main themes of the extant literature in the analysis of algorithms.

CERTIFICATION: DOES THE ALGORITHM DO WHAT IS DESIRED?

Many combinatory algorithms, generally stated, do not require detailed formal certification of correctness and/or termination because it is obvious that these properties are satisfied. Most sorting algorithms, for example, fall into this category, as do most search algorithms. As noted earlier, there are two levels at which one can question these properties—that of the abstract or "pure" statement of the algorithm, and that of a particular implementation. Obviously, even verification at the level of implementation in a source language program will not guarantee that the compiled program will perform as desired, but it is a much better guarantee than verification at the abstract level. In practice, however, both levels are frequently desirable, since the techniques required for one are often qualitatively different from those for the other, and it is most desirable to know that the algorithm is free of flaws before carrying it to the level of a detailed implementation. As an example of some of these ideas let us consider the following problem:

Consider a linear graph consisting of a finite collection of vertices, some of which are joined pairwise by a collection of edges. With each such edge is associated a positive length, and each pair of vertices may be joined by at most one edge. The only other restriction is that there must be some sequence of edges, or path, joining any pair of vertices (i.e., no group of vertices is "isolated"). A (spanning) *tree*, T, is a collection of edges having the property that within T there is exactly one path joining any pair of vertices. Our problem is to find a tree of minimum total length, $T_{\min}$.

A very effective algorithm (in fact, the best published to date) for this problem is due independently to Prim[15] and Dijkstra:[3] We begin by selecting an arbitrary vertex, v_0, and assigning to $T_{\min}$ the shortest of its incident edges, say one linking v_0 to v_1, denoted $\langle v_0, v_1\rangle$. Next, from all of the edges linking either v_0 or v_1 to other vertices we select the shortest, which links v_0 or v_1 to, say, v_2. We now repeat the process, looking this time for the shortest edge joining v_0, v_1, or v_2 to some other vertex, and continue in this manner until all vertices have been included. Notice that at any time we need only keep track of a shortest edge from some vertex already in $T_{\min}$ to each of those vertices not yet included. As each new vertex is joined to $T_{\min}$, the lengths of its edges to vertices not yet in $T_{\min}$ are compared with the current minima, and the latter replaced where appropriate.

That this procedure will terminate is clear, even from the informal statement just given, because a new vertex is added to the tree at each step. It is only slightly less clear that the resulting collection of edges will be a tree, but a moment's reflection will convince the reader that a path between any pair of vertices must be found and will be unique. There is no way to add to $T_{\min}$ an edge joining vertices already joined by a path, since the only edges under consideration are those joining such vertices to vertices not yet reachable by edges in $T_{\min}$.

The remaining major question, that of the minimality of $T_{\min}$, is less obvious. Suppose $T_{\min}$ were not minimal, and suppose there were some minimal tree T' which differed from $T_{\min}$ in a minimal number of edges. Let E be the set of edges of $T_{\min}$ not in T' and let e be a shortest edge of E. Now, in $T_{\min}$, e uniquely joins the set of vertices already in $T_{\min}$ at the time e was added, V_e, to the set of the remaining vertices of the graph, W_e. Since T' is a tree, it also has at least one edge

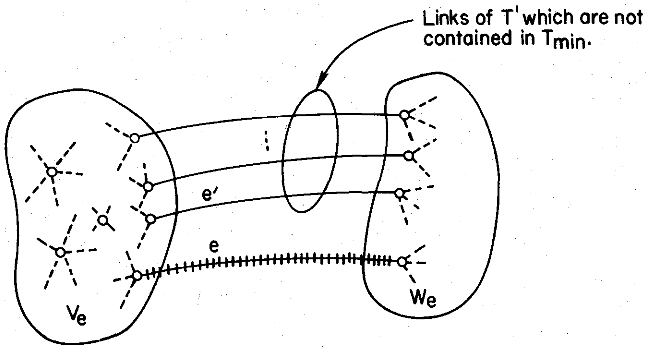

Figure 1

joining V_e to W_e; furthermore, adding e to T' will create two paths (in $T' \cup \{e\}$) between some vertices of V_e and some of W_e, one path via e and one via some edge, e', of T' (cf. Figure 1). Now length $(e') \geq$ length (e), since e was chosen by our algorithm. On the other hand, if we substitute e for e' in T' the result will still be a tree, T_e'. (The vertices in V_e and W_e formerly connected in T' via e' will now be connected via e.) But T_e' can have no less total length than T', since T' was minimal; hence, length $(e) \geq$ length (e'). Combining these observations, length $(e) =$ length (e') and length $(T_e') =$ length (T'). But T_e' differs from $T_{\min}$ in one fewer edges than T' and this contradicts our choice of T'; thus, T' does not exist and $T_{\min}$ is minimal, as required.

We note in passing that the device employed here is a powerful tool in the analysis of graph algorithms. One verifies the optimality of the solution produced by an algorithm by postulating the existence of an optimal solution differing from the generated solution in a minimal way, and then constructively refutes the minimality of this difference.

Having satisfied ourselves as to the basic soundness of the algorithm, the next step is to embody it in a program and verify the correctness of the program. We will not pursue this step in detail here for lack of time and space but will rely upon the reader's experience to assist in understanding the qualitative difference between such an undertaking and what we have just discussed. To begin with, even in a higher level language one is now faced with a host of syntax related problems having to do with whether variables are of the appropriate type and with the legitimacy of program statements, for example. There are also semantic questions such as whether loop indices are tested against range boundaries before or after incrementing and whether their values are preserved intact where required, as well as implementation-dependent considerations such as whether input and output is performed correctly, and so on. Next come considerations of program logic and control flow including again the question of termination, this time for the program. Finally, and perhaps most difficult, one has the question of whether the program actually embodies the algorithm at all. This process is clearly vastly more detailed than our proof above, even if the latter were to be thoroughly formalized. The most commonly accepted current approach to such a certification entails first supplementing the program code with assertions about statements in that code and verifying by hand that these assertions reflect accurately the desired properties of the statement [cf. e.g., References 5, 10, 18]. Next the assertions, couched in a form more suitable for treatment via classical mathematical proof techniques, are themselves verified. There is substantial effort under way in a number of areas to address these problems. It is abundantly clear that the first process—that of establishing the correspondence between statements and assertions—could benefit from mechanical assistance. On the other hand, a hopeful sign is that the prospects for providing such assistance appear reasonably good as a consequence of increased understanding of programs resulting from, for example, compiler optimization studies.[1] Automatic verification of the assertions is considerably more difficult, though a good deal of work is being done [cf. References 5, 10, 18]. There are a number of recent instances, however, in which humans have been quite successful in accomplishing this without undue tedium, and thus automatic *assistance* may be all that is required for a viable system.

EXTREME PERFORMANCE: WHAT HAPPENS AT BEST (OR AT WORST)?

Granted that one has assured himself of the validity of an algorithm, it is next natural to ask how well the algorithm performs its assigned task. Here again, we find the opportunity (or need) for two levels of analysis: one at the general algorithm level and the other at the detailed program level.

In the case of our example, the best and worst cases would arise when the graph being processed consisted of a single path and a "complete graph" (i.e., when each vertex has an edge link to every other vertex), respectively. It is clear that a reasonable figure of merit for the performance of this algorithm must include some measure of the work performed in finding the shortest edge at each stage; it may or may not be appropriate in addition to examine the amount of storage space required by the procedure.

Suppose that we have n vertices. Then in the former case, only $(n-1)$ edges need be examined since only a single choice is available at each stage, while in the latter one must choose the first edge from among $(n-1)$, the second from among $2\times(n-2)$, etc., and the last from among $(n-1)$ again. It should be fairly obvious that one can find the smallest of k objects in $(k-1)$ comparison steps, and that one can do no better than this. (This is an instance in which one can make a very strong statement about existence and optimal performance of a whole family of algorithms.) Thus, a first analysis might lead to the conclusion that $\sum_{i=1}^{n-1} i(n-i) = [n(n-1)(n+1)/6]$ comparison steps are required. Recall, however, that as each new vertex joins the growing $T_{\min}$, its edges to vertices not yet included need be compared only with the *shortest* of the corresponding edges from vertices already included, and not with all such edges. This is the essence of the efficiency of the procedure. Thus $(n-1)$ comparison steps are required for selecting v_1, followed by $(n-2)$ steps to establish a set of $(n-2)$ minimal length edges to other vertices and then $(n-2)$ steps to find a shortest such edge in order to pick v_2. The total number of comparison steps is thus $(n-1)+2(n-2)+2(n-3)+\cdots+2(2)+1=n(n-2)$. At a cost of some additional storage to keep track of the current minima, we have avoided a cumbersome search at each stage and improved performance from $0(n^3)$ to $0(n^2)$. This serves to emphasize that even at this general level of analysis, one must exercise great care to be sure that he has captured the essence of the algorithm, for $0(n^2)$ performance is significantly different from $0(n^3)$.

Of course, the analysis is not yet complete. We must still account for the work required to keep track of which vertices and edges are already in $T_{\min}$ and which are not, and to do the bookkeeping for the maintenance of the list of minimal distances, for example. An accurate account of this kind, however, really requires that one move to the next level of analysis—that of the program itself.

Not surprisingly, the level of detail in such an analysis is again considerable. Still, the number of parameters is not overwhelming, for the flow of control in a program—at least in a *good* one—is normally highly systematic. In addition, the certification process has by this time assured one that his program is both consistent and free of infinite loops. Thus, each loop will be entered and exited an equal number of times, and this number can be used as a parameter characterizing the number of executions of a whole set of statements within and without the loop; also, several of these parameters are often available from the analysis of the algorithm at the "general" level. Again, we shall omit this phase of the analysis in order to move on. It is worthwhile noting, however, that the *kind* of analysis would be essentially similar to that which we have just seen—i.e., finite discrete mathematics involving integer quantities—although quite likely more complex than our simple example [cf. Reference 13].

There is a drawback in this kind of extreme analysis, however, which may not yet be apparent. Observe that there is a major qualitative difference between the best and worst case performance. It is probably fairly unlikely that one would encounter either in practice, and thus, while the time performance for most graphs lies somewhere between these extremes, the range is so large as to furnish little information. This is the motivation for undertaking the kind of analyses we shall consider next, those which attempt to quantify "average" performance. Before moving on to consider analysis of average performance, however, let us digress briefly to consider a problem in which extreme performance is of paramount importance.

Consider a two-input, two-output device which compares the values of, and then propagates, its inputs in such a way that the larger input reappears on the first output line and the smaller on the second. The objective in the construction of "sorting networks"[2] is to devise arrays of such devices which accept a string of input items as input and then shuttle these input items about internally over fixed connections to permute the items into sorted order. For such networks one figure of merit is obviously the number of comparisons (i.e., devices) required. The major difference between this approach and most standard approaches to sorting, however, is that here the set of comparisons is immutable regardless of the input sequence (since the connections are fixed). In return for this inflexibility, one gains a potential for parallel operation and a saving in time. Thus, an equally important figure of merit for most applications is the total *time* required to sort, and this is determined by the *maximum* number of comparisons made against any item in moving from input to output. In this instance, as with many involving algorithms whose course of action is essentially independent of the values or positions of data items, extreme performance is of primary interest.

EXPECTED PERFORMANCE: HOW GOOD IS THE ALGORITHM "ON THE AVERAGE"?

A more difficult kind of analysis of algorithm performance, in general, is that required to determine expected or "average" performance. Still, it is precisely this kind of analysis which usually yields the most insight into actual observed algorithm performance. Outside the realm of information theory where random coding arguments have found some utility, it is highly unusual to find an analysis of expected performance of families of algorithms; far more often is a single algorithm analyzed in this way, and this is the kind of analysis we shall pursue next. For reasons to which we shall return later, we shall forsake our minimal spanning tree algorithm and concentrate on another algorithm to illustrate how such an analysis is carried out.

The algorithm we shall examine is one which sorts (i.e., permutes) an input sequence of records, each of which consists of both a "key" chosen from some linearly ordered set and other associated information, into, say, ascending lexicographic key order. For convenience in analysis and description, we shall assume that all of the key values are distinct. That this makes no essential difference will be easily verifiable in retrospect. For brevity, we shall refer to "record values" when speaking of the values of keys associated with these records. The algorithm is known as "Quicksort"[8] and it works as follows.

Quicksort constructs a binary tree whose vertices correspond to the, say n, records in the input sequence. The construction of the tree is controlled by the following rule, applied recursively to each subtree: if a record with (key) value x_0 is assigned to vertex i during construction, then any subsequent record, with value x, assigned to the (sub)tree rooted at i, will be assigned to the left subtree of i if $x<x_0$ and to the right subtree if $x>x_0$. Thus, the first input record becomes the root of the Quicksort tree, the second input record the root of one of the two principal subtrees, and so on.

Evaluation of expected values presupposes the existence of a probability distribution over input permutations; we shall adopt the hypothesis that all such permutations are equally likely. Although there are definitely situations in which such is not the case, there are many others to which it is a reasonable approximation. In addition, the results of such an analysis usually are observed to be good indicators of the measured performance of running programs. Parenthetically, although this may seem a strong assumption, it is actually weaker than assuming, for example, that the key values are independent, identically distributed, random variables.

To proceed with the analysis, we need once again to choose a figure of merit, but before we can choose one we need more information about how the algorithm is to be implemented. Suppose the input sequence is in locations numbered 1 through n: Transfer the first record to another location t, and begin a search of $2, 3, \ldots,$ looking for the first record, say x_j in location j, larger than $x_1 (x_j>x_1)$. Following examination, each such record is returned to a location numbered one less than its original one. Now begin a search of locations $n, n-1, \ldots,$ looking for the first record, say x_k in location k, smaller than x_1, and returning each record to its original location. Interchange the contents of locations $(j-1)$ and k—i.e., x_j and x_k. Now all records in locations 1 through $j-1$ are smaller than x_1 and all those in locations k through n are larger; location j is redundant. We now repeat the above process on locations $(j+1)$ through $k-1$ and continue this until the pointers j and k converge to adjacent locations, say, r and $r+1$. Then x_1 is inserted into r, its correct position in the output sequence, and the two sequences in locations 1 through $(r-1)$ and $(r+1)$ through n are each treated by the above process.

At the level of detail we are considering, the only obvious figure of merit is the number of comparisons made in the searches. There are no other obvious memory accesses or operations, except those required to maintain pointers to the boundaries of partitioned subsequences, such as $(r-1)$ and $(r+1)$ above. In fact, it is possible to hold this requirement to quite reasonable limits[6,7,8] and we shall therefore concentrate on the expected number of comparisons, which corresponds to the expected path length of the Quicksort tree.

Let $E(n)$ be the expected compares required to sort a sequence of n records. Then, if $p(r)$ = probability that the root of the Quicksort tree ranks rth in the input sequence,

$$E(n)=\sum_{r=1}^{n} p(r)[E(r-1\mid r)+E(n-r+1\mid r)+(n-1)]$$

where $E(y\mid r)$ denotes the expected compares to sort a sequence of y records conditioned on the fact that r is the root. But under our assumptions, any record is equally likely to be the root; thus $p(r)=1/n$ for all r; furthermore $E(y\ r)$ is similarly independent of r. Thus:

$$E(n)=(n-1)+\frac{2}{n}\sum_{r=1}^{n} E(r-1)$$

Similarly, following Windley:[19]

$$E(n-1)=(n-2)+\frac{2}{(n-1)}\sum_{r=1}^{n-1} E(r-1)$$

$$nE(n)-(n-1)E(n-1)=2(n-1)+2E(n-1) \qquad (1)$$

$$\frac{E(n)}{n+1}-\frac{E(n-1)}{n}=\frac{2(n-1)}{n(n+1)}=\frac{4}{n+1}-\frac{2}{n}$$

$$\frac{E(n)}{n+1}-\frac{E(1)}{2}=\left[\frac{4}{n+1}-\frac{2}{n}+\frac{4}{n}-\frac{2}{n-1}+\cdots+\frac{4}{3}-\frac{2}{2}\right]$$

$$=\frac{4}{n+1}+\sum_{i=2}^{n-1}\frac{2}{i+1}-1$$

or

$$E(n)=2(n+1)\sum_{i=1}^{n}\frac{1}{i+1}-2n$$

$$\approx 1.39(n+1)\log_2 n-0(n)$$

This kind of analysis is roughly the same as that which we encountered previously, and the technique of arranging for some linear combination of the variables on the left which will be equal to a tractable sum is one frequently employed. Often, however, recurrence equations will not succumb to such analysis. Consequently, another technique frequently called upon is the use of generating functions. A *generating function* for a sequence is an infinite formal power series expansion in which the coefficient of x^n is the nth term in the sequence. Thus, if $G(x)$ is the generating function for $E(n)$:

$$G(x)=E(1)x+E(2)x^2+\cdots+E(n)x^n+\cdots$$

Furthermore the generating function for $nE(n)$ is $x(d/dx)G(x)=E(1)x+2E(2)x^2+\cdots$. Now using this fact the recurrence equation (1) can be rewritten in terms of generating functions as

$$x\frac{d}{dx}G(x)=G(2(n-1))+\frac{d}{dx}(x^2G(x))$$

where

$$G(2(n-1))=\frac{2x^2}{(1-x)^2}$$

$$=2x^2+4x^3+6x^4+\cdots$$

Notice that this equation is in fact an equation involving infinite power series and thus constitutes an infinite set of coefficient equations, one for each power of x since the powers of x are linearly independent. Setting $y=G(x)$, we have

$$xy'=[2x^2/(1-x)^2]+2xy+x^2y'$$

$$y'-[2/(1-x)]y=2x/(1-x)^3$$

This differential equation has an integrating factor

$$\exp\left[-\int\left(\frac{2}{1-x}\right)dx\right]=(1-x)^2.$$

Thus

$$(1-x)^2y'-2(1-x)y=2x/(1-x)$$

Integrating both sides:

$$y(1-x)^2=2(-x-\ln(1-x))+c$$

or

$$G(x)=y=\frac{2}{(1-x)^2}\ln\left(\frac{1}{1-x}\right)+\frac{c}{(1-x)^2}-\frac{2x}{(1-x)^2}$$

Now

$$\frac{1}{(1-x)}\ln\left(\frac{1}{1-x}\right)=x+(1+\tfrac{1}{2})x^2+(1+\tfrac{1}{2}+\tfrac{1}{3})x^3+\cdots$$

Thus

$$\frac{d}{dx}\left[\frac{1}{(1-x)}\ln\left(\frac{1}{1-x}\right)\right]$$

$$=1+2(1+\tfrac{1}{2})x+3(1+\tfrac{1}{2}+\tfrac{1}{3})x^2+\cdots$$

$$=\frac{1}{(1-x)^2}\ln\left(\frac{1}{1-x}\right)+\frac{1}{(1-x)^2}$$

$$\therefore y=2\frac{d}{dx}\left[\frac{1}{(1-x)}\ln\left(\frac{1}{1-x}\right)\right]-\frac{2x}{(1-x)^2}+\frac{c-2}{(1-x)^2}$$

Looking at $E(1)$, the coefficient of x in $G(x)$:

$$E(1)=0=4(1+\tfrac{1}{2})-2+2(c-2)$$

$$\therefore c=0$$

and

$$E(n)=2(n+1)\sum_{i=1}^{n+1}\frac{1}{i}-2(n+1)-2n$$

$$=2(n+1)\sum_{i=1}^{n}\frac{1}{i+1}-2n$$

as before.

Although in this instance the generating function solution is somewhat more elaborate than the direct solution, we took the trouble to illustrate both because the existence of a direct solution is rather a fortuitous circumstance. (The example was chosen, in fact, because both kinds of solution were possible.) The availability of all of the functional power of infinite series vastly increases one's flexibility when dealing with problems of analysis, as may be apparent from the operations above. Of course, there are a large number of other approaches to the solution of recurrence and difference equations [cf. References 9, 12, 14, 17].

A final remark is in order regarding the question of expected performance of graph algorithms. The unfortunate fact is that there seems at present to be no way effectively to characterize a "random" graph. The kinds of graphs submitted to graph algorithms normally have the imprint of human intelligence in design or at least selection. This imprint is not captured effectively by choosing a random incidence matrix, for example, nor by any of the other obvious choices of a definition of randomness to which one is tempted. The discovery of a natural and analytically tractable characterization of a random graph remains a major open question in the analysis of algorithms.

VARIANCE: HOW OFTEN DOES "AVERAGE" PERFORMANCE OCCUR?

Expected performance is most probable performance, but for some algorithms actual performance can be a highly variable function of input data as we have noted. Among all of the kinds of analysis to which algorithms are subjected, analysis of the variance of performance is unquestionably the most difficult—and the most often omitted.

There are, however, sometimes legitimate ways in which to justify omission of computation of the variance. For example, in the case of Quicksort, the extremes of performance occur when the tree is a single path (i.e., completely unbalanced) and when it is completely balanced. In the former case, this number of comparisons is $[n(n-1)/2]$, while in the latter it is $(n+1)\log_2(n+1)-2n$. Thus, expected performance is qualitatively the same as best performance, i.e., $0[(n)\log(n)]$. Therefore, even though performance in the worst case can deteriorate somewhat severely, this must be a consequence of a long "tail" in the distribution and hence quite unlikely under the hypothesis of equally likely input permutations.

As a final example, consider the problem of inserting a new record into a sorted sequence of records. Rather than adopt the standard "binary search" approach, however, let us proceed as follows: Given an nth record to be inserted into a sorted sequence of $(n-1)$ records, we shall pick a point, i, *at random*, make a comparison with the ith record, and thereby determine whether the new record belongs among the first $(i-1)$ or the last $(n-i+1)$. (We shall again assume that all key values are distinct.) We will then repeat the "random probe" process on the appropriate subsequence and continue recursively in this way until the proper position for the new record has been found. Again, let us assume that the new record is equally likely to belong anywhere in the sequence—including at the ends. Let $p(k, n) =$ prob. that k compares are required to insert an item into a set of n. Then

$$p(k,n) = \sum_{i=1}^{n}\left[\left(\frac{1}{n}\right)\left(\frac{i}{n+1}\right)p(k-1,i-1)\right.$$
$$\left. + \left(\frac{n-i+1}{n+1}\right)\left(\frac{1}{n}\right)p(k-1,n-i)\right]$$

where

$1/n =$ prob. that the ith record is chosen at random

$i/(n+1) =$ prob. that the new record belongs among the first $(i-1)$, given that i was chosen

$(n-i+1)/(n+1) =$ prob. that the new record belongs among the last $(n-i)$, given that i was chosen

By symmetry

$$p(k,n) = \frac{2}{n(n+1)}\sum_{i=1}^{n} i\,p(k-1,i-1)$$

Setting

$$G_n(x) = \sum_{k=1}^{\infty} p(k,n)x^k$$

we have

$$G_n(x) = \sum_{k=1}^{\infty}\left[\frac{2}{n(n+1)}\sum_{i=1}^{n} i\,p(k-1,i-1)\right]x^k$$

It now appears that we are in trouble, for not only do we have two indices in the recurrence, but, in addition, the index upon which we based the definition of the generating function will not help with the factors i or $[1/n(n+1)]$. In order to get such assistance, we define

$$F = \sum_{n=0}^{\infty} G_n(x)y^n$$

$$A = \frac{\partial}{\partial y}(yF) = \sum_{n=1}^{\infty} nG_{n-1}y^{n-1}$$

$$\frac{A}{1-y} = \sum_{n=1}^{\infty}\sum_{i=1}^{n} iG_{i-1}y^{n-1}$$

$$\int\frac{A\,dy}{1-y} = \sum_{n=1}^{\infty}\sum_{i=1}^{n} iG_{i-1}\frac{y^n}{n}$$

$$\iint\frac{A\,d^2y}{1-y} = \sum_{n=1}^{\infty}\sum_{i=1}^{n} iG_{i-1}\frac{y^{n+1}}{n(n+1)}$$

$$= \sum_{n=1}^{\infty}\sum_{i=1}^{n} i\sum_{k=0}^{\infty}\frac{p(k,i-1)x^ky^{n+1}}{n(n+1)}$$

Notice how we have approached, step by step, the form we wish on the right hand side. Each step utilizes a standard technique for generating functions, and the result is very close to what we need; all that is required is a factor of two and an adjustment of the x and y indices:

$$\frac{2x}{y}\iint\frac{A\,d^2y}{1-y} = \sum_{n=1}^{\infty}\left[\sum_{k=1}^{\infty}\left[\sum_{i=1}^{n}\frac{2ip(k-1,i-1)}{n(n+1)}\right]x^k\right]y^n$$
$$= F$$

Differentiating:

$$A=\frac{1-y}{2x}\frac{\partial}{\partial y}A$$

$$\frac{1}{A}\frac{\partial A}{\partial y}=\frac{2x}{(1-y)}$$

$$A=\frac{c}{(1-y)^{2x}}$$

$$=c\sum_{n=0}^{\infty}\binom{-2x}{n}(-y)^{n}$$

where $\binom{-2x}{n}$ is a "generalized" binomial coefficient[11] defined by

$$\binom{-2x}{n}=(-1)^{n}\frac{2x(2x+1)(2x+2)\ldots(2x+n-1)}{n!}.$$

Therefore, using the fact that $G_1(x)=x$ to find $c=1$,

$$A=\frac{\partial}{\partial y}yF=1+xy+\frac{(2x)(2x+1)y}{2}y^2+\cdots$$

$$yF=\sum_{n=0}^{\infty}\binom{-2x}{n}\frac{(-y)^{n+1}}{n+1}$$

$$F=\sum_{n=0}^{\infty}\frac{1}{n+1}\binom{2x+n-1}{n}y^{n}$$

and

$$G_n(x)=\frac{1}{n+1}\binom{2x+n-1}{n}.$$

Why go to all this trouble? Observe that

$$G_n{}'(x)=\frac{d}{dx}G_n(x)=\sum_{n=0}^{\infty}kp(k,n)x^{k-1}.$$

This means that $G_n{}'(1)=\text{mean }(k)$. Similarly

$$G_n{}''(x)=\sum_{n=0}^{\infty}k(k-1)p(k,n)x^{k-2}$$

and

$$G_n{}''(1)=\text{variance}\quad(k)-\text{mean}\quad(k)+\text{mean}\quad{}^2(k)$$

or

$$\text{variance}\quad(k)=G_n{}''(1)+G'(1)-[G'(1)]^2.$$

This provides the motivation; when the generating function is a generating function for a probability distribution, the moment information can be obtained easily from it as shown. A particularly fortuitous occurrence is the occasional emergence of a tractable recurrence involving the derivative of the generating function itself which enables one to arrive at an expected value and a variance without ever obtaining a closed form for the generating function (cf. Reference 12, *Vol. I*, p. 99), but this did not happen here.

Pursuing our analysis, we find that

$$G_n{}'(x)=\frac{2}{(n+1)!}\sum_{i=0}^{n-1}\frac{2x(2x+1)\ldots(2x+n-1)}{2x+i}$$

or

$$G_n{}'(1)=2\sum_{i=1}^{n}\frac{1}{(i+1)}\approx 2[\ln(n+1)-1]$$

Thus, strangely enough, as n grows larger this "random probing" insertion requires only about (2 ln 2) or less than 1.4 times as many compares on the average as does binary search. We shall leave it as a simple mathematical exercise to complete the computation and verify that

$$\text{variance}\quad(k)=2\sum_{i=1}^{n}\frac{1}{i+1}-4\sum_{i=1}^{n}\left(\frac{1}{i+1}\right)^2.$$

So, in this instance, average performance is fairly typical, since the variance is nearly equal to the mean.

By comparison, the "worst case" performance for this algorithm requires comparison of the new item with each of the $(n-1)$ others. Thus, here again, there is a long tail to the distribution. This is not surprising in light of the close relationship between this procedure and Quicksort, the precise nature of which we shall leave to the reader to discover for himself.

As a final remark, we observe that the factor of (2 ln 2) which appears in both the analysis just completed and that of Quicksort is characteristic of binary tree-based random algorithms. As we have seen, the technique of basing the course of action of an algorithm upon operations made on a randomly selected argument is rather more powerful than might at first be apparent [cf. Reference 6].

SUMMARY

In this brief space, it has of course been impossible to do justice to even the nascent field of combinatory algorithm analysis. We have, however, attempted to indicate at least in a qualitative way both the types of information usually sought (and why) and the general character of the accompanying analysis. By far the most authoritative single current source in the areas of performance is the Knuth series,[12] but having the techniques and ideas in hand, there is a broad range of more classical literature to which one may turn for assistance [e.g., References 4, 9, 11, 14, 17].

This is an area of very rapid growth. As it matures, one would expect to see a considerable broadening of analytic technique, but more important will be (a) results which increase our understanding of the principles of algorithm design analogous to, but deeper than, our earlier remark about randomized binary tree algorithms, and (b) results which broaden the scope of possible analysis—such as a good definition(s) of a "random" graph.

On the complexity of proving functions*

by ANDY N. C. KANG

University of California
Berkeley, California

INTRODUCTION

Let f be a recursive function. We shall be interested in the following question: given x and y, how difficult is it to decide whether $f(x)=y$ or $f(x)\neq y$? Since the problem of deciding $f(x)=y$ or $f(x)\neq y$ is the same problem as that of computing the characteristic function C_f of the graph of f, we can study the above question by looking into the complexity of computing C_f.

We say that algorithm j serves to prove (or disprove) $f(x)=y$ if $\phi_j^{(2)}\in R_2$ and $\phi_j^{(2)}$ computes the characteristic function, C_f, of the graph of f and $\phi_j^{(2)}(x,y)=1$ $(\phi_j^{(2)}(x,y)=0)$.

We shall show that the complexity of computing functions and the complexity of proving them are approximately equal modulo some recursive function h. Let g and f be recursive functions. We say that "f is difficult to prove almost everywhere (infinitely often) modulo g" if every algorithm which computes C_f takes more than $g(x,y)$ steps to output a 1 for almost all x (infinitely many x) and all y. We say that "f is difficult to disprove almost everywhere (infinitely often) modulo g" if every algorithm which computes C_f takes more than $g(x,y)$ steps to output a 0 for almost all x (infinitely many x) and at least one y.

Based on these definitions, we prove the following results: (1) A function is difficult to prove infinitely often if and only if it is difficult to disprove infinitely often. (2) There exists a function which is difficult to prove almost everywhere, but, surprisingly, it is not difficult to disprove almost everywhere. (3) There exists a function which is difficult to disprove almost everywhere, but it is not difficult to prove almost everywhere.

Before proceeding with our study, we give some preliminaries. Let R_n be the set of recursive functions of n variables. Let $\phi_0^{(2)}, \phi_1^{(2)}, \ldots$ be an acceptable Godel numbering of all the partial recursive functions of two variables [Ref. 4]. A partial recursive function $\Phi_i^{(2)}$, the "step counting function," is associated with each $\phi_i^{(2)}$. The set of partial recursive functions $\{\Phi_i^{(2)}\}_{i\geq 0}$ is arbitrary save for two axioms:
(1) $\phi_i^{(2)}(x,y)$ converges $\rightleftarrows$ $\Phi_i^{(2)}(x,y)$ converges, and
(2) the function

$$M(i,x,y,z)=\begin{cases}1 & \text{if } \Phi_i^{(2)}(x,y)=z\\ 0 & \text{otherwise}\end{cases}$$

is recursive.

Intuitively $\Phi_i^{(2)}(x,y)$ represents the amount of time (or space) used by program i when it finally halts after receiving inputs x and y.

THE COMPLEXITY OF COMPUTING VERSUS PROVING FUNCTIONS

Definition 1:

Let $f\in R_1$. $\phi_k^{(2)}$ is a *characteristic function* for the graph of f if

$$\phi_k^{(2)}(x,y)=\begin{cases}1 & \text{if } f(x)=y\\ 0 & \text{if not}\end{cases}$$

We write $\phi_k^{(2)}=C_f$, where C_f is the *characteristic function* for the graph of f.

Definition 2:

$\Phi_k^{(2)}(x,y)$ is the complexity of algorithm k of *disproving* $f(x)=y$ if $\phi_k^{(2)}=C_f$ and $\phi_k^{(2)}(x,y)=0$.

Definition 3:

$\Phi_k^{(2)}(x,y)$ is the complexity of algorithm k of *proving* $f(x)=y$ if $\phi_k^{(2)}=C_f$ and $\phi_k^{(2)}(x,y)=1$.

The following lemma asserts that the complexity of computing $f(x)$ and the complexity of proving $f(x)=y$ are approximately equal modulo some recursive function h.

* Research sponsored by the National Science Foundation, Grant GJ-708.

Lemma 1:

Let Φ be any complexity measure. There exist three functions $h\in R_3$, $\gamma\in R_1$, $\sigma\in R_1$ such that for any given $f\in R_1$:

(a) If $\phi_i=f$, then $\phi_{\gamma(i)}^{(2)}=C_f$ and

$$\overset{\infty}{\forall}x\forall y[f(x)=y\rightarrow\Phi_{\gamma(i)}^{(2)}(x,y)\leq h(x,y,\Phi_i(x))]$$

(b) If $\phi_k^{(2)}=C_f$, then $\phi_{\sigma(k)}=f$ and

$$\overset{\infty}{\forall}x\forall y[f(x)=y\rightarrow\Phi_{\sigma(k)}(x)\leq h(x,y,\Phi_k^{(2)}(x,y))]$$

Proof:

(a) Any algorithm to compute f can obviously be used to obtain an algorithm for proving f. The complexity of the algorithm for proving f is then bounded by the complexity of the algorithm for computing f. Formally: let γ be a recursive function such that:

$$\phi_{\gamma(i)}^{(2)}(x,y)=\begin{cases}1 & \text{if } \phi_i(x) \text{ converges and } \phi_i(x)=y\\ 0 & \text{if } \phi_i(x) \text{ converges and } \phi_i(x)\neq y\\ \text{diverge} & \text{otherwise}\end{cases}$$

If $\phi_i=f$, then $\phi_{\gamma(i)}^{(2)}$ is recursive since ϕ_i always converges. Then $\phi_{\gamma(i)}^{(2)}(x,y)=1\rightleftarrows\phi_i(x)=y$, i.e., $\phi_{\gamma(i)}^{(2)}=C_f$.

Let

$$p_1(i,x,y,z)=\begin{cases}\Phi_{\gamma(i)}^{(2)}(x,y) & \text{if } \Phi_i(x)=z \text{ and } \phi_i(x)=y\\ 0 & \text{otherwise}\end{cases}$$

p_1 is recursive, since $\lambda xz[\Phi_i(x)=z]$ is a recursive predicate, and $\phi_i(x)$ convergent implies $\Phi_{\gamma(i)}^{(2)}(x,y)$ converges.

Define $h_1(x,y,z)=\max\{p_1(i,x,y,z)\mid i\leq x\}$.

Then we have that for all i:

$$\overset{\infty}{\forall}x\forall y[\phi_{\gamma(i)}^{(2)}(x,y)=1\rightarrow\phi_i(x)\text{ converges and }\phi_i(x)=y\rightarrow h_1(x,y,\Phi_i(x))\geq\Phi_{\gamma(i)}^{(2)}(x,y)].$$

If $\phi_i=f$. Then

$$\overset{\infty}{\forall}x\forall y[f(x)=y\rightarrow\Phi_{\gamma(i)}^{(2)}(x,y)\leq h_1(x,y,\Phi_i(x))].$$

(b) Given an oracle $\phi_k^{(2)}$ for the graph of f, a program can compute f by asking questions about $\phi_k^{(2)}$. Because the graph of f is single-valued, an affirmative answer from $\phi_k^{(2)}$ gives the value of f. Formally: let σ be a recursive function such that:

$\phi_{\sigma(k)}(x)=$"With input x, compute $\phi_k^{(2)}(x,0)$, $\phi_k^{(2)}(x,1)$, ... by dovetailing, until a y appears such that $\phi_k^{(2)}(x,y)=1$; let the output be y."

If $\phi_k^{(2)}$ computes C_f. Then $\phi_{\sigma(k)}$ is recursive and

$$\forall x[\phi_{\sigma(k)}(x)=y\rightleftarrows\phi_k^{(2)}(x,y)=1\rightleftarrows f(x)=y]$$

whence $\phi_{\sigma(k)}=f$.

Let

$$p_2(k,x,y,z)=\begin{cases}\Phi_{\sigma(k)}(x) & \text{if } \Phi_k^{(2)}(x,y)=z \text{ and } \phi_k^{(2)}(x,y)=1\\ 0 & \text{otherwise}\end{cases}$$

p_2 is recursive, since $\lambda xyz[\Phi_k^{(2)}(x,y)=z]$ is a recursive predicate, and $\phi_k^{(2)}(x,y)=1$ implies $\Phi_{\sigma(k)}(x)$ converges. Define $h_2(x,y,z)=\max\{p_2(k,x,y,z)\mid k\leq x\}$

Then we have that for all k:

$$\overset{\infty}{\forall}x\forall y[\phi_k^{(2)}(x,y)=1\rightarrow\Phi_{\sigma(k)}(x)\leq h_2(x,y,\Phi_k^{(2)}(x,y))].$$

If $\phi_k^{(2)}=C_f$. Then

$$\overset{\infty}{\forall}x\forall y[f(x)=y\rightarrow\Phi_{\sigma(k)}(x)\leq h_2(x,y,\Phi_k^{(2)}(x,y))].$$

h in the lemma is defined by

$$h(x,y,z)=\max\{h_1(x,y,z),h_2(x,y,z)\}$$

for all x, y, and z.

Notice that h is independent of the choice of f.

Let (ϕ,Φ) be the class of multitape Turing machines with step counting measure. Then the function h of lemma 1 is roughly given by $h(x,y,z)\approx z^3$. This can be done by a straightforward construction of a Turing machine.

We will now show that a recursive f exists for which there is no lower bound on the complexity for proving $f(x)=y$. This result basically follows from the speed-up theorem [Ref. 2] and lemma 1.

Theorem 1:

Let Φ be any complexity measure. For all $r\in R_1$ there is a $0-1$ valued recursive function $f\in R_1$ such that:

$$\forall k(\phi_k^{(2)}=C_f)\exists j(\phi_j^{(2)}=C_f)\overset{\infty}{\forall}x\forall y[f(x)=y\rightarrow\Phi_k^{(2)}(x,y)>r(\Phi_j^{(2)}(x,y))]$$

Proof:

Without loss generality, we assume r to be monotone increasing. Let $h\in R_3$ be any sufficiently large recursive function monotone increasing in the third variable (h need only be large enough to satisfy lemma 1). Define

$$r'(x,z)=\max\{h(x,y,r(h(x,y,z)))\mid y=0,1\} \tag{1}$$

By the speed-up theorem, there exists a $0-1$ valued function $f\in R_1$ such that:

$$\forall i(\phi_i=f)\exists l(\phi_l=f)\overset{\infty}{\forall}x[\Phi_i(x)>r'(x,\Phi_l(x))] \tag{2}$$

Given $\phi_k^{(2)}=C_f$, it follows from lemma 1 that there exists an i such that:

$$\phi_i = f$$

and

$$\overset{\infty}{\forall} x \forall y [f(x) = y \rightarrow \Phi_i(x) \leq h(x, y, \Phi_k^{(2)}(x, y))] \quad (3)$$

Then by Eq. (2) there is an l such that $\phi_l = f$ and

$$\overset{\infty}{\forall} x [\Phi_i(x) > r'(x, \Phi_l(x))] \quad (4)$$

Applying lemma 1 again, we get $j = \gamma(l)$ such that:

$$\phi_j^{(2)} = C_f$$

and

$$\overset{\infty}{\forall} x \forall y [f(x) = y \rightarrow \Phi_j^{(2)}(x, y) \leq h(x, y, \Phi_l(x))] \quad (5)$$

Therefore we have:

$$\begin{aligned} \overset{\infty}{\forall} x \forall y [f(x) = y \rightarrow h(x, y, \Phi_k^{(2)}(x, y)) & \\ \geq \Phi_i(x) \quad & \text{(by Eq. (3))} \\ > r'(x, \Phi_l(x)) \quad & \text{(by Eq. (4))} \\ \geq h(x, y, r(h(x, y, \Phi_l(x)))) \quad & \text{(by Eq. (1) and the fact that } y = f(x) \in \{0, 1\}) \\ \geq h(x, y, r(\Phi_j^{(2)}(x, y)))] \quad & \text{(by Eq. (5) and the fact that } r \text{ is monotone increasing)} \end{aligned}$$

This implies that

$$\overset{\infty}{\forall} x \forall y [f(x) = y \rightarrow \Phi_k^{(2)}(x, y) > r(\Phi_j^{(2)}(x, y))],$$

since h is monotone increasing in the third variable.

Although the faster program exists, we cannot effectively get such a program. This fact follows from the theorem in Ref. (3).

THE COMPLEXITY OF PROVING VERSUS DISPROVING FUNCTIONS

Next we are going to investigate the complexity for proving and disproving functions. First we make a definition.

Definition 4:

Let $g \in R_2$, $f \in R_1$. We say f is "difficult to prove almost everywhere (infinitely often) modulo g" if every $\phi_i^{(2)}$ computing C_f has the property that for almost all x (infinitely many x) and all y $f(x) = y$ implies $\Phi_i^{(2)}(x, y) > g(x, y)$.

Let $f \in R_1$. For each x there is only one y with the property that $y = f(x)$. Hence it is ambiguous to say f is difficult or easy to disprove at x, since the complexity of disproving f at x also depends on argument y. For example, Rabin's $0-1$ valued recursive function f [Ref. 1] is difficult to compute, hence by lemma 1, f is difficult to prove. As to the complexity of disproving f: if $y \notin \{0, 1\}$, then we know immediately that $f(x) \neq y$. However, if $y \in \{0, 1\}$, then $f(x) \neq y$ is not easy to verify; it is easy to show that this must be the case, i.e., if $y \in \{0, 1\}$, then to prove $f(x) = y$ or to disprove $f(x) = y$ is of the same difficulty.

Since functions, like Rabin's $0-1$ valued function, are generally treated as difficult, we have the following definition for the complexity of disproving functions.

Definition 5:

Let $g \in R_2$, we say that f is "easy to disprove almost everywhere (infinitely often) modulo g" if some $\phi_i^{(2)} = C_f$ has the property that for almost all x (infinitely many x) and all y,[*] $f(x) \neq y \rightarrow \Phi_i^{(2)}(x, y) \leq g(x, y)$.

The complement of this definition is:

Definition 6:

Let $g \in R_2$, we say that f is "difficult to disprove almost everywhere (infinitely often) modulo g" if every $\phi_i^{(2)} = C_f$ has the property that for almost all x (infinitely many x) and some y, $f(x) \neq y$ and $\Phi_i^{(2)}(x, y) > g(x, y)$.

The following theorem asserts that if function f is difficult to prove infinitely often, then it is also difficult to disprove infinitely often.

Theorem 2:

Let Φ be any complexity measure. There is an $h \in R_3$ such that for every step counting function $g \in R_2$ and for all $f \in R_1$, if f is difficult to prove infinitely often modulo $\lambda xy[h(x, y, g(x, y))]$, then f is difficult to disprove infinitely often modulo g.

Proof:

Assume to the contrary that there is a program for C_f, which disproves f easily almost everywhere modulo g, i.e.,

$$\exists j_0 (\phi_{j_0}^{(2)} = C_f) \overset{\infty}{\forall} x \forall y [f(x) \neq y \rightarrow \Phi j_0^{(2)}(x, y) \leq g(x, y)]. \quad (1)$$

Then we may use this program to construct a program which easily proves f almost everywhere. This relies on g being a step counting function. With inputs x and y, our program simply computes $g(x, y)$, then starts computing the given program $\phi_{j_0}^{(2)}(x, y)$. When

[*] If this were "almost all y," then every f would be easy to disprove almost everywhere.

x is sufficiently large, if the computation of $\phi_{j_0}{}^{(2)}(x, y)$ takes more than $g(x, y)$ steps, then we know $f(x)=y$ immediately. Otherwise $\phi_{j_0}{}^{(2)}(x, y)$ takes less than $g(x, y)$ steps to converge. In that case we can prove or disprove $f(x)=y$ according to the value of $\phi_{j_0}{}^{(2)}(x, y)$. Now we are going to give a formal proof of the above outline.

Let α be a recursive function such that:

$$\phi_{\alpha(i,j,l)}{}^{(2)}(x, y)=\begin{cases} \phi_{j(x,y)}{}^{(2)} & \text{if } x<l \text{ or} \\ & (x\geq l \text{ and } \phi_i{}^{(2)}(x, y) \text{ converges} \\ & \text{and } \Phi_j{}^{(2)}(x, y)\leq\Phi_i{}^{(2)}(x, y)) \\ 1 & \text{if } x\geq l \text{ and } \phi_i{}^{(2)}(x, y) \\ & \text{converges and} \\ & \Phi_j{}^{(2)}(x, y)>\Phi_i{}^{(2)}(x, y) \\ \text{diverge} & \text{otherwise} \end{cases}$$

Lemma:

If $g=\Phi_{i_0}{}^{(2)}$ and if $j=j_0$ is given by Eq. (1), then for some l_0, $\phi_{\alpha(i_0,j_0,l_0)}{}^{(2)}=C_f$.

Proof:

Since $\phi_{i_0}{}^{(2)}$ and $\phi_{j_0}{}^{(2)}$ are total, $\phi_{\alpha(i_0,j_0,l)}{}^{(2)}$ is total. By Eq. (1) there is a number l_0 such that for all x and all y, if $x\geq l_0$ and $f(x)\neq y$, then $\Phi_{j_0}{}^{(2)}(x, y)\leq g(x, y)$. Therefore $\phi_{\alpha(i_0,j_0,l_0)}{}^{(2)}$ computes C_f. End of lemma.

Now we shall construct the h of the theorem. Define: $p(i, j, l, x, y, z)$

$$=\begin{cases} 0 & \text{if } x<l \\ \Phi_{\alpha(i,j,l)}{}^{(2)}(x, y) & \text{if } x\geq l \text{ and } \Phi_i{}^{(2)}(x, y)=z \\ 0 & \text{otherwise} \end{cases}$$

p is recursive, for if $x\geq l$ and $\Phi_i{}^{(2)}(x, y)$ converges, then $\Phi_{\alpha(i,j,l)}{}^{(2)}(x, y)$ converges.

Let

$$h(x, y, z)= \max\{p(i, j, l, x, y, z) \mid \max\{i, j, l\}\leq x\}.$$

Thus we have that for all i, j, l:

$$\overset{\infty}{\forall} x \forall y[h(x, y, \Phi_i{}^{(2)}(x, y))\geq\Phi_{\alpha(i,j,l)}{}^{(2)}(x, y)].$$

Hence, particularly for $i=i_0$, $j=j_0$, $l=l_0$:

$$\overset{\infty}{\forall} x \forall y[h(x, y, g(x, y))\geq\Phi_{\alpha(i_0,j_0,l_0)}{}^{(2)}(x, y)],$$

since $\Phi_{i_0}{}^{(2)}(x, y)=g(x, y)$.

This contradicts the hypothesis that f is difficult to prove infinitely often modulo $\lambda xy[h(x, y, g(x, y))]$, since by the lemma: $\phi_{\alpha(i_0,j_0,l_0)}{}^{(2)}$ is a program that computes C_f.

Conversely, we can show that if f is difficult to disprove infinitely often, then it is also difficult to prove infinitely often.

Theorem 3:

Let Φ be any complexity measure. There is an $h\in R_3$ such that for every step counting function $g\in R_2$ and for all $f\in R_1$, if f is difficult to disprove infinitely often modulo $\lambda xy[h(x, y, g(x, y))]$, then f is difficult to prove infinitely often modulo g.

Proof:

The proof is similar to the proof of theorem 2. Notice that if there is a program $\phi_j{}^{(2)}$ for C_f which proves f easily almost everywhere modulo g, then by definition this means that for almost all x there is a y such that $f(x)=y$ and $\Phi_j{}^{(2)}(x, y)\leq g(x, y)$. Since the graph of f is single-valued, if x is large and $\Phi_j{}^{(2)}(x, y)>g(x, y)$, then $f(x)$ cannot possibly be equal to y.

Theorems 2 and 3 show that a function is difficult to prove infinitely often if and only if it is difficult to disprove infinitely often.

Naturally, we may ask the question: if $f(x)=y$ is difficult to prove for almost all x, then does it follow that for each such x there is a y such that $f(x)=y$ is also difficult to disprove? This is false by the following theorem.

Theorem 4:

Let Φ be any complexity measure. There is a function $b\in R_2$ such that for all function $g\in R_2$, there exists a function $f\in R_1$ with two properties:

(a) f is difficult to prove almost everywhere modulo g.

(b) f is easy to disprove infinitely often modulo b.

Proof:

The theorem follows from the fact that even if a function f has the property that there is a bound $b(x, y)$ on the number of steps to disprove $f(x)=y$ for infinitely many x and all y, it may still be difficult to locate these x for which $f(x)=y$ is easy to disprove.

Let $g\in R_2$ be given. Let $h\in R_3$ be any sufficiently large function monotone increasing in the third variable (h need only be large enough to satisfy lemma 1). Let $\lambda x[a(x)]$ be a $0-1$ valued recursive function such that:

$$\forall i(\phi_i=a)\overset{\infty}{\forall} x[\Phi_i(x)>h(x, 0, g(x, 0))] \qquad (1)$$

The existence of $\lambda x[a(x)]$ follows from Rabin's theorem [Ref. 1].

Let ϕ_{i_0} be a fixed program for $\lambda x[a(x)]$. We define f as follows: $f(x)$: "With input x, first compute $f(y)$ for all $y<x$. (In the process of doing this, some finite set of ϕ_i will be cancelled.) Second compute $\phi_{i_0}(x)$.

Case 1: $\phi_{i_0}(x)=0$, let the output be 0.

Case 2: $\phi_{i_0}(x)=1$, look for $j_0=\mu j[j\leq x$ and j is not cancelled and $\Phi_j(x)\leq 1+\max\{h(x, y, g(x, y))\mid y\in\{\Phi_{i_0}(x)+1, \Phi_{i_0}(x)+2\}\}$.

If no such j_0 is found, let the output be $\Phi_{i_0}(x)+1$. Otherwise, let the output be $\Phi_{i_0}(x)+2$ if $\phi_{j_0}(x)=\Phi_{i_0}(x)+1$. Let the output be $\Phi_{i_0}(x)+1$ if $\phi_{j_0}(x)\neq\Phi_{i_0}(x)+1$.

Then cancel ϕ_{j_0} from the standard list."

Let us see why f works:

(b) We know that for any sufficiently difficult $0-1$ function a, $a(x)=0$ for infinitely many x. From the construction of f, $a(x)=0$ implies $f(x)=0$. We shall exhibit a program which has the property that it disproves $f(x)=y$ quickly whenever $a(x)=0$ and $y\neq 0$. In fact, we will define a recursive function b, which does not depend on f such that b is an upper bound for the number of steps to disprove $f(x)=y$ whenever $a(x)=0$ and $y\neq 0$.

First we construct $\phi_{\sigma(i,k)}{}^{(2)}$. We will show that $\phi_{\sigma(i,k)}{}^{(2)}$ is the program that disproves f quickly when k is an index for f and i is i_0, where ϕ_{i_0} is the program used in the construction of f.

Let σ be a recursive function such that:

$$\phi_{\sigma(i,k)}{}^{(2)}(x, y)=\begin{cases} 1\dot{-}\phi_k(x) & \text{if } y=0 \text{ and } \phi_k(x) \text{ converges}\\ 0 & \text{if } y\neq 0 \text{ and}\\ & \quad(\Phi_i(x)>y \text{ or } \phi_i(x)=0\\ & \text{or } v(\phi_k(x) \text{ converges and}\\ & \quad \phi_k(x)\neq y))\\ 1 & \text{if } y\neq 0 \text{ and } \Phi_i(x)\leq y \text{ and}\\ & \quad \phi_i(x)\neq 0 \text{ and } \phi_k(x) \text{ converges and } \phi_k(x)=y\\ \text{diverge} & \text{otherwise}\end{cases}$$

Lemma 4.1:

If k is an index for f and if ϕ_{i_0} is the program used in the construction of f, then $\phi_{\sigma(i_0,k)}{}^{(2)}=C_f$.

Proof:

Observe that ϕ_k is total implies that $\phi_{\sigma(i_0,k)}{}^{(2)}$ is total.

Case 1: $y=0$.

$$\phi_{\sigma(i_0,k)}(x, y)=\begin{cases} 1 & \text{if } \phi_k(x)=0\\ 0 & \text{if } \phi_k(x)\neq 0\end{cases}$$

$$\phi_{\sigma(i_0,k)}(x, 0)=C_f(x, 0) \text{ for all } x.$$

Case 2: $y\neq 0$.

Subcase 1: $\Phi_{i_0}(x)>y$. In this subcase,

$$\phi_{\sigma(i_0,k)}{}^{(2)}(x, y)=0.$$

Now look at the construction of f. $f(x)\in\{0, \Phi_{i_0}(x)+1, \Phi_{i_0}(x)+2\}$. Therefore $f(x)$ will either be 0 or will be greater than y. Therefore $f(x)\neq y$.

Subcase 2: $\Phi_{i_0}(x)\leq y$ and $\phi_{i_0}(x)=0$. Again,

$$\phi_{\sigma(i_0,k)}{}^{(2)}(x, y)=0.$$

Look at the program for f. $\phi_{i_0}(x)=0$ implies $f(x)=0$, therefore: $f(x)\neq y$.

Subcase 3: $\Phi_{i_0}(x)\leq y$ and $\phi_{i_0}(x)\neq 0$ and $\phi_k(x)=y$ implies $\phi_{\sigma(i_0,k)}(x, y)=1 \therefore$ $\phi_{\sigma(i_0,k)}{}^{(2)}$ gives the correct answer. End of lemma 4.1.

Define b as follows:

$$b(x, y)=\begin{cases}\max\{\Phi_{\sigma(i,k)}{}^{(2)}(x, y)\mid i\in A \text{ and } k\leq x\}\\ \qquad \text{if } y\neq 0 \text{ and } A\neq\emptyset, \text{ where}\\ \qquad A=\{i\mid i\leq x \text{ and } [\Phi_i(x)>y \text{ or } \phi_i\\ 0 \qquad (x)=0]\} \text{ otherwise}\end{cases}$$

b is recursive since one can effectively decide whether or not $A=\emptyset$, and in case $y\neq 0$ and $A\neq\emptyset$, then by definition of σ, $\phi_{\sigma(i,k)}{}^{(2)}(x, y)=0$, so $\Phi_{\sigma(i,k)}{}^{(2)}(x, y)$ converges for all x.

Lemma 4.2:

$$\forall i\forall k\overset{\infty}{\forall} x\forall y[\phi_i(x)=0$$

and

$$y\neq 0\rightarrow\Phi_{\sigma(i,k)}{}^{(2)}(x, y)\leq b(x, y)] \quad (2)$$

Proof:

Let $x\geq\max\{i, k\}$. If $\phi_i(x)=0$, then i will be in A. If i is in A and $y\neq 0$, then $b(x, y)\geq\Phi_{\sigma(i,k)}{}^{(2)}(x, y)$. End of lemma 4.2.

Let $i=i_0$, and let k be an index for f. By lemma 4.1, $\phi_{\sigma(i_0,k)}{}^{(2)}=C_f$. By lemma 4.2,

$$\overset{\infty}{\forall} x\forall y[\phi_{i_0}(x)=0$$

and

$$y\neq 0\rightarrow\Phi_{\sigma(i_0,k)}{}^{(2)}(x, y)\leq b(x, y)].$$

By the definition of f, we know that $\phi_{i_0}(x)=0\rightleftarrows f(x)=0$. Because ϕ_{i_0} is a sufficiently complex $0-1$ valued function, we know $\phi_{i_0}(x)=0$ for infinitely many x. Hence, we have:

$$\overset{\infty}{\exists} x\forall y[f(x)\neq y\rightarrow\Phi_{\sigma(i,k)}{}^{(2)}(x, y)\leq b(x, y)].$$

This finishes the proof of part (b).

The proof of part (a) is easier: Let ϕ_k be any program which computes f.

Lemma 4.3:

$$\overset{\infty}{\forall} x[\Phi_k(x)>h(x, f(x), g(x, f(x)))] \quad (3)$$

Proof:

Case 1: $f(x)=0$

Assume to the contrary that

$$\overset{\infty}{\exists}x[\Phi_k(x)\le h(x,0,g(x,0))]$$

By the definition of f, we know $f(x)=0\rightleftarrows\phi_{i_0}(x)=0$. By assumption, program ϕ_k computes f in less than $h(x,0,g(x,0))$ steps infinitely often when $f(x)=0$. Hence, it computes $\phi_{i_0}(x)$ in less than $h(x,0,g(x,0))$ steps infinitely often when $\phi_{i_0}(x)=0$. This is a contradiction, since

$$\forall i(\phi_i=\phi_{i_0})\overset{\infty}{\forall}x[\Phi_i(x)>h(x,0,g(x,0))],$$

by Eq. (1).

Case 2: $f(x)\neq 0$.

Assume to the contrary that

$$\overset{\infty}{\exists}x[\Phi_k(x)\le h(x,f(x),g(x,f(x)))].$$

Notice that $f(x)\neq 0$ implies $f(x)\in\{\Phi_{i_0}(x)+1, \Phi_{i_0}(x)+2\}$. Look at the definition of f: there are infinitely many chances for k to be cancelled. Since at most k programs with index less than k may be cancelled, ϕ_k will eventually be cancelled and the value of f will be made different from ϕ_k. This contradicts $\phi_k=f$. End of lemma 4.3.

Let $\phi_i^{(2)}=C_f$. By lemma 1, there is a k such that $\phi_k=f$ and

$$\overset{\infty}{\forall}x\forall y[f(x)=y\rightarrow\Phi_k(x)\le h(x,y,\Phi_i^{(2)}(x,y))] \qquad (4)$$

Combining Eq. (3) and Eq. (4), we have:

$$\overset{\infty}{\forall}x\forall y[f(x)=y\rightarrow h(x,y,\Phi_i^{(2)}(x,y)) \ge\Phi_k(x)>h(x,y,g(x,y))].$$

If follows that:

$$\overset{\infty}{\forall}x\forall y[f(x)=y\rightarrow\Phi_i^{(2)}(x,y)>g(x,y)],$$

since h is monotone increasing in the third variable.

This finishes the proof of part (a).

Let (ϕ, Φ) be the class of multitape Turing machines with step counting measure. Then the function b of theorem 4 is given by $b(x,y)=C\cdot y$, where C is a constant. To see this, we simply present a program to prove $f(x)\neq y$ in $C\cdot y$ steps when $\phi_{i_0}(x)=0$ (note that $\phi_{i_0}(x)=0$ occurs for infinitely many x), informally: given inputs x and y, if $y>0$, run y steps of $\phi_{i_0}(x)$. If $\phi_{i_0}(x)$ does not converge in y steps, we know immediately $f(x)\neq y$ (since $f(x)\in\{0, \Phi_{i_0}(x)+1, \Phi_{i_0}(x)+2)\}$). Otherwise $\phi_{i_0}(x)$ converges in y steps, and in case $\phi_{i_0}(x)=0$, then we conclude that $f(x)\neq y$ (since $\phi_{i_0}(x)=0\leftrightarrow f(x)=0$).

Parallel to the question asked before theorem 4, we may ask the question: if f is difficult to disprove almost everywhere, is it also difficult to prove almost everywhere? The answer is again negative by a similar construction of f as in theorem 4.

Theorem 5:

Let Φ be any complexity measure. There is a function $b\in R_2$ such that for all function $g\in R_3$, there exists a function $f\in R_1$ with two properties:

(a) f if difficult to disprove almost everywhere modulo g.
(b) f is easy to prove infinitely often modulo b.

Proof:

The proof is similar to that of theorem 4. First we define a function $h_1\in R_4$, the reason we define h_1 will be clear later.

Let δ be a recursive function such that

$$\phi_{\delta(i,j)}{}^{(2)}(x,y):$$

"With input x and y. Compute $\phi_i(x)$. If and when $\phi_i(x)$ converges. Check following 3 cases.

Case 1: $\phi_i(x)=0$; give output $1\dot{-}|y-\Phi_i(x)|$
Case 2: $\phi_i(x)=1$; compute $\phi_j{}^{(2)}(x,0)$ and $\phi_j{}^{(2)}(x,1)$ simultaneously until one of them converges.

Subcase 1: $\phi_j{}^{(2)}(x,0)=0$ or $\phi_j{}^{(2)}(x,1)=1$; give output $1\dot{-}|y-1|$

Subcase 2: $\phi_j{}^{(2)}(x,0)=1$ or $\phi_j{}^{(2)}(x,1)=0$; give output $1\dot{-}y$

Subcase 3: $\phi_j{}^{(2)}(x,0)$ converges and $\phi_j{}^{(2)}(x,0)\notin\{0,1\}$ or $\phi_j{}^{(2)}(x,1)$ converges and $\phi_j{}^{(2)}(x,1)\notin\{0,1\}$; give output 0

Case 3: $\phi_i(x)$ converges and $\phi_i(x)\notin\{0,1\}$; give output 0."

Define:

$$h_1(x,y,w,z)=\begin{cases}\max\{\Phi_{\delta(i,j)}{}^{(2)}(x,y)\mid\langle i,j\rangle\in A\}\\ \quad\text{if } A\neq\phi\text{, where}\\ A=\{\langle i,j\rangle\mid i\le x\text{ and } j\le x\\ \quad\text{and }\Phi_i(x)=w\text{ and}\\ \quad(\Phi_j{}^{(2)}(x,0)\le z\text{ or }\Phi_j{}^{(2)}(x,1)\le z)\}\\ 0\quad\text{otherwise}\end{cases}$$

h_1 is recursive, since we can effectively decide whether $\langle i,j\rangle\in A$ or not. And in case $\langle i,j\rangle\in A$, $\Phi_{\delta(i,j)}{}^{(2)}(x,y)$ converges.

Lemma 5.1:

$$\forall i\forall j\overset{\infty}{\forall}x\forall y[\phi_i(x)\text{ converges and }(\phi_j{}^{(2)}(x,0)\text{ converges or }\phi_j{}^{(2)}(x,1)\text{ converges})\rightarrow\Phi_{\delta(i,j)}{}^{(2)}(x,y)\le h_1(x,y,\Phi_i(x),\min\{\Phi_j{}^{(2)}(x,0),\Phi_j{}^{(2)}(x,1)\})]$$

Proof:

Let $x \geq \max\{i, j\}$. Since either

$$\Phi_j^{(2)}(x, 0) \leq \min\{\Phi_j^{(2)}(x, 0), \Phi_j^{(2)}(x, 1)\}$$

or

$$\Phi_j^{(2)}(x, 1) \leq \min\{\Phi_j^{(2)}(x, 0), \Phi_j^{(2)}(x, 1)\},$$

by the definition of A we know that $\langle i, j\rangle \in A$. Therefore, for all $x \geq \max\{i, j\}$ and all y

$$[\Phi_{\delta(i,j)}^{(2)}(x, y) \leq h_1(x, y, \Phi_i(x), \min\{\Phi_j^{(2)}(x, 0), \Phi_j^{(2)}(x, 1)\})].$$

End of lemma 5.1.

Now we are going to define f. Let h_1 be any sufficiently large function monotone increasing in the fourth variable (h_1 need only be large enough to satisfy lemma 5.1 above). Let $g \in R_2$ be given. Let $h \in R_3$ be any sufficiently large function monotone increasing in the third variable (h need only be large enough to satisfy lemma 1). Let $\lambda x[a(x)]$ be a $0-1$ valued recursive function such that:

$$\forall i(\phi_i = a) \overset{\infty}{\forall} x[\Phi_i(x) > 2 + \max\{g(x, 0), g(x, 1)\}]. \quad (1)$$

The existence of $\lambda x[a(x)]$ follows from Rabin's theorem [Ref. 1].

Let ϕ_{i_0} be a fixed program for $\lambda x[a(x)]$. We define f as follows: $f(x)$: "With input x, first compute $f(y)$ for all $y < x$. (In the process of doing this, some finite set of ϕ_i will be cancelled.) Second compute $\phi_{i_0}(x)$.

Case 1: $\phi_{i_0}(x) = 0$, let the output be $\Phi_{i_0}(x)$.

Case 2: $\phi_{i_0}(x) = 1$, look for $j_0 = \mu j[j \leq x$ and j is not cancelled and

$$\Phi_j(x) \leq \max_{y \in \{0,1\}} \{h(x, y, \max_{w \in \{0,1\}} \{h_1(x, w, \Phi_{i_0}(x), \max\{g(x, 0), g(x, 1)\})\})\}]$$

If no such j_0 is found, let the output be 0. Otherwise, let the output be $1 \dot{-} \phi_{j_0}(x)$. Then cancel ϕ_{j_0} from the standard list."

Let us see why f works:

(a) We will show that for all sufficiently large x, there exists some y such that $f(x) \neq y$ and $\Phi_i^{(2)}(x, y) > g(x, y)$ for every $\phi_i^{(2)}$ computing C_f.

Lemma 5.2:

For all sufficiently large x such that $\phi_{i_0}(x) = 0$, $f(x) = y$ is difficult to disprove modulo g for some y. i.e.,

$$\forall j(\phi_j^{(2)} = C_f) \overset{\infty}{\forall} x[\phi_{i_0}(x) = 0 \rightarrow \exists y[f(x) \neq y$$

and

$$\Phi_j^{(2)}(x, y) > g(x, y)]].$$

Proof:

Assume to the contrary that: $\phi_{j_0}^{(2)} = C_f$ and

$$\overset{\infty}{\exists} x[\phi_{i_0}(x) = 0$$

and

$$\forall y[f(x) \neq y \rightarrow \Phi_{j_0}^{(2)}(x, y) \leq g(x, y)] \quad (2)$$

From the construction of f, we know that $\phi_{i_0}(x) = 0 \leftrightarrow f(x) > 1$. Therefore, if we can decide $f(x) > 1$ in less than $\max\{g(x, 0), g(x, 1)\}$ steps for infinitely many x, then we can compute $\phi_{i_0}(x)$ in less than $\max\{g(x, 0), g(x, 1)\}$ steps for infinitely many x. This will be a contradiction to Eq. (1). Since $\phi_{j_0}^{(2)}$ computes C_f, a way to decide whether $f(x) > 1$ or not is to compute $\phi_{j_0}^{(2)}(x, 0)$ and $\phi_{j_0}^{(2)}(x, 1)$ simultaneously. For those x satisfying Eq. (2), the computation of $\phi_{j_0}^{(2)}(x, 0)$ and $\phi_{j_0}^{(2)}(x, 1)$ will converge in less than $g(x, 0)$ and $g(x, 1)$ steps respectively, since by the definition of f for those x with the property that $\phi_{i_0}(x) = 0$. We know that $f(x) \neq 0$ and $f(x) \neq 1$. Therefore, we can decide $f(x) > 1$ in less than $\max\{g(x, 0), g(x, 1)\}$ steps for infinitely many x. End of lemma 5.2.

Lemma 5.3:

For all sufficiently large x such that $\phi_{i_0}(x) = 1$, $f(x) = y$ is difficult to disprove modulo $g(x, y)$ for some y. i.e.,

$$\forall_j(\phi_j^{(2)} = C_f) \overset{\infty}{\forall} x[\phi_{i_0}(x) = 1 \rightarrow \exists_y[f(x) \neq y$$

and

$$\Phi_j(x, y) > g(x, y)]]$$

Proof:

Claim:

For all sufficiently large x such that $\phi_{i_0}(x) = 1$, $f(x) = y$ is difficult to prove modulo

$$\lambda x[\max_{w \in \{0,1\}} \{h_1(x, w, \Phi_{i_0}(x), \max\{g(x, 0), g(x, 1)\})\}]$$

for all y. i.e.,

$$\forall_j(\phi_j^{(2)} = C_f) \overset{\infty}{\forall} x[\phi_{i_0}(x) = 1$$
$$\rightarrow \forall y[f(x) = y \rightarrow \Phi_j^{(2)}(x, y)$$
$$> \max_{w \in \{0,1\}} \{h_1(x, w, \Phi_{i_0}(x),$$
$$\max\{g(x, 0), g(x, 1)\})\}]]$$

Proof:

First we show that: for every ϕ_k computing f

$$\overset{\infty}{\forall} x[\phi_{i_0}(x) = 1 \rightarrow [\Phi_k(x)$$
$$> \max_{y \in \{0,1\}} \{h(x, y, \max_{w \in \{0,1\}} \{h_1(x, w, \Phi_{i_0}(x),$$
$$\max\{g(x, 0), g(x, 1)\})\})\}]] \quad (3)$$

Since otherwise there is a ϕ_k such that $\phi_k = f$ and

$$\overset{\infty}{\exists} x[\phi_{i_0}(x) = 1$$

and

$$\Phi_k(x) \leq \max_{y\in\{0,1\}} \{h(x, y, \max_{w\in\{0,1\}} \{h_1(x, w, \Phi_{i_0}(x), \max\{g(x, 0), g(x, 1)\})\})\}].$$

Look at the definition of f, then there are infinitely many chances for k to be cancelled and ϕ_k will eventually be cancelled and the value of f will be made different from ϕ_k. This contradicts that ϕ_k computes f.

Second, let $\phi_j^{(2)} = C_f$. By lemma 1 there is a k such that $\phi_k = f$ and

$$\overset{\infty}{\forall} x \forall y[f(x) = y \rightarrow \Phi_k(x) \leq h(x, y, \Phi_j^{(2)}(x, y))] \quad (4)$$

Therefore, we have:

$$\overset{\infty}{\forall} x[\phi_{i_0}(x) = 1 \rightarrow \forall y[f(x) = y$$
$$\rightarrow h(x, y, \Phi_j^{(2)}(x, y)) \geq \Phi_k(x)$$
$$\text{(by Eq. (4))}$$
$$\geq h(x, y, \max_{w\in\{0,1\}} \{h_1(x, w, \Phi_{i_0}(x), \max\{g(x, 0), g(x, 1)\})\})]]$$
$$\text{(by Eq. (3) and } \phi_{i_0}(x) = 1 \rightarrow y = f(x) \in \{0, 1\})$$

It follows that:

$$\overset{\infty}{\forall} x[\phi_{i_0}(x) = 1 \rightarrow \forall y[f(x) = y \rightarrow \Phi_j^{(2)}(x, y) \geq \max_{w\in\{0,1\}} \{h_1(x, w, \Phi_{i_0}(x), \max\{g(x, 0), g(x, 1)\})\}]];$$

since h is monotone in the third variable. End of claim.

Next we assume to the contrary to lemma 5.3 that there is a $\phi_{j_0}{}^{(2)}$ computes C_f has the property that:

$$\overset{\infty}{\exists} x[\phi_{i_0}(x) = 1$$

and

$$\forall y[f(x) \neq y \rightarrow \Phi_{j_0}(x, y) \leq g(x, y)]] \quad (5)$$

We will use ϕ_{j_0} to construct a program which proves $f(x) = y$ in less than

$$\max_{w\in\{0,1\}} \{h_1(x, w, \Phi_{i_0}(x), \max\{g(x, 0), g(x, 1)\})\}$$

steps for infinitely many x such that $\phi_{i_0}(x) = 1$. Then this is a contradiction to the claim above.

We claim $\phi_{\delta(i_0, j_0)}{}^{(2)}$ will do: from the definition of δ, it is easy to see that $\phi_{\delta(i_0,j_0)}{}^{(2)}$ computes C_f, since ϕ_{j_0} computes C_f and ϕ_{i_0} is used in defining f.

Since $\phi_{j_0}{}^{(2)}$ is total and $\phi_{i_0}(x) = 1$ implies that $f(x) \in \{0, 1\}$. From lemma 5.1 and Eq. (5) above we have the result that for infinitely many x such that $\phi_{i_0}(x) = 1$ and for $y \in \{0, 1\}$,

$$\Phi_{\delta(i_0,j_0)}{}^{(2)}(x, y) \leq h_1(x, y, \Phi_{i_0}(x),$$
$$\min\{\Phi_{j_0}(x, 0), \Phi_{j_0}(x, 1)\}) \leq \max_{w\in\{0,1\}} h_1(x, w, \Phi_{i_0}(x),$$
$$\min\{\Phi_{j_0}(x, 0), \Phi_{j_0}(x, 1)\}) \leq \max_{w\in\{0,1\}} h_1(x, w, \Phi_{i_0}(x),$$
$$\max\{g(x, 0), g(x, 1)\})$$

(since h_1 is monotone increasing in the fourth variable and either $\Phi_{j_0}{}^{(2)}(x, 0) \leq g(x, 0)$ or $\Phi_{j_0}{}^{(2)}(x, 1) \leq g(x, 1)$ by Eq. (5)).

This is a contradiction to the claim above. End of lemma 5.3.

Combining lemma 5.2 and lemma 5.3, we have the proof of part (a).

(b) We will construct $\phi_{\sigma(i,k)}{}^{(2)}$. When we choose $i = i_0$ and k to be an index for f, then $\phi_{\sigma(i_0,k)}{}^{(2)}$ computes C_f. In addition, we will show that there is a recursive b, which does not depend on f and g such that b is an upper bound for the number of steps to compute $\phi_{\sigma(i_0,k)}{}^{(2)}(x, y)$ whenever $\phi_{i_0}(x) = 0$ and $y = \Phi_{i_0}(x)$. Look at the definition of f, $f(x) = \Phi_{i_0}(x)$ when $\phi_{i_0}(x) = 0$. Therefore b is an upper bound for the number of steps to prove $f(x) = y$ by algorithm $\sigma(i_0, k)$ when $\phi_{i_0}(x) = 0$. Since ϕ_{i_0} is a sufficiently complex $0-1$ valued function, we know $\phi_{i_0}(x) = 0$ for infinitely many x.

Let σ be a recursive function such that:

$$\phi_{\sigma(i,k)}{}^{(2)}(x, y)$$
$$= \begin{cases} 1 \dot{-} \mid y - \phi_k(x) \mid & \text{if } y \leq 1 \text{ and } \phi_k(x) \text{ converges} \\ 1 & \text{if } y > 1 \text{ and } \Phi_i(x) = y \\ & \quad \text{and } \phi_i(x) = 0 \\ 0 & \text{if } y > 1 \\ & \quad \text{and } (\Phi_i(x) > y \text{ or } (\Phi_i(x) = y \\ & \quad \text{and } \phi_i(x) \neq 0) \text{ or } \Phi_i(x) < y) \\ \text{diverge} & \text{otherwise} \end{cases}$$

Lemma 5.4:

If k is an index for f and if ϕ_{i_0} is the program used in the construction of f, then $\phi\sigma_{(i_0,k)}{}^{(2)} = C_f$.

Proof:

Observe that ϕ_k total implies that $\phi_{\sigma(i_0,k)}{}^{(2)}$ is total. It is obvious to see $\phi_{\sigma(i_0,k)}{}^{(2)}(x, y) = C_f(x, y)$ when $y \leq 1$. By definition of f, $f(x) \in \{0, 1, \Phi_{i_0}(x)\}$ and $f(x) = \Phi_{i_0}(x)$ only when $\phi_{i_0}(x) = 0$. End of lemma 5.4.

Define b as follows:

$$b(x,y)=\begin{cases}\max\{\Phi_{\sigma(i,k)}(x,y) \mid k\leq x \\ \quad \text{and } i\in A\} \text{ if } A\neq\emptyset, \text{ where} \\ A=\{i \mid i\leq x \text{ and } y>1 \\ \quad \text{and } \Phi_i(x)=y \text{ and } \phi_i(x)=0\} \\ 0 \quad \text{otherwise}\end{cases}$$

b is recursive since one can effectively decide whether or not $A=\emptyset$, and in case $A\neq\emptyset$, then by definition of σ, $\phi_{\sigma(i,k)}{}^{(2)}(x,y)=1$. So $\Phi_{\sigma(i,k)}{}^{(2)}(x,y)$ converges.

Lemma 5.5:

$$\forall i\forall k\overset{\infty}{\forall} x\forall y[y>1 \text{ and } \phi_i(x)=0 \text{ and } \Phi_i(x)=y\rightarrow\Phi_{\sigma(i,k)}{}^{(2)}(x,y)\leq b(x,y)].$$

Proof:

Let $x\geq\max\{i,k\}$. If $y>1$ and $\phi_i(x)=0$ and $\Phi_i(x)=y$, then i will be in A then $b(x,y)\geq\Phi_{\sigma(i,k)}{}^{(2)}(x,y)$. End of lemma 5.5.

Let $i=i_0$, and let k be an index for f. By lemma 5.4, $\phi_{\sigma(i_0,k)}{}^{(2)}=C_f$. Because ϕ_{i_0} is a sufficiently complex $0-1$ valued function, we know $\phi_{i_0}(x)=0$ for infinitely many x. By definition of f, $\phi_{i_0}(x)=0$ implies $f(x)=\Phi_{i_0}(x)$ and $\Phi_{i_0}(x)>1$ by Eq. (1). Hence by lemma 5.5, we have:

$$\overset{\infty}{\exists} x\exists y[f(x)=y \text{ and } \Phi_{\sigma(i_0,k)}{}^{(2)}(x,y)\leq b(x,y)]$$

i.e., we show that f is easy to prove infinitely often modulo b. This ends the proof of part (b).

ACKNOWLEDGMENTS

The author is deeply indebted to Professor M. Blum for suggesting the topic and close supervision throughout the whole study, especially in the proof of theorem 4.

PRELIMINARIES

We assume that the reader is familiar with the basic paper of Blum,[1] and Borodin's paper on the existence of complexity gaps.[2]

$\mathcal{N}$ is the set of nonnegative integers. $\mathcal{R}_n$ is the set of (total) recursive functions of n variables. $\mathcal{P}_n$ is the set of partial recursive functions of n variables.

The abbreviation "a.e." is used for "almost everywhere." If $P(x)$ is a statement containing the variable x then $\lambda x[P(x)]$ is a predicate of one variable on $\mathcal{N}$. The λ-notation is also used for functions. The statement "$\lambda x[P(x)]$ (a.e.)" means that $P(x)$ is true for all but finitely many $x \in \mathcal{N}$. Similarly, "$\lambda xy[P(x, y)]$ (a.e.)" means that $P(x, y)$ is true for all but finitely many pairs of x and $y \in \mathcal{N}$. The phrase "for sufficiently large function $f \in \mathcal{R}_n \ldots$" means "there is a $b \in \mathcal{R}_n$ such that for all $f, f \geq b$ (a.e.)$\Rightarrow \ldots$."

The function ϕ_i is then ith partial recursive function in a standard enumeration of $\mathcal{P}_i$. A Blum *measure* $\Phi = \{\Phi_0, \Phi_1, \ldots\}$ is a sequence of functions in $\mathcal{P}_1$ satisfying two axioms:

1. domain $(\phi_i) =$ domain (Φ_i) for all $i \in \mathcal{N}$, and
2. $\lambda i, x, y[\Phi_i(x) = y]$ is a recursive predicate.

As an aid in exposition, we say f is less (greater) than g, *modulo* r to mean that $rf < g$ a.e. ($f > rg$ a.e.).

Choose a recursive 1-1 map of the integers onto the set of all 2-tuples of integers. Let $\langle x, y \rangle$ denote the integer which maps onto (x, y).

"DENSENESS" OF BLUM MEASURE

Borodin[2] has shown that given any recursive function r, there exists a recursive t such that no step-counting function takes values between $t(x)$ and $rt(x)$ except on a finite number of integers. The gap, here, appears between two recursive functions, t and rt.

At this point, a natural question to ask is the following: for every recursive function r, does there exist a pair of recursive step-counting functions Φ_i and Φ_j such that $\Phi_j(x) > r(x, \Phi_i(x))$ for almost all x and there are no step-counting functions between them? Corollary will show that, in fact, for all sufficiently large recursive function r, there can be no such gaps between any two recursive step-counting functions, or even any two *partial* recursive step-counting functions with same but infinite domain.

The following proposition shows that for any partial recursive function ϕ_i there exists another program u, which computes ϕ_i but takes slightly more steps than that required to compute ϕ_i.

Proposition

There exist functions $\sigma \in \mathcal{R}_1$ and $h \in \mathcal{R}_2$ such that for every i, we have

(a) $\phi_{\sigma(i)} = \phi_i$ and
(b) $\Phi_i(x) < \Phi_{\sigma(i)}(x) \leq h(x, \Phi_i(x))$
a.e. in the domain of ϕ_i.

Proof:

Let σ be defined as follows:

$$\phi_{\sigma(i)}(x) = \begin{cases} \text{diverge} & \text{if} \quad \phi_i(x) \quad \text{diverges} \\ & \text{or} \quad \Phi_{\sigma(i)}(x) \leq \Phi_i(x) \\ \phi_i(x) & \text{otherwise} \end{cases}$$

Clearly σ is recursive and $\phi_{\sigma(i)} = \phi_i$. Also, for all x in the domain of ϕ_i, we have $\Phi_i(x) < \Phi_{\sigma(i)}(x)$.

Let p and h be defined as follows:

$$p(i, x, z) = \begin{cases} \Phi_{\sigma(i)}(x) & \text{if} \quad \Phi_i(x) = z \\ 0 & \text{if otherwise} \end{cases}$$

$$h(x, z) = \max_{i \leq x} \{p(i, x, z)\}$$

* Research sponsored by the National Science Foundation, Grant GJ-708

Clearly p is recursive and so is h. Further we have for almost all x in the domain of ϕ_i

$$\Phi_{\sigma(i)}(x) \leq h(x, \Phi_i(x))$$

Corollary:

Let $r \in \mathcal{R}_2$ be sufficiently large. For every i, j, if

(a) domain (ϕ_i) = domain $(\phi_j) = W$ and
(b) $\Phi_j(x) > r(x, \Phi_i(x))$ a.e. in W

then there is a u such that

(c) $\phi_u = \phi_i$ and
(d) $\Phi_i(x) < \Phi_u(x) < \Phi_j(x)$ a.e. in W.

Proof:

Let σ and h be as in Proposition (2.1). Assume r be such that $r > h$ a.e.

For every i, j satisfying (a) and (b) above, we have that for almost all x in the domain of ϕ_i

by Proposition (2.1) $\Phi_i(x) < \Phi_{\sigma(i)} \leq h(x, \Phi_i(x))$
by choice of r $< r(x, \Phi_i(x))$
by choice of j $< \Phi_j(x)$

Further $\phi_{\sigma(i)} = \phi_i$

Hence $\sigma(i)$ is the u desired by the corollary.

"TOP" AND "BOTTOM" OF GAPS

There is another slightly weaker way to talk about gaps. With $h \in \mathcal{R}_2$ fixed, pick a recursive function r much greater than h. Then we say that "Φ_i is the top (bottom) of a gap of size r," if whenever Φ_k is less (greater) than Φ_i modulo h a.e. then Φ_k is much less (greater) than Φ_i, in the sense that Φ_k is less (greater) than Φ_i modulo r.

Now we can ask the following question: does there exist an $h \in \mathcal{R}_2$ such that for every recursive r there is some Φ_i which is the top (bottom) of a gap of size r? Theorem (3.1) says that there exists a Φ_i which serves for the top of a gap, while for sufficiently large r, Theorem (3.2) says that no Φ_i can serve as the bottom of a gap of size r.

Theorem (*Top of the gap theorem*)

There exists an $h \in \mathcal{R}_2$ such that for every r, $g \in \mathcal{R}_1$, there is a u uniform in r and g with the following properties:

(a) Φ_u is recursive and
(b) $\forall x[\Phi_u(x) > g(x)]$ and

(c) $\forall k \overset{\infty}{\forall} x[h(x, \Phi_k(x)) < \Phi_u(x)$
$\rightarrow r(\langle x, \Phi_k(x) \rangle) < \Phi_u(x)]$

Proof:

Instead of working directly with r, $r = \phi_i$ and g, $g = \phi_j$, we choose to work with $\Phi_{\alpha(i)}$ (in place of ϕ_i) and $\Phi_{\alpha(j)}$ (in place of ϕ_j). Besides majorizing the recursive functions, these $\{\Phi_{\alpha(n)}\}_{n \geq 0}$ have other useful properties.

Lemma 1:

Let Φ be a Blum measure. There is a recursive function α such that for every i, x, y

(a) $\Phi_{\alpha(i)}(x) \geq \phi_i(x)$
(b) $\Phi_{\alpha(i)}(\langle x, y \rangle) > y$
(c) if $\Phi_{\alpha(i)}(\langle x, y \rangle)$ and $\Phi_{\alpha(i)}(\langle x, y+1 \rangle)$ converge, then $\Phi_{\alpha(i)}(\langle x, y \rangle) < \Phi_{\alpha(i)}(\langle x, y+1 \rangle)$
(d) $\Phi_{\alpha(i)}$ recursive iff ϕ_i recursive.
(e) if $\Phi_{\alpha(i)}(\langle x, y \rangle)$ diverges for some y, then for all $z \geq y$ $\Phi_{\alpha(i)}(\langle x, z \rangle)$ diverges

Lemma 2:

With α as in Lemma 1, there is $\delta \in \mathcal{R}_2$ such that

(a) for every i, j, x $\phi_{\delta(i,j)}(x) \geq \Phi_{\alpha(j)}(x)$
(b) $\lambda ijxz[\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x) \rangle) = z]$ is recursive
(c) if ϕ_i, ϕ_j are recursive, then $\phi_{\delta(i,j)}$ is recursive and has the following property:

$$\forall k \forall x \geq k[\neg[\phi_{\delta(i,j)}(x) \leq \Phi_k(x) \leq \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x) \rangle)]]$$

Lemma 2(b) is needed to make the construction of h in Lemma 4 become recursive.

Lemma 3:

With α as in Lemma 1 and δ as in Lemma 2, there exists $\sigma \in \mathcal{R}_2$ such that for every i, j, x

(a) $\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x) \rangle)$ converges if and only if $\Phi_{\sigma(i,j)}(x)$ converges and
(b) $\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x) \rangle) \leq \Phi_{\sigma(i,j)}(x)$

Lemma 4:

With α, δ, and σ as in Lemma 1, 2, 3 respectively, there exists an $h \in \mathcal{R}_2$, monotonically increasing on the second variable such that

$$\forall i, j \forall x \geq \max\{i, j\}[h(x, \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x) \rangle)) \geq \Phi_{\sigma(i,j)}(x)]$$

Now we are ready to prove the theorem. The function h is given by Lemma 4. Let recursive function $r = \phi_i$ and $g = \phi_j$ be given. We choose $u = \sigma(i, j)$. Since ϕ_i, ϕ_j recursive imply, by Lemma 1(d) and Lemma 2(c), that $\Phi_{\alpha(i)}$ and $\phi_{\delta(i,j)}$ are recursive, we conclude, by Lemma 3(a), that $\Phi_{\sigma(i,j)}$ recursive. This proves (a) of the theorem.

From Lemma 3(b), we have

$$\Phi_{\sigma(i,j)}(x) \geq \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x) \rangle) \quad \text{for every } x.$$

Recalling Lemma 1(b), Lemma 2(a), and Lemma 1(a), this implies

$$\Phi_{\sigma(i,j)}(x) > \phi_j(x) = g(x) \quad \text{for every } x.$$

This proves (b) of the theorem.

It remains to show that $\sigma(i,j)$ also satisfies (c) of the theorem.

Let Φ_k be such that for some $x > \max\{i, j, k\}$

$$h(x, \Phi_k(x)) < \Phi_{\sigma(i,j)}(x)$$

By Lemma 2(c), $\phi_{\delta(i,j)}$ is recursive. Since by Lemma 4, for $x \geq \max\{i, j\}$:

$$\Phi_{\sigma(i,j)}(x) \leq h(x, \Phi_{\alpha(i)}(\langle x, \Phi_{\delta(i,j)}(x)\rangle))$$

we have

$$h(x, \Phi_k(x)) < h(x, \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle))$$

Since h is monotonically increasing on the second variable, this implies

$$\Phi_k(x) < \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle)$$

by Lemma 2(c)

$$\Phi_k(x) < \phi_{\delta(i,j)}(x)$$

by Lemma 1(c)

$$\Phi_{\alpha(i)}(\langle x, \Phi_k(x)\rangle) < \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) \; (*)$$

Since by Lemma 1(a),

$$\phi_i(\langle x, \Phi_k(x)\rangle) < \Phi_{\alpha(i)}(\langle x, \Phi_k(x)\rangle).$$

and by Lemma 3(b),

$$\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) < \Phi_{\sigma(i,j)}(x)$$

the inequality (*) implies

$$\phi_i(\langle x, \Phi_k(x)\rangle) < \Phi_{\sigma(i,j)}(x)$$

That is, we have shown that for every k and almost all x,

$$h(x, \Phi_k(x)) < \Phi_{\sigma(i,j)}(x) \rightarrow \phi_i(\langle x, \Phi_k(x)\rangle) < \Phi_{\sigma(i,j)}(x)$$

Proof of Lemma 1:

It is easy to construct a recursive function α satisfying Lemma 1 and so the proof is omitted here.

Proof of Lemma 2:

Given $\Phi_{\alpha(i)}$ and $\Phi_{\alpha(j)}$, then for each x we wish to set $\phi_{\delta(i,j)}(x) = y$ for the least y such that y is greater than $\Phi_{\alpha(j)}(x)$ and there is no $\Phi_k(x)$ between y and $\Phi_{\alpha(i)}(\langle x, y\rangle)$ for all $k \leq x$. If we know in advance that both $\Phi_{\alpha(i)}$ and $\Phi_{\alpha(j)}$ are recursive, then this is exactly like the proof of Borodin's Gap Theorem. But in general, $\Phi_{\alpha(i)}$ and $\Phi_{\alpha(j)}$ may not converge at some inputs and therefore we may not be able to define $\phi_{\delta(i,j)}$ at some x. Hence, in order to make the predicate $\lambda ijxz[\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) = z]$ recursive, we have to take extra trouble in defining $\phi_{\delta(i,j)}(x)$.

We first introduce a recursive predicate Q and then define $\phi_{\delta(i,j)}(x)$ in terms of Q, such that if $Q(i, j, x, z)$ is true for some z, then $\phi_{\delta(i,j)}(x)$ converges.

$$Q(i, j, x, z) \equiv \exists y[(1)\ \Phi_{\alpha(j)}(x) < y$$

and

$$(2)\ \Phi_{\alpha(i)}(\langle x, y\rangle) = z$$

and

$$(3)\ \forall k \leq x[\neg(y \leq \Phi_k(x) \leq z = \Phi_{\alpha(i)}(\langle x, y\rangle))]$$

Since Φ is a Blum measure and by Lemma 1(c) and 1(e) for every i, $\Phi_{\alpha(i)}$ is strictly increasing on its domain on second variable, we can check effectively whether there exists a y satisfying conditions (1) and (2) above. If there is such a y, then we can check condition (3). Thus we see that Q is recursive.

Now define

$$\phi_{\delta(i,j)}(x) = \begin{cases} \text{diverge} & \text{if } \forall z[\neg Q(i, j, x, z)] \\ y & \text{otherwise,} \\ & \text{where } y \text{ is the unique integer} \\ & \quad \text{such that} \\ & \Phi_{\alpha(i)}(\langle x, y\rangle) = \mu z[Q(i, j, x, z)] \end{cases}$$

δ is recursive, because the predicate Q is recursive. By condition (1) in the definition of Q, we have that for every i, j, and x, $\phi_{\delta(i,j)}(x) \geq \Phi_{\alpha(j)}(x)$. This proves (a) of the lemma. Now, for every i, j, x, z:

$$\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) = z \leftrightarrow Q(i, j, x, z)$$

and

$$\forall w < x[\neg Q(i, j, x, w)]$$

Since the right-hand-side in the above expression is recursive, we see that $\lambda\, i, j, x, z[\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) = z]$ is also recursive. This proves (b) of the lemma.

To prove (c), we assume ϕ_i and ϕ_j to be total. By Lemma 1(d), we have $\Phi_{\alpha(i)}$ and $\Phi_{\alpha(j)}$ total. By examining the definition Q, we see that for every x, there is always some z such that $Q(i, j, x, z)$ holds. Therefore, $\phi_{\delta(i,j)}(x)$ converges for every x, and so $\phi_{\delta(i,j)}$ is recursive.

Also, from construction of δ, for every x, $\phi_{\delta(i,j)}(x)$ defined implies that

$$\forall k \forall x \geq k[\neg[\phi_{\delta(i,j)}(x) \leq \Phi_k(x) \leq \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle)]]$$

Proof of Lemma 3:

Let α and δ be as in Lemma 1 and Lemma 2 respectively. Let σ be the function defined as follows:

$$\phi_{\sigma(i,j)}(x) = \begin{cases} 0 & \text{if } \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) \text{ converges} \\ & \quad \text{and } \Phi_{\sigma(i,j)}(x) > \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) \\ \text{diverge} & \text{otherwise} \end{cases}$$

This definition makes implicit use of the recursion theorem.

Since $\Phi_{\alpha(i)}$ and $\phi_{\delta(i,j)}$ are partial recursive, σ is recursive. From the definition of σ it is clear that $\Phi_{\sigma(i,j)}$ has the same domain as $\lambda x[\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle)]$ and for every x, $\Phi_{\sigma(i,j)}(x)$ exceeds $\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle)$ whenever the latter converges.

Proof of Lemma 4:

Let α, δ, and σ be as in Lemma 1, 2, 3, respectively. Let

$$p(i, j, x, z) = \begin{cases} \Phi_{\sigma(i,j)}(x) & \text{if } \Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) = z \\ 0 & \text{otherwise.} \end{cases}$$

By Lemma 3, if $\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle)$ converges then $\Phi_{\sigma(i,j)}(x)$ also converges, and by Lemma 2,

$$\lambda i, j, x, z[\Phi_{\alpha(i)}(\langle x, \phi_{\delta(i,j)}(x)\rangle) = z]$$

is recursive. Therefore, p is recursive.

Let

$$h(x, 0) = 1 + \max_{i \leq x, j \leq x} \{p(i, j, x, 0)\}$$

and for $z > 0$

$$h(x, z+1) = 1 + \max_{i \leq x, j \leq x} \{p(i, j, x, z), h(x, z)\}$$

Clearly h has the desired properties.

Theorem (*Bottom of the gap theorem*)

Let $t \in \mathcal{R}_2$ be given. If $r \in \mathcal{R}_2$ is sufficiently large, then for every ϕ_i there exists u such that:

(a) $\phi_u = \phi_i$ and

(b) $t(x, \Phi_i(x)) < \Phi_u(x) < r(x, \Phi_i(x))$ a.e. in the domain of ϕ_i.

Proof:

By a trivial modification in the proof of Proposition, we can show the following lemma:

Lemma:

For every $t \in \mathcal{R}_2$ there exist $\sigma \in \mathcal{R}_1$ and $h \in \mathcal{R}_2$ such that for every i, we have:

(a) $\phi_{\sigma(i)} = \phi_i$ and

(b) $t(x, \Phi_i(x)) < \Phi_{\sigma(i)}(x) < h(x, \Phi_i(x))$ a.e. in the domain of Φ_i.

The theorem follows from the Lemma, if we let $u = \sigma(i)$ and assume r is greater than h a.e.

CONCLUSION

Besides Borodin's Gap Theorem, we have presented two other ways to look at the gap phenomenon in the structure of Blum measure. It is no accident that the proof of Theorem (Top of the Gap Theorem) is closely related to that of Borodin's Gap Theorem while the proof of Theorem (Bottom of the Gap Theorem) is very similar to that of Corollary. In a way, they explain why the gap that exists in Borodin's formulation fails to appear in Corollary. Our main results point out the existence of an interesting asymmetry in the properties of step-counting functions.

ACKNOWLEDGMENTS

The author is deeply indebted to Professor M. Blum for suggesting the topic and close supervision throughout the whole study, especially in the proof of Theorem (Top of the Gap Theorem).

Management information systems, public policy and social change

by ABE GOTTLIEB

Office of State Planning and Development
Harrisburg, Pennsylvania

I would like to address a few of my remarks to the character and implications of computer usage in government but before I do so, I might indicate that I'm with the Pennsylvania Office of State Planning and Development and my frame of reference has three outward tracks—as an urban planner, as a participant in data systems and as an official and sometimes unofficial stimulator of social change. These three biases ought to surface in the remarks I am going to make.

State governments as well as national and local ones are basically concerned with two kinds of computer uses. The first, and much less important, puts the computer to work at massaging multi-purpose information that can cover an almost infinite spectrum of urban oriented subject areas. These have come to be known as urban information systems. In theory, they can furnish the planner and decision maker with data and analyses in land use changes, population and housing shifts, economic trends, fiscal information and social statistics for a community or any group of communities.

But computer technology in government plays a much more critical role than what is inherent in the operations and outputs of such urban information systems. It is almost a truism today that no public agency, bureau, commission, board or any other unit of government can operate without some computerized control of its programs, processes and service delivery capabilities. For example, in Pennsylvania each of the 18 executive departments and most of the commissions and boards have their own data systems. Many of these, especially the larger ones, are computerized to a fairly high level of sophistication. The State Departments of Transportation, Labor and Industry, Revenue, Education and Public Welfare all have a tremendous amount of stored information and a commensurate technology to utilize that data.

This kind of operation and use of computers is associated with a relatively new breed called Management Information Systems. Its focus is the day to day, month to month control of inventory, bookkeeping, record keeping, disbursements and receipts in the myriads of government programs that inter-act with each other and with many recipients of public services. My concern therefore, is with the Management Information Systems that are utilized by States and municipalities throughout the country. These systems exist by virtue of controlling an inventory or a process and by sometimes delivering a service to public or private recipients.

INFORMATION SYSTEMS AS MANAGEMENT TOOLS

Now as I get into the substance of my discussion, I want to explore a number of ideas that relate more directly to the relationship of these computerized systems to the bureaucracies in which they flourish, to the formation or paralysis of public policy and to their impact on the possibilities of social change. Since these are the central themes around which our discussion will resolve, I will direct my remarks to the following points:

1. Urban data systems and management information systems are not merely respositories of facts and instructions for manipulating them. They are also collections of technologies as well and if there ever was any truth to the cliche that the "medium is the message," I am almost tempted to make the point that it is really the computer and its applications that will fashion, modify and transform our social structure and not the data that is poured into and out of it.
2. Management information systems at the State, local and national levels are used to serve management. In Pennsylvania State government as elsewhere the data systems are designed to assist in the operation of a Department's or agency's program more efficiently and perhaps more

cheaply than would have been possible under other arrangements.

3. Management rationality and efficiency are the overriding considerations of the "worth" of such systems. Whether to design, install, enlarge, merge with other systems or evaluate, the principal factors are judged to be speed, thoroughness, cost and labor savings. These are managerial-administrative considerations and almost never socially oriented ones. They look inward to the process, not outward to the consequences.
4. The programs or process controls which are the heart of such data systems sometimes result in services to various segments of the State's population. Sometimes they do not and we will speak about both situations shortly.
5. Management information systems that typically extend such services as auto registrations, tax notifications and collections, unemployment and welfare assistance, etc., may or may not be necessary or desirable. They can, however, make little claim to generating, sustaining or otherwise influencing the direction, depth or quality of social change in the State.
6. Any data management system with the capability of mounting substantially greater research and analytic capabilities than was previously possible, can sometimes produce an innovative breakthrough, a new way of seeing and understanding the dynamics of a community. Conceivably, this might lead to important changes and realignments in our social, political and economic structures but I remain skeptical and would like to be convinced.
7. Finally, I feel that if we turned the proposition the other way around and considered the impact of currently changing social values on the information systems and their related technologies, we would get a new dimension to the problem. If the events, moods and changes that surfaced in the latter part of the 1960s mean anything for the coming decades, we can expect major incursions into the organization, content and uses or perhaps even selective abandonment of urban oriented information systems.

THE REACH OF MANAGEMENT INFORMATION SYSTEMS

Now before anyone hands in his union card, I would like to make it clear that while data and management information systems are rarely the catalysts for social change, they can and do penetrate to the lives of a great many people in all segments of our society. This stems directly from the operations of the record keeping and process controls that are at the very heart of the systems. At the State level of government in Pennsylvania such operations probably account for over 90 percent of all computer usage so that it would not be amiss to say that both the administrators of the information systems and the machinery itself is thoroughly committed to keeping the records and controlling the processes. For example, the State Department of Public Education receives a veritable deluge of data from the local school districts relating to almost all aspects of running an educational bureaucracy. The Department of Revenue must maintain a computerized information system for the calculation, billing, mailing, recording and analyzing of tax receipts. Similarly, the information systems of the State Department of Labor and Industry and the Department of Transportation (just to name a few of the larger operations) are deeply committed to the routinized processes of maintaining a complex unemployment insurance system in the first case and keeping auto ownership inventories, issuing licenses and recording accidents in the second.

Basically, therefore, the data systems of the State work towards the delivery of services to a wide range of individual residents as well as to local communities and to other State agencies. There are of course adjacent and parallel operations such as internal payroll, bookkeeping and property inventory and control that generally do not reach out to any segment of the population. One can easily see the counter-part of these operations at the city, county and township levels as well. This is, admittedly, a capsule version of the Pennsylvania Management Information System but I think it is important to appreciate the data areas, the kinds of controlled operations and a few examples of the services delivered before we speak about the roles, if any, that these systems play in social change.

THE LIMITING LIDS ON SOCIAL INNOVATIONS

You may have noticed that I have deliberately divorced the objectives and operation of management information systems from the larger State programs of which they are part. I admit that this is not quite fair and that such a division would be a highly artificial one so I would like to bridge the gap at this point. The State of Pennsylvania has defined eight broad, long range objectives toward which it wants to move and had identified several hundred currently operating programs (many in the social arena) that may or may not be reinforcing these objectives. All the data systems I have been talking about live and operate in some uneasy relationship to these programs and objectives and it is these connections that I would like to discuss.

To begin with, the State information systems that keep records, control processes and deliver some services in Pennsylvania (and there are almost no other kinds) are themselves very substantial organizational entities. The investment in time, professional staff, money hardware and software and support personnel is quite considerable and this whole range of activity has gained structural and administrative solidity in the last few years. In Pennsylvania and in many other States we can speak of an information system bureaucracy that is not without substantial power and influence. Like all bureaucracies, it does not always look kindly upon change inside or outside its own domain; social, managerial or otherwise.

I have also made the point earlier that management information systems are tools to serve management which means more precisely to serve administrators and decision makers in operating programs and process as efficiently, rapidly and cheaply as possible. Now while these are the criteria that make the computer so valuable they are also the criteria that draw the administrator to the narrow focus of the procedural rationality of his program rather than towards an examination and concern with the impacts and consequences of his acts. In other words, the machine together with its operations, controls and data base induce the administrator to look inwards to the managerial objectives of his world when he should be involved with the political, social and economic meaning of what he does. We are very accustomed to visualize information systems as devices to facilitate policies and programs but it seems to me that the feedback (if you will pardon the expression) might be even more significant than the initial impulse that is, the systems themselves (singly and in concert) set the pattern, depth and range of current and future concerns of the State and many municipalities. From this point of view, the tail is very definitely wagging the dog and something is wrong.

I am not intimating that programs made effective by the use of information systems and process controls are unimportant or negative accomplishments in the State. But I am saying that the systems, controls and processes should not be the measuring rod for the social and economic interactions between the State and its residents. Nor should they be (as they almost inevitably become) the determinants that freeze public policy.

CONSTRAINTS ON PUBLIC POLICY

At this point in our discussion, I feel that we are beginning to zero in on a critical area. Almost at the outset, I made the observation that social changes among various groups and segments of our population can usually be traced to a shift in values, attitudes and aspirations that arise in these groups and the conviction that such aspirations can be realized in one's lifetime. However, to these basic stimulants I would like to add a second kind of possibility and that is the nature and scope of public policy.

Under certain circumstances, public policy can translate the values and aspirations of various groups into attainable benefits. Such policies and programs can even set off a chain reaction extending into social, political and economic areas far beyond the point of initial program impact. It is my contention that what happens to existing programs and especially the breadth and vision brought to bear by public administrators in creating new social objectives will go a long way towards making a management information system responsive to social realities. The field is wide open in health, criminal justice, education, consumer protection, public welfare, environmental improvement and others. And it is in these areas and among these kinds of public efforts that I have some qualified reasons to believe that the State may become attuned to the explosive social transformations that are sometimes above and usually just below the surface in the major urban areas of the State.

However, the obstacles to this kind of sequence are formidable. To begin with, public policies, objectives and programs are heavily dependent on what the agency or the administrator is doing now and doing it with all the management tools, personnel and investments at his disposal. Realistically speaking, there is no particular reason to assume that State, city or national management people look forward to gearing themselves, their program control processes, their machines and their data to ventures that cannot be justified beyond running smooth, self-regulating and almost self-perpetuating operations.

For example, it is with considerable fear and trepidation that many administrators look upon program evaluations where the focus is on social, educational and economic consequences, ameliorations and status changes rather than what is expected and dictated by the flow processes of paper, forms and data. This feeling is especially acute when the validity of existing programs and sequenced actions are questioned and new ones might be suggested. The real threat of P.P.B. is not that cost-effectiveness studies are hard to define and difficult to mount (all too true) but that P.P.B. insists that management and its information systems clarify and justify their efforts in terms of its impacts and consequences on all classes and categories of recipients. In the social arenas of criminal justice, poverty, education, housing and even science and technology, this begins to get close to tampering with the cement that holds the structure together and whether we call it P.P.B. or anything else it is clearly a kind of opening wedge in that direction.

Therefore, the way I see it two related things must happen. The first is a willingness for the public policy makers to realign State and local objectives and programs so that definable improvements are explicitly built into them and the second a willingness for the information systems directors to accept new standards, criteria, data and processes to make this work. It could be that the policy makers and the information directors are not always the same people with the same interests and outlooks on all issues of program and process control. Sometimes they wear the same hat and sometimes they don't but it seems reasonable to suppose that they have been mutually reinforcing each other as long as information systems have continued to remain program and management tools. If I were to venture a guess, I would say that the policy and program makers are as much locked into the uniquely narrow perspectives of data, inventory and process control as are the information systems directors themselves.

SOME PROOF OF THE PUDDING-SOCIAL INDICATORS

My *theory* about management being quite allergic to social change might be reinforced by a telling *fact* about management and here I mean the public agencies, State, Federal and local that operate in what we have been calling the social arena. For the brutal fact of the matter is that they have shut ourselves off from the data and intelligence that might tell them just a tiny bit about the social world around us. In "Towards a Social Report" of the Department of Health, Education and Welfare we are made painfully aware of the fact that "the nation has no comprehensive set of statistics reflecting social progress or retrogression. There is no government procedure for stock taking of the social health of the nation."

Somebody has said this much better than I can and I would like to quote from Elizabeth Drew writing in a publication called "The Public Interest":

> *"Those who picture Washington as one mass of files and computers containing more information than they would like will be comforted by the experiences of program-planners in attempting to evaluate on-going programs. Whatever the files and computers do contain, there is precious little in them about how many and whom the programs are reaching, and whether they are doing what they are supposed to do. If the purpose of an adult basic education program is to teach people how to read and write, the Office of Education might reasonably be expected to know how many people thereby actually learned how to read and write but it does not. . . . The Public Health Service might be expected to know whether its various health services are in fact making people healthier but it does not. The study of disease control was to have encompassed more diseases, but so little was known about the effective treatment of alcoholism and heart disease that these components had to be dropped. Those working on the income maintenance study found that the Welfare Administration could not tell them very much about the public assistance case load—who was on welfare, where did they come from, why were they on it; what they needed in order to get off."*

If this is true of the national level and with Federal programs, it is more than doubly so with the States and the localities. Our knowledge vacuum is truly an anomolous situation. It stares us in the face despite the fact (or more correctly because of the fact) that the Federal, State and local governments have amassed and computerized a vast body of statistical information necessary to run their programs and churn their processes. Paradoxically, while we are inundated in a sea of paper, ink and printouts, we cannot measure the human toll of illness, the pollution of the environment, the quality of our education and the nature of the alienation expressed in burning and looting in the ghetto, strife on the campus and crime in the city streets. From everything I have said up till now, management and its information systems want to have no part of these "social" changes except perhaps to wish that they go away.

Geographic information systems in the U.S.—An overview

by ROBERT AMSTERDAM, EDWARD ANDRESEN and HARRY LIPTON

Office of the Mayor—Office of Administration
New York, New York

A Geographic Information System (GIS) can be defined as one which is oriented to supplying information pertaining to the geography or spatial relationships of the information in the system.

When one asks for the total of all school aged children from a welfare file who are in school district 52 or when one wants to affix the health area code to a file of birth or death records, one is involved in relating geographic descriptors (e.g., the school district and health area codes which represent finite, fixed areas of space), to other geographic descriptions (e.g., the address of the welfare child, the home address of the mother . . . etc.).

Information such as the above has only recently become processable via computer. Heretofore, for a file of any significant size, large amounts of manual effort were required in order to enable one to relate one set of geographic descriptors to another. Now, through the use of the principal components of a typical Geographic Information System, these files can be related at computer processing speeds.

The principal components of a typical GIS are:

- Geographic information files (GIF) containing all the geographic descriptors of interest for the geographic area covered
- A program or set of programs that enable the GIF to be accessed (matched) against data files and appropriate geographic descriptor information appended from the "matched" GIF record to the "matched" data file record.
- Graphical display programs and equipment which enable the matched output to be displayed, via computer, in the form of maps or charts in addition to the usual listings.

GEOGRAPHIC INFORMATION FILES

Geographic files can encompass the entire range of local government activities. Two types of files, however, have played a major role in the development of Geographic Information Systems; these are the Address Coding Guide/Geographic Base File and the Parcel/Building File.

Address coding guide/geographic base files

These files were first developed in the early 1960's for regional transportation studies such as the Penn-Jersey Study in the Philadelphia area and the Tri-State Transportation Study in the Metropolitan New York area. The files were used in compiling information on origin and destination of trips by all means of travel within the study area. The results were used in planning new transportation routes, determining patterns of economic and residential growth, and planning for development of new resources. Comparable files were developed by private firms for use in market analysis by commercial organizations. Such files have also been developed by the Post Office to assist in zipcoding. By the mid-1960's, the U. S. Bureau of the Census recognized the value of these files in coordinating a mail-out census and began encouraging their development in all urban areas of the country. Since then their broad range of uses has been increasingly recognized by local government and groups engaged in analysis of small area data. The files have been modified, expanded and updated to meet the demands of local users.

In its basic form, an Address Coding Guide (ACG) relates ranges of addresses to defined geographic areas. Most simply, it could contain the range of building addresses in a traffic zone or postal area. A series of records is prepared for each street name. Each record contains the highest and lowest building numbers on that street which lie within the specific zone. Generally, separate records are prepared for odd and even house number ranges.

As Address Coding Guides have developed, it has been recognized that as more different area designations are incorporated in the file, the more useful it becomes.

Since many operational jurisdictions (e.g., post office routes, police precincts, census enumeration districts) bound whole city blocks, it is usually convenient to create a separate record for each block side. This record contains the street name, highest and lowest building numbers that can be used on that street section, and whatever area codes can be usefully related to that block or block side. Additionally, the record can contain alternate names for that street, the names of intersecting streets, the width of the street, whether it is paved, the type of paving, whether it is privately or publicly owned, direction of traffic, speed limit and other information of general interest

This information can be related to other data files in order to develop a profile of a community, to coordinate operational data or to retrieve specific information contained in the ACG. One significant example of its use is in relating the number of incidents in an area, such as number of births, or crime reports, to the total population in the area in order to calculate the overall birth rate or crime rate for the community. Such data is required for many types of community planning and deployment of facilities.

An important extension of the ACG is the Geographic Base File (GBF). In a GBF, each record can be the same as an ACG record but it also includes x and y coordinates of one or more fixed points on the block related to a grid system which is uniformly referenced for the entire locality. The individual record may contain the coordinates of a corner of the block, the center of the block, the center of the blockside, the intersections of the streets bounding the blockside or some other recognizable point. With this added data, the location of any block or address is determined with reference to any other location in the area. This allows the user to calculate distance, determine the entities in a given perimeter or radius and make other spatial determinations. This capability is important in transportation planning, in setting up routes or district lines and in determining the potential users for a new facility. Grid coordinates are also valuable in the preparation of computer-generated maps. Maps are essential in many local government operations and the ability to produce detailed maps showing the locations of specific properties or addresses is increasingly playing an important part in administrative decisions.

As one example of use of the GBF, complaints of cracks or holes in street paving can be correlated with street segment identification numbers in the GBF. When street repair work is scheduled, crews can be readily informed of all complaints in a compact area so that minimal time is lost in traveling.

ACG's and GBF's are being used in many local areas throughout the United States and Canada. They are also being developed for several major cities in Europe, Israel and South America. Their development requires a considerable investment by the locality to check out and inventory all streets, blocks and significant land features in their jurisdiction and to update the information as changes occur. However these files are critical for the development of many types of municipal information systems and operational activities and the effort is increasingly proving to be justified.

The U. S. Census Bureau is developing a standard format for these files called DIME (for Dual Independent Map Encoding). In a DIME file, each record is related to a street segment. It identifies the street name, address range on each side of the segment, census block on each side of the segment and intersection node coordinates at each end of the segment.[1]

Parcel/building files

The second major file important for local area data collection systems is the Building File. This contains one record for each building in the region with its address, dimensions, floor space, usage, owner's name and whatever additional data the local government finds useful to maintain.

Traditionally, the source for this data is the property assessment department. Assessors are required to maintain a complete inventory of the property in their district in order to insure that all land is taxed and that valuations are reviewed and updated periodically to reflect improvements to the property, improvements to the neighborhood and changes in market values. In most parts of the United States assessment is a county responsibility. Cities lying within a county and metropolitan areas which lie in several counties frequently have administrative problems in gaining access to assessors' files.

There have also been technical obstacles to using this data: Many assessors' files are in detailed, handwritten records which have been accumulated over long periods of time. Data is not standardized and difficult decisions must be made on which data can most usefully be converted to computerized form. Another obstacle has been that assessors usually keep records of land parcels or lots, since this allows the most complete inventory of the land in a county. However this makes it difficult to obtain clear information on individual buildings when there is more than one building on a lot.

One final problem will be mentioned: it is frequently impossible to record the owner of a parcel on a compact, fixed-length field. The property may be owned by a corporation, a partnership or a group of heirs. For some operational purposes, it is more important to know the name of the mortgage holder, taxpayer or managing agent. These identities are frequently confused, ambiguous or deliberately concealed by the owner.

As a result of these and other obstacles, development of comprehensive building files which can be used for inter-agency activities has proceeded slowly. Washington, D.C., and Philadelphia are among east-coast cities which have developed such files. New York City plans to have one in use by the spring of 1972. New York's has been used on a pilot basis to prepare a list of selected office buildings for use by the Fire Department in evaluating a new fireproofing code for fully air-conditioned buildings and development work has begun to use it for estimating population.

In general, the most significant work in this area has been done in localities which grew up in the days of electronic data processing. Southern California communities have been particularly outstanding in developing and using Building Files.

Los Angeles County, for example, has had a tape-oriented property records system since 1958 for use by the Assessor, Tax Collector and County Auditor. The system contains 1,850,000 records describing every parcel in the county. Los Angeles County contains 77 cities plus countless water, school and fire districts and other taxing entities with overlapping jurisdictions such as are found in most counties. All property tax bills are calculated by the county. Receipts are distributed to the local taxing groups based on their particular tax rates and the amount of taxable property in their jurisdiction.

The Los Angeles master parcel file contains the following data: tax block and lot number, which uniquely identify the property; the address of the property; the name of up to two owners; the address of each owner if it differs from the property address; the land and building dimensions; the tax area codes which identify the agencies with jurisdiction for that parcel; zoning classification, use codes, current and prior year valuations for both land and buildings; history of up to three last sales prices for the property; homeowner, veteran and religious exemption codes. In the last two years the county has been adding more detailed data describing specifics of construction on the property; year built, quality, class and shape of building, number of bedrooms, number of bathrooms, total square feet, cost of construction, quality of view, presence of mineral deposits and other data which would help the assessor in more accurately computing the value of the property.

This data is of great value for functions such as city planning, renewal and site selection activities. Local governments are working with the county authorities to obtain greater access to this wealth of data.

Looking into the future a few years, we predict that building files will be accessed by on-line systems, with every agency that currently keeps building related files, having instant access to fields related to their special areas of interest. Thus, the Fire Department can develop a history of fires by building and even apartment; the Housing Agency can manipulate data concerned with elevator inspections, building code violations and their status by building or apartment, rent control status by apartment, building and occupancy permits status; the Environment Pollution Agency can access fields concerned with incinerators, boilers and so on.

Thus, instead of each agency developing and maintaining its own building file, it can be centrally maintained, and where required, the interagency information can be readily analyzed for operational and planning purposes by other than the agency controlling the data in the field of interest.

In addition to ACG/GBF's and Parcel/Building Files, several other files may be developed, depending on local conditions. These could include *Alias Street Names* which include alternate names or alternate spellings of street names in the locality; *Familiar Places* which includes places not known by normal address, such as parks, landmarks, department stores and shopping centers; *Highways* which identify limited-access highways in terms of segments; and *Boundary (Polygon) Files*. Boundary Files are used to describe the perimeter of a jurisdiction. They may be organized in terms of the street intersections which form the boundary of an area, or, especially if used for automatic mapping, they will give the (x, y) coordinates of the points which form the polygon describing the area.

All of these files require considerable effort to develop and maintain in urban areas which are complex and constantly changing. However, as they are used more widely, more local agencies will participate in their development and exchange of information.

ACCESSING (MATCHING) APPROACHES

ADMATCH

Admatch is a set of address matching programs that enables a blockside type of GBF (e.g., ACG, DIME, etc., file) to be matched against any data file on street address. This package was originally developed by the U. S. Bureau of the Census for the New Haven Census Use project in 1967. It has since been significantly upgraded and improved.

It consists of a preprocessor and a matcher program separated by a standard sort program. The preprocessor program analyzes the address field of each record to be matched, identifies the specific components of the address and places these components into specific fields of a record segment called the "match key" which is appended to the original data record as part of the preprocessor output record.

For example, the address:

2520 South Flatbush Avenue Extension
Brooklyn, New York

would have the address components stored in the "match key" as follows:

2520	=House number
*South	=Primary directional
Flatbush	=Street Name
*Avenue	=Primary Street Type
*Extension	=Secondary Street Type
*Brooklyn	=County
*New York	=State

All the * items are first standardized through the use of tables before being placed in the output record.

The next step in the overall matching procedure is to sort the preprocessor output file on house number within odd/even-side of the street parity code within street name (within county, within state if a multi-county and multi-state file is involved).

The sorted data file is now matched on the "match key" field against a blockside GBF reference file "match key" field that has previously been created via preprocessing and sorting as above. The matcher program compares the data record match key to all the GBF records with the same street name and selects the "best match." The "best match" is determined by a weighting scheme determined by the user. That is, each component of the address is given a weighted value and thus each component that matches, or in the case of house number, falls within the high-low blockside range of house numbers gets the weighted value added to its total weighted score. Thus, a record can be accepted as "matching" even though each address component does not match identically with the "matched" GBF record.

Admatch is available in IBM 360 DOS and OS and RCA Spector 70 versions, at a nominal fee ($60) from the Bureau of the Census. Over 100 municipalities and regional entities are using this package. The package requires a minimum of 32K bytes of magnetic core to run under DOS.

In Charlotte, North Carolina, a file of 35,000 sewer connection records were put into machine readable form and via Admatch, matched against a master water billing file and a master sewer billing file. Seventy-five percent of these records matched at a 98 percent acceptance level. The balance of the man-matched records were then manually processed. Of these, 10 percent were true non-matches, that is, they had sewer connections but were never billed for water and/or sewer services. This resulted in considerable additional yearly revenue for Charlotte.

In the Los Angeles area, both the City of Los Angeles and the Census Bureau's Southern California Regional Information Study (SCRIS) have been making extensive use of Admatch.

Building Permit information has had Census Tract and Block numbers added to it. This has been done for every year since 1960. It enables one to ascertain the yearly growth of the housing stock and via the housing stock, an estimation of the population growth.

Motor Vehicle applications have been coded with Census tracts and blocks via Admatch. This enables transportation planners to get an accurate fix as to where the vehicle owners are located.

Orange County, California has used Admatch to code housing inspection reports with census tract and block codes. This is used to analyze the quality of housing stock in the various geographic areas of the county.

UNIMATCH

The Bureau of the Census is currently developing this package which, in essence, is a generalized file linkage system. It is structurally similar to ADMATCH, however, not only will it match on street addresses, but also on street intersections, major traffic generators or any other logical connection. This generality is achieved by allowing the user to specify what fields to compare, what comparisons to make, what significance to attach to a success or failure to compare and finally what action to take depending on the level of success of that comparison.

STREET ADDRESS MATCHING SYSTEM (SAMS)

SAMS is a proprietary package of Urban Data Processing, Inc. of Cambridge, Massachusetts that matches addresses in a fashion similar to Admatch. This may not be too surprising since the authors of SAMS were involved in the development of the original Admatch package. SAMS processing, like Admatch, consists of a preprocessor run, a sort on the house number and street name, and a match against a similarly processed GBF.

SAMS operates under IBM 360 DOS and OS operating systems with a minimum of 96K bytes of core storage.

The City of New York (our home town) has used SAMS for numerous address matching applications. In one very dramatic application, we were able to match the Department of Social Services Welfare Recipient file to the GBF and affix the census tract and block number to 95 percent of the records. The Board of Education then used the file to determine the school district of each welfare recipient between the ages of 5 and 18. This was ultimately used to satisfy both the Federal Government and community school boards in the allocation of federal free lunch money to the school districts based upon the percentage of school children qualified for this program and not on a simple percentage of school children in each school district. With over 1,000,000 school children and over 300,000 of these qualified for the free lunch program via their welfare status, one can readily see the difficulty in performing this analysis any other way.

Work is under way to use SAMS to automatically code each birth and death record with the health area and district of the person's home address. This will eliminate a time consuming and somewhat inaccurate current clerical effort. Plans are also under way to use SAMS to add all the various types of geographic descriptors to the citywide building file we are creating. The building file, which contains the key dimensions and building classifications of each building in the city can be used for population estimation. Couple this with the geographic description, and one can then readily estimate population by specific census tracts, health areas, school districts, . . . etc., for a multitude of planning activities.

OTHER BATCH PROCESSING ADDRESS MATCHING PROGRAMS

Kettering, Ohio, has developed an Admatch type package that operates on an IBM 1130. They have utilized it to code and analyze health data by various geographic descriptors.

Raymond Soller of Florida State University has developed an Admatch type package for the CDC 3600 which may be available to other CDC users.

REAL TIME ADDRESS MATCHING

A number of real time address matching systems exist. They tend to differ based upon the amount of conversation one wishes to accept between the terminal operator and the system and the average amount of time, during peak load conditions, that one is willing to wait in order to find the address in question. Generally speaking, the less conversation between the system and the operator and the faster the access required, the more expensive the system in terms of programming and file storage.

In Chicago, building code violation complaints are being entered on-line via terminals. The street name is first converted to a standard street number code. The house number is then used with the street code to access the file. In New York City, the Police Department has installed a system, SPRINT, which enables telephone operators to enter the request for emergency help, including the house number or the street intersection into the system via CRT type terminals. The system analyzes the address portion of the message and finds the blockside record which either:

(a) contains the house number within its high-low address range or
(b) is adjacent to the intersection.

Finding the matching blockside record enables the system to then determine:

(1) the police precinct and sector for that blockside
(2) the police car(s) nearest the precinct and sector that are free

and to flash the original message and the police car availability message to a radio dispatcher who in turn broadcasts a dispatching message to the police car(s) he selects to assign to the call. It should be noted that the SPRINT address file was built from the same base file that was used to create New York City's GBF. This illustrates that a GBF can support both batch processing and real time operating systems.

ACCESSING OTHER GEOGRAPHIC DESCRIPTORS POINT-IN-THE-POLYGON ACCESSING

This approach requires that a file be develcped which represents, in essence, polygons for the specific geographic descriptor of interest. That is, the extreme (X, Y) coordinate sets for each vertex of an area, say a health area, are recorded as a specific polygon. This is done for every health area in the system. Then, given the (X, Y) values for a specific item of interest, say a birth, one can determine, through the use of a point-in-the-polygon algorithm which polygon, and thus which health area, the item falls in. Tulsa, Oklahoma, has used this approach in a real-time system to determine which police district a specific address lies in, so that it can dispatch the proper police car to the scene.

MULTI-INDEX GEOGRAPHIC FILES

Kettering, Ohio, has developed a multi-indexed geographic information system which enables one to access their 22,200 record parcel file by (a) plat, section, and lot code; (b) tract, block and parcel number code; or (c) book, page and index code in addition to the parcel's address. A series of index files for each of these access items has been developed to support this capability. This system has been used by their Planning Division to obtain building and land valuations on proposed zoning changes and to analyze the parcel file to determine the existence of non-conforming land uses.

COMPUTER GRAPHICS

In this section we confine the broad subject of computer graphics to the aggregation, analysis, reformatting and graphic display via computers for the support of urban planning in all its facets.

In almost all instances, government use of computer graphics has taken the form of producing maps or map representations at various scales and, most important, the insertion into these maps of the aggregation and factor analysis of data in varied formats.

To focus more sharply on our topic let us glance at some classes of data displays as they have appeared on maps used by government urban planners.

1. Specific quantitative data by volume, capacity or total incidence represented on the map by shading and/or specific numbers.
2. Exception type data resulting from the comparison of two quantities, such as surplusses or deficits of various resources.
3. Time oriented data which focus on trend analysis or the comparison of specific resources at two or more points of time.

It might be well at this point to remind ourselves that there is a considerable difference between an information system supporting an administrative process such as invoicing, payroll or tax collection, and one designed to support any planning or programming activity. In the first instance the system must handle data by individual documents or transactions. The planner, however, is concerned with data behavioral patterns, trend analysis of many types, simulations or model studies. All of these demand the aggregation of information from many diverse sources, such as the Bureau of the Census, Housing and Development Authority, or the tax assessor's records—and perhaps the total incidence of police or fire calls, welfare cases and so on.

With the increasing mountain of data being made available by the growing world of computers, the planner, to avoid being buried or immobilized, must be supported by distilled data in the form of computer reports or graphic displays or, most likely, a combination of both.

The need of a combination of maps and specific data was proven, and was used by military, navigational, and government planners thousands of years ago. Today the fantastic growth in available planning data and the volatile nature of today's world will force further sophistication and use of computer-driven graphic displays.

Now let's take a look at the classes and specific types of computer-driven graphics currently in use by government at various levels.

HIGH-SPEED PRINTERS

First and currently most widely developed and used are high-speed printers which use the characters of the

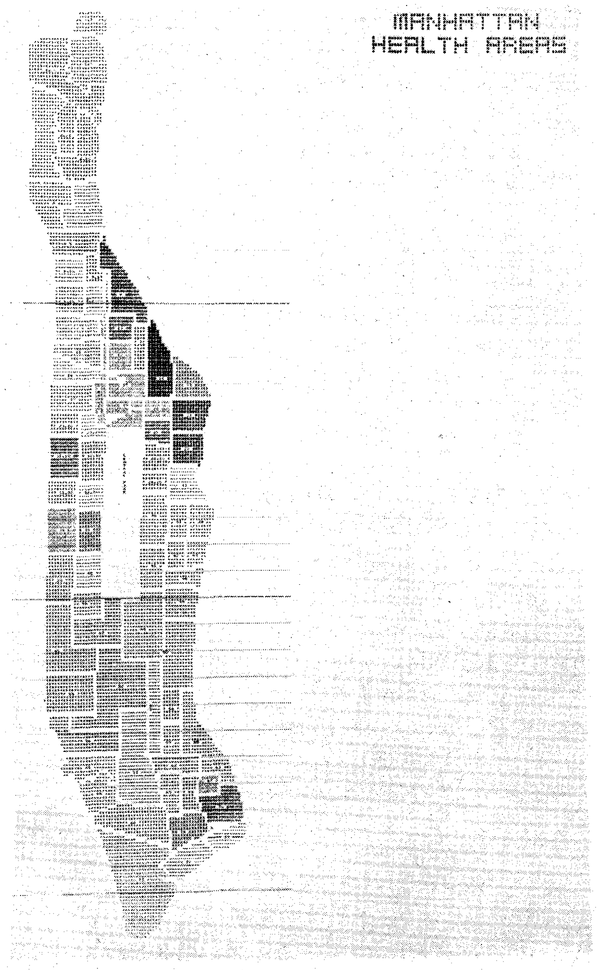

Figure 1—Manhattan Health Areas—Shading is proportional to number of public assistance cases—SYMAP—Conformal option

printer and overprints of characters to produce various levels and densities of shading to illustrate data on areas representing map areas. Since lines cannot be drawn on this type of map, boundaries of areas can only be approximated. These approximations, however, are often adequate for planning support. In addition to shading, specific data values can be shown for certain points on the map.

The two mapping programs using high-speed printers that are in most common use by governmental planners are "SYMAP" and "GRIDS."

SYMAP is the best known, most comprehensive, and most widely used computer mapping program currently available. It uses a standard high-speed printer to print typewriter-like characters, on a standard 11×15-inch computer printout sheet. Lines can be roughly approximated with printer characters, and areas can be shaded with up to 10 progressively darker shades. The darkest shades are created by overprinting two or more printer characters.

The original SYMAP program was written in 1963 under the direction of Howard Fisher at Northwestern University. The program is currently being maintained by the Harvard Laboratory for Computer Graphics, where it is supported by a technical staff, ongoing research, and teaching materials such as correspondence courses and seminars.

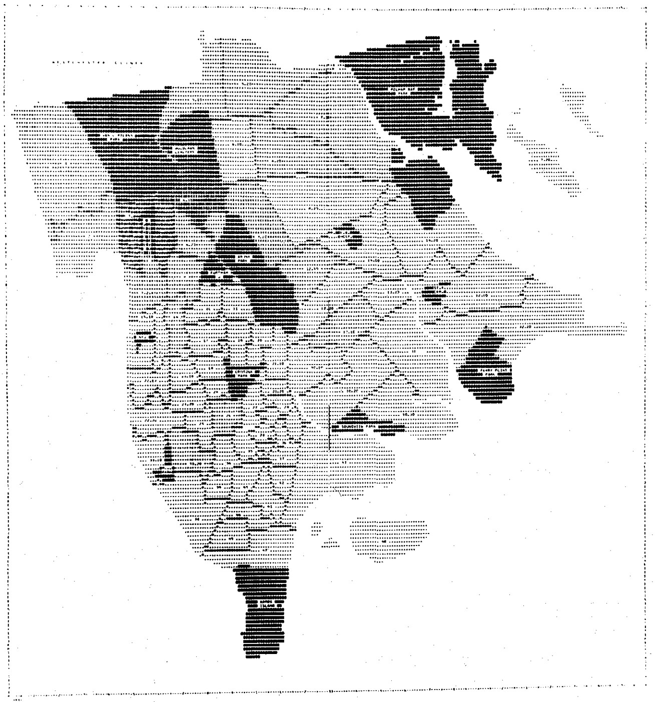

Figure 2—Outpatient residence distribution for Montefiore Hospital by Bronx health areas—SYMAP—Conformal option

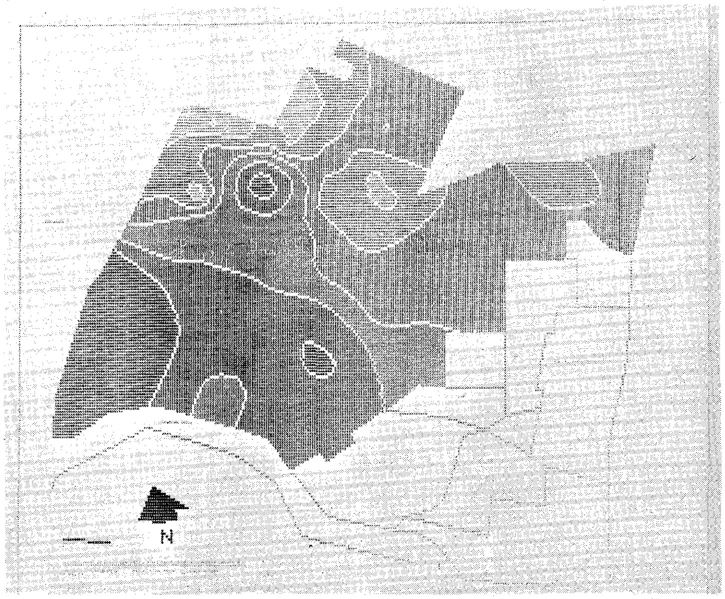

Figure 3—Ratio of shelters to daytime population in Long Island City—SYMAP—Contour option

Generally, SYMAP has been programmed for the larger scale IBM systems, although modifications of SYMAP have been used on other computer vendors' large scale computers.

SYMAP enables three basic types of maps to be produced through its three primary options: the conformal option, where the areas shaded are approximate representations of the polygonal geographic areas that they represent; the contour option, where the data values are assigned to particular points (such as block face centers or block or tract centroids) and the program shades contours by establishing equal-width intervals representing the range of values between each pair of points; and the proximal option, where the data values are again assigned to particular points and the program shades the respective values from each point to an imaginary line equidistant between each pair of adjacent points.

In Conformal (see Figures one and two), the areas shaded represent the actual areas which the data values represent. In Contour (see Figures three and four)[2], the areas shaded represent equal-width intervals between the centroids of the data areas. For example, between the centroid of the area with data value six and the centroid of the area with data value four, three equal-width intervals have been established representing data values six, five and four. In Proximal, the areas shaded are represented by imaginary polygons whose boundaries are described as equidistant from the centroids of the actual data areas. For example, the

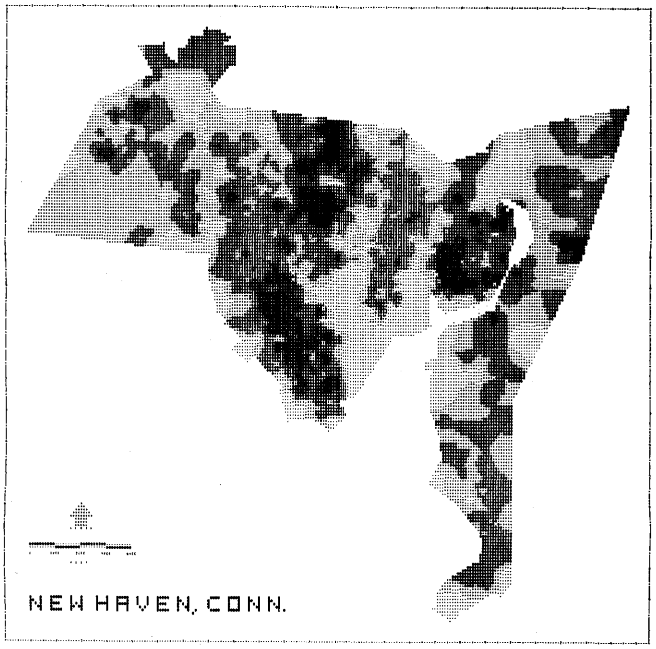

Figure 4—SYMAP shading map showing contour levels—Density of preschool children

boundaries of the imaginary polygon describing data value two are equidistant from the centroid of the actual data area for two and the centroids of the surrounding actual data areas.

In addition, SYMAP has a large number of statistical-support options which permit calculations of means, standard deviations, histograms, and percentile groups—all within the same mapping program package.

Within the SYMAP system, changing from one type of map using one mapping option to another type of map is not easy. For instance, switching from a map using irregular polygon areas, as in conformal block shading, to a map using single data points, as in contour shading, requires the input of a completely rearranged geographic data base.

"GRIDS" (Grid Related Information Display System) produces maps by dividing the area to be mapped into a network of rectangular grid cells. A grid cell may be as small as one printed character or as large as 55×55 characters.

The system was developed by the Census Bureau's Southern California Regional Information Study in an effort to simplify required programming skills and data preparation.

GRIDS is very flexible both in digesting input data and producing maps. There are three types of maps available: (1) shaded, in which data values are represented by overprinted characters of varying darkness; (2) density, in which a character is splattered randomly throughout each grid cell with more characters representing higher values; (3) value, in which the actual data value is printed in each grid cell.

GRIDS accepts as many as 10 input variables to be mapped, provides for manipulation of the data in any desired way, and produces up to five different maps for each run. No previous preparation of the data is necessary and no knowledge of the data values is necessary. GRIDS provides for data manipulation through MAPTRAN, a built-in FORTRAN-like programming language, or a user exit routine if necessary.

GRIDS is especially easy to use because all specifications are free format keyword type and there are many default values for the user with simple needs.

The program will run on nearly any system with a FORTRAN Compiler. It has been run on an IBM 360-30 with 32K bytes of storage.

Among the most published users of line printers and SYMAP for graphical display programs is the U. S. Census Bureau. They have used both census related data and locally obtainable data to perform comparisons and display of results such as Densities of Populations of Preschool Children, and Hour's Spent by Visiting Nurses (Figures four and five).[2]

The University of Kansas, at Wichita, has experimented with line printer graphics at the block level using SYMAP, to display correlated data of land value

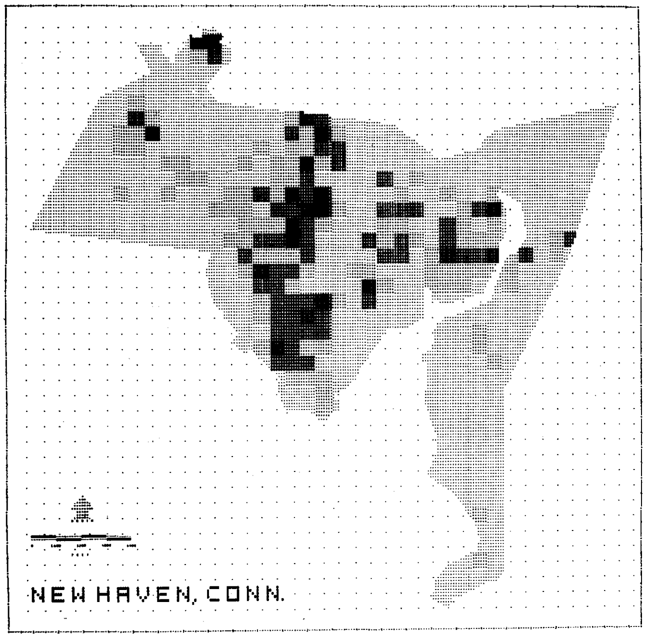

Figure 5—SYMAP shading map showing grid cell levels—Adjusted hours spent by visiting nurses association

by block area. This is different from Census Bureau studies which are predominantly oriented to aggregations at the tract level.

New York City has made extensive use of SYMAP capabilities to analyze and display a variety of City problems, including air pollution, health statistics and public assistance cases. It has also been used in conjunction with a highly sophisticated emergency preparedness display system.

The Battelle Memorial Institute is using SYMAP in conjunction with their pollution research efforts. These include studies that determine patterns of waste-water discharges from industrial and municipal operations and to evaluate their effects on surrounding waters. The research technique, developed by Battelle, consists of collecting aerial infrared and tracer dye imagery of surface water discharges. Data recorded from the infrared imager is processed and a high-speed printer then prints out isothermal plots, density plots, and contour plots. The contour plots provide two different views. Used with a stereoscope, these two views provide simulated three-dimensional temperature contours.

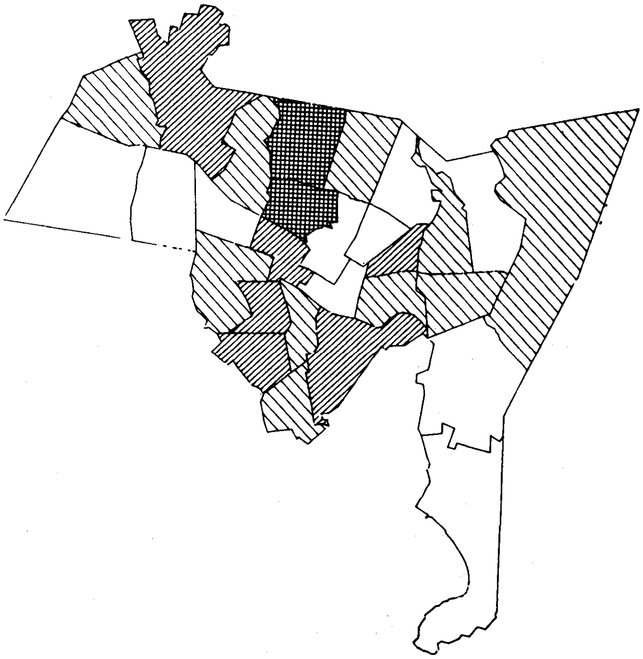

Figure 6—Pen plotter tract outline map showing tract levels—Percent non-white

PEN PLOTTERS physically move a pen over a piece of paper, under program control, to produce a graphic output. Examples of graphics produced by these plotters are shown in Figures six, seven and eight.[2] The first mechanical computer-driven pen plotters were flatbed models on which the pen is moved over a flat sheet of paper in both the X and Y direction.

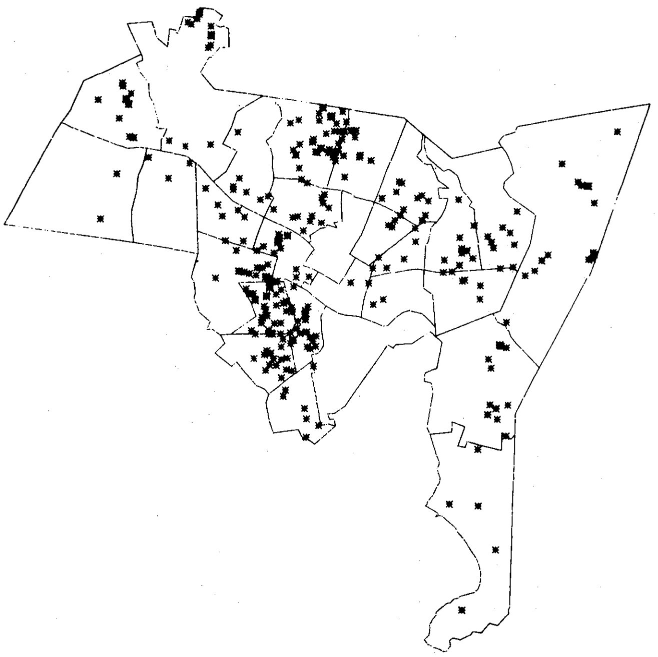

Figure 7—Pen plotter tract outline map showing incidence occurrence—Under-weight births

Later, California Computer Products, Inc. (CAL COMP) and the Benson-Lehner Corporation developed

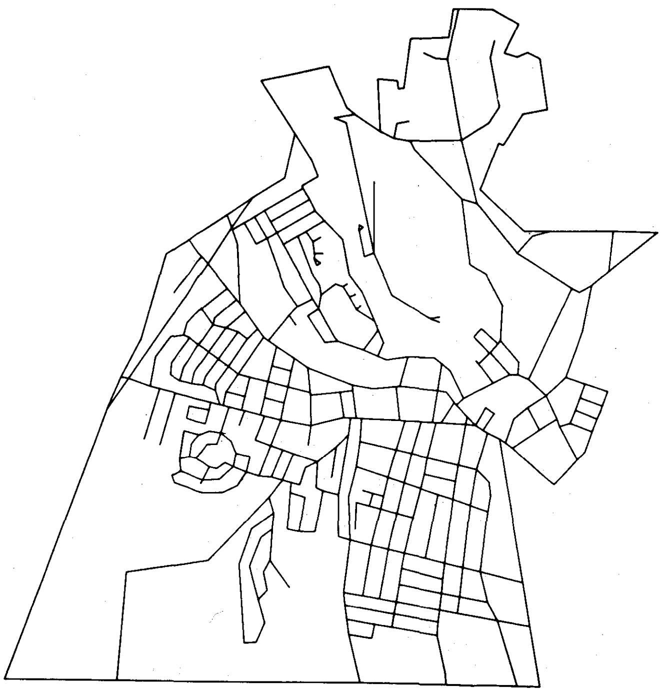

Figure 8—Pen plotter outline map of Northwestern New Haven

drum plotters which move the pen to obtain one direction and the paper to obtain the other.

An important difference in plotters is the manner in which the movement of the pen is controlled.

Analog Plotting Systems convert the (X, Y) distance through which the pen must be moved to a voltage or other electrical measurement which in turn is used to drive motors through a proportional number of turns to reposition the pen. Thus the digital input is converted to a specific distance or analog value.

Digital Incremental Plotting Systems drive the pen (and the paper, in the case of drum plotters) on a quite different principle. The drive mechanisms on these machines operate in discrete steps, or increments. The step size is usually 0.005 or 0.010 inch, or the metric equivalent to the nearest tenth of a millimeter. So-called step motors control these motions. The step motors can make from two hundred (on the slowest plotters) to about sixteen or eighteen hundred (on the fastest) steps per second for a corresponding plotting speed of between two and eighteen inches per second.

The input to the step motors comes from the magnetic tape or computer to which the plotter is attached. This input, under program control, specifies the exact number of steps through which the motors are to move. There is thus no conversion from digital to analog values. At any one time the program preparing input for the plotter "knows" the exact location of the pen, and thus, even after drawing thousands of lines on the paper the pen can return to the exact starting point.

There is another important difference between the analog and the incremental plotters. On the former the regular pen is useful for drawing lines, and can draw them quickly once set into motion; but the line-drawing pen is very slow if used to annotate the plot with numbers or letters. Hence, many analog plotters have a separate device, which may ride on the same arm as the regular pen or on a separate one and which is used exclusively for annotating the plot. The mechanism usually consists of a type wheel set in a vertical plane, which is rotated to bring each desired character next to the paper and then forced down to make its impression on the plot through a ribbon. The process is slow and cumbersome. Such a character-printing turret can increase the price of the plotter by several thousand dollars. Moreover, the size of the characters is fixed, and they can be placed on the plot only in one or at most two orientations.

On the incremental plotters the same pen mechanism that draws lines is also used to perform all desired annotation. Only with such plotters is it usually practical to do extensive annotating on a plot. The characters can be made in any size, at any desired orientation, and they may be of any kind, subject only to the symbol table built into the computer programs used to create the plot.

The New Haven Census Use study was an early user of a GBF and SYMAP to plot census data. This was done to show comparisons of data at the Census Tract level, with distinctly drawn tract boundary lines, such as percent of non-white to white populations throughout New Haven, Connecticut (Figure six).[2]

The Santa Clara County (Cal.) Planning Department has developed a census tract polygon base file which they have been using with a pen plotter to graphically depict employment, population and housing data by Census tracts within the county. They are also using their pen plotter to prepare map overlays, which

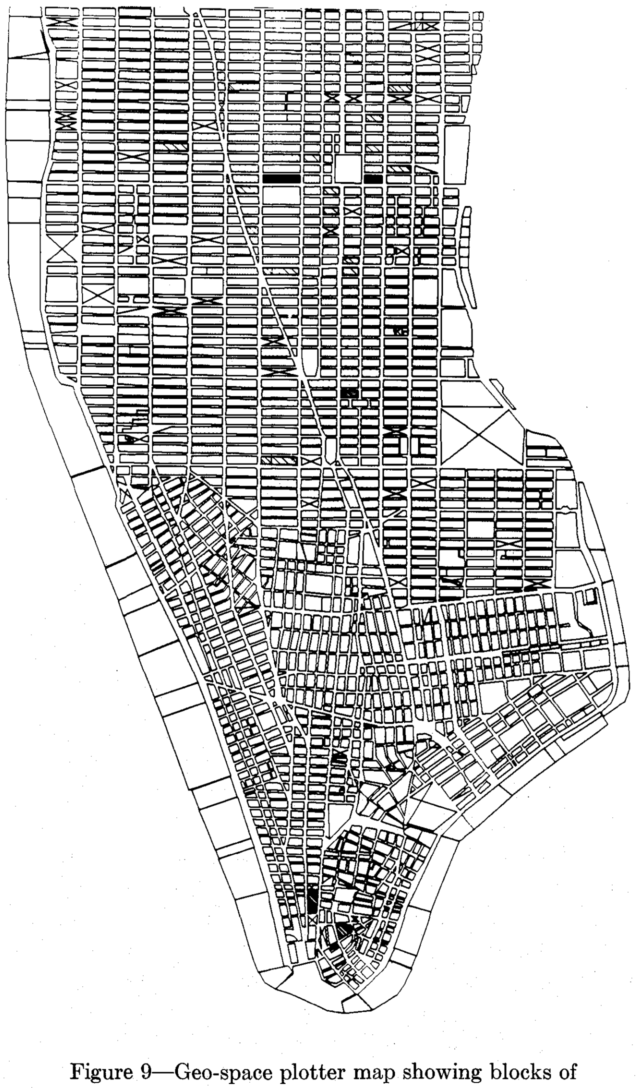

Figure 9—Geo-space plotter map showing blocks of lower Manhattan

correspond to county base maps with a high degree of resolution, to illustrate census tract level information in conjunction with block level street maps.

New York City, as part of a voter redistricting demonstration project, prepared a block map of a section of the City which indicated the number of registered voters at the approximate location of their house on the block.

CATHODE RAY TUBE (CRT) PLOTTERS most likely will show the greatest advancement in computer graphics in the next few years. As most of us know, a cathode ray tube (CRT) is a display device similar to a television picture tube for which programs are written to control the generation of displays on the face of the tube. These images can be observed, recorded on microfilm for permanent storage or recorded on photosensitive paper which can be developed into distributable hard copy.

There are a number of CRT based scanning and plotting devices currently in the research and development stage and under intensive study by various branches of the government.

Although some of these projects offer the possibility of significant advances in computer graphics, conclusions that would be useful to you do not yet exist. We will confine our discussion, therefore, to hardware and systems that have given at least limited support to government planners.

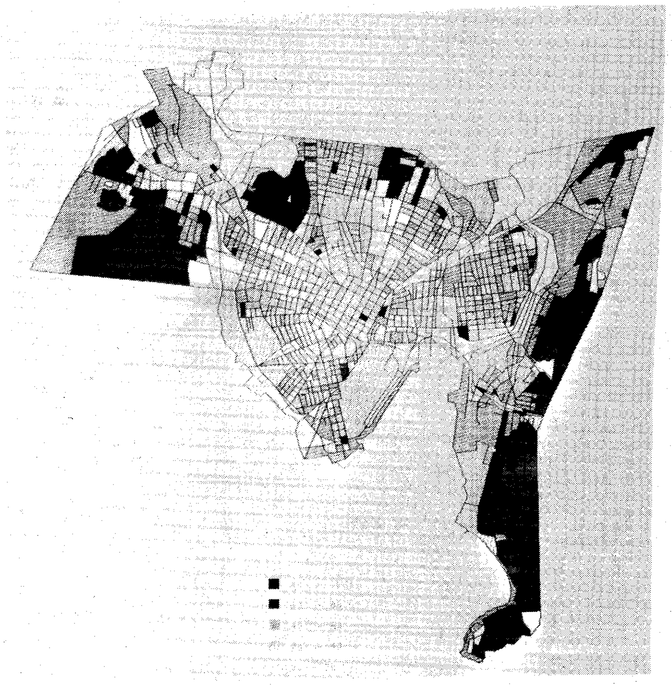

Figure 10—Geo-Space plotter shading map identifying block area levels percent of owner occupied housing

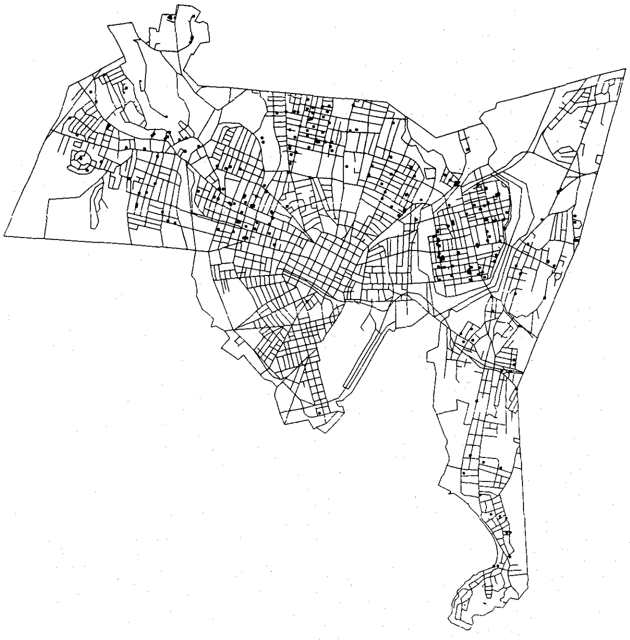

Figure 11—Geo-Space plotter outline map showing incidence occurrence—Police calls

The *Geo-Space* Plotter produced by the Geo-Space Corporation of Houston, Texas is a digital CRT drum plotter that will produce map and data representations on up to 40″×60″ film or photo sensitive paper. Figures 9, 10 and 11 illustrate maps drawn by this device (Figures 10 and 11).[2]

The Geo-Space uses a cathode ray tube and a lens assembly which focuses its ray on the film or paper. The CRT and lens assembly are housed in a tube that can be moved horizontally 40 inches. The media (paper or film) is attached to a drum large enough to hold a sheet sixty inches long. The arrangement is analogous to a drum pen plotter with the CRT and lens replacing the pen.

The Geo-Space is designed for on-line operation with a digital computer and is available with the channel interface for several different computers. Information to be plotted is developed within the digital computer central processing unit and stored in a prescribed format in core storage, or disk storage. The information to be plotted is then transferred from the on-line storage device to the plotter for display.

Plotting can be accomplished at 32 levels of intensity. A plot of 40 by 60 inches can be completed in less than two minutes regardless of the amount of data to be plotted. This rate is many, many times faster than the fastest mechanical plotters.

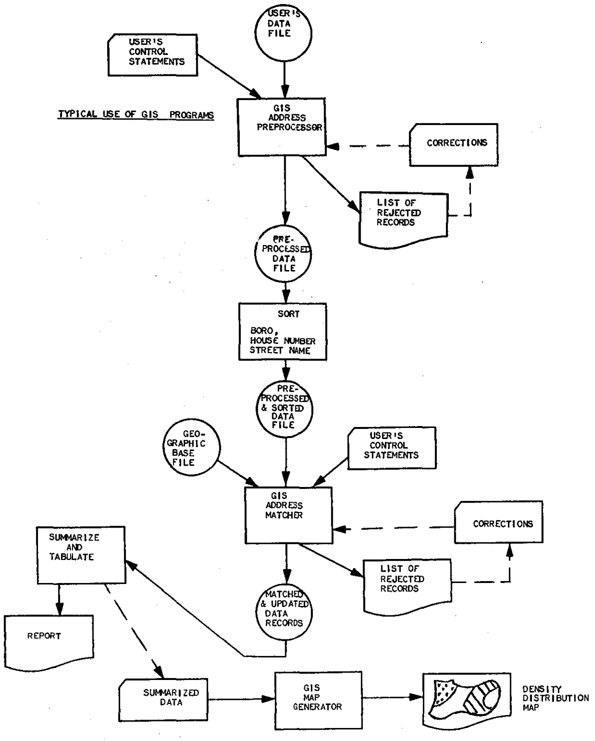

Figure 12—Typical use of GIS programs

The software support supplied by Geo-Space is a program called ALPACA which uses FORTRAN subroutines to perform character generation, generate lines and circles and control the operation of the plotter.

It might be timely to remind ourselves that each computer driven plotter, including the Geo-Space, requires the user to develop the programs needed to edit and to reformat the data to be displayed in the array or sequence demanded by the plotter under consideration.

In the case of Geo-Space, the data to be plotted must be manipulated within core on a large computer or retrieved from a disk on smaller computers to enable the plotter to produce 2-inch wide strips up to 60 inches long and then produce the adjacent 2-inch strip until the entire sheet (up to 40 inches wide) has been completed.

SCRIS (Southern California Regional Information Study) is currently developing user software to facilitate data comparisons and display of Census data on a "Geo-Space" CRT plotter. They are also preparing state and county outlines for use throughout the United States. Previous use of Geo-Space equipment was performed during the New Haven Census Use Study.

The United States Army Map Service, in conjunction with IBM, is developing software for use with IBM's Multipurpose Digitizer/Plotter. This work has been primarily concerned with automated cartography; however, the equipment and software developed appears to have direct applicability to urban data users.

A frequent need in planning operations is to determine where a pattern or a concentration of a particular activity is occurring. New York City, using a Geo-Space plotter, has prepared a block map of Manhattan, indicating where high valued real estate changed hands. This provided a good indicator of the areas where new building activity is likely to be concentrated and where new utilities and support services will be needed.

TYPICAL GIS PROCESSING

Figure 12 is a system flowchart that illustrates the typical processing one may go through in utilizing the principal components of a GIS.

SUMMARY

Geographic Information System development and application is proceeding at a rapidly accelerating pace. We envision a continuance of this over the foreseeable future as improved files get built, as more files are put on-line with more sophisticated accessing schemes, and as these systems become more and more involved with operational as well as planning type applications.

UNIMATCH—A computer system for generalized record linkage under conditions of uncertainty

by MATTHEW A. JARO

U.S. Bureau of the Census
Washington, D.C.

INTRODUCTION

The Census Use Study of the Bureau of the Census is planning to release a computer program package to the general public providing a generalized record linkage capability, under the name of UNIMATCH (for UNIversal MATCHer).

For the purposes of this paper, *record linkage* may be defined as the process of examining each record independently on a *data file*, and comparing information with a domain of records on a second file, which will henceforth be referred to as the *reference file*, according to pre-determined comparison criteria with the object of selecting a unique record on the reference file that maximally meets or exceeds the criteria (if such a record exists), and transferring (or linking) information from the selected reference file record (if any) to the data file record.

If a unique reference file record is successfully obtained for a given data file record, that data file record is considered to be *accepted* (or matched), and the transfer of information from the reference file to the data file can occur. If no unique reference file record is obtained, the data file record in question is considered to be *rejected* (or nonmatched), and no linkage of information will transpire.

The most rudimentary example of the record linkage process is the file update problem, where a master data file is examined sequentially, and a key field (such as a record control number) is compared with an identical field on the transaction update file (the reference file). If the fields match, information is transferred from the reference file to the data file, thereby updating the master record. If the fields do not match, the data file is advanced to the next record with no data transfer occurring. The reference file is sorted by the key field, and every equal or high comparison causes the reference file to be advanced by one record. In this case, the domain of the candidate records on the reference file is one, since a single reference file record is a prospective match candidate for each data file record (it is assumed that the key numbers are unique in this example).

CRITICAL FIELDS AND CANDIDACY DOMAIN

Any key field where an exact match is necessary before any further comparisons or data transfer can be considered will be referred to as a *critical field*. It follows then, that a mis-match on any critical field is sufficient to cause the rejection of the data record. Matches (successful comparisons) on all critical fields are necessary (but often, not sufficient) conditions to cause the acceptance of a data file record.

Critical fields serve to limit the domain of reference file candidacy. If no critical fields are defined for a record linkage application, the entire reference file must be examined for each data file record. This universal domain will provide the greatest potential for a high match rate, but is often prohibitively expensive in terms of execution efficiency, and generally does not provide a sufficient cost/benefit for a real application. The total number of records that must be examined by the system in a universal domain application is the product of the number of data file records and the number of reference file records, added to the number of data file records, so that large files will require a considerable number of comparisons.

The number of records that must be examined in the other extreme, where the reference file candidacy domain is limited to one record (as in the file update example), is equal to the sum of the number of data file records and the number of reference file records.

In this case, the selectivity of the system is nearly zero, since at most only one record is considered for candidacy. For this reason, a match on critical fields only will provide the least potential for a high match rate.

The reference file domain of a real application can be determined by weighing the reliability gained by increasing the domain against the resultant cost increase. Let the *average domain* be defined as the number of reference file records accepted as match candidates for the average data record. The average domain can be computed by first summing the number of candidates for each data record. If a data record does not match on all critical fields, the number of candidates is considered to be zero. If a data record does match on all critical fields, the number of candidates is equal to the number of reference file records having identical critical field values. The final sum can be divided by the number of data records read, yielding the average domain. The average domain ranges from zero (if no data record matches any reference file record on all critical fields) to the number of reference file records (if the entire reference file becomes the domain because of the omission of critical field comparisons). The average domain is not meaningful if all comparisons are critical field comparisons (that is, there are no probabilistic or weighted comparisons), since the result of the match is based only upon the values of the critical field keys, and additional reference file records bearing the same key values need not be examined. In the file update problem, for example, where the only comparisons made are key field comparisons, no additional information will be obtained by reading all reference file records having the same key values. In fact, such applications generally require that the key numbers be unique.

THE COST OF A RECORD LINKAGE APPLICATION

The *cost* of an individual record linkage application can be computed as follows:

$$\text{Cost} = n\cdot C_n + m\cdot C_m + \max(n,m)\cdot C_c + D\cdot n\cdot C_d + f\cdot n\cdot C_t + H \quad (1)$$

where:

n = number of data file records read

m = number of reference file records read. All the reference file records on the file will not be read if the reference file contains critical field key data values that are greater than any found on the data file.

C_n = cost of reading and writing one data file record.

C_m = cost of reading one reference file record from original data set.

C_c = cost of comparing the critical fields. This cost is an average cost, since the highest level critical fie!d mis-match terminates the comparison algorithm.

D = average domain. The number of reference file records accepted as match candidates for the average data file record.

C_d = cost of comparing all non-critical fields for one data record with one reference file record within the domain.

f = the fraction of the file that will be matched (successfully linked).

C_t = cost of linking one reference file record to one data file record. This is an average cost based on the number of comparisons and lengths of strings to be moved.

H = system overhead.

The cost of comparing all non-critical fields for one data record with one reference file record within the domain (C_d), which is the most complex factor in equation (1), may be computed as follows:

$$C_d = g\cdot(C_z + P_x\cdot C_x) + \sum_{i=1}^{g}\sum_{j=1}^{k_i} C_{ij}$$

where:

g = number of ranked groups (the concept of ranked groups is discussed in the section on ranked grouping).

k_i = number of fields in group i.

C_z = cost of determining whether group score for one reference file candidate record exceeds maximum score.

C_x = cost of storing all group scores in the case that the reference file candidate record has a higher score than any yet encountered.

P_x = fraction of ranked groups whose scores are monotonically increasing (i.e., the number of groups where it is necessary to replace a previously encountered maximum score divided by the total number of groups).

C_{ij} = cost of comparing field j in group i. This includes the cost of string compression (such as SOUNDEX), field padding, fixed or interval logical comparisons, weight determination and adding the derived weights and penalties to the total ranked group scores.

Note: The derivation of these terms will become apparent when the ranked grouping algorithm is discussed.

CRITICAL FIELD HIERARCHY

Since the critical fields serve to limit the domain of reference file candidacy, each critical field is an identification key. For sequential files, these identification keys must be sort keys, and both the data file and the reference file must be sorted on all such keys in ascending collating sequence. For direct access files, the identification keys can be used to retrieve records sequentially. For the purposes of this paper, it is assumed that both files are sequent:al files, since direct access files can be processed sequentially.

Let the *major critical field* be defined as the critical field with the highest level (major) sort key. The major critical field must be the major sort key. The *minor critical field* (or *search field*) is, of course, the critical field with a sort key of lower hierarchy (more minor) than any other critical field. It is therefore the minor sort key in the set of all critical fields, and not necessarily the true minor sort key. The minor critical field is the search field. This field is used to construct the domain of reference file candidacy. All reference file records having the same search field (minor critical field) contents as the equivalent field on the data file will become prospective match candidates for that data file record. S:nce the minor critical field defines the domain (which is the most important factor to the cost of a record linkage application), this field should be chosen with great care.

THE UNIMATCH LANGUAGE

Before embarking upon a discussion of the record linkage theory governing the comparisons of noncritical fields, the relationships between critical field hierarchy, domain construction, and field definitions within the UNIMATCH language will be explained. The basic operation of the system and the structure of the UNIMATCH language are prerequisite topics toward an understanding of these relationships, and will therefore be discussed presently.

The language itself is composed of a series of statements consisting of fixed-field keywords with operands, and tables which follow some statements. The keyword identifying a certain statement type is always punched in column one of the control stream record. The number and position of the operands are dependent upon the individual statement. In general, the statements are not directly executable commands (like the FORTRAN Arithmetic statements), but are for the most part, definitions. The statements are edited, and reduced to numerical form by the UNIMATCH Compiler. Arrays defining the structure of the problem, and blocks containing control information are created. The UNIMATCH Assembler reduces this basically tabular compilation into blocks of relocatable executable machine code for the IBM System/360, and blocks of control information. These blocks are loaded and executed under control of the UNIMATCH Executer. The three programs of the UNIMATCH system (the Compiler, the Assembler and the Executer) are written in IBM System 360 Assembler Language, and both OS and DOS versions of the system will be released.

As many runs as desired may be compiled, assembled and executed by each phase, respectively, so that multiple-pass linkage applications can be executed during one job step. Splitting the system into three phases enables the generation of efficient program code that will not penalize the user for features not desired, and provides greater core storage for users of limited computer facilities. Furthermore, production runs need only be compiled and assembled initially because the assembler creates object modules that can be retained.

FIELD DEFINITION

Due to their importance in subsequent discussion, considerable attent:on will be g:ven to the KEYFIELD and EQUATE statements. In general, however, exact details of the language will not be presented in this paper. Every field used in a comparison (critical or non-critical), and every fie:d used in a field manipulation context must be defined via the KEYFIELD statement. This statement consists of the keyword (KEYFIELD) followed by the beginning character position of the field, the field width in characters, and a 1-8 character label (or field name) which provides reference to the unique field. Unless otherwise specified (via the EQUATE statement), all fields are considered to be identical (having the same beginning column and fie:d width) in both the data and reference files. The inclusion of a field in the KEYFIELD or EQUATE statements does not necessarily imply that any actions or comparisons will be made on the field, but :nclusion does define the comparison configuration, should subsequent statements require such comparisons.

The EQUATE statement allows the user to define the appropriate comparison configuration for the defined fields, and to establish which fields belong to either the data file or the reference file (the omiss'on of an EQUATE statement for a field results in that field belonging to both the data and reference files). The EQUATE statement consists of the keyword followed by a two character code, followed by two or three names (prev:ously defined in a KEYFIELD statement). The first name given in all cases is called the base name. All subsequent references to equated fields should be by base name. The true configuration of the comparison and al fields involved will be utilized in creating the object code blocks, without having to be restated by the user. A code of FC or FN requires two names: the name of the data file field followed by the name of the reference file field. The locations and lengths of these fields have been previously defined (by KEYFIELD statements). The field on the data file will be compared character by character with the equated field on the reference file should any subsequent statement require a comparison. Codes FC and FN differ in their treatment of unequal length fields (the data file field is not equal in length to the reference file field). FC causes padding of the short field with blanks to the right, and FN causes padding of the short field with leading zeros, to equalize the lengths. FC can therefore be used with character data, and FN with numeric data.

Codes RI and RP requ're three names: the name of the data file field, followed by the name of the reference file field contain:ng the low extreme of a closed interval, followed by the name of the reference file field containing the high extreme of the interval. By this means, comparisons may be made between fixed values on the data file, and closed intervals (where the endpoints are included in the interval) on the reference file. Subsequent statements will only require the base name (in this case the data file field name) to cause the appropriate interval comparisons to be made. Code RP is identical to RI except that the parity of the fixed field must match the parity of the low extreme of the interval. In this case parity refers to whether the values are even or odd. Parity agreement is useful for street address matching, where a house number is to be compared to a range of addresses on a street, and the odd and even addresses are on differing street sides. Codes DI and DP pertain to fixed fields on the reference file being compared to intervals on the data file. All interval fields are treated as numeric, and the short fields are padded with leading zeros at execution time before comparisons are made.

CRITICAL FIELD DEFINITION

The MATCH, SORT, and SEARCH statements define the hierarchy of the critical field structure and the domain construction. The keyword MATCH, followed by a field name, indicates that the field is a critical field, and the appropriate comparisons will be made for the configuration defined via the KEYFIELD and EQUATE statements. A mis-match on any critical field is sufficient to reject the data file record. The domain of candidacy is thereby reduced by means of the MATCH statements. If a critical field represents an interval comparison, the ranges covered by the interval must not overlap. The SORT statement defines the sort order of the critical fields by requiring a level number and critical field name. The SEARCH statement defines the reference file domain. The keyword *SEARCH* is followed by a field name (which must appear in the SORT statement). All reference file records having the same search field contents as the equivalent field on the data file record will become prospective match candidates for that data file record. Operationally, reference file records are read into core storage, until the end of the partition is reached, at which time they are written on disk and paged in as required. The program will operate more efficiently in larger storage partitions. If the domain is chosen carefully, there should be few (if any) input/output operations of this sort. The program will process domains as large or small as desired without any user modification. The disk paging operations are optimized to minimize the number of accesses.

WEIGHTED COMPARISONS

After the reference file domain is constructed, it is often desirable to make a number of comparisons with the object of selecting the most probable record for a match if that record is within the acceptability tolerances. The concept of *weighted* comparisons makes this possible. Much work has been done on the derivation of weighting schema. A paper written by Sidney H. Brounstein of the IBM Corp.[1] provides a comprehensive review of the weighting techniques developed, and will be quoted extensively in this section. Robert T. O'Reagan of the Census Bureau[2,3] has done considerable work in the derivation of practical weighting algorithms. The fundamental weight'ng theory underlying most modern methods is the "Direct Weighting Concept", derived by Newcombe[4,5]. The following quote from Brounstein will illustrate the basic concept:

> Given a pair of records that are candidates for a match, the number of the components that agree and disagree is observed. If equal impact were given to each component, the discriminating power of some components that are measurably

> more powerful than others would be wasted. For example, if two American health records agree on the surname Smith, that would be some ind:cation that this m'ght be a true match. However, if they agree and both say Hinton in that component, it is a much stronger clue. The rarer the argument, the less like y that accidental agreement will occur between components in records brought together at random.
>
> If the sets M (matched pairs) and U (unmatched pairs) preexisted in totality, there would be no matching problem. The problem exists because some method of characterizing M and U is required to decide to which of the sets a new comparison pair (representing two records not previously linked) belongs. This implies the use of sampling methods, computations based on frequency analyses of the separate files, or inferences based on knowledge of the total populations from which the data files are drawn.

Practical weights and penalties (negative weights) can be computed by determining the following four probabilities (by dividing the frequency of occurence by the number of comparison pairs tested).

$P_1 = Pr$(component agrees|pair is a true match)
$P_2 = Pr$(component agrees|pair is not a true match)
$P_3 = Pr$(component disagrees|pair is a true match)
$P_4 = Pr$(component disagrees|pair is not a true match)

The appropriate weight for the comparison pair can be computed by:

$$S_w = \log_2 (P_1/P_2)$$

The appropriate penalty can be computed by:

$$S_p = \log_2(P_3/P_4)$$

Weights and penalties can be derived in this manner for all components (or configurations of components). A component is a field for which a weighted comparison is to be made, and its configuration is the value of the field on both the data and reference files. The score for each prospective candidate in the domain can be computed by adding (separately) the weights and penalties for each component (determined before the actual record linkage application by means of a sample population, and the above method). The reference file record with the greatest weight and lowest penalty is the most probable match within the domain. If the penalty of this best record is greater than a certain threshold value, the data file record can be rejected on the basis that the probability of the chosen reference file record being a correct link is too low for the particular application.

This method of computing weights and penalties assumes the statistical independence of each component (if this is not true, then joint distributions must be computed by taking the set of all components at one time, generally an immense undertaking). For address matching purposes (geographic coding), the assumption of independence is fairly good. Allowing this assumption, the addition of the logarithmic weight scores for each component is equivalent to multiplying the likelihood ratios, thereby attaining the joint probability for the record being a match.

The following example will illustrate the method of deriving weights for an address coding application. The probabilities P_1 to P_4 are computed using a sample file where all records have been linked manually (assuming no clerical error!). Consider the component "street type":

$P_1 = Pr$(street type agrees|pair is a match) $= 0.64$
$P_2 = Pr$(street type agrees|pair is not a match) $= 0.16$
$P_3 = Pr$(street type disagrees|pair is a match) $= 0.02$
$P_4 = Pr$(street type disagrees|pair is not a match) $= 0.74$

These probabilities are based on frequencies of occurrences divided by the number of comparisons made. One comparison is made for every reference file record in the domain for a given data file record. The weight for a match on street type is:

$$\log_2(0.64/0.16) = \log_2(4) = 2$$

The penalty for a mis-match on street type is:

$$\log_2(0.02/0.74) = \log_2(1/32) = -5$$

Next consider an additional component "direction". Assume that weights derived in a similar manner are 4 and -6 respectively.

In future record linkage applications the two components can be examined against the equivalent reference file components. If both street type and direction matched, the total weight for the candidate record would be $2+4=6$, with a penalty of zero. If direction matched, but street type did not, the weight would be 4 and the penalty would be 5 (the penalty score is considered to be a positive number, not a negative weight). The converse case would produce a weight of 2 and penalty of 6. Disagreement on both components would produce a weight of zero and a penalty of 11.

THRESHOLD LEVELS

The we'ghts and penalties computed in the previous section can be used to determine the threshold level for the data file record rejection. If the weight obtained for a particular record is equal to the penalty score, then there is a 50 percent chance (1:1 odds) that the reference file record will provide a correct match. If the weight obtained is one greater than the penalty, the odds favoring a correct match are 2:1. If the weight is less than the penalty, the odds do not favor a correct match. In general, the difference between the weight and penalty scores is the logarithm (to the base two) of the odds favor ng a match.

Odds in favor of a correct match $=2^{(S_w-S_p)}$

The amount of error tolerable for a given application must be determined by the user, in order to set an appropriate threshold level.

RANKED GROUPING

The UNIMATCH system has a feature whereby as many fields as desired may be grouped together. Grouping establishes a separate weight and penalty score counter for the set of fields in each group, as well as group hierarchy (or ranking). The selection of the best reference file candidate is determined by examining the domain, and retaining only those reference file records having the maximum weight in the highest ranking group. All other records are removed from the domain. The remaining records are examined, and only those reference file records having the maximum weight in the second highest ranking group are retained. All others are removed from the domain. This process is continued until the lowest ranking group weights are examined. In practice, this process is conducted in a single pass through the reference file domain. The weights for all groups are computed for a given record, if the weights are better than the maximum encountered previously, then the current record becomes the prospective candidate, if not, the next record is inspected. At the termination of the scan, the weight and penalty counters reflect the values of the best record, and pointers indicate the position of that record in the domain. A record is better than a previous one if there exists a weight in a high ranking group that is greater than the existing weight (weight scores are maximized within rank, e.g., a record bearing a score of 1,4,7 will not replace a record bearing a score of 2,1,1 where the first number in each set of three is the highest rank).

A further condition is added to the criteria for reference file record selection: If the weight score for any group (regardless of rank) is zero, that record will not be considered a prospective candidate. This convention allows a secondary hierarchy to be constructed. It may be desirable to automatically reject the data file record if certain minimum information is desired.

The ranked grouping concept allows a system of intuitive weighting to be established, where the ranks are assigned upon the basis of the information content of each field, and group of fie'ds. More importantly, the ranked grouping concept permits reduction of the reference file domain when the fields cannot be expressed as sort keys (via the critical field MATCH statements). A common example of this is the comparison of a field to an interval where the intervals are allowed to overlap. No sorting scheme will be able to construct a domain that will ;nclude various values of the single field if the ranges of the intervals vary and the values overlap. Including all va'ues of the intervals (within the critical sort keys, of course) into the domain, and defining the interval comparison to be within a group, and assigning a weight of one for a match and a weight of zero for a mis-match, will result in the retention of all intervals containing the field value (or vice versa, if the interval is on the data file) in the domain. Another example, is the phonetic compression of a character string (another feature provided by UNIMATCH). All values sufficiently close to the data file value can be retained in the domain. This is useful for name matching. The interval comparison method given is useful for matching a street address to a range of addresses in a city.

IMPLEMENTATION OF WEIGHTED COMPARISONS

The UNIMATCH system requires all fields where weighted comparisons are needed, to be organized into ranked groups. The GROUP statement requires a group name (which is a 1-8 character label not previously used, that will uniquely identify the group), and a list of all fields (by field name) that comprise the group. Any particular field may be used in as many groups as desired. At least one group must be defined to allow weighted comparisons, but fields may be grouped in any fashion desired. Each group carries its own weight and penalty score counters. The LEVEL statement defines the group ranking. It consists of the level number and group name. The ACCEPT statement defines the maximum penalty score permitted for the group named. If the penalty score of the chosen candidate (the reference file record with the highest ranked positive weight scores) is greater than the amount specified in the ACCEPT statement, the data file record will be rejected.

WEIGHT statements must be provided for all fields specified in GROUP statements. Rather than specifying the two states discussed earlier (match and mis-match), the WEIGHT statement prov des for five possible states:(1) the data file field matches the reference file field, and neither field contains blank nor zero entries (match);(2) the data file field contains a blank or zero entry and the reference file field does not (data file omission);(3) the data file field contalns a coded entry and the reference file field contains a blank or zero entry (reference file omission);(4) both fields contain blank or zero entries (null match);(5) the fields conta'n conflicting non-zero (or non-blank) entries (mis-match). These states also apply to intervals.

An interval is considered null if both extremes are zero. Conditional weight tables may be created which will modify the group weights contingent upon certain configurations of reference file field values. For example, if the "street type" field is considered, and the data file record has no entry coded, it might be desirable to give added weight to those reference file candidates containing a street type of "ST", "BLVD", "RD", etc., over those containing street types of "PL", "CT", "SQ" etc., on the basis that the frequency of occurrence of "ST", "BLVD" etc., is likely to be higher. Conversely, if the data file field value is "COURT" and it matched the reference file field, a higher weight may be assigned because the frequency of occurrence is less than "ST" and therefore the information content is greater.

DATA TRANSFER CONTROL

Since the object of the record linkage process is the transfer of data from the reference file to the data file, considerable thought was given to the design of an effective data transfer control system. The system allows the user to code a number of executable commands describing the procedure for transferring information from the chosen reference file record to the data file record (or if the data file record is rejected, transferring messages to the data file record). The unconditional "move" is the simplest operation. A field in the reference file is moved to a location on the data file (or appended to the end of the record, if desired). A "compare" command causes transfer of information contingent upon the stated value being present in the data file or reference file. This allows records of different types to be processed correctly. UNIMATCH maintains a set of internal flags which indicate whether individual fields were successfully matched for the chosen candidate record. Data transfer can occur contingent upon the successful linking (or non-linking) of any individual field for the candidate.
