## Preface

MERLIN SMITH  
Conference Chairman

The Proceedings of the 1979 National Computer Conference represents the most comprehensive, in-depth treatment of computing developments available today. It stands as a lasting credit to Richard Merwin and his program committee, and to the many authors, session chairpersons, reviewers and other contributors recognized on these pages.

Data processing has rapidly become one of the more vital factors in the economic and personal well being of all. The NCC program was directed to these many new interests of participants. Such an objective required many panel and discussion sessions beyond the formal papers, and the limits of this Proceedings. We owe a special debt to these participants who helped make our conference a success. Their names are recorded herein.

We appreciate this opportunity to be a part of recorded computer history.

## Introduction

**RICHARD E. MERWIN**  
NCC '79 Program Chairman

The NCC '79 technical program was planned to be a learning experience for all attendees. A broad range of paper and panel sessions was selected to emphasize social implications of computers, management issues, technical developments and applications. Each of these areas is represented by both paper and panel sessions which are designed to bring the attendees of this "biggest of all" computer conference to the forefront of knowledge of each specialty.

A major attempt has been made to broaden the scope of the NCC '79 technical program by including three mini-conferences covering the application of computers to financial transactions, law and health services. Thirty-two sessions dealing with these topics will expand the coverage of NCC '79 to an audience of specialists in fields which are increasingly becoming allied with data processing techniques.

The urge to participate in the NCC '79 technical program was overwhelming. Because of a limitation on the size of this Proceedings, the number of papers that could be accepted for publication was curtailed. A large number of proposals were received for panel sessions and a selection of the best of these was made. This trend for more and more participation in both the technical program and the exhibition of the latest computer products mirrors the tremendous growth of the computer industry, especially in the areas of micro-processors.

In response to the wide interest in the use of computers by the non-professional, a special set of sessions and a separate publication devoted to personal computing has been organized to augment the technical program and regular exhibits. The interest in this aspect of the computer industry has increased rapidly and represents a major factor in this industry.

This Proceedings is organized by specialized areas including Applications, Social Implications, Architecture, Data Base Management, Computer Technology, Networking and Software Techniques, in that order. Unfortunately, we had to eliminate overview statements by topical area organizers along with descriptions of panel sessions to maximize the number of technical papers that could be published. I regret these omissions but feel that our policy of publishing only technical papers best serves the technical goals of the conference.

The planning and organization of the NCC '79 technical program involved a number of area coordinators, session organizers and leaders and the panelists and presenters of technical papers. I want to extend my sincere appreciation to all those who supported the organization of this outstanding technical program. Special thanks is due to the hundreds of referees who helped us select the best papers. Finally, I want to thank the program committee staff who tirelessly worked with all participants to make this conference a success.

---

# CONTENTS

Preface .....	iii
Merlin Smith	
Introduction .....	iv
Richard E. Merwin	
APPLICATIONS	
Computer technology in the movie industry .....	1
Suzanne Landa	
The system architecture evaluation facility—An emulation facility at Rome Air Development Center .....	7
N. Bruce Clark and Michael A. Troutman	
Teaching and research experiences with an emulation laboratory .....	13
Steven F. Sutphen	
Simulating the delay in logic networks for large, high-speed computers .....	19
E. A. Wilson	
Languages for operating systems description, design and implementation .....	29
Philip H. Enslow, Jr.	
The simulation language SIML/I .....	39
M. H. MacDougall	
Mix-dependent job scheduling—An application of hybrid simulation .....	45
Steve Tolopka and Herb Schwetman	
Parametric instabilities in computer system performance prediction .....	51
Lawrence W. Dowdy and Ashok K. Agrawala	
Aids to the development of network simulators .....	57
Imrich Chlamtac and W. R. Franta	
A stochastic state space model for prediction of product demand .....	67
William C. Cave and Evelyn Rosenkranz	
The Bus Link—A microprogrammed development tool for the CMOS/SOS processor system .....	73
Avner Ben-Dor, Paul Baker and Jon Selden	
A computer analysis tool for structural decomposition using entropy metrics .....	83
Aaron N. Silver	
Interactive modeling systems for managers—Semantic models should underlie quantitative models .....	89
Rand B. Krumland	
Modeling regular, process-structured networks .....	95
Bruce W. Arden and Hikyu Lee	
The City of New York's integrated financial management system—From mandate to working system in 18 months .....	103
Sally J. Rupert	
Recurrent dilemmas of computer use in complex organizations .....	107
Rob Kling and Walt Scacchi	
Project management through the Accomplishment Value Procedure (AVP) .....	117
Donald J. Aharonian	

---

Textfax—Principle for new tools in the office of the future .....	125
Wolfgang Horak and Walter Woborschil	
Microcomputer programming skills .....	135
C. Wrandle Barth	
Program conversion—One successful paradigm.....	139
Charles Lynn, Jr., Jean Risley and Robert Wells	
A generalized zooming technique for pictorial database systems .....	147
S. K. Chang, B. S. Lin and R. Walser	
An approach to real-time scan conversion .....	157
Franklin C. Crow	
The evolution and architecture of a high-speed workstation for interactive graphics .....	165
William L. Paisner	
A mathematical model for distributed free space .....	175
Y. H. Chin and S. H. Yu	
Forecasting computer resource utilization using key volume indicators .....	185
David E. Y. Sarna	
Workflow—A technique for analyzing JES systems.....	193
H. Pat Artis	
MMPS—A reconfigurable multi-microprocessor simulator system .....	199
Daniel Klein	
A (31,15) Reed-Solomon code for large memory systems .....	205
Raymond S. Lim	
English dictionary searching with little extra space .....	209
Douglas Comer	
New indices for bibliographic data and their applications .....	217
Yahiko Kambayashi, Shuzo Yajima, Osamu Konishi and Takaki Hayashi	
Visual inspection of metal surfaces .....	227
J. L. Mundy	
Monitoring the earth's resources from space—Can you really identify crops by satellite? .....	233
David Landgrebe	
Digital image shape detection .....	243
R. Michael Hord	
PM <sup>4</sup> —A reconfigurable multiprocessor system for pattern recognition and image processing .....	255
Fayé A. Briggs, King-Sun Fu, Kai Hwang and Janak H. Patel	
Transportable image-processing software .....	267
R. G. Hamlet and A. Rosenfeld	
A data-handling mechanics of on-line text editing system with efficient secondary storage access .....	273
Sakti Pramanik and Edgar T. Irons	
<b>SOCIAL IMPLICATIONS</b>	
How do we best control the flow of electronic information across sovereign borders? .....	279
Peter Safirstein	
Privacy and security in transnational data processing systems .....	283
Rein Turn	
A modular approach to computer security risk management .....	293
Robert P. Campbell and Gerald A. Sands	
The design and operation of public-key cryptosystems .....	305
Eric H. Michelman	

Safeguarding cryptographic keys .....	313
G. R. Blakley	
Applications for multilevel secure operating systems .....	319
John P. L. Woodward	
The foundations of a provably secure operating system (PSOS) .....	329
Richard J. Feiertag and Peter G. Neumann	
A security retrofit of VM/370 .....	335
B. D. Gold, R. R. Linde, R. J. Peeler, M. Schaefer, J. F. Scheid and P. D. Ward	
KSOS—The design of a secure operating system .....	345
E. J. McCauley and P. J. Drongowski	
UCLA Secure UNIX .....	355
Gerald J. Popek, Mark Kampe, Charles S. Kline, Allen Stoughton, Michael Urban and Evelyn J. Walton	
KSOS—Development methodology for a secure operating system .....	365
T. A. Berson and G. L. Barksdale, Jr.	
KSOS—Computer network applications .....	373
M. A. Padlipsky, K. J. Biba and R. B. Neely	
Considerations in the employment of blind computer professionals .....	383
James A. Kutsch, Jr., and Kimberly B. Kutsch	
Hiring a deaf computer professional .....	385
Karen K. Anderson and Philip W. Bravin	
MIS effects on managers' task scope and satisfaction .....	391
Daniel Robey	
Some neglected outcomes of organizational use of computing technology—And their implications for systems designers .....	397
M. Lynne Markus	
An academic meets industry—Rethinking computer-based education and personalized systems of instruction ..	403
Kenneth L. Modesitt	
Recent developments in computers and society research and education .....	407
Richard H. Austing and Gerald L. Engel	
Interactive monitoring of computer-based group communication .....	411
Kathleen Spangler, Hubert Lipinski and Robert Plummer	
The status of women in health science computing .....	415
Lynn L. Peterson	
Women and minorities in the computer professions .....	419
Helen M. Wood	
Computers in judicial administration .....	425
Charles L. Aird and Barbara H. Todd	
Police and computer technology—The expectations and the results .....	443
Kent W. Colton	
 ARCHITECTURE	
Distributed algorithms for global structuring .....	455
Raphael A. Finkel, Marvin Solomon and Michael L. Horowitz	
The tree-structured distributed network front-end processor architecture .....	461
Robert M. Monroe, Ronald J. Srodawa and Franklin H. Westervelt	
Analysis of real-time control systems by the model of packet nets .....	469
Mohamed Gawdat Gouda	

---

Performance and economy of a fault-tolerant multiprocessor .....	481
Jaynarayan H. Lala and Charles J. Smith	
Serviceability features of the HP 300 small business computer .....	493
Curtis R. Gowan	
Automatic tuning of computer architectures .....	499
Ken Sakamura, Tatsushi Morokuma, Hideo Aiso and Hajime Iizuka	
The BTI 8000—Homogeneous, general-purpose multiprocessing .....	513
George R. Lewis, J. Shirley Henry and Brian P. McCune	
A survey of interconnection methods for reconfigurable parallel processing systems .....	529
Howard Jay Siegel, Robert J. McMillen and Philip T. Mueller, Jr.	
Adaptation properties for dynamic architectures .....	543
Steven I. Kartashev, Svetlana P. Kartashev and C. V. Ramamoorthy	
Architectural considerations of the NEC mass data file subsystem .....	557
Akira Sekino and Takuo Kitamura	
Error-oriented architecture testing .....	565
Larry Kwok-Woon Lai	
A survey of methods for intermittent fault analysis .....	577
Yashwant K. Malaiya and Stephen Y. H. Su	
Architectural and design perspectives in a modular multi-microprocessor, the DPS-1 .....	587
Kells A. Elmquist	
Work flow view of a distributed application .....	595
J. R. Hamstra	
The use of self-inverse program primitives in system evaluation .....	605
John E. MacDonald, Jr.	
A loosely-coupled applicative multi-processing system .....	613
Robert M. Keller, Gary Lindstrom and Suhas Patil	
A prototype data flow computer with token labelling .....	623
Ian Watson and John Gurd	
A view of dataflow .....	629
Kim P. Gostelow and Robert E. Thomas	
A hardware-independent virtual architecture for PASCAL .....	637
Viswanathan Santhanam	
Design of a high-level language machine .....	649
G. J. Battarel and R. J. Chevance	
A programming language for high-level architecture .....	657
Yaohan Chu and Edward Ray Cannon	
 DATA BASE MANAGEMENT	
Data management in distributed data bases .....	667
C. V. Ramamoorthy and Benjamin W. Wah	
A unified architecture for data and message management .....	681
Georges Gardarin	
Design of a prototype ANSI/SPARC three-schema data base system .....	689
Eric K. Clemons	
On the implementation of a conceptual schema model within a three-level DBMS architecture .....	697
Shamkant B. Navathe and Johann Lemke	

---

The practice of data base administration .....	709
Jay-Louise Weldon	
An approach to automatic maintenance of semantic integrity in large design data bases .....	713
Gilles M. E. Lafue	
On query-answering in relational data bases .....	717
E. L. Lozinskii	
ASTROL—An associative structure-oriented language .....	721
James F. Wirth	
An associative search language for data management .....	727
Amar Mukhopadhyay and Alireza Hurson	
Updating defined relations .....	733
I. M. Osman	
Performance enhancement for relational systems through query compilation .....	741
Randy H. Katz	
 COMPUTER TECHNOLOGY	
System considerations for predicting mass storage subsystem behavior .....	749
E. J. McBride, A. B. Tonik and G. R. Finnin	
A software reliability study using a complexity measure .....	761
Thomas J. Walsh	
A Markovian model for reliability and other performance measures of software systems .....	769
Amrit L. Goel and Kazu Okumoto	
Partial match retrieval for non-uniform query distributions .....	775
V. S. Alagar and C. Soochan	
 NETWORKING	
Comparing interactive computer services—Theoretical, technical and economic feasibility .....	781
S. A. Mamrak and P. D. Amer	
Characterizing a workload for the comparison of interactive services .....	789
Domenico Ferrari	
Control of computing funds and resources in a networking environment .....	797
Beverly O'Neal and Ronald Segal	
The economic impact of network affiliation upon institutions of higher learning .....	805
Norman R. Nielsen	
Approaches to concurrency control in distributed data base systems .....	813
Philip A. Bernstein and Nathan Goodman	
Access control mechanisms for a network operating system .....	821
Helen M. Wood and Stephen R. Kimbleton	
Public key vs. conventional key encryption .....	831
Charles S. Kline and Gerald J. Popek	
SIGMA—An interactive message service for the Military Message Experiment .....	839
Robert Stotz, Ronald Tugender, David Wilczynski and Donald Oestreicher	
The SIGMA experience—A study in the evolutionary design of a large software system .....	847
David Wilczynski, Ronald Tugender and Donald Oestreicher	
The terminal for the Military Message Experiment .....	855
Robert Stotz, Paul Raveling and Jeff Rothenberg	

---

On-line tutorials and documentation for the SIGMA message service .....	863
Jeff Rothenberg	
Maintaining order and consistency in multi-access data .....	869
Ronald Tugender	
Exact solution for the initialization time of packet radio networks with two station buffers .....	875
Daniel Minoli	
Fixing timeout intervals for lost packet detection in computer communication networks .....	887
Robert J. T. Morris	
Comparison of some end-to-end flow control policies in a packet-switching network .....	893
G. Pujolle	
Alternatives for providing highly reliable access to X.25 networks .....	905
Richard J. Chung and A. M. Rybczynski	
A fail-safe distributed local network for data communication .....	917
Jane W. S. Liu, Izumi Suwa, Robert Stepp, Sergio M. Hinojosa and Tsutoma Utsuqi	
An analysis of a distributed switching network with integrated voice and data in support of command and control .....	927

# Computer technology in the movie industry

by SUZANNE LANDA

*The Rand Corporation*  
Santa Monica, California

## INTRODUCTION

The movie industry uniquely provides the opportunity to combine the creativity of the artist with the technology of science. It was in fact the marriage of art and science that gave birth to filmmaking. While many advances and discoveries have been made in the tools used to make movies, support their production and distribution, and enhance their exhibition, perhaps none since the camera will have the pervasive effect of the computer. Both behind the scenes and on the screen the ubiquitous computer is beginning to have an impact on the movie industry.

This paper follows a movie from its initial conception through production, distribution, exhibition, preservation and redistribution, surveying current and planned applications of computer technology and identifying areas requiring further research. It purposely focuses on the problems of motion picture production amenable to computer application and not on specific technical solutions. The latter will be provided in the session by guest speakers from the movie industry. With the emphasis on movies for this session, computer applications unique to television and other related fields have been excluded.

## CONCEPT

A movie begins with an idea. The source of the idea may be an individual's fantasy, an article or book, a newspaper story, or even the preferences of thousands of people compiled and analyzed by computer. Sunn Classics Productions, Inc. has successfully applied the latter approach to come up with the idea for "The Lincoln Conspiracy," "In Search of Noah's Ark," and other box office successes.<sup>1</sup> Their extensive computer analysis approach, which involves not only idea but also story generation, has only been applied to movie making for special audiences (family entertainment). Successful application for general audiences has not yet been ascertained.

However, once an idea exists, studios do use market research and computer analysis to estimate its potential for success. For example, after producing several successful disaster films, Twentieth-Century Fox relied on market research to indicate when audiences had reached a saturation point for that genre.<sup>2</sup> Market research with computer anal-

ysis for this type of general information is expected to increase.

A movie idea is given life by the writer who turns it into a screenplay. Script writing remains primarily an individual art form centered around the typewriter with occasional forays to the library or other information sources. While the task of typing dialogue lends itself to automated text editing, the author is aware of only one screenwriter who has invested in such a system. Within several years, as the costs of personal computer systems (particularly peripherals) drop, repair support increases, and computerized library and periodical services become more accessible over communications networks, the personal computer will undoubtedly become a valuable aid in screenwriting.

Starting with the purchase of a script and continuing through the distribution and exhibition of a movie, payment to employees is accomplished through a payroll system more complex than any in other industries. The continually changing rules and regulations of over 65 unions and guilds must be handled. Many workers must be paid within 24 hours of the time labor was terminated. If a worker's job is upgraded during the day, his pay for the entire day may have to be adjusted and also the payments to those who worked with him. Depending on when, what, and where he is working, he may earn up to eight times his regular pay. Each union's definition of a work week also varies. Not only must union regulations be tracked, but also the tax structure of every state since the studio must provide a W2 form for every state in which an employee has worked. Another factor contributing to the complexity of the payroll system is that the size of the work force is constantly changing. While a studio may employ 3500-7000 people permanently, total annual employment may easily exceed 50,000 with the total number of checks issued ten times greater. Predominately COBOL written, batch-oriented systems provide payroll support for producers. These services are available from the major studios, e.g. Universal and Warner Bros., and from service bureaus.

In addition to payroll, contracts are issued and modified during all stages of production. This task is handled in Disney's and Fox's legal departments through the use of word processing systems. Interconnectivity of these systems with other departments and those of external concerns, e.g. law firms, has been limited to homogenous systems because of problems with nonstandard communication protocols.

## PRE-PRODUCTION

Once a shooting script has been prepared, the pre-production activities of budget and schedule planning commence. These tasks are compounded by the problem that scripts are not shot chronologically. A shooting schedule depends on the availability of actors, sound stages, locations, props, etc. It also depends on economics. For example, since an actor filmed on Monday and Friday must be paid for the entire week, economics dictate that his scenes be shot at closer intervals. Outdoor scenes are usually filmed before interiors because uncontrollable environmental factors reflected in outdoor scenes may impact the indoor scenes. In addition to schedule planning, scene requirements for sets, props, technical equipment, etc. must be estimated before a budget can be set. It is not unusual for a feature film budget to consist of many thousands of separate items. Both scheduling and budgeting are basically manual processes today with some automated support through data entry systems using formatted displays. However, at the University of New South Wales, an interactive system is being designed for film budgeting, the generation of an economic shooting schedule and the breakdown of individual scene requirements. During the pre-production phase of scheduling and costing, the system will accept as data the script breakdown and all relevant costs. Output will be an initial draft schedule and a total cost estimate. When cast, locations, and budgets have been determined, a detailed shooting schedule is then generated through a tree search. Such an approach does not produce the optimum schedule, but experience with other industrial scheduling situations have indicated to the developers that schedules at least as good as those generated by experienced people could be expected.<sup>3</sup> While production people have shown interest in this type of total system approach, computer aided budgeting and scheduling will probably expand first through subtask application.

One of the requirements determined for each scene is the number and types of extras. The casting of extras presents a particularly formidable problem. At Universal, for example, between 50 and 2000 extras are required daily to appear as background and atmosphere people in productions. Requests are usually very specific: five men with black beards between 20-30 years old, 5'10"-6'2", who can ride horses and duel with swords. It is even better if they own their own horses and swords. Universal uses an interactive system which accesses a data base containing the names of available extras and information about their skills, attributes, costumes, props, etc. When the next day's casting requirements are released, potential extras who best fit the part can be selected online. A similar system for creative talent, i.e. producers, writers, directors, and actors, will be available at Universal in 1979. A producer may then ask to see, for example, a list of directors who specialize in feature westerns and whose credits have grossed over \$30,000,000.

Once the budget and schedule have been determined and actors, locations, equipment, and crews selected, the director, art director and cameraman must design the sets. Sets are usually overbuilt because they are designed for all con-

tingencies. For example, only two-thirds of a \$3,000,000 set may appear in the final print. In this case, \$1,000,000 was spent on a set that will never be seen by the audience. To avoid this waste, those at Robert Abel & Associates involved in full-scale spaceship set designs for the movie "Star Trek" (to be released December, 1979) are using computer graphic aids to determine the parts of each set which must be built. Line drawn versions of sets and people are entered into an Evans & Sutherland Picture System 2 through a tablet. For each set, camera angles and moves are executed using the System 2 controls. In this way, those portions of a set that need not be built because they will never be visible can be determined. It is also possible to identify areas of a set that may be visible but are amenable to matte effect in place of construction.

For movies which include animation or special effects sequences, storyboards outlining the action are developed during pre-production. At Universal's new special effects facility (Universal Hartland), a computer graphics system on a stand-alone microcomputer is being used to create the storyboard for "Buck Rogers." Since storyboards only include sketches of key actions, during the actual filming it may be discovered that the pacing required to move from one sketch to the next varies from that planned. To avoid this problem in the making of "Star Trek," Robert Abel's is using the Evans & Sutherland to preview action sequences in real-time before filming begins.

## PRODUCTION

The actual shooting of a movie may occur at the studio, on location, or a combination of both. Through computer support, producers at the major studios get daily reports on the previous day's expenditures for a particular feature. Overruns are immediately visible so that modifications can be made in the remaining stages of production to absorb or minimize the extra costs. In some cases, early cost excesses result in a project's termination.

Location shooting presents severe cost control and payroll problems. At Paramount, timely and accurate cost information and local payroll capabilities are provided on location by a minicomputer-driven terminal system. Universal is currently implementing a similar minicomputer-based system. At Disney, a microcomputer system with dual-diskettes and printer will be tested on location in Hawaii in early 1979. Disney also expects to use the system on stage at the studio for backlot production sequences. These reporting systems are used during the day on location to record transactions. At night the daily records are transmitted to the central processor. Reports, updated master files, and data discrepancies are then returned to the location for next-day availability. The decrease in reporting time through use of on-location computer support is as much as ten to one. A capability to be added in the future will allow the location auditor to explore the costs of various courses of action when an unforeseen event occurs. For example, should a storm break, with an expected duration of two weeks, the location auditor would like to determine the costs of keeping

everyone on location versus sending them home, paying required penalties and bringing them back later.

Computer technology is also used during production to assist in the generation of the animated images seen on the screen. Animation techniques can be divided into two categories: 2-D animation, involving the use of hand-drawn images, and 3-D animation, involving the manipulation of models and puppets. Both techniques make use of storyboards which are subject to computer application as described under *Pre-Production*. 3-D animation using models will be discussed under *Post-Production*, as it is traditionally associated with the post-production area of special effects.

For 2-D animation, like those of Disney and Hanna Barbera, the first production step requires an artist's rendition of key frames in each scene. The next step calls for an assistant animator or "inbetweener" to fill in the action by providing transition frames between the key frames. Each of these drawings is then photographed, shot onto celluloid, and painted. Finally, each cel or the required combination of cels is placed on an animation stand for filming. For feature films, the only step involving a computer today is the last: Camera settings required to simulate movement are computed and provided to the cameraman filming off the animation stand. However, by mid-1979, several research efforts will have systems commercially available to aid in all these steps of animated feature film production. The systems allow for input of key frames by an artist using a light pen and tablet with the computer performing inbetweening. The artist then "paints" the stored frames interactively with light pen and color selectors. To obtain consistency in scene and character colorization, the systems will allow for the storing and retrieving of colors by picture elements. The need for celluloids is eliminated since frames will be filmed directly off a CRT.<sup>4</sup> A major difficulty in providing computer aids to the animator has been to provide him with input tools with which he feels as artistically free as with conventional methods. The designers of these systems feel they have overcome the problem by providing paintbrush, pencil, and spraygun options to the artist through software. The other area still open to question for commercial application is whether these systems will produce the high-quality, high-resolution animation required for feature films. An answer to this should be forthcoming in 1979 when at least one production company plans to make a full-length animated movie using this type of computer system.

The use of computers to aid live-action filming premieres this year with the release of "The China Syndrome" (Michael Douglas Productions). For story realism and for legal protection, it was necessary in this movie to duplicate precisely the interior of a nuclear power plant during the various stages of an alert. This required the operation of 131 circuits controlling 2500 instrument panel lights in differing sequences and in differing states (off, slow-flash, fast-flash, solid-on) for each stage of the alert, synchronized with live-action performances. The task was compounded by the need to restart the sequences at any point for retakes and for daily continuity. A combination of manual and electronic methods to handle this type of operation has proved in the past to be costly and unpredictable. To avoid these problems

for "The China Syndrome," Eyewitness, Ltd. programmed a microcomputer in assembly language to allow accurate, flexible, and reliable operation of the panel lights in coordination with the actors' performances.

Computers, of course, have been known to appear or even star in a movie. Usually, however, what is seen are whirling tape drives and a card sorter or maybe a terminal flashing Christmas tree lights. Universal has taken steps to remedy the situation by creating realistic computer environments and systems for production shots. For example, simulated interactive hospital and law enforcement systems are available for use as dictated by a script.

A print of the original camera footage must be made each day for viewing the following day. The automation used to print dailies is part of the systems used for post-production processing in film laboratories which is discussed in the next section.

## POST-PRODUCTION

The post-production phase of movie making consists of creating and adding special visual effects and titles, adding music and sound effects, and, finally, processing, editing, and printing the finished product in the motion picture laboratory.

Special visual effects using models have become well known through such movies as "2001: A Space Odyssey" and "Star Wars." Contrary to popular opinion and some press reports, special-purpose, hard-wired machines, not computers, were used to control cameras and models in these and other recent movies. Not until 1979 with the release of "Buck Rogers" (Universal), "The Black Hole" (Disney), and "Star Trek" (Paramount) will the public view special effects created with the aid of computer-controlled cameras and models.<sup>5-7</sup> Computer-control is a solution to the problem of repeatability of camera movements for long, intricate shots and movements of the model or objects being photographed. In addition, the automated camera is expected to make some effects possible which were not either physically possible or economically feasible before. Input to the microcomputer-based system may be from a walk-through with the camera or from stored data previously entered via keyboard. At Disney, a cameraman will either manually or electronically operate the camera through the initial shot using a hand-held or small console control unit. Subsequent shots will be repeated automatically from the stored data. At Universal Hartland, designers are using their stand-alone microcomputer system to graphically plan the shots within a scene, calling up stored images of the models, setting model size, roll, pitch, and yaw and grid location together with lens size. At Robert Abel's, with the Evans & Sutherland system, the process is carried one step further: The shots may be played beforehand in real time. For both these systems, the stored data is used to control the microcomputer-driven camera system.

An alternative approach to 3-D animation is computer-generated imagery which eliminates the need to build and manipulate models. This approach was used for a 40-second

sequence in the movie "Futureworld" in which a mask-like image of Peter Fonda's head is seen spinning through space.<sup>8</sup> While 3-D graphics have been successfully employed in television commercials, the level of complexity and detail required for high-quality, high-resolution feature films currently limits its cost-effective application.

In addition to images, a movie almost always has a musical score and special sound effects. While computer-generated music has not yet been used in a theatrical release, proponents feel that the computer will enable the musician to create scores not otherwise obtainable and that these, like computer synthesized images, will expand the medium of filmmaking. For the time being, however, musical scores for movies are still totally created by composers and arrangers. The use of original music always introduces the possibility of copyright infringement. To minimize the problem at Universal, new scores are translated by an operator into codes which are matched against a stored database of copyright music. Matches exceeding the legally acceptable number of bars are flagged.

Sound editing, like film editing, is a particularly tedious, time-consuming and therefore costly task. The sound editor views a reel of film, noting the sounds and footage required. From a library index, he selects a tentative list of sounds. A technician retrieves the sounds and transfers them to tape. The editor then begins the cutting and modifying process. If the sound he needs is too short he must create a physical loop of the tape so the sound repeats without obvious repetitious characteristics. Synchronizing the sound to the film is literally a cut-and-try process. The assembled edited cuts are mixed down onto a final track and then mixed with music and dialogue. Sound quality is degraded with each transfer from library master to work copy to final mix. The Automated Computer Controlled Editing Sound System (ACCESS) developed by Mini-Micro Systems, Inc. for Neiman-Tillar Associates eliminates manual handling of tape and allows electronic synchronization. It provides immediate availability of sound effects which have been digitized and stored on magnetic disk packs. Sounds may also be modified via computer-assisted controls. While cutting editing time by 80 percent, use of ACCESS has also improved the quality of sound produced. The microcomputer-based system was used for the sound editing of "I Want To Hold Your Hand," "Sorcerer," "The Island of Dr. Moreau" and other feature films.<sup>9</sup>

Final print production involves cutting the original negative, adding special optical effects, and performing color correction. Computers probably first entered the motion picture production cycle in the film processing laboratories which perform these functions. Academy Awards for contributions to movie making that involved the use of computers were first earned by these labs. In 1972 DeLuxe General, Inc. received a Class III (Technical Achievement) Academy Award for a computer system that performs color positive process analysis. Using photographic test results and considering interlayer effects, the system compares sample densities to the laboratory reference densities. In the same year, Consolidated Film Industries received a Class II (Science and Engineering) Academy Award for the devel-

opment of an on-line computerized light valve monitor system.<sup>10</sup> While these systems used minicomputers, MGM Labs has recently implemented a microcomputer system to operate the optical printers and control the firing of the light valves.<sup>11</sup>

Also at MGM Labs, a system is under development to automatically track and retrieve the myriad of film pieces with which the negative cutter must work. Many hours are spent searching through thousands of feet of film for just the right spot to cut and splice together other cut pieces in building up scenes. Each piece must be carefully labelled and stored for possible later use. A major cost in this operation is the time it takes to search and keep track of all the heads and tails for possible later trimming. The new system will use codes on film to allow automated tracking and retrieval of film segments.

## DISTRIBUTION

Long before prints become available, an analysis of where and when to release the film is conducted and advertising campaigns are organized. Computer analysis of revenue and advertising expenditures for previous, similar films by geographical area is used by several studios to help formulate the distribution and advertising plans for new films. Revenue reporting on distributed prints is supported at most studios by online systems. A more comprehensive approach has been taken by Buena Vista Distributors in implementing a microcomputer-based system to automate the following functions: bidding, print control, booking, grosses, box office reports, cash reporting, advertising, and messages. Near the release date of a film, standard letters with specific film details will be produced by the central computer and communicated to the branches for issuance to local exhibitors. Bids received will be entered into the system at the branch offices, and prints assigned based on availability. Previously, branch offices have been limited to the print inventory initially assigned to them. With the automated system, the nearest available print may be located. Revenue reports will be entered daily, providing timely information needed to direct exhibition and advertising. An electronic bulletin board and memo system will aid communication among branch offices and the studio.

## EXHIBITION

While theatres make use of data processing for normal business applications, computer technology is not yet used for the actual control of movie theatre operations and equipment. Rather, lights, drapes and projectors operate electronically. Within a year, however, manufacturers like RCA expect to incorporate microprocessors into their advanced projector systems. Eventually we may see computer technology used to provide operational and environmental control in movie theatres as in other buildings and businesses. But even beyond the common applications, the decreasing cost and increasing capability of computers may enable

movie theatres to create total visual and audio environments similar to those available today at special-purpose theatres such as the Space Theatre in San Diego. At this theatre, over 60 pieces of equipment are operated and controlled by microcomputer to create special effects for up to five different shows daily. As a first step towards the expanded theatre concept, but not yet using computer control, Universal is installing special equipment to produce lightning, thunder, and other natural sounds and effects in theatres which will be showing "Weather Wars."<sup>5</sup>

## PRESERVATION AND RESTORATION

Eventually (or sometimes very soon) a movie is removed from distribution and stored in a film library. Since film degenerates, there is interest in storing movies digitally to preserve them until actively destroyed. To store a 90-minute, high-quality, color film digitally would require tens of trillions of bits of storage. Data compression techniques exist that might reduce this amount 20-30%, but the storage requirement still remains excessively large for today's technology. At the current rate of advancement, digital storage of films may be feasible within five years.

A film may become damaged during any of the steps described, including storage. Methods of restoration are currently being explored and there is interest in using the computer to analyze previous and successive good frames in order to reconstruct the in-between damaged frames. Similarly, the analysis of good areas within a frame may be used to reconstruct damaged or missing parts. However, computer-aided film restoration must await the availability of digital storage of films or other methods for handling the high-resolution requirement.

Computer-aided restoration has been successfully applied to films transferred to tape. For example, "Gone With the Wind" was reconstructed on videotape from a 1956 Technicolor dye transfer print by Image Transform, Inc. The minicomputer-based system resolved outlines, restored color intensities, and reduced noise.<sup>12</sup>

## REDISTRIBUTION

A film never dies—it is just recycled to foreign markets and television. The recycling process takes the film back to the post-production process where the original parts are re-edited to meet television and foreign time, censorship and film size requirements. Residuals must be paid to writers, actors, etc. whenever a film is recycled and this is handled automatically at most studios. Once a film enters the realm of television, another story of automation begins which is beyond the scope of this paper.

## SUMMARY

This survey, while not exhaustive, does identify the major areas of current computer usage and the key areas for future

applications in the movie industry. Until recently, computer applications primarily focused on:

1. Batch-oriented accounting support for payroll, costing, residuals, and statistical support for market research;
2. Minicomputer systems for process control;
3. Very limited application of computer graphics for special effects.

Current and planned applications include, in addition:

1. Broader computer use for market research and corporate information systems;
2. Word processing support for script preparation and contracts;
3. Interactive system support for budgeting and scheduling subtasks, for resource information retrieval, for sound editing, and for film processing;
4. Computer graphic aids for set design, storyboarding, and animation with increased use for special effects;
5. Expanded use of on-location reporting systems;
6. Functional expansion of automated distribution systems to include print control, bidding and booking, and electronic mail;
7. Computer control of cameras, projectors, and lab processing equipment;
8. Computer control of set elements for live action filming.

In fact, in 1979 several movies will be released whose creation will have involved the first uses of computers in camera-control, set design, storyboarding, animation, and live action filming.

The one development most responsible for the current growth in computer applications in the movie industry is the microcomputer. For business data processing, it is appearing on stage, on location, and in distribution offices. As part of text editing systems, the microcomputer is now in legal departments and will soon enter the script preparation stage. For equipment control, microcomputers are being used in film processing labs, to operate special effects cameras, and will be used in the near future in projectors. As an aid in scene design, stand-alone microcomputer-based graphics systems are now in use. For live-action filming, microcomputers are controlling parts of sets in synchronization with live performances. The high processing power required to generate images by computer may soon be provided through arrays of microprocessors.

Automated techniques for film editing, storage, and restoration still require further research and development in mass storage and image processing.

In any discussion of computer technology and movie making, the question arises as to the possibility that someday movies will be made without actors or cameras but rather totally by computer. The answer is, I think, an undeniable "yes," but whether movies produced by computer will be competitive in cost and quality to those produced by the traditional process with computer aids remains highly questionable.

## CREDITS

As with a movie, this paper is the result of contributions by many people. In particular, the following individuals are acknowledged for their valuable inputs: William Eberly, Walt Disney Productions; Al Jerumanis and Paul McManus, MCA Inc.; Charles C. Tucker, Twentieth-Century Fox; Harold Steintrager, Warner Bros., Inc.; Bob Johnson, Hanna Barbera; Jerry Jeffress and Colin Cantwell, Universal Hartland; Don Miskowich, Robert Abel & Associates; Richard Hollander, Eyewitness, Ltd.; William Dietrich, Mini-Micro Systems, Inc.; Michael Chewey, MGM Labs; Mike Scully, IBM; Toni Shetler, Xerox; and Gary Martins and David Leinweber, The Rand Corporation.

# The System Architecture Evaluation Facility—An emulation facility at Rome Air Development Center

by N. BRUCE CLARK and MICHAEL A. TROUTMAN

*Rome Air Development Center*  
Griffiss AFB, New York

## INTRODUCTION

Military requirements for data processing systems with unusual characteristics to perform specialized jobs have led to research into advanced architectures by the Department of Defense (DoD). Some of the requirements for systems have no counterpart in the civilian industry. Command, control and communications systems are typically complex and must be reliable and available with a high degree of certainty. This places great stress on the development of new data processing systems. The architecture, as the bedrock of all systems, must be continually improved in order to accomplish the increasingly complex software functions now demanded. Spaceborne automated systems simply cannot have an onboard team of vendor maintenance engineers to diagnose problems and replace components; a fault tolerant architecture is needed. Advanced radar surveillance systems provide a tremendous potential for information gathering but must be supported by parallel architectures which are still in the research phase. The DoD is actively involved in research and development of advanced architectures for tomorrow's data processing needs and the System Architecture Evaluation Facility (SAEF) is an example of the use of microprogrammable (and other special purpose) computers to reduce the cost and improve the efficiency of this research.

Direct experimentation with unique hardware architectures is extremely expensive and time-consuming. It is also wasteful of resources, as the prototypes are rarely usable systems and must be discarded. Rather than actually build hardware components, they can be emulated by microprogrammable computers. Emulation is similar to a simulation of hardware, but with an important difference. Software simulation of hardware has existed for years, but traditionally has been limited in its use because of the time versus detail tradeoff. If the architecture is modeled at a very high (or gross) level then that simulation executes very fast. As more and more detail is included down towards the register or gate level of machine design, the simulations become excruciatingly slow, running tens of thousands of times slower than the proposed design will actually execute. The development of computers which are microprogrammable allows a "simulation" to be written in a different way.

Instead of the traditional software programs, the microprograms which determine the actual control signals generated for machine language instructions are modified (or rewritten) to execute a different instruction set, the one for the "simulated" machine. In effect, the microprogrammable computer is molded to look and act like the proposed design at the instruction set (machine language) level. Thus, machine level programs written for the proposed design will execute on the microprogrammable machine.

It is an arguable position that this is still a software simulation, since microprogramming is just a lower level of programming. The difference is that the level of detail being used to describe the target machine is lower than the level it is describing. This is in contrast to using assembly language or a higher order language to simulate the instruction set of a computer. This gives a tremendous advantage in the time versus detail tradeoff, and thus this type of simulation is usually referred to by the special designation of emulation. Well written emulations of most architectures can execute within one order of magnitude of "real-time" for the proposed design. Thus a software function which takes one minute of execution time in the target machine might take 10,000 to 100,000 minutes (one to ten weeks of 24-hour days) on a detailed simulation, but only ten minutes on an emulation. Obviously these figures vary widely depending on the architecture being emulated and the computer being used to emulate, but are representative of the speed advantages gained with emulation over simulation.

## SAEF ELEMENTS

To provide the emulation capabilities described, the core of SAEF consists of two microprogrammable computers, the Nanodata QM-1 and the Multiple Microprocessor System (MMS) (Figure 1). Also included is a Goodyear Staran Associative Processor which will aid in evaluating single-instruction stream-multiple-data stream (SIMD) architectures. A larger general purpose computer will be used for the hosting of software tools to be used in connection with SAEF. Finally, all of these elements will be connected via the ARPAnet to facilitate intercommunication.

## SYSTEM ARCHITECTURE EVALUATION FACILITY (SAEF)

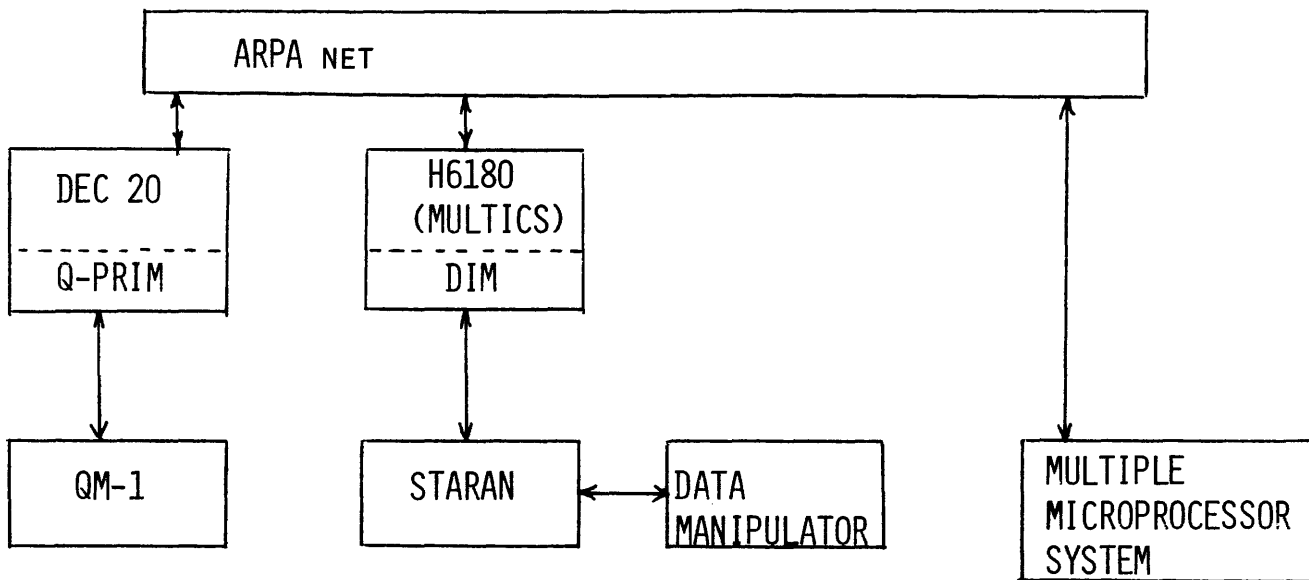

Figure 1—Projected facility.

*QM-1*

The QM-1 is a high-speed general purpose digital computer that operates under two levels of microprogram control.<sup>1</sup> These two levels provide extreme flexibility in machine definition and allow the advantages of both vertical and horizontal control. Machine instructions resident in Main Store are executed and defined by microprograms in Control Store. Control Store is a vertical level which is in turn implemented by Nanoprograms in Nanostore. The Nano level is a true horizontal architecture which has ultimate control over the total resources of the machine.

The QM-1 is primarily composed of a hierarchy of stores. At the lowest level is Nanostore consisting of 1K of 360 bit words with an access time of 75 ns. One nanoword is made up of a 72-bit K vector and four 72-bit T vectors (only one T vector is in control at any one time). Nanostore is a true read/write memory giving the programmer the ability to dynamically change its contents. Sharing control of the QM-1 with nanostore is F Store. F store consists of 32 six-bit registers which are used for residual control purposes. These registers determine the bus connections between the various units of the QM-1 as well as maintain the state of the machine. Moving away from the low level control of the QM-1, local store consists of 32 18-bit registers. The majority of these registers are general purpose but several of them have specific functions such as microinstruction registers and microprogram counters. External store is a group of 32 18-bit registers which provides specific functions including I/O interfacing, special main store addressing and generation of addresses for interrupts. Control store is a 16K by 18-bit read/write memory having an access time of 75 ns. This memory can be used for data storage and target register

storage in addition to the vertical microinstructions. At the next level up is main store consisting of a maximum 256K 18-bit words. This is a read/write core memory having an access time of 750 ns.

The QM-1 contains several other functional units which are not considered part of the store hierarchy. These include a full 16-function 18-bit ALU, a 36-bit double shifter/shifter extension, an Index ALU for fast indexing and logical operations on local store, an RMI unit for rotating/masking/indexing the output of main store, and an ALU for operating on the six-bit F store.

The QM-1 is operable in both a stand-alone mode and in a time share mode connected to a DECSYSTEM-20. In stand-alone, the QM-1 supports a full complement of peripherals. An operating system is available which maintains control over these devices as well as providing editor, assemblers and other useful routines. Also included are complete emulation debug and support packages which are independent of the operating system. These packages provide simple interfaces between an emulation and QM-1 resources and allow highly interactive sessions between an emulation and its user/developer. While in a stand alone mode, the QM-1 is directly usable by a single user thru the system console. When several users wish simultaneous access to the QM-1 it can be operated in a time-share mode.

In time-sharing the QM-1, it is connected to a DECSYSTEM-20 via a common main store and the DECSYSTEM-20 I/O bus. This system, which is known as Q-PRIM, provides an interactive microprogrammable environment in much the same way as when the QM-1 is stand-alone.<sup>2</sup> However, in this case the QM-1 is treated as an I/O device by the DECSYSTEM-20 operating system, TOPS-20. In this mode the QM-1 will have no peripherals of its own but will rely on TOPS-

20 to provide all its I/O capabilities. This resource will also be available to remote users because of the ARPAnet connection to the DECsystem-20.

The Q-PRIM software consists of four major modules. These are the QM-1 supervisor or "microvisor," the TOPS-20 QM-1 driver, Q-PRIM Exec and Q-PRIM debugger. The QM-1 microvisor interacts directly with the user's emulation and the TOPS-20 QM-1 driver. It is a small module which communicates between the QM-1 and the DECsystem-20. The microvisor provides context switching capabilities and handles the virtual memory addressing and paging from the QM-1 side. Accessing the QM-1 from TOPS-20 processes is done through the QM-1 driver. The driver communicates with the microvisor and TOPS-20 system calls. It is responsible for initializing the microvisor, controlling, scheduling, and swapping users, accumulating accounting data, and passing along I/O requests. The Q-PRIM Exec provides an environment on the DECsystem-20 which supports each of the emulations executing on the QM-1. The Exec provides a variety of commands that allow a user to build and interact with his emulated system. The Q-PRIM debugger is a table-driven, interactive, symbolic debugger that permits a user to debug target-machine programs in terms of symbols defined for the target machine. Data representations are controllable, thus allowing the user to tailor the emulation interface to more closely match the target machine.

### *MMS*

Another key component of SAEF will be the MMS which is currently in the design phase. The MMS will consist of 64 microprogrammable microprocessors each operating autonomously or connected as part of an SIMD or MIMD architecture. It will contain a highly flexible and versatile interconnection system under software control which facilitates communication between MMS processors. The MMS will be able to effectively emulate shared memory, bus oriented, and crossbar switch interconnection schemes used in distributed multiprocessor systems. Control over the MMS will be accomplished by a Facility Control Processor (FCP) which is expected to be a minicomputer. This system will be usable in both a stand alone mode with the user communicating directly with the FCP, and in a remote mode via its connection to the ARPAnet. For the purpose of this discussion the MMS can be broken down into four sections—(1) FCP, (2) Emulation Engine Support, (3) Processing Elements and (4) Memory Subsystem.

The primary function of the FCP is to maintain control over the operation of the MMS. The FCP will provide both user and ARPAnet interfaces to the MMS. It will contain a host of run time tools which will allow the loading, modification, and control of individual PEs. Other support tools will include microassemblers, assemblers, compilers and software packages for processing of performance data. In its job of control over the MMS, the FCP is aided by the emulation engine support.

Emulation engine support is broken into four areas. The Time Align Controller maintains master pseudo time for the MMS. The Emulated Local I/O Processor will create an I/O

environment for each individual PE. The job of the Shared Resource Controller is to manage memory and communication paths. Last, the function of the Performance Monitor Processor is to collect all Performance Monitor System (PMS) event data from the PEs and emulation support and store this data on mass storage for processing by the FCP. Each of these four devices communicates with controllers which are distributed among the PEs.

Each of the 64 PEs in the MMS will consist of a microprogrammable microprocessor and control hardware for I/O, memory, pseudotime, and messages. The microprocessors will be composed of microstore and an RALU based on bit slice architecture. A 16-bit RALU is the most likely size, with hardware aid for more efficient emulation of smaller word size architectures. Emulation of larger machines will be done with multiple instruction cycles. The I/O and memory controllers work in unison to provide an environment with memory mapped and I/O space I/O, local memory and shared memory. The pseudotime controller coordinates with the master time align controller for keeping PEs in step and the message controller handles communication between the local I/O memory unit and the appropriate emulation support processor.

The memory subsystem is partitioned into 64 each 32K word blocks each associated with a particular processing element. Individual blocks may be subpartitioned in any manner desired between local and global memory. Arbitration for the memory is handled by a portion of the shared resource controller and a local arbitration unit. The memory was partitioned in this way so as to give each PE fast access to 32K local words. Nonlocal accesses will be slower, because they take place through a shared bus.

The MMS as described allows for very detailed system emulations. In addition to emulating the computer architecture and peripherals as usual, one also has the capability to emulate the exact protocols of interprocessor communication and memory accessing. This is made possible by the programmable nature of many of the controllers located throughout the MMS. These features also enable the efficient emulation of I/O devices and virtual memory because the microprogrammable microprocessors are not burdened with these tasks, they can actually be done in parallel by the programmable controllers.

### *STARAN*

Although not an emulation machine, a Goodyear Aerospace Corporation STARAN S-1000 associative processor interfaced to the HIS 6180 Multics system is included in SAEF as an aid in evaluating SIMD architectures. The associative processor can be operated in two modes, a stand-alone mode and an on-line mode to the Multics time-sharing system. In the latter mode, a Multics user is able to control the STARAN from his terminal as he would if he were using the STARAN in stand-alone mode. He can create program and data files using the capabilities of Multics and transmit them to STARAN. Currently the associative processor cannot be time-shared; that is, only one user at a time may utilize the STARAN. All communications between

STARAN and Multics are via a 12-bit parallel buffered I/O channel.

The STARAN basically consists of a conventionally addressed control memory for program store and data buffering, four associative memory arrays, a control logic unit for sequencing and decoding instructions from control memory, and a control logic unit associated with a special parallel I/O (PIO) capability.<sup>3</sup> The associative array memories are the heart of the STARAN system. The array memories provide content-addressability and parallel processing capabilities. Each array consists of 65,536 bits of multi-dimensional access (MDA) memory organized as a matrix of 256 words by 256 bits with parallel access to up to 256 bits at a time in either word (horizontal) direction, bit-slice (vertical) mode or mixed mode (combination of the two). In addition to the MDA memory, each array contains 256 bit-serial processing elements. These processing elements provide the parallel processing capabilities for each array. Processing in the STARAN system can be overlapped with some arrays performing I/O while others are executing arithmetic and logic instructions.

The sequential control portion of STARAN consists of a PDP-11/20 minicomputer with 8K of memory and associated peripherals. The sequential processor also contains logic to interface with other STARAN elements. It runs system software programs such as the assembler and macro preprocessor, operating system, file handling programs, diagnostic programs and debugging routines.

#### Data manipulator

Another element of SAEF is the Data Manipulator which provides a flexible bit manipulation capability.<sup>4</sup> The basic approach follows that described by Dr. Tse-Yun Feng of Wayne State University.<sup>5</sup> Currently the Data Manipulator is attached to STARAN and allows the programmer to establish a relationship between input and output words such that, for each of the bit positions in the output word, any bit location in the input word may be specified as its data source. In addition, both input and output data can be masked.

#### Host computers

In order to provide many of the support tools required by SAEF a larger host computer must be included. At the present we will be using the Honeywell 6180 Multics and DECsystem-20 time share systems located at RADC. These two computers will provide capabilities otherwise unattainable on the other elements of SAEF, either because of their small size or specialized nature. Hosting tools on a common computer also has the added benefit of reducing the number of operating systems the user has to learn. This is a primary concern as ease of use is the most important factor for SAEF. Because these hosts provide multiprogramming environments, several users of SAEF may be working on some aspect of a system emulation concurrently. Other obvious advantages are access to the ARPAnet and the amount of

mass storage available on these computers. The host computers will communicate with the remainder of SAEF through the local ARPAnet connections.

#### Progression of SAEF

SAEF as described above will be developed over the next several years. At the present, SAEF consists of the DECsystem-20 and HIS 6180 both connected to the ARPAnet, the STARAN and Data Manipulator with their connection to Multics, and the QM-1 in a stand-alone mode (Figure 2). Multics is the primary support host with its Meta Assembler, compilers, and editors. A 1200-baud serial line exists from Multics to the QM-1 for downloading purposes. The DECsystem-20 currently supports a preliminary PRIM system utilizing a resident simulation environment instead of emulation by the QM-1. The Q-PRIM system is expected to be operational near the end of 1979. The MMS is currently in the design phase and is projected to be built by the end of 1981.

#### SUPPORT TOOLS

The hardware elements and software directly supplementing those elements are the core of SAEF. Several additional software support tools are in being or currently under development for use in SAEF, but are not exclusively limited to the facility and may, in fact, be most beneficial in contexts other than SAEF. Specifically, this section discusses the development of a hardware description language called SMITE for writing emulations, and study on the concepts of an automatically retargetable compiler which will accept machine descriptions written in a hardware description language like SMITE and produce an emulation of the machine.

Inherent in the design requirements for any usable item, be it a facility such as SAEF or any of its individual support tools, is its ease of use. No tool, no matter how vital, will be consistently and easily used if it is poorly interfaced with

#### SYSTEM ARCHITECTURE EVALUATION FACILITY (SAEF)

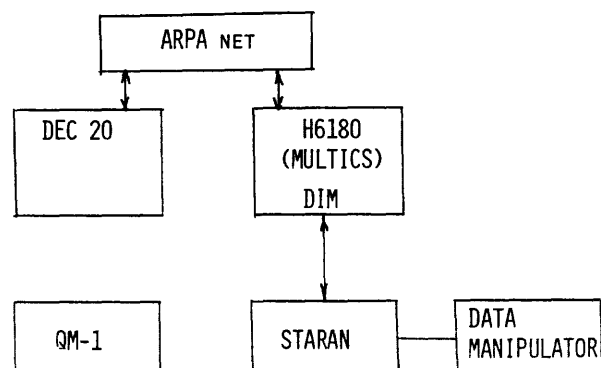

Figure 2—Current facility.

the human link. The necessity to describe machine architectures is a valid research requirement, but the reality of writing an emulation in microcode, where typical productivity is a fraction that of assembly language programming, seriously impairs the utility of the facility. In order to overcome this problem, the development of a "high-order" language for machine description has been undertaken at TRW under contract from RADC. The result is Advanced SMITE (Software Machine Implementation Tool for Emulation), an ISPS based language which allows machine descriptions at the register transfer level to be compiled into microcode for the QM-1.<sup>6</sup> To support SMITE, a software system resident on the QM-1 is necessary. This system, called SASS (SMITE Applications Support Software), uses an augmented instruction set which is a superset of MULTI, the vertical level instruction set of the QM-1 normally considered to be a "native" instruction set, although it is in itself defined by the nanostore instruction set. SASS is a modification of the vendor supplied run-time package called TASK/PROD. SASS is resident on the QM-1, while the SMITE compiler is written in Fortran and resides on a CDC-6600 located at the Air Force Weapons Laboratory in New Mexico. Compilation of source code is accomplished remotely through the ARPAnet, after which the object code is transferred to the Honeywell 6180 (via file transfer protocol on the ARPAnet) and then to the QM-1 for execution. By the summer of 1979, a new version of SMITE with language enhancements will be delivered written in PL/I and installed on the Honeywell 6180 (Multics) system at RADC. The advanced version of SASS will provide interactive debugging and performance monitoring capabilities not now possible.

To illustrate the basic syntax of the SMITE language, the following example describes a trivial eight-bit-wide machine consisting of three registers, 64 words of memory, and four instructions:

```
EXAMPLE: PROCESSOR;
DECLARE MEM(0:63)(0:7) MEMORY,

Once the description of an architecture has been implemented on a microprogrammable computer, there will be a need to write software for that emulated machine. In the same manner that support tools are necessary for writing machine descriptions, tools are necessary for applications

software (the word applications is used to distinguish from the emulation software, or machine description, even though the "application" may be an operating system for the emulated machine). If no support tools are available, the system designer is thrown back to the dark ages of writing machine code for an emulated machine! Cross assemblers make this situation slightly more bearable, but a need exists for a compiler which would automatically compile to the object code of the machine described to it. It has been feasible to rewrite the back end of a compiler for new models of machines as they evolve, but the use of emulation and a high-level language like SMITE means that "new" machines are available from perturbations of the emulations due to fine tuning a design. The several man-months' worth of effort required to modify a compiler is clearly unacceptable.

Recognizing the need for such a compiler, RADC has contracted for the development of a support tool to be called the Retargetable Compiler. As an interim, users of SAEF are writing applications software in the assembly language of the emulated machine and using the Meta-Assembler, developed by McDonnell-Douglas, to create the object code.

## RESEARCH AREAS

SAEF is currently projected for use in two distinct areas of research. The most obvious research is into unique machine architectures for special purpose data processing systems and requires no further elaboration. The existence of SAEF also provides for a different type of research which may best be described as the implementation of the "Software First" concept. In the development of computer systems, it has traditionally been necessary and expedient to separate hardware and software functions early in order to define the "machine" and begin work building it. Since a major portion of the cost of systems involved hardware, the software was considered of secondary importance, and was developed to fit the machine. The advent of microprogramming and the tremendous decrease in the percentage of cost devoted to hardware implies that the software now can (and should) be designed to fit the problem being solved and the hardware is then molded to fit the software necessary for that problem. The concept of "Software First" has now been made possible through emulation of hardware and systems development can now be accomplished in a much more orderly and logical fashion. Research into systems development is being conducted at RADC under the name of Total Systems Design (TSD) Methodology.<sup>7</sup>

The TSD Methodology represents a departure from the traditional concepts of computer systems development. Instead of initially dividing the system into hardware and software subsystems and developing each independently until the integration phase, TSD encourages design of the system independent of the ultimate realization of individual functional elements.

The flow of the TSD Methodology breaks into three major divisions. The first portion addresses the general area termed requirements definition. Next is an area of detailed analysis which takes the requirements definition and results in allocated functions implementable in hardware and soft-

ware. Finally, there is an expression of the design process which uses emulation as a substitute for actual hardware until the system is validated to an extent justifying hardware acquisition.

# Teaching and research experiences with an emulation laboratory

by STEVEN F. SUTPHEN

*University of Alberta*  
Edmonton, Alberta, Canada

## INTRODUCTION

User-microprogrammable computers have been generally available since the early 1970s, although in the past few years they have become quite popular. The primary reason for the increased popularity is the decrease in price made possible by technological advances in high-speed memories. Also, the computer manufacturing industry is looking towards microprogramming for increasing throughput of large operating systems, which cannot be replaced because of the large investment for them in software.

Our experiences with a microprogramming or emulation laboratory have come from two points of view—research and instruction. The research has explored several areas including emulation of computers, microprogramming languages and emulation of language machines. The main emphasis in instructional aspects is to illustrate the problems of microprogramming and the difference between it and conventional programming by practical examples programmed in our emulation laboratory.

To provide some insight into our use of the laboratory, a short history of its development will be given. This is followed by our experience with the laboratory in both instructional and research applications.

## DEVELOPMENT OF THE EMULATION LABORATORY

In 1971 the Department of Computing Science laid the groundwork for acquiring a minicomputer laboratory for undergraduate instruction.<sup>1</sup> This laboratory was specified to have many diverse computers including one with microprogramming capability. The Microdata 1600 was selected, since it was small and cheap and fit in well with the rest of the laboratory. The machine was purchased in 1972 with 8K bytes of mainstore, 512 16-bit words of writable control store (WCS), and an ASR Teletype as an I/O device. Subsequently, another 512 words of WCS have been added, and an interface to a digital (eight-bit parallel) cassette has been built.

When the department was formulating the mini-lab it was envisaged that a medium sized machine microprogrammed

to emulate all of the minicomputers would be acquired. A special grant was obtained in the spring of 1973, and the QM-1 was selected in the fall of that year; the only other choice was the Burroughs B1700 which was rejected for reasons of cost, restrictions on usage and the fact that it did not support interrupt-driven I/O. The department ordered the QM-1 initially with 32K of mainstore, 3K of control store, 256 words of nanostore, and support peripherals including tapes, disks, a CRT console terminal, a line printer and a card reader. Over the last five years the system has grown to that illustrated in Figure 1.

In late 1973 a Varian V73 was acquired. Although that computer was intended mainly for use in the mini-lab it was purchased with 512 words of WCS, 8K 16-bit words of mainstore and an ASR 33. Since then a dual floppy disk unit has been added and software support developed in-house. The V73 has been used in the minicomputer class with good success and, since the floppies were added, has been utilized in the microprogramming course.

## TEACHING WITH THE EMULATION LABORATORY

The Computing Science Department offers a graduate-level course (CMPUT 512—Advanced Minicomputer Systems) which deals primarily with microprogramming. Typically, 10 to 15 students enroll in the course, which covers the structure of emulators and the topics outlined in the text,<sup>2</sup> along with a brief introduction to the current microprogramming research being done in this department as well as at other sites. In the following discussion the method of using the machines will be mentioned, as well as the learning aspects gained from programming each machine.

Several assignments to teach the fundamental theories and practices of microprogramming have been developed. The main criterion for microprogramming assignments is an algorithm which references mainstore, employs several conditional branches and is familiar, repetitive and computationally simple with easy to check results. Several examples of basic assignments are producing a count of the number of one bits from locations 'A' to 'B' in mainstore; generating a parity bit for a word; and the assignment referred to in the following discussion, sorting into ascending order mainstore

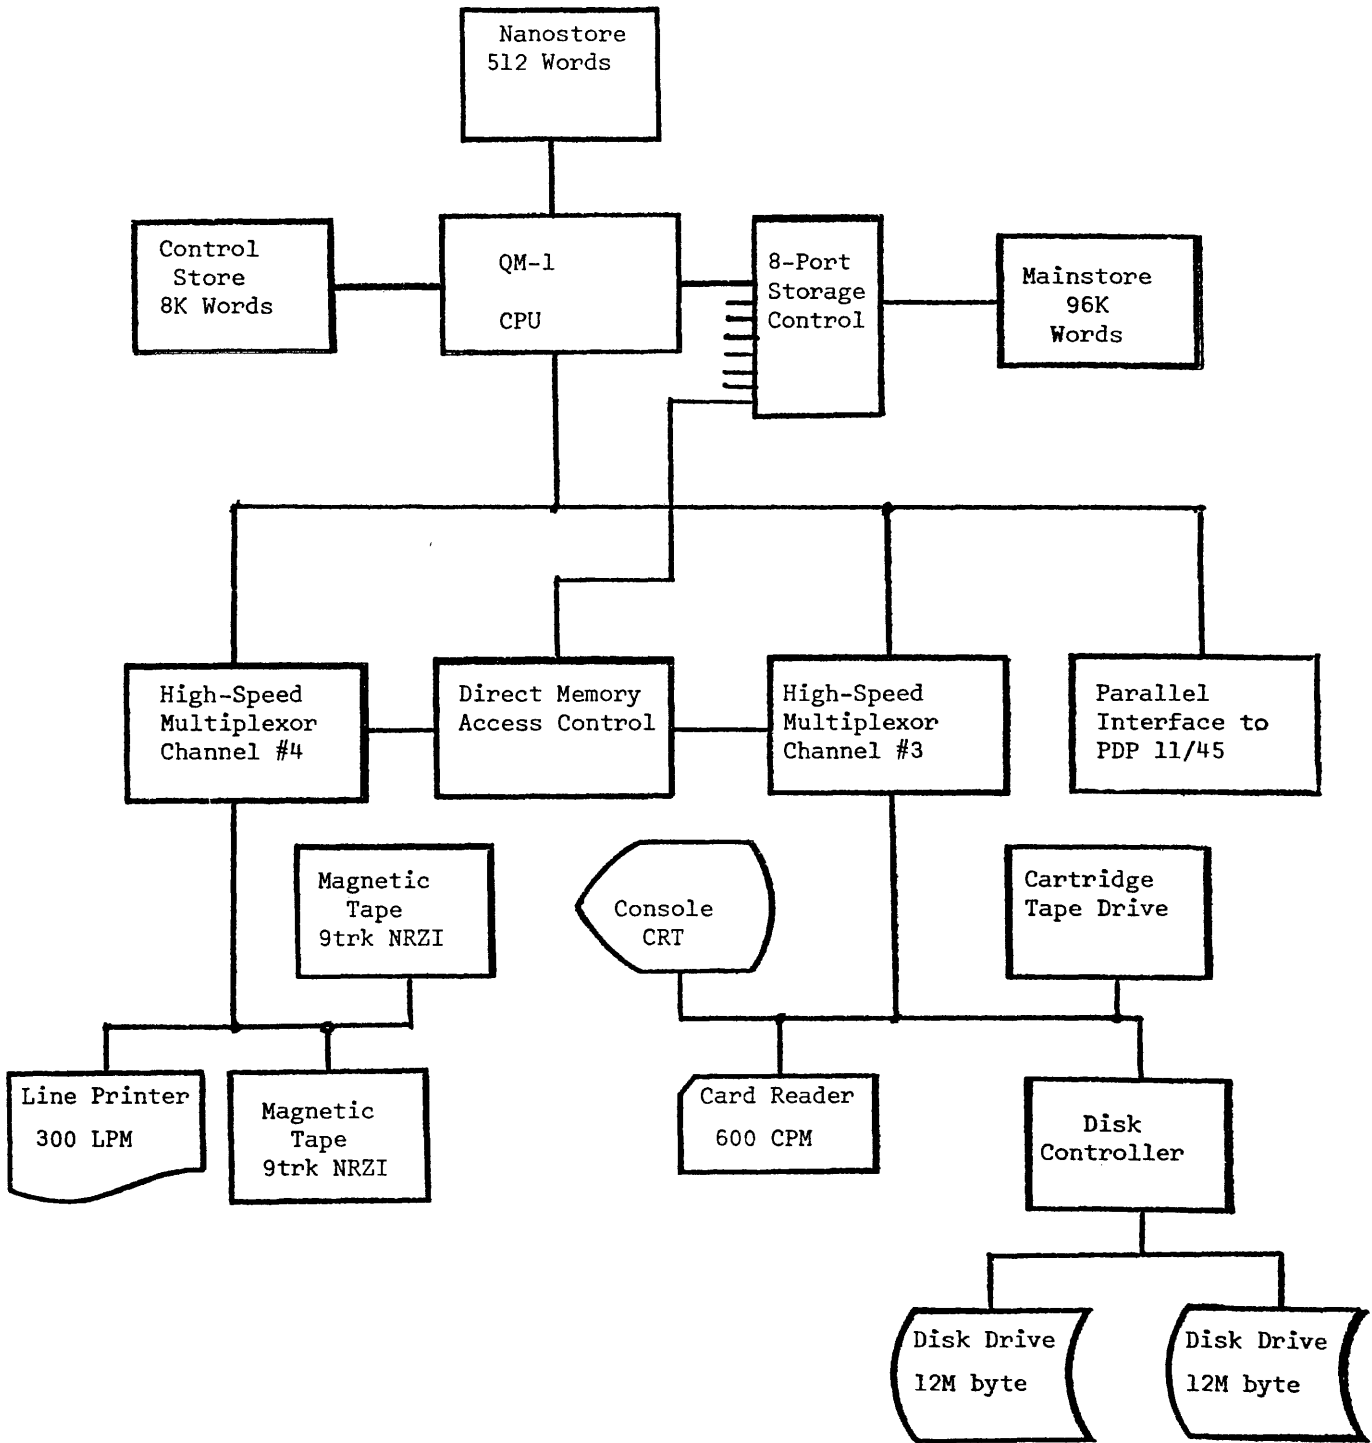

Figure 1—QM-1 configuration.

from 'A' to 'B.' The parameters 'A' and 'B' were to be entered at run-time, as operands for a 'sort' opcode, or in the case of the QM-1, read in from the console terminal. The assignment illustrates the following concepts associated with microprogramming—mainstore accessing, parameter passing, and complex condition testing.

*Microdata 1600*

The Microdata 1600<sup>3</sup> has a vertical micro-instruction word of width 16. Internally the busses are eight bits wide, and there are 16 internal file registers. To minimize the complexity (workload) of the assignment, the students were not

required to program the Microdata to print the results, but rather a system utility was invoked to verify the correctness of the results produced by their sorter.

The scenario, used by students to accomplish the assignment, was to edit and cross-assemble the source on the university's service computer, punch the binary (usually quite small) onto paper tape and load it into the Microdata using the utility program AROS. They would then proceed to debug the program by inserting halts (or using the address-compare stop feature of the 1600 front panel) at critical points, single-stepping through small sections, correcting the results and re-editing the source. There are a few important points in the previous technique which should be noticed. A service computer was used to generate the binaries, even though an assembler exists on the Microdata. This is because it utilizes the various components as they were intended, the Microdata to microprogram, and the service computer for software development. Others<sup>4</sup> have also found a service computer helpful in increasing throughput on a microprogrammed computer. The second point concerns the usage of the front panel for debugging microcode. Even though a simulator exists it is not only awkward to use, as are most simulators, but also slow to load from paper tape—which can be circumvented through new cassette support. With the exceptionally good front panel support given to micro-debugging, the students did not find the simulator worthwhile.

Besides the basic microprogramming concepts just discussed, the assignment illustrated the following problems—multi-precision arithmetic as 16-bit words were sorted; the largest negative number causes complex condition testing in the sort; simple parallelism as mainstore fetches/stores can be overlapped with other processing; and simple timing problems (the 'U' register is finicky).

In addition to describing the general architectural features of the Microdata, the lectures included a discussion of I/O and used a teletype echo microprogram as an example. Concurrent I/O (a poor man's DMA) was discussed in relation to the small amount of hardware required to implement this relatively powerful concept (similar to the IBM 360/50 channel implementation).

As a machine for teaching elementary microprogramming the Microdata 1600 is very good. The format of its instruction set is quite close to that of conventional machines (as are most vertical microprogrammable machines), it is a general purpose machine and yet it illustrates some of the elementary problems in microprogramming.

#### *Varian V73*

The Varian V73<sup>5</sup> has a horizontal micro-instruction word of width 64. The fields which make up this word have up to four levels of encoding. The branching capability is very general, although ordering control store words to take good advantage of the branching is quite complex. The assignment was, once again, to sort 16-bit words of memory between specified (variable) limits.

Most students prepared source tapes offline on a service

computer with an editor, file system, and other useful utilities such as cross-reference programs. The sources were then transferred to the Varian where they were read from paper tape with the micro-assembler, MIDAS. A modified version of Micro-util was then used to load, execute and debug the binaries. As there is very little front panel support for microprogram debugging, the debug portion was quite trying for the students. The front panel is an I/O device which must be supported in microcode before any internal registers may be displayed. On the Microdata quite the opposite is true; the front panel is an intelligent piece of hardware requiring no software support. Varian intended microprograms to be debugged from an attached processor which could step, trace, etc. the V73 micro machine.

Notice that once again the students used service machines to develop the source code. Most likely the reason for not using the program preparation facilities on the Varian is because they are awkward to use (paper-tape-based). This could have been rectified by adding several thousand dollars worth of main store, disks, tapes and printers to the V73 and using Varian's operating system (VORTEX or MOS), but then the system would be so large that it would not be cost-effective to allow individual students hands-on experience. The assembler supplied by Varian is quite primitive (the service computer's editor helped the students use mnemonics), and a more powerful one has been developed elsewhere.<sup>6</sup>

The Varian illustrates the multi-way branch (for opcode decoding), horizontal microprogramming, and the difficulties of using conventional program design methods for designing microprograms. Also the independent I/O control store and processor are a unique feature discussed in the lectures.

#### *Nanodata QM-1*

The QM-1<sup>7</sup> offers both vertical (control store) and horizontal (nanostore) microprogramming. The higher-level control store is a fully readable and writable general-purpose memory whose word width is 18 bits. Eighteen bits is also the width of mainstore, the internal registers, and the ALU and shifter (although there is also a 16-bit mode). The lower level nanostore is a fully writable, executable memory whose word length is 360 bits. Two 72-bit fields are activated (from the five possible) during each 75 nsec machine cycle. The architectural organization is very parallel, allowing several functional units to perform simultaneously. The QM-1 was designed as an emulation tool, and as such has no native (or most efficient) instruction set. Support software executes on a NOVA emulation, and although reasonable peripherals are attached to the QM-1, the operating system is quite primitive by today's standards.

Since NCS (Nanodata Control System) only supports one terminal it is not time/cost-effective to allow online entry of student programs. Therefore, once again, a service computer was used to produce the source statements for the assembler, read them onto disk, assemble, load and debug them on the QM-1. We have found offline source preparation

so useful that a high-speed interface to a time-sharing PDP 11/45 is being built.

In the class assignment on the QM-1, the students were to program the sort algorithm in nanocode, and output the resulting sorted array onto the console terminal. The I/O portion was microcoded in the MULTI<sup>8</sup> micro-instruction set. The combination of these elements taught the students the interfaces between the three major stores in the QM-1, and the parallelism and flexibility of the QM-1.

The QM-1 performs very well as a teaching tool. The very horizontal architecture (and parallelism) of the nanomachine illustrate two major theoretical research areas in microprogramming—optimization theory and high-level microprogramming languages. Also, the two-level micro-instruction structure provides a methodology for generating efficient emulators (nanocoding the instruction set for run-time efficiency and microcoding the I/O and console functions for programmer efficiency).

## EMULATION RESEARCH

Although three microprogrammable computers are available for emulation research, the QM-1 has been used for most research projects. Quite likely the preference for the Nanodata machine is a reflection of its flexibility as a universal host and the fact that it has a disk file system. The emulation research performed at the University of Alberta can be subdivided into three major areas—emulation of hardware computers (conventional instruction sets), tools for developing emulations (microprogramming languages) and language machine emulations. The current status or results of these projects are summarized in the following sections: the reader is referred to the papers referenced for details.

### *Conventional machine emulations*

A PDP 11/10 emulator has been constructed and evaluated for the QM-1.<sup>9</sup> This emulator would be a class 'A' emulator, as defined by Flynn,<sup>10</sup> except that it does not check for odd PC values, or handle the trace trap bit in the PS. These features were not included in the emulation only because the implementor did not feel that their usefulness outweighed the overhead involved in the nanoprograms. The PDP-11 emulator successfully executes standard instruction diagnostics, memory, tape and disk exercisers, and also the DOS-11 and MINI-UNIX operating systems. No changes were made to these programs; the MINI-UNIX operating system ran successfully the day it arrived.

After the PDP-11 emulation was thoroughly debugged and MINI-UNIX was obtained, a profiling feature was added to instrument operating system efficiency studies. This program counter-sampling allows one to find where a system is spending the majority of its time. By nanocoding a few identified functions, we have reduced the execution time of a benchmark from over 16 minutes to under six minutes. Further studies with the profiling mechanism need to be done to tune the emulation to an operating system.

Multiple concurrent emulations, sharing a common micro-coded I/O section, have been investigated<sup>11</sup> on the QM-1. The QM-1 has been found suitable as a host for multiple emulations, but several problems are yet to be resolved. Device-sharing is the major problem, especially with devices such as magnetic tapes—how does the emulator control program determine when an emulator is finished with the tape? The micro-operations passed to the emulated controller are too small to determine the intentions of the emulated system. (Open and close calls would be required to give the ECP enough information to know when it may allocate the drive to another emulator.) Successful experiments have been performed with dual Nova emulators with a manual task switch facility, sharing the console terminal, disk and clock.

### *Microprogramming languages*

Research has been done on the design and implementation of high-level microprogramming languages for both the QM-1 micro-instruction set (MULTI) and the lower-level nanoprograms. A nano-level language presents difficult problems to the language designer, as illustrated in the Lizard language.<sup>12</sup> After examining the problems of building efficient nanocode, the researcher concluded that an automatic translator would not be cost-effective compared to human nanocoders. Although this result is somewhat discouraging and shows that theory and practice are sometimes disjoint, we have not terminated our research in this area and have achieved better results at the micro-level.

CQ,<sup>13</sup> a high-level microprogramming language based on the programming language C (produced at Bell Telephone Laboratories), produces code in a slightly extended MULTI instruction set. The compiler (including a MULTI assembler and linker) for CQ is being developed on a time-sharing PDP-11 using the UNIX operating system. It is believed that when this system is operational it will provide much better software development tools than the current QM-1 system has to offer.

### *Language machines*

Language machine research within the department is being done at two levels—high-level language machines, and intermediate-level language machines. APL is the target language for the high-level language machines. A general plan for implementation has been drawn up,<sup>14</sup> and the indexing portion has been coded<sup>15</sup> on the QM-1. Also, research is being performed on the multi-user scheduling portion of the system.

Intermediate-level languages are those languages which fall between high-level languages (FORTRAN, Pascal, APL, COBOL, . . .) and conventional assembler language. These languages are intermediate in both syntax and semantics. An example would be the Pascal 'P' machine for which a microcoded interpreter has been written on the QM-1 by UCSD. Our research group has formulated a methodology

for evaluating intermediate language machines (machines which interpret/emulate intermediate-level languages).<sup>16</sup> To date the methodology has only been shown feasible by modeling on a service computer; actual experiments will be performed on the QM-1.

## CONCLUSION

Throughout the previous discussion the notion of using a service computer to support an emulation machine frequently appears. This is quite reasonable when the computers are thought of as tools used to build an emulator. The two functions, development and execution, could be combined on one computer (as Nanodata has done on the QM-1), but this leads to inefficient or primitive development tools, or to host machines which are not universal (for example the Varian).

Having surveyed instructional and research usage of an emulation laboratory our experience indicates that a suitably supported universal host provides an excellent vehicle for exploring many areas. An important area is the relationship between high-level languages (or algorithms written in them) and the instruction sets (architectural machines) which these languages are translated into (or interpreted by).

# Simulating the delay in logic networks for large, high-speed computers

by E. A. WILSON

*Honeywell Information Systems*  
Phoenix, Arizona

When designing a computer with TTL logic circuits, the delays of logic paths have been estimated by considering the number of gate delays and adding in load and media factors. Such a simplistic approach is not accurate enough for calculating delays when designing high-performance large systems using high-speed, non-saturating circuits such as HCML (Honeywell's Current Mode Logic). There are several reasons:

- The clock (cycle) time is considerably faster for a high speed machine, hence the calculations must be very accurate in order to meet performance goals.
- The loading on the driving gate varies with the number of driven gates, hence affecting the rise time of the line (interconnect) voltage.
- The geometry of the interconnect (branch points, connectors, various media impedances) has an effect on signal propagation with high-speed edges.
- Media delay is a significant percentage of path delay as ICs become faster.

All of the above leads to a need for an ability to simulate the delay for proposed interconnects which do not meet simple driver-line-load configurations without intermediate branch points and/or media changes.

The large package programs which are available on the open market are well suited for circuit design work when developing the circuit set, but they are unsuitable for the multitude of cases which must be run when simulating the full design. They require too much memory, take too long to execute, and are too general when the same gate can be used for every case simulated.

This paper presents a simulation program and a design methodology which have proven successful in our actual large-computer design environment. The simulation program has been tailored to the HCML circuit set and optimized for small storage, very fast execution and minimal data input. Also, the program has been written so that automatic or manual modes of operation are available.

In the automatic mode, the network checking program (which checks the logic designer's data base for correct pin assignments, wiring rule violations, etc., but is not a part of this paper) feeds the data into the delay simulation program

and receives back the interconnect portion of the delay for each load gate. The delay data are added to the logic designer's data file and reported to him when he accesses the file for the results of the network checking run.

In the manual mode, the designer selects an interconnect which has a problem (such as an unexpected long delay) or inputs a proposed interconnect for which he wants to calculate the delay before continuing his design. In this mode, he has several options for the output. He may select just the individual interconnect delays for the loads; a printout of driver and load voltages with time; or a plot of the waveforms of the driver and load voltages. In addition, the load voltages may be printed/plotted as either the input voltage to the load gate, or the output voltage from the load gate. By using one or more of these options wave reflections, effect of input rise on load delay, turn-on/turn-off/turn-on, etc. may be observed and frequently the problems corrected by interconnect modification before the design is released. If interconnect modifications do not correct the problem, then either an alternate logic implementation may be used, or the problem may be compensated for in the rest of the logic chain. In any case, the simulation provides the designer with the information before the design is released and built as hardware.

The simulation program uses a two-model approach with an interaction between the models similar to substructuring in finite element programs, except in this case the interaction is a function of time.

## INTERCONNECT (LINE) MODEL

This model is based on a finite element rather than a mesh or loop current formulation which actually only affects the terms in the resulting capacitance matrix, as will be seen. A basic goal was to minimize the execution time and past experience has shown that if this goal is kept in mind from the beginning, a more efficient program can be written than would be if the theory were developed and then the programming tacked on as an independent activity. Therefore, a method (finite elements) was chosen for the theoretical model which was known to lead to a straightforward matrix model.

The basic current voltage relations for a line element are:

$$\frac{\partial e}{\partial x} = -iR, \quad i = -k \frac{\partial e}{\partial x} \quad (1)$$

$$\frac{\partial e}{\partial x} = -L \frac{di}{dt}, \quad i = -m \int_0^T \frac{\partial e}{\partial x} dt \quad (2)$$

$$e = S \int_0^T i dt, \quad i = c \frac{\partial e}{\partial t} \quad (3)$$

where in equation (3), the voltage,  $e$ , is relative to ground (or some fixed reference).

In vector form (although this is only a one dimensional problem, it does not hurt to be mathematically correct), the divergence of the current at any point along the line element yields:

$$\nabla \cdot i = c \frac{\partial e}{\partial t} \quad (4)$$

and using the second relations of (1) and (2),

$$k \nabla^2 e + m \int_0^T \nabla^2 e dt = c \frac{\partial e}{\partial t} = c \dot{e} \quad (5)$$

with the boundary conditions

$$i \cdot n = -(k \nabla e + m \int_0^T \nabla e dt) \cdot n \quad (6)$$

where  $n$  is an outward vector from each end of the line element.

Equations (5) and (6) may be combined in a variational equation as:

$$\begin{aligned} \delta(\text{Integral}) = & \int (k \nabla^2 e + m \int_0^T \nabla^2 e) dt - c \dot{e} \phi dx \\ & - \int (i \cdot n + (k \nabla e + m \int_0^T \nabla e dt) \cdot n) \phi db \end{aligned} \quad (7)$$

where  $\phi$  is an approximation function for  $e$  and (*Integral*) will have to be minimized. The term  $db$  is an increment of the boundary, which in this case consists of the two ends of the line element.

Using Green's theorem,

$$\begin{aligned} \delta(\text{Integral}) = & \int (-k \nabla e \cdot \nabla \phi - m \int_0^T \nabla e \cdot \nabla \phi dt - c \dot{e} \phi) dx \\ & - \int (i \cdot n) \phi db \end{aligned} \quad (8)$$

where  $e$  has been assumed to be piecewise continuous in time. Since  $\phi$  is a variation of  $e$  ( $\phi = \delta e$ ), the integral becomes

$$\begin{aligned} (\text{Integral}) = & -\frac{1}{2} k \int (\nabla e)^2 dx - \\ & \frac{1}{2} m \int \left[ \int_0^T (\nabla e)^2 dt \right] dx - \frac{1}{2} c \int \dot{e} dx + \\ & \int (\text{input current}) e db \end{aligned} \quad (9)$$

Now assume a function for  $e$  of the form

$$e = a_1 + a_2 x = [1 \ x] \{a\} = [E] \{a\} \quad (10)$$

In the terms of the end (nodal values),

$$e = [E][A^{-1}]\{V\} \quad (11)$$

where

$$[A] = \begin{bmatrix} 1 & 0 \\ 1 & l \end{bmatrix}, \quad l = \text{line element length}$$

$$\{V\} = \text{vector of nodal voltages}$$

then,

$$\nabla e = \frac{\partial e}{\partial x} = [0 \ 1][A^{-1}]\{V\} \quad (12)$$

Placing the above into equation (9) and taking the variation with respect to the nodal voltages yields;

$$\begin{aligned} \delta(\text{Integral}) = & 0 = \\ & -k[A^{-1}]^T \int (\{\nabla\}[E])^T (\{\nabla\}[E]) dx [A^{-1}]\{V\} \\ & - m \int_0^T [A^{-1}]^T \int (\{\nabla\}[E])^T (\{\nabla\}[E]) dx \\ & [A^{-1}]\{V\} dt \\ & - c[A^{-1}]^T \int [E]^T [E] dx [A^{-1}]\{\dot{V}\} \\ & + \{\text{input current at nodes} = I\} \end{aligned} \quad (13)$$

where a subscript  $T$  means the transpose of a matrix, which is of the form

$$[K]\{V\} + \int_0^T [M]\{V\} dt + [C] \frac{\partial}{\partial t} \{V\} = \{I\} \quad (14)$$

and the matrices are given by

$$[K] = kl \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \quad (k = \text{mm/ohm}) \quad (15)$$

$$[M] = ml \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \quad (m = \text{mm/nanohenry}) \quad (16)$$

$$[C] = cl/6 \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix} \quad (c = \text{nanofarads/mm}) \quad (17)$$

If a mesh current formulation had been used, the capacitance matrix (17) would have had only diagonal terms instead of the true distributed line capacitance which is inherent in the finite element approach.

## LOAD (GATE) MODEL

The particular gate used in this paper is a CML circuit; however, the load model does not have to be confined to any single type of circuit set since the model in the preceding section can be used with any load which uses a voltage input as a boundary condition. This will be more fully explained in the "Substructure" section.

The seven-node model which uses an Ebberts-Moll model for the transistors is shown in Figure 1. The voltages  $V_1, \dots, V_7$  are unknown and vary as  $V_m$  varies. The node (subscript) numbers are specifically chosen to reduce the

Figure 1—Model of Honeywell Current Mode Logic gate.

number of arithmetic operations required for solving the simultaneous equations (a seven-by-seven matrix will be obtained from Figure 1).

The basic equations for the transistor model are:

$$B_N = \frac{1}{B_N} + 1 \quad (18)$$

$$B_I = \frac{1}{B_I} + 1 \quad (19)$$

$$I_I = I_{cs} \exp(\theta_I V_{bc}) \quad (20)$$

$$I_N = I_{es} \exp(\theta_N V_{be}) \quad (21)$$

$$C_{be} = a_1 N_1 / (\phi_1 - V_{be}) + \theta_N T_{CN} I_N \quad (22)$$

$$C_{bc} = a_2 N_2 / (\phi_2 - V_{bc}) + \theta_I T_{CI} I_I \quad (23)$$

$$I_{be} = (I_N - I_{eN}) B_N - I_I + I_{cs} \quad (24)$$

$$I_{bc} = (I_I - I_{cs}) B_I - I_N + I_{es} \quad (25)$$

The values for  $a_1$ ,  $a_2$ ,  $\phi_1$ ,  $\phi_2$ ,  $I_{cs}$ ,  $I_{es}$ ,  $\theta_I$ ,  $\theta_N$ ,  $T_{CN}$ ,  $T_{CI}$ ,  $B_N$ , and  $B_I$  are experimentally determined from actual circuits.

In relation to Figure 1,

$$C_{be} = C_3, C_4 \quad (26)$$

$$C_{bc} = C_1, C_2 \quad (27)$$

$$V_{be} = (V_3 - V_5), (V_4 - V_6) \quad (28)$$

$$V_{bc} = (V_3 - V_1), (V_4 - V_2) \quad (29)$$

$$I_{be} = I_{be3}, I_{be4} \quad (30)$$

$$I_{bc} = I_{bc3}, I_{bc4} \quad (31)$$

Writing the nodal equations will lead to an equation of the form

$$[A]\{V\} = \{r\} \quad (32)$$

where the right hand side ( $\{r\}$ ) will be composed of a current vector, a vector containing capacitance terms times nodal voltages, and a vector of known voltages ( $V_{in}$ ,  $V_{26}$ ,  $V_G$ ,  $V_{33}$ ). The approximation of constant capacitance during each time step (which is due to the finite difference approximation which will be imposed in the next section on equation (14)) is consistent with the interconnect model. However, such an approximation for the current generation is not made since a better approximation is easily achieved.

For example, in terms of the voltage at the beginning of the time step, the current at the end of the time step may be written as

$$I_{bc} \approx -I_{cs} + I_{cs} (e^{\theta_I V'_{bc}} + e^{\theta_I V_{bc}} (V_{bc} - V'_{bc}) \theta_I) \quad (33)$$

where  $V'_{bc}$  is the voltage at the beginning of the time step. A similar expression exists for  $I_{be}$ . This expression is obtained from the first two terms of a series expansion of the exponential factor.

These expressions for current will contribute terms to the matrix  $[A]$  in (32), and also destroy its symmetry. However, since the matrix is sparse, it can be easily solved by hand and the solution can be coded directly into the program. The method of solution follows.

The matrix  $[A]$  is of the form

$$\begin{bmatrix} A_{11} & A_{13} & A_{15} & & & & \\ & A_{22} & & A_{24} & & & \\ A_{31} & & A_{33} & & A_{35} & & \\ & A_{42} & & A_{44} & & A_{46} & \\ A_{51} & & A_{53} & & A_{55} & & A_{57} \\ & A_{62} & & & & A_{66} & A_{67} \\ & & & & & A_{75} & A_{76} & A_{77} \end{bmatrix} \quad (34)$$

The vector  $\{r\}$  is given by

$$\{r\} = \begin{Bmatrix} I_1 \\ I_2 \\ -I_1 - I_5 \\ -I_2 - I_6 \\ I_5 \\ I_6 \\ 0 \end{Bmatrix} + \begin{Bmatrix} 0 \\ 0 \\ V_{in} K_B \\ -0.26 K_B \\ 0 \\ 0 \\ -3.3 K_3 \end{Bmatrix} +$$

$$\begin{bmatrix} C_1 & & -C_1 & & & & \\ & C_2 & & -C_2 & & & \\ -C_1 & & C_1 + C_3 & & -C_3 & & \\ & -C_2 & & C_2 + C_4 & & -C_4 & \\ & & -C_3 & & -C_3 & & \\ & & & -C_4 & & C_4 & \\ & & & & & & 0 \end{bmatrix} \begin{Bmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \\ V_5 \\ V_6 \\ V_7 \end{Bmatrix} \quad (35)$$

where

$$I_1 = -I_{cs} B_I + I_{es} + I_I B_I (1 - \theta_I (V_3' - V_1')) - I_{cs} (1 - \theta_N (V_3' - V_5')) \quad (36)$$

$$I_2 = -I_{cs} B_I + I_{es} + I_I B_I (1 - \theta_I (V_4' - V_2')) - I_{cs} (1 - \theta_N (V_4' - V_6')) \quad (37)$$

$$I_5 = -I_{es} B_N + I_{cs} + I_N B_N (1 - \theta_N (V_3' - V_5')) - I_I (1 - \theta_I (V_3' - V_1')) \quad (38)$$

$$I_6 = -I_{es}B_N + I_{cs} + I_N B_N (1 - \theta_N (V_4' - V_6')) \quad (39)$$

$$- I_f (1 - \theta_f (V_4' - V_2'))$$

and the values of  $I_N$  and  $I_f$  are functions of the voltages in each current equation.

By using the Crout algorithm, the matrix  $[A]$  may be easily modified into a new matrix  $[\tilde{A}]$  which permits a simple solution to the seven simultaneous equations.

$$\tilde{A}_{ij} = A_{ij} - \sum_{k=1}^{j-1} \tilde{A}_{ik} \tilde{A}_{kj} \quad i \geq j, j \geq 2 \quad (40)$$

$$\tilde{A}_{ij} = (A_{ij} - \sum_{k=1}^{j-1} \tilde{A}_{ik} \tilde{A}_{kj}) / \tilde{A}_{ii} \quad i < j, i \geq 2 \quad (41)$$

$$\tilde{A}_{1j} = A_{1j} / A_{11} \quad j \geq 2 \quad (42)$$

$$\tilde{A}_{i1} = A_{i1} \quad (43)$$

Then the vector  $\{r\}$  is modified by

$$\tilde{r}_i = (r_i - \sum_{k=1}^{i-1} \tilde{A}_{ik} \tilde{r}_k) / \tilde{A}_{ii} \quad i \geq 2 \quad (44)$$

$$\tilde{r}_1 = r_1 / A_{11} \quad (45)$$

and the voltage vector is obtained by

$$V_7 = \tilde{r}_7 \quad (46)$$

$$V_i = \tilde{r}_i - \sum_{k=i+1}^7 \tilde{A}_{ik} V_k \quad i \leq 6 \quad (47)$$

The above solution is applied for each time step of the interconnect model solution and the capacitance values are updated for each time step.

## SUBSTRUCTURE ASSEMBLY

Equation (14) must be represented in a finite difference form for calculation purposes. This will be of an implicit, trapezoidal integration form to obtain a better approximation than a simpler explicit, rectangular integration form would provide. The result is that larger time steps may be used, hence faster execution.

This is easily achieved by writing the discreteized form of equation (14) for the voltage at time  $T - \frac{1}{2}\Delta T$  instead of time  $T$  (the end of the present time step for which the nodal voltages are unknown). This means

$$\{V\}_{i-1/2} = \frac{1}{2}(\{V\}_i + \{V\}_{i-1}) \quad (48)$$

in terms of subscripts ( $i$  at  $T$  and  $i-1$  at  $T - \Delta t$ ). Then, for the D.C. terms,

$$\{I\}_{i-1/2} = \frac{1}{2}[k](\{V\}_i + \{V\}_{i-1}) \quad (49)$$

for the capacitive terms,

$$\{I\}_{i-1/2} = \frac{1}{\Delta t} C(\{V\}_i - \{V\}_{i-1}) \quad (50)$$

and for the inductive terms,

$$\{I\}_{i-1/2} = (\Delta t)[M](\frac{1}{2}\{V\}_i + \frac{1}{2}\{V\}_{i-1} + \sum_{j=1}^{i-2} \{V\}_j) \quad (51)$$

where the factors  $\frac{1}{2}$  and  $\frac{1}{2}$  come from using

$$\{V\}_{i-3/4} = \frac{1}{4}\{V\}_i + \frac{3}{4}\{V\}_{i-1} \quad (52)$$

for the integration in the half time step from  $T - \Delta t$  to  $T - \frac{1}{2}\Delta t$ .

The resulting finite difference equation is (let  $(\Delta t)[M]$  become just  $[M]$  and  $[C]/(\Delta t)$  become just  $[C]$ ):

$$(\frac{1}{2}[K] + \frac{1}{2}[M] + [C])\{V\}_i = \{I\}_{i-1/2} - \frac{1}{2}[K]\{V\}_{i-1} \quad (53)$$

$$+ [C]\{V\}_{i-1} - \frac{1}{2}[M]\{V\}_{i-1} - \sum_{j=1}^{i-2} ([M]\{V\}_j)$$

Given the above equation, the two models may now become interactive in time.

For the interconnect model,  $1/R_B$  from the load model may be included in the conduction matrix,  $[K]$ , with the gate voltage  $V_3$  as a known boundary condition for the interconnect model. At any given time step, the gate voltage is known for  $T - \Delta t$ ,  $T - 2\Delta t$ , etc., but not  $T - \frac{1}{2}\Delta t$ . This is easily resolved by the finite difference extrapolation formula

$$(V_3)_{i-1/2} = \frac{1}{2}(3(V_3)_{i-1} - (V_3)_{i-2}) \quad (54)$$

Defining the subscript  $R$  as identifying quantities associated with the gate (i.e.  $-R_B$  and  $V_3$ ) model, equation (53) may now be written as:

$$(\frac{1}{2}[K] + \frac{1}{2}[K]_R + \frac{1}{2}[M] + [C])\{V\}_i = \{I\}_{i-1/2} \quad (55)$$

$$- \frac{1}{2}[K]\{V\}_{i-1} - \frac{1}{2}[K]_R(\{V\}_{i-1} - 3\{V_R\}_{i-1} + \{V_R\}_{i-2})$$

$$+ [C]\{V\}_{i-1} - \frac{1}{2}[M]\{V\}_{i-1} - \sum_{j=1}^{i-2} ([M]\{V\}_j)$$

where  $[K]_R$  is null except for diagonal elements to which loads are attached (or terminating resistors if the need arises).

The final boundary condition is the input or driver. This is simply an input current to the first node ( $I_1$  in the vector  $\{I\}$ ) which matches the wave form for actual experimental data.

Once the interconnect model has been solved for time  $T$ , the nodal voltage at each load location becomes  $V_{in}$  for the load model in Figure 1. The same basic model is used for each load, but the voltages ( $V_1$ ,  $V_2$ , etc.) are stored in arrays so that the loads at different positions in the network can be simulated autonomously.

The substructure interaction scheme follows two simple repetitive steps:

1. Impose boundary conditions for time  $T - \frac{1}{2}\Delta t$  from current source (driver) and extrapolated load voltages ( $V_{R's}$ ) on interconnect model and solve for nodal voltages at time  $T$ .
2. Impose  $V_{in}$  boundary conditions from interconnect nodes on load model and solve for gate voltages at time  $T$  for all load locations. Then repeat Step 1 for next time increment.

This process is repeated until all of the loads have reached a stable on (or off) condition. The stable condition is defined by a prescribed voltage above the threshold switching volt-

age below which  $V_{v2}$  (Figure 1) does not fall once it has been attained.

IMPACT OF MATRIX STORAGE ON EXECUTION TIME

The line model developed in the earlier section cannot be used for unlimited lengths as a single element. For example, a 75 ohm transmission line with a propagation delay of 5 nanoseconds per meter should be limited to a 50 or 60 mm long element. Therefore, long line segments must be broken into shorter elements. This can result in large matrices (200 by 200 for example) if the lines are long and there are many branch points. Such large matrices not only require much storage, but also much computation time. This can be reduced by considering the nature of the interconnect problem. An example is shown in Figure 2. Each line segment would have one or usually more elements. The resultant matrix would be tridiagonal except at the branch points. Since all arithmetic operations outside of the banded portion of the matrix will result in zero, there is no need to either store or operate on these outside elements.

Advantage was taken of the matrix type and a one-dimensional, variable bandwidth storage scheme was developed which stores, hence, operates on, only the affected elements in the matrix. This results in a reduction of storage of almost one order of magnitude and a similar reduction of execution time. This makes the manual version of the program practical since the user gets the results from the terminal within seconds after he types in the data.

SAMPLE PROBLEM

Figure 2 is typical of those types of logic networks which can be simulated with this approach. The four basic media

are the multichip package, the board, the cable between boards, and the connectors. The type of each line segment is given in Table I.

For the sake of simplicity, the plot in Figure 3 shows only the voltage at the source and the output of the gates at loads 3 and 5. Notice the reflections, turn off of load 5, etc., which affect the delay of the network. Such information is extremely important in the early stages of design in order to assure meeting performance goals.

As a contrast, a simple hand calculation based on propagation time would have predicted turn-ons for load 3 at 13 ns and load 5 at 13.3 ns. The difference between the simple assumption and the full simulation (17 ns for load 3 and 35 ns for load 5) is obvious from Figure 3. This illustrates the importance of a full simulation instead of estimates based on run lengths and loading factors which can not take into account reflections caused by mismatched impedances.

STAR CONFIGURATION SAMPLE PROBLEM

While the preceding example demonstrated the complex logic interconnection which can be modeled, a simple problem will help to demonstrate further the need for full simulation.

This problem will be developed from a simple, impractical (in the sense that it would not appear in a real design) star to a more realistic interconnect which may loosely be described as a star.

The simple star is shown in Figure 4 and for the first simulation, all of the lines were treated as board lines instead of using the connector or micropackage parameters. Then the micropackage and connector parameters were used for the appropriate segments and the load output plots are shown in Figure 4 along with the driver output voltage for the case of all three media in the problem. Because all signal

22	25	MICROPACKAGE

Figure 3—Voltage waveform, plots for the sample problems shown in Figure 2.

paths are the same length and all load factors equal, only one load output plot exists for each case. Of note is the fact that when all media are considered, the delay is three nanoseconds longer than for the all board lines case. This is important because if the difference in propagation speed between board lines and connector or micropackage lines is multiplied by the appropriate line lengths, only .48 nanoseconds can be accounted for in the three-nanosecond difference. The bulk of the difference is therefore due to the variation of line characteristics in the signal paths. This can be noted by the dip in the source (driver) voltage.

The next case also uses the star except that the top load has a load factor of 2.5 (for example, two "high" current gates and a "low" current gate driven in parallel on the same chip or adjacent chips) and the other three loads only have a load factor of 0.5. Note that the total load seen by the source is still four, the same as the previous case. The output plots are in Figure 5 and show a 1.5-nanosecond

difference in delay time. However, the possibly surprising result is that the gates on the more heavily loaded line turn on before the half loads. This is due to the capacitance of the larger loading making the top line less sensitive to the dip in the source voltage which the lightly loaded lines track closer.

A true equal line length star would not likely be found in a real design since board routing and micropackage placement would preclude such an ideal case. The quasi star in Figure 6 is more representative of a real interconnect. The board line lengths are chosen to relate to the previous star configuration. The average distance to the four loads is the same as the previous equal board line lengths. Likewise, the total loading (four) is the same. In Figure 6, only the output of loads one and two and the source are shown for the sake of clarity. Load one turns on 10.5 nanoseconds sooner than for the equal line length case yet the difference in distance only accounts for the signal reaching the load two nanose-

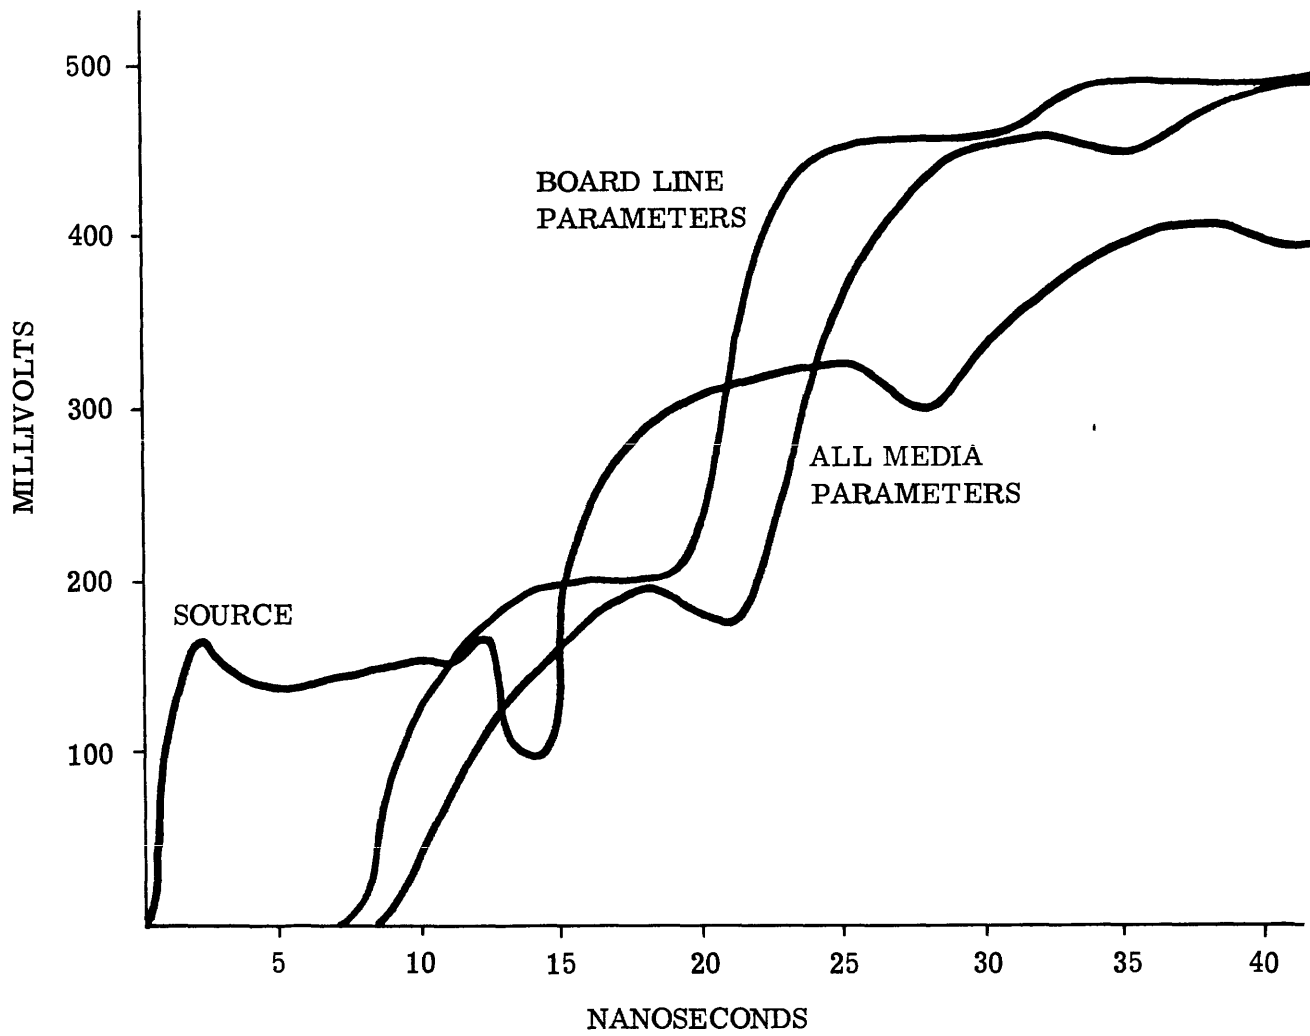

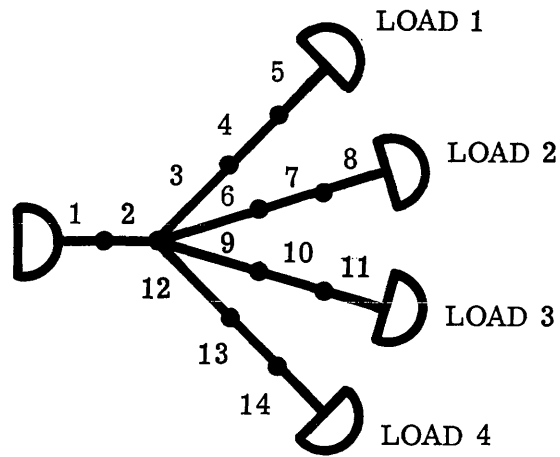

Figure 4—Simple star sample problem. The SOURCE waveform is for the ALL MEDIA PARAMETERS case.

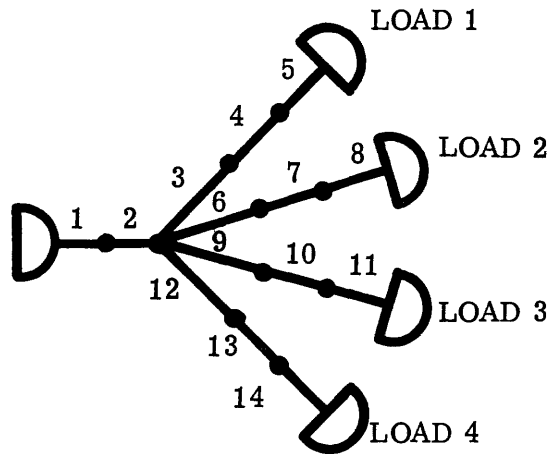

Figure 5—Simple star configuration except LOAD 1 has a load factor of 2.5 while the other loads are only 0.5.

Figure 6—Quasi star configuration. The average distance to each load is the same as for the simple star and all loads factors are 1.

conds sooner. The reason for the faster turn-on can be seen in the source voltage. It reaches a higher initial plateau which is due to the first branch point having only two instead of four branches. The waveform of load two is also noteworthy. Although it turns on before load one, it turns off at 23 nanoseconds and on again at 24 nanoseconds. Hence, 24 nanoseconds must be taken as the true turn-on time since the load is itself a driver for the next step in the logic path and must be stable before turn-on of its loads can be assured.

#### SIMULATION PROGRAM CHARACTERISTICS

Once the program had been developed, it was checked for accuracy by running several sample problems which were also modeled on a popular circuit analysis program, SCEPTRE. The voltage plots were identical and the only variations were in the third significant digit when the voltage values were printed instead of plotted. An important difference between the two programs is that the version of SCEPTRE used required a minimum of 25k words of storage and approximately one minute of execution time (plot suppressed to reduce I/O time), while the program used for this paper took less than 12k of storage and ran the comparison problems in less than a second (also, plot suppressed). Both programs were run on the same Honeywell Level 66 Computer.

The program can handle up to 100 nodes and line elements

(each line segment may be one or more line elements which are 125 mm. or less) but that may be increased by just a dimension statement change. The first sample problem required only about 50 nodes. The program is written in FORTRAN and may run on any computer with adequate storage.

#### CONCLUSION

The simulation method presented in this paper is proving to be a useful tool in the early design phases of logic networks for two reasons. First, it provides essentially automatic timing analysis of all designs without any extra work on the part of the designer when the design data base is used for input. The typical execution time of less than one second per simulation run allows the computer-aided design automation system to include a full set of timing analyses without any adverse effect on turn-around time or competition for resources. Second, the designer is free to use more complex branch schemes than could be used if the delay predictions had to be done according to simplified wiring rules. This freedom allows more efficient design and routing while assuring that the result will be predictable. Again, the fast execution and the small storage makes desk-top terminal operation practical. The designer may obtain voltage waveform plots on the terminal as fast as it will type, and then check out design modifications as fast as he can type.

# Languages for operating systems description, design and implementation

by PHILIP H. ENSLOW, JR.

Georgia Institute of Technology  
Atlanta, Georgia

## INTRODUCTION

The transfer of information about operating systems is severely hampered by the lack of suitable means for precise communication. If major progress is to be made in reducing the high cost of developing and maintaining system software, new communication techniques must be fashioned to improve both vertical and horizontal transfer of information about operating systems.

“Vertical information transfer” refers to communication between individuals or groups working at the various levels on the development or use of some specific operating system. Designations of these levels might be specification, description, design, experimentation, implementation, evaluation, use and maintenance. However, these classifications are not all mutually exclusive, nor is this the only taxonomy possible. In contrast, “horizontal information transfer” refers to communication between different projects or between individuals working on an operating system and outsiders (i.e., a new member of the team, another operating system development project, students, etc.). The essential factor characterizing the horizontal flow of information is that the recipient is not already intimately familiar with the total environment of the system under study, and does not want to be forced to learn more about that environment than necessary.

Although some work has been done in support of information transfers along both axes, most of the effort has been focused on vertical flow, with only a small amount of effort devoted to horizontal transfer to a different environment. In only a very few instances has the combined problem been considered. (Examples of the combined approach are References 17, 58 and 59.) Previous work was performed primarily within the framework of problem-solving or systems development and focused on the development of formalized approaches involving a statement of the functional requirements of the system, specifying these requirements in a formal language, similarly defining process interactions, and progressing through various other steps such as the use of a high-level programming language, assembly language, etc. Unfortunately, such work results in the development of different languages for specific purposes without regard to their position in the hierarchy.

From a vertical point of view, the concept of structured programs suggests the possibility of utilizing the same language at different levels of abstraction. This possibility may prove workable when the requirements of only two levels are considered; however, the requirements for efficient horizontal transfer of information may well make such a solution a poor one.

In the vertical direction, the value of a complete operating system language(s) system meeting the characteristics to be described will be primarily economic. The total time, and hence the cost, required to design, implement, test and maintain an operating system will be most directly affected. In the horizontal direction, the resulting effect will be primarily an improved transfer of technology and general knowledge about operating systems. This will of course have an ultimate effect on the economics of operating system development, but the emphasis here is on knowledge transfer. The question has often been raised as to why operating system developments from universities are not utilized better by industry. The availability of a suitable means of accurate, succinct and informative communication would certainly aid this transfer process.

The emphasis of this paper is on the role of the languages as effective information transfer mechanisms, but this orientation is not meant to deny the value of complete software development systems which not only require “good” languages but also the ability to handle the design data bases. (Good examples of discussions of this type of system are References 3 and 50.) The primary thesis of this paper is that the horizontal transfer of information, though certainly as important as the vertical one, has been seriously neglected in most of the work thus far.

## LEVELS OF USAGE

The language available at each “level” must provide the ability to “describe” the operating system; however, the purpose of each of these is quite different:

- Specification*—Functional requirements of the system and the criteria of performance in providing those functions;
- Design*—Proposed solutions to meet the specifications;
- Simulation*—A functional model of the proposed system

that can be utilized for experimenting with various designs;

*Implementation*—The detailed solution of the problem in a form that can be directly translated to a machine-executable form;

*Description*—A description of the functionality, implementation and performance of the operating system usable for instruction and training, maintenance, demonstration or study.

The relationships of these activities one to another and to the other activities involved are shown in Figure 1.

It appears that none of these is driven totally by either the vertical or horizontal transfer requirements. For example, instruction about an operating system is performed horizontally for general students; it is also an extremely important, but expensive and time-consuming, factor in the training of new individuals on a specific operating system project. Similarly, design and experimentation may be carried on horizontally for instructional or research projects on a specific aspect of operating systems in general or vertically in the analysis of the performance of a specific system. The one level that does seem to have almost total vertical orientation is check-out and test support; however, even here the horizontal influences and features of the system implementation, such as good programming practices, will certainly be felt.

### Specification

A specification language should be problem-oriented. It is a statement of the problems to be solved, the functionality

of the system, and the criteria to be met in solving these problems. The specification may also include restrictions on system behavior. What must not be included in the specification are any *unnecessary restrictions on how* the problem will be solved. The specification for an operating system should be organized on the basis of functions provided (i.e., a problem orientation) and should be as non-prescriptive as possible. A specification is also a statement of the *policies* to be implemented in the system but not the mechanisms that will be implemented.

### Design

A system design prescribes the general mechanisms that will be utilized to implement the policies and functions set forth in the specification. The major difference between a design and an implementation is in the level of abstraction. The design will not include all the details of the mechanisms implementations. There is, in fact, a large degree of machine-independence present in a design.

### Simulation

One well demonstrated requirement of the total design methodology is "the need to test proposed modifications to a complex system before they are made, regardless of how beneficial these changes might appear. The number of times that the system . . . did not react as expected in response to adjustments should serve as a warning."<sup>45</sup> Although much work has been done on the simulation of operating systems

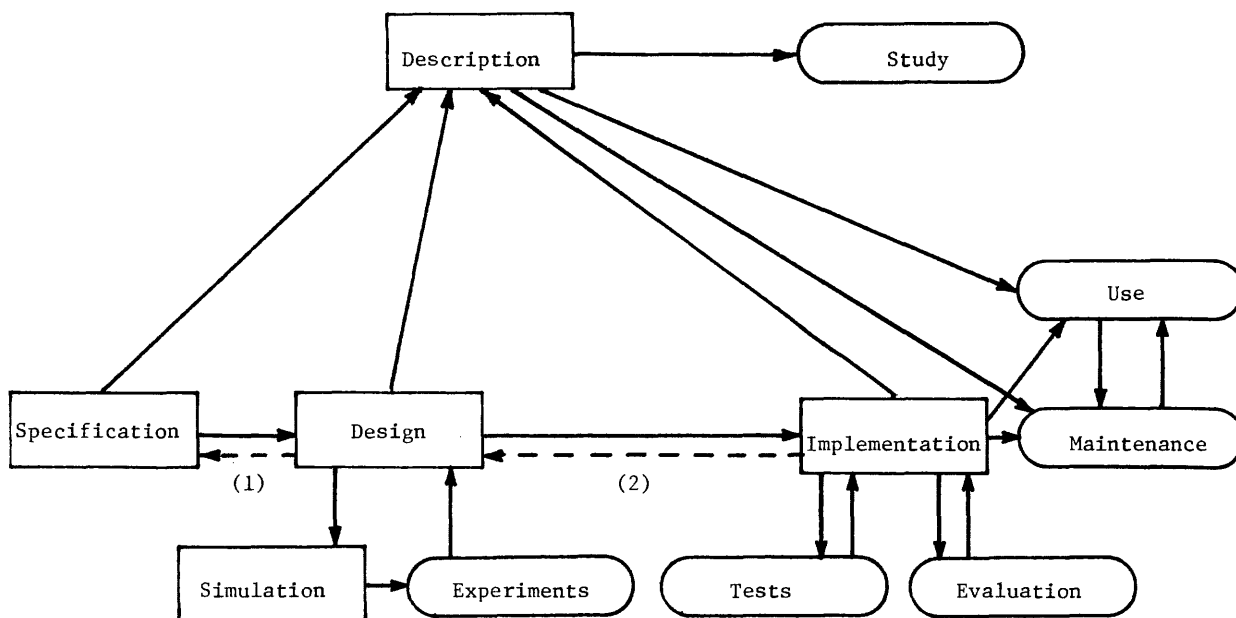

Figure 1—Operation system activities.

1) Changes in the specifications as a result of changes in the design based on simulation experiment result and/or evaluation tests of the implemented system.

2) Changes in the design based on the results of evaluation tests of the implemented system.

and on special languages to facilitate the construction of simulation models, the fact is that the cost of simulation studies of operating systems remains almost as high as the cost of experimenting with the actual system. The reason for this is that there is an almost total lack of continuity or direct transferability between the design description of the system and its simulation description. Although it is shown in Figure 1 as an adjunct activity, the language support for simulation must be unified with the "main-line" activities.

### *Implementation*

A statement of the implementation of the system must be a description containing sufficient detail that it can be executed after appropriate processing by a language translator. The description of mechanisms in the implementation are machine-dependent except to the degree that there may exist some capability for portability of the programming language utilized for the implementation description.

### *Description*

Whereas the problems associated with specifying, designing and implementing operating systems are well recognized, the difficulties encountered in *describing* such a system are *not* so well recognized—nor, as any student of the subject is well aware, have effective techniques been developed to accomplish such a task. What is commonly seen is a description of only one portion of the system, such as the kernel (e.g., References 53 and 72); a specific feature, such as protection (e.g., Reference 7); or the design/implementation policy (e.g., Reference 34). The weakness of our present capabilities to describe operating systems succinctly and completely is evidenced by the few overview papers that have been produced (e.g., References 14, 54, 73). Although each of these papers is informative, none provides a large amount of insight nor the detail necessary for understanding the design and implementation of the complete system. At the other end of the spectrum of descriptions of a single system is the complete coverage of MULTICS.<sup>48</sup> It is interesting to note that even in non-system specific discussions of a topic such as security, there is no common basis for discussion and presentation. The presentation techniques encountered in open publication range from totally verbal (e.g., References 15 and 44) to theorem-based discussions (e.g., Reference 22) and a combination of theorem and code (e.g., Reference 52).

## DESIRABLE CHARACTERISTICS AND CAPABILITIES

### *A single unified system*

It is important that the "language" support provided be a single unified system, not a large collection of separate design and programming aids each applicable to merely one

level. When the various levels are considered, this unification may initially be only a philosophical one; however, the ultimate goal should be physical unification through capabilities to automatically translate the representation at one level into that applicable at the next.

### *Graphical techniques*

Graphical or pictorial techniques have always been extremely useful and powerful tools for explaining the operation of relatively complex systems. In computer systems, such techniques have usually taken the form of flowcharts. Though one experimental study has indicated that flowcharting has little value in *increasing* programmer productivity,<sup>60</sup> it is nonetheless clear that flowcharts do have a positive value in facilitating information transfer about the logic and sequencing in an existing program. On the other hand, the extreme complexity of operating systems and the inability of flowcharts to portray concurrency work together to greatly diminish the value of this technique for documentation and information transfer with respect to operating systems. A modification of flowcharting called flowgraphs has been presented in Reference 32 as a technique for detailed analysis to include timing studies of real-time systems. However, since the level of detail presented in flowgraphs is quite high, its value for the analysis and description of a complete operating system is also questionable.

### *Language-based*

Formal languages have been studied extensively and have a strong theoretical base for their design and the automation of checks for internal consistency and completeness as well as translation. These characteristics, plus the ability to easily manipulate a collection of statements in a formal language system, are strong arguments for having the support for each level be based on a formal language.

It is possible to modify a formal language definition tool such as the Vienna Definition Language<sup>70</sup> to support "the formal description of operating system features, like the concepts of parallelism and information sharing."<sup>43</sup> However, based on the example applications of this technique, it does not appear that the results are very easy to understand. The problems here are primarily the language notation and semantics.

### *Ability to express the same abstraction or control structure at all levels*

The capability of the language system to perform this task is central to the entire argument for its development. However, basic research is still needed to provide full "abstraction expression" capabilities at even one level. Work is presently being performed on languages that may provide the facilities necessary to fully describe (define) the types of structures used by Dijkstra in the T.H.E. operating system,

but it does not appear that current projects will adequately support the two dimensions of information transfer presented here.

#### *Separation of policies and mechanisms*

It is on this point that there might be divergence of goals in considering both horizontal and vertical information flows. From a vertical point of view, an objective might be that "We would like to develop a language mechanism which allows us to capture an *abstraction* and its *implementation* in the program text."<sup>71</sup> However, from the point of view of horizontal flow of information, if the abstraction of the policy and its implementation mechanism are inextricably combined, there is probably too much information being passed, since the boundary between the levels of design and implementation has been removed. There is nothing sacred about these boundaries, nor has it been proved that they are essential; however, the desirability of this characteristic should be examined. At the descriptive level there is no question that one would wish to be able to describe various policies without considering their implementations.

There are several readily-apparent reasons for the separation recommended above. The study of operating systems can be divided into two general classifications; (1) The investigation of the logic and operation of algorithms that control specific functions of the operating system; and (2) The consideration of the various implementations (mechanisms) possible for the logic underlying these policies. In addition to clearly identifying just what it is that is being examined, this fundamental separation directly supports two other objectives of any design and implementation system—a systematic approach to performance analysis (Which is the cause and which is the effect, the policy or the mechanism?) and the identification and cataloging of reusable policy modules even though their implementations might be unique (i.e., target system dependent).

Separation of policy and mechanism should greatly assist in the development of automatic checks of the program developed. The methodology employed for such checks will be different at each level, but all methodologies will have the goals of ensuring consistency and facilitating verification. A full consideration of this requirement is present in the work of several workers at the implementation level.<sup>63</sup> However, all of the problems have not been solved at even that single level.

#### *Understandability and intelligibility*

William Wulf has commented that "Whatever it is that makes a program understandable *must* be a property of the program text." The problem is one of attaining and retaining understandability for both vertical and horizontal information transfer. A descent of one vertical level might be characterized as the removal of one level of abstraction whereas a horizontal transfer implies a complete understanding of the abstraction at that level. Entering into the discussion

here is the old argument about the use of comments vs. a verbose language (e.g., COBOL). It appears at this time that the total "understanding" required for either direction of transfer should be provided by the program statements themselves; and, since the language itself must support horizontal transfers, the demands made on the information content of the language exceed those made in the past. There is a grave danger that, in attempting to increase the information content of the basic language statements so as to improve understanding, the result will be the development of an extremely complex or artificial notation system that greatly diminishes intelligibility.

#### *Promote (enforce) good programming practices*

The promotion—or better, the enforcement—of good programming practices is one of the most desirable characteristics of the complete system from the point of view of actual usage in a vertical manner. Much has been said about the desirability of omitting several types of constructs from the language; unfortunately, much less has been said about what should be included to provide the capability to do "good systems design and implementation;" and research on the enforcement of procedures that will result in quality work is almost non-existent. It appears that the problem is divisible into two general subjects—the organization of the control structures used in the program and the physical organization of the program.

#### SURVEY OF PREVIOUS WORK

In the past, the primary motivation for language work in this area has been the need to develop tools that will facilitate the evaluation of various features included in an operating system, the selection of parameter values, etc. This is obvious from the number of citations given below in the section on simulation. The area with the next higher level of activity has probably been implementation languages, although only a small selection of references is cited here. There has been some work on design languages, but descriptive systems have received very little attention. The work on languages or programming systems that addresses more than one level of usage has been very small.

#### *Hardware languages*

It is not advisable to attempt too close an analogy between software systems design languages and those developed for hardware; however, a few comments on the latter appear to be in order. One is inclined to think of the problem of "common" notation as being much simpler for hardware, but such a situation is not the case. A 1967 review of documentation in use at the lowest (logic gate) design level showed nine techniques then in use.<sup>11</sup> The problem was

actually even worse than this diversity of systems would seem to indicate. The motivations for the use of higher-level languages or machine manipulatable notations for hardware are almost the same as they are for software—vertical and horizontal information transfer plus automatic translation and expansion to take care of the simple repetitive tasks, error and consistency checks, and interfaces with automated systems that carry the design process through the next logical step.

An example of a notational system that was originally designed to support horizontal information transfer is ISP.<sup>2</sup> Of particular interest is the later work on ISP that focused on expanding its use along the vertical dimension with complete, automatic translation support down through simulation and implementation. ISP corresponds to a lower-level of language hierarchy discussed above; however higher-level languages have not been neglected. Some early work was on the development of an Algol-type language,<sup>5</sup> and today there is much activity within a group known as the Conference on Hardware Design Language (CHDL). Of particular note is the sentiment that several members of the CHDL group have expressed on the importance of the use of the output of this group as a teaching or descriptive language.

#### *Descriptive languages*

The first language developed specifically for operating system description was a notation introduced by Leo Cohen in his preliminary text, *Theory of the Operating System*.<sup>8</sup> Cohen was one of the first individuals presenting introductory courses on operating systems and his notation reflects an appreciation of the importance of understanding the concurrent operation of the operating system with the user program and concurrency within the operating system itself as well as recognition of the fact that it is a “transaction” that is being processed. The technique, which involved identifying the “Current Operating Transaction” and the “Available Transaction” as the operating system crossed logical boundaries was described fully and used extensively in Cohen’s book.<sup>9</sup> Although the COT-AT technique was quite limited in its capabilities, it did provide the basis for a rather concise description of an existing operating system, OS/360 MVT, in 18 small flowcharts<sup>40</sup> and a conceptual design for a proposed operating system.<sup>41</sup> The early work with the COT-AT notation system also greatly influenced the design of the first operating system simulation language, S3, to be discussed.

Another notational technique applied to the descriptions of both software and hardware is the contour model.<sup>27</sup> This technique, which can illustrate the nesting of control and concurrent execution environments, was used extensively in a complete treatise on the Burroughs 5700 and 6700 systems.<sup>49</sup> This technique may not have been available for use by the same author in an earlier text on the Multics system<sup>48</sup> which also has a block-type structure; however, there also appears to be some question of its applicability to this situation. The contour model also formed part of the basis of the picture-system.<sup>24–26</sup>

#### *Experimentation and simulation languages*

Simulation has long been recognized as a very useful tool in the study and evaluation of operating systems. As can be seen from the references to be cited, there has been much work done in this area—far more than that done at any other level.

Almost any general-purpose discrete event simulation language, e.g. GPSS<sup>39,55</sup> and SIMSCRIPT,<sup>30</sup> or even a general-purpose language such as FORTRAN could be used to model an operating system,<sup>35,45</sup> and many such models have been constructed. However, most of these models cover only a small portion of the complete system such as the scheduler/dispatcher subsystem, the memory allocator/manager, etc. GPSS has been popular for this purpose. Although a model programmed in a general-purpose language can provide an accurate description of the logic of the target system, the source code is not easy to read, and the depiction of many of the operations found in operating systems requires some rather involved coding that obscures the basic logic. Some work of note in this area has been the use of SIMULA as the simulation language. A specific example is a complete model of the CDC 6600/SCOPE.<sup>51</sup> SIMULA has several features, particularly the CLASS concept, which made it extremely attractive for use in this application and its applicability has been considered by several individuals at the Norwegian Computer Center.<sup>13,47,42</sup>

The earliest known example of a programming system developed expressly for simulation studies of computer systems is the Computer System Simulation (CSS)<sup>62</sup> which was utilized by IBM in three ways: “First, in the development of a programming system . . . so that proposed changes can be evaluated . . . second, in establishing a system configuration for a given workload . . . third, after a system is operational . . . to predict the effect of expected or proposed changes to the actual system.”<sup>62</sup> The CSS model consisted of (1) a description of the system, (2) description of the operating system, and (3) description of the workload. The CSS language provided a means to describe the model of the operating system so that each block in the flowchart was represented by a single statement. What was lacking was a clear picture of the concurrency present. (See Reference 39 for an application of CSS.)

The earliest known example of a simulation language developed expressly for operating systems is S3, the Systems and Software Simulator.<sup>6</sup> This system was developed under contract to the U.S. Army which was exploring alternatives to benchmarking as a system evaluation procedure for procurement purposes. (Although the review of the S3 System indicated that it would provide sufficient accuracy for this purpose, its use was not adopted because of the high cost of maintaining a data base containing up-to-date descriptions of all of the various hardware and software systems that might be proposed by suppliers. Benchmarking was retained as the most cost-effective technique that would satisfy both the vendors and the Army.) The S3 simulation language provided full capabilities to describe both the hardware and the software involved to include both user programs and the operating system. The simulator provided a “true discrete

event simulation'' utilizing a complete future events chain. The language provided statements to accurately model the logic of the software as well as statements to maintain the proper timing with respect to the hardware and the system actually being modeled. The power and usefulness of the language is best attested to by the fact that a completely validated and time-adjusted simulation of the GE 635 computer and the GECOS II operating system required *only 211 S3 statements*. (The instructional value of such a language as a descriptive tool was first appreciated by this author during his review and evaluation of the S3 contract.<sup>12</sup> S3 was used internally by Cohen Associates for verifying the performance of the operating system for an airborne computer which had extremely stringent timing requirements, e.g., proper recovery and handling of six different interrupts that could occur during one microsecond. The work on S3 obviously influenced Cohen in the development of the commercially available simulation system SAM.<sup>1</sup>

OSSL was another language developed primarily for generalized simulation studies of computer systems.<sup>10</sup> The OSSL model had three components: ''(a) The hardware characteristics and system configuration, (b) the operational philosophy of the system [the manner in which user jobs flow through the system], and (c) the environment in which the system is to function [the services that the system is called upon to perform].''<sup>10</sup> Simulation languages and systems developed expressly for operating system study do provide models with a rich content of system description. Their major weakness in application has been the cost in processor time of executing the model. An example is the GECOS II/635 model referred to above which produced validated results within five percent of actual system runs but required 10-15 times as much time even when executing on a UNIVAC 1108. The high time requirement for executing the simulator is not totally the result of using a ''high-level'' simulation language. Even for models written in assembly language ''the simulated-time/real-time ratio is much greater than one.'' <sup>46</sup>

Analytic models can provide the same degree of accuracy with execution costs much less than actual runs. Although the state-of-the-art in analytic models has progressed to very high levels of both completeness and detail (a comprehensive survey is presented by Reference 65), the description of the model, in whatever language is utilized, provides little, if any, intuitive understanding or insight into the nature of the system being modelled.<sup>64</sup>

A compromise between the two forms of modelling or simulation has resulted in the development of hybrid techniques in which both discrete event and analytic procedures are utilized.<sup>16,31,61</sup> ''In computer system models, it is convenient to partition the resources of the system into two mutually exclusive sets, denoted long-term resources and short-term resources respectively, creating a two-phase model. In a hybrid model, discrete-event simulation is used to model the first phase, which is the arrival of tasks and the allocation of long-term resources. This second phase—use of short-term resources by active tasks—is then modeled by any technique which produces an expected residency time (active time) for each active task.'' <sup>61</sup> The intuitive un-

derstanding obtainable from the ''language'' statement of a hybrid model does exceed that present in pure analytic models, but the logic of the system being simulated is still often submerged in programming details of the model.

#### *Instructional laboratory project languages*

It is not clear exactly where to place those languages developed expressly to support operating system laboratory courses. To support the general teaching objectives, they certainly should be highly descriptive in nature, but it appears that this aspect of the language has often been sacrificed for the sake of expediency in getting the laboratory exercise completed in a limited amount of time. However, this latter comment certainly does not apply to all of the work in this area. Several of these instruction-oriented systems provide very usable simulation capabilities, e.g., OASIS<sup>66,68</sup> and ITS,<sup>36,37</sup> while others provide a language intended for the actual implementation of a complete operating system or portions of a system, e.g., Concurrent Pascal<sup>4</sup> and Concurrent SP/k.<sup>23</sup>

Certainly, a primary objective of any instruction language is the transfer of information about concepts as well as implementation techniques and examples. Also, the influence of an operating system simulation language on system descriptions is quite beneficial;<sup>67</sup> however, the instructional environment must be able to accommodate student time limitations, which results in shifts in emphasis on the various capabilities of the language as contrasted to what they might be in a ''production'' environment.

#### *Design languages*

There are two examples of design languages. These are definitely multi-level, and either could *possibly* be made to span the entire spectrum of language levels being discussed here. Both of these projects date from 1972—one as academic research that was utilized for one small job and the other as a totally operational support system. The first phase in the academic project was a study of ''A Programming Language for Concurrent Processing.'' <sup>26</sup> The underlying model of this system is based on the contour model discussed earlier.<sup>27</sup> Of more interest to this paper is the follow-up work which led to the development of the Picture-System model and the PS notation which supports model development.<sup>24,25</sup> Picture-system models ''are useful in defining, communicating, and simulating computer system designs, especially in the early design stages.'' <sup>24</sup> The PS system generates the models ''from a description of a computer system as a structure of finite-state components. The PS system also does an analysis of the state-transition graph of the subject computer system which detects design problems such as deadlocks, looping, and races.'' <sup>24</sup>

The other project,<sup>18-21</sup> known as Higher Order Software (HOS), is ''a formal methodology for reliable systems specification and development.'' <sup>21</sup> A specific goal of the HOS system is to tightly control those areas causing most of the

design errors, such as interface problems, and to automate that control.

It is now possible within the framework of HOE to develop automatic tools to aid verification as well as design. For example, the interfaces of an HOS system can be exhaustively tested by an automated analyzer without program execution. This is especially significant since interface testing in a large system is known to be a very costly procedure. (73 percent of all problems found during the APOLLO integration effort were interface problems; and verification accounts for 50 percent of the total software development effort.)

Higher Order Software is software expressed in its own meta-language and conforming to a formalized set of laws. The basic components of HOS methodology are: (1) the application of the formal set of laws to the design of a given problem; (2) a meta-language adhering to these laws; (3) the automatic analysis of design interfaces by the design analyzer and the structuring executive analyzer; (4) the architectural virtual layers produced from analyzer output in the form of software, firmware or hardware, and (5) the hardware that is transparent to the user. (Our work, to date, has concentrated on the first three areas of HOS methodology.) In addition, support tools based on axiomatic consistency can enhance a given development process in such areas as: performance analysis, simulation, design automation, definition of subsystem requirements, automatic documentation and automatic management techniques.<sup>21</sup>

There have been several design approaches involving path descriptions. A large amount of it centers around the basic concepts of Petri nets. It is well known that the original work by Petri in this area remained unnoticed and unused for some time after its initial publication. The long-term value of the technique appears to be as difficult to predict as it was to recognize its immediate applicability. There is something inherently attractive about the use of graphical representation to depict parallelism, but this author has difficulty in visualizing clearly how such techniques can be integrated into a unified "vertical" information-transfer system. Activity continues in this area, and it appears quite reasonable to anticipate more progress along these lines.

### *Implementation languages*

Activity in this area has been very high, and work on the topic has been identified by the designation "machine-oriented high-level languages," "systems programming languages" as well as "operating system implementation languages." IFIP has established a technical group on Machine-Oriented Higher-Level Languages and a working conference has been held.<sup>69</sup> This working conference led to the establishment of a permanent working group, WG 2.4, under the auspices of the IFIP Technical Committee on Programming, TC 2. It is not possible to cover all of the work done in this area; however, a typical example is Reference 38. Markstein developed an operating system programming language, PSETL, which is based on SETL, a set-theoretic programming language. The extensions required for PSETL are capabilities "to allow the description of algorithms involving

interrupts, parallelism, and to some extent, machine dependent features."<sup>38</sup> Although it is stated that PSETL is "intended for operating system description," it is much more of an implementation language. The extensive examples given in the report illustrate that the program is not very "descriptive" nor very understandable without the liberal use of comments (perhaps as much as 50 percent).

A general discussion of the desired characteristics of implementation languages including specific comments on Concurrent PASCAL and MODULA is presented in Reference 28. Another derivative of PASCAL is CCNPASCAL.<sup>29</sup>

### *Multi-level language systems*

As was stated previously, there has been only a limited amount of work done in this area. A useful survey of languages for specification and design was presented in Reference 56. Language classifications that were identified and briefly discussed in that survey are state-based languages such as TOPD and DREAM, event-based languages such as path expression and flow expression systems, and relational language systems such as ISDOS and REVS. All of these systems do provide some formal linkage between the statement of the specification and the design.

An early example of a development system that extends into even the simulation level is DES. A Design and Evaluation System. "A system which integrates performance evaluation with design and implementation" is described in Reference 17. "[T]his system is based on a simple, high level language which is used to describe the evolving system at all stages of its development. The source language description is used as direct input to performance analysis and simulation routines."

A description of a complete program development methodology focused specifically on "the design, implementation, and proof of large systems, based upon a hierarchical decomposition of the system" is given in Reference 57.

## SUMMARY

A major factor contributing to the high cost of the development and use of an operating system is the lack of effective means for transferring information vertically within one operating system project and horizontally between projects. Most of the work in the past has addressed only vertical information flow. It is important that the importance of the description of operating systems and the value of horizontal transfers also be recognized and addressed by future work.

## ACKNOWLEDGMENT

The ideas expressed in this paper were developed during discussions with several individuals, among whom were E. Dijkstra, C. A. R. Hoare, Gerhard Seegmueller, and W. Wulf. As I look back on these discussions, I think I detect

a definite dichotomy of points of view—I was interested in a balanced solution considering both horizontal and vertical information transfer, whereas these individuals were focusing primarily on vertical transfer between the lower levels (e.g., Reference 63). In attempting to sort out and properly place the various concepts we discussed, I am sure that I have made errors in interpreting their comments. The responsibility for that is totally mine, as is a sincere appreciation for their help.

# The simulation language SIML/I

by M. H. MACDOUGALL

*Amdahl Corporation*  
Sunnyvale, California

## INTRODUCTION

The conceptual advantages of process-oriented simulation languages have become generally recognized. SIMULA<sup>1,4</sup> is the best known and most widely available language of this type; others include ASPOL,<sup>3,12</sup> SIMPL/I,<sup>9</sup> and SOL,<sup>10,11</sup> and processes have been retrofitted into SIMSCRIPT.<sup>14</sup> SOL was the genesis of the process view of system behavior. SIMULA is an elegant general-purpose programming language; its particularization to system simulation is nicely described by Franta.<sup>7</sup>

The process view introduced by SOL evolved more rapidly in the area of operating systems than in system simulation, with consequent influence on the development of process synchronization constructs. In SOL, processes could control their activities in accordance with the values of expressions involving global variables. In operating systems, considerations including efficiency and the need for hierarchical structures resulted in the development of more specialized constructs for process synchronization; these included events,<sup>2,5</sup> semaphores,<sup>6</sup> and monitors.<sup>8</sup> Recent simulation languages often incorporate similar constructs. Among the advantages of this approach is the extent to which similitude—the resemblance of the model to the design—can be realized in system-level models. (While it is possible that a simulation model can be a valid representation of a system in a behavioral sense and, at the same time, bear little resemblance to the system, it usually is difficult to extend such a model to represent increased detail or to reflect design changes. At the very least, a lack of similitude can hinder communication between designer and modeler.) This trend ultimately may result in the merger of simumodel and design specification, as proposed by Randell.<sup>13</sup>

The improvements such languages bring to system-level modeling, and the relative ease with which they permit expansion of the level of detail of models of software elements, may not be realized when the modeling objective is oriented more toward the hardware elements of the system. For example, ASPOL is a simulation language whose process synchronization facilities, based on entities called "events," derive from operating system constructs. It serves quite well for the development of various kinds of system-level models (perhaps its main shortcomings at this level are in the area of facility preemption and the associated process interruption and queuing). For models requiring a more detailed

representation of hardware elements (instruction pipeline simulations, bus conflict models, etc.), the operating-system-oriented event facilities are much less satisfactory. For the sake of both simplicity and similitude in such models, it often is desirable to represent important control functions essentially at the logic level. Modeling these functions with events is awkward at best; less specialized constructs are needed at this level of detail.

SIML/I is designed to provide a simulation capability which extends into the current gap between system-level and register-transfer-level simulation languages. Its process synchronization facilities are logic-oriented; they permit straightforward representation of the logical expressions involved in modeling hardware structures, as well as meeting the generally simpler needs of system models. SIML/I takes the form of an extension of PL/I, so the general programming facilities of PL/I are available to the modeler. The basic simulation constructs of SIML/I—models, processes, and signals—are described in the following sections.

## MODELS AND SUBMODELS

The procedural forms of SIML/I include model, submodel, and process descriptions, together with the procedure descriptions of PL/I. A SIML/I simulation program may comprise a single model description, or may comprise a model description together with one or more submodel descriptions. A model description begins with a MODEL declaration, which is analogous to the PL/I declaration PROCEDURE OPTIONS(MAIN), and ends with the delimiter END MODEL. Model execution is initiated by the system as directed upon completion of loading. Submodel descriptions are separately compiled components of a simulation model and constitute separate load modules. A submodel description begins with the declaration SUBMODEL, which may be accompanied by a formal parameter list, and ends with the delimiter END SUBMODEL. Execution of a submodel is initiated by a model or submodel via an INITIATE statement, which may include an actual parameter list. Once initiated, a submodel executes independently of its initiator unless their activities are explicitly coordinated. Parameters may be transmitted to submodels at the time of their initiation. Thereafter, a model and its submodels may communicate with one another only through variables and signals declared external in each description.

The bodies of model and submodel descriptions essentially are identical in form. All process descriptions appear directly in a model or submodel description; a process description may not itself contain process descriptions. Model, submodel, and process descriptions may contain PL/I procedures, but these may not contain simulation declarations or statements. Rules for the scope of names of simulation entities are similar to those defining the scope of PL/I names. Signals declared in a model or submodel description, as well as PL/I variables declared in that description, are global to all contained process descriptions. Only a single instance of execution of a model description occurs in a simulation, so only a single instance of variables and signals declared in a model description is created. Multiple instances of submodel description execution may be initiated; for each, a unique instance of the signals and variables declared in that description (except for those declared external) is created.

Once initiated, a model or submodel executes like and exists in the same states as any process. A model or submodel may initiate submodels and processes, wait for and set signals, etc. The current simulation time is maintained as the global variable TIME. A model, submodel, or process may suspend its execution for an interval T via the statement HOLD(T); it will be returned to execution at time TIME+T. Execution of a TERMINATE statement in a model terminates the simulation; execution of a TERMINATE statement in a submodel terminates only that particular instance of submodel description execution. The delimiters END MODEL and END SUBMODEL are implicit TERMINATE statements.

Submodels are important in developing large simulation models (since model components can be separately compiled), in multi-level modeling (where submodels of different levels of detail can be constructed and combined as needed for a particular simulation), and in modeling parallel systems (since multiple instances of execution of submodel descriptions can be initiated). As an example of the last, suppose a submodel of a disk subsystem is developed as part of a computer system simulation model. This submodel might represent a data channel, the controllers connected to that channel, and the devices connected to each controller. To simulate a configuration containing several similar (but not necessarily identical) disk subsystems, several instances of execution of this submodel description could be initiated.

## PROCESSES

A process description begins with the declaration PROCESS (which may have a formal parameter list) and ends with the delimiter END PROCESS. A process is a particular instance of execution of a process description; a number of such instances may simultaneously exist at any point in a simulation. A process may be initiated by the model or submodel in which it is contained, or by some other process in that model or submodel, including a process of the same description. Upon initiation, a unique set of the variables and signals declared in the process description is created. After initiation, a process executes independently of its initiator and of processes of the same or different descriptions

unless explicitly synchronized. Process execution is terminated via execution of a TERMINATE statement or the delimiter END PROCESS; upon termination, variables and signals local to the process are destroyed.

A process (or model or submodel) exists in one of four states: execute, ready, hold, or wait (queue). A process in execute or ready state is active; a process in hold or wait state is suspended. Since the simulation of a system of concurrently-executing processes is carried out sequentially, only one simulation process is in execute state at any instant; any others able to execute at that instant are in ready state. For example, when a process is initiated, it is placed in ready state; its initiator continues in execute state.

A process may suspend its execution until a signal changes state via a wait (or queue) statement, in which case it is placed in wait state. When the selected signal changes state, the process is placed in ready state (activated). A signal's change of state may activate several processes, so that a number of processes may be in ready state at any instant; these processes are placed on the ready list. When the currently-executing process suspends its execution, the process at the head of the ready list is removed and placed into execution. The ready list is ordered on the basis of priority; equal-priority entries are ordered first-in, first-out. Priority is an attribute of a process (or model or submodel) which may be changed at any time via an assignment statement of the form PRIORITY = expression. Submodels and processes inherit the priority of their initiators.

A process may suspend execution until a specified reactivation time is reached via a HOLD statement, in which case it is placed in hold state and some other process selected from the ready list and placed into execution. When a process suspends execution and the ready list is found empty, the process with the earliest-occurring reactivation time is selected from the set of processes in hold state, the simulation time TIME is advanced to that time, and the process is placed on the ready list. If several processes have the same reactivation time, all are placed on the ready list in priority order. The process at the head of the ready list then is placed in execution.

Parameters may be transmitted to a process or submodel by its initiator. Parameter transmission is uni-directional; parameters are passed by value at initiation time, and modification of a variable which is a formal parameter does not result in modification of the corresponding actual parameter. An actual parameter may be a signal local to (declared and created in) the initiator. The corresponding formal parameter is identified as a signal name by its appearance in a SIGNAL declaration in the process description of the initiated process.

## SIGNALS

Processes (and models and submodels) in SIML/I coordinate their activities via operations on signal elements. A signal element is a two-state variable which may be assigned either the value '1' ('set') or '0' ('reset') via SET or RESET statements. A process may suspend execution until a signal element S becomes set or reset via the statements

WAIT(S) or WAIT( $\neg$ S), or QUEUE(S) or QUEUE( $\neg$ S). Throughout this discussion, signal elements are, for the sake of brevity, referred to simply as signals. However, a signal actually should be viewed as a dynamic entity—a particular occurrence of a signal element's change of state; the medium should be distinguished from the message. Signal elements and their associated operations provide a general mechanism for process coordination; a signal element may represent a gate or a latch in a hardware-oriented model, or a table lock or semaphore in a software-oriented model.

Signals are defined, named, and created via SIGNAL declarations. Both simple (single) signals and sets (one-dimensional arrays) of signals may be defined, and signals may be defined in terms of logical combinations of other signals. A signal which is defined in terms of other signals is called a *derived* signal; a signal which is not defined in terms of other signals is a *basic* signal. In the declaration

```
SIGNAL A, B, C, D(6), E INITIALLY SET,
      F=A|B, G= $\neg$ B &  $\neg$ C;
```

A, B, C, D, and E are basic signals; F and G are derived signals. Basic signals are placed in the reset state when created (unless placed in the set state via an initial clause, as in the previous case of signal E). The initial state of derived signals is determined from the states of the signals on which they are defined. In the preceding declaration, F will be initially placed in the reset state and G will be placed in the set state. Only basic signals can be operated on by SET and RESET statements.

Signals declared in a model or submodel description are global to all process descriptions contained in the model or submodel description. Several instances of execution of a submodel description may be initiated; a unique set of the signals declared in that description is created for each instance (except for signals declared external). Only processes initiated directly or indirectly by a particular submodel have access to the signals created in that submodel. Signals declared in a process description are created whenever a process of that description is initiated. Local signals may be passed from one process to another as process initiation parameters. A typical application of local signals arises when one process initiates another and then suspends execution until the initiated process reaches a particular point in its execution; the initiator passes a local signal to the process being initiated and then waits for that signal to be set (or reset).

Signals are created at execution time, not at compile time. Thus, the dimension of a signal set may be determined by computations within the model, and signal creation can be made dependent on model input parameters.

## SIGNAL OPERATIONS

A simple basic signal S is set or reset by the statements SET(S) or RESET(S); this may cause a change of state of a derived signal directly or indirectly defined on the basic signal. The I<sup>th</sup> element of a basic signal set S can be set or reset by the statements SET(S(I)) or RESET(S(I)). The

statement SET(S) or SET(S,I), where S is a basic signal set, causes the set to be searched for an element in the reset state; if one is found, it is placed in the set state and, in the second form, the index of the element is assigned as the value of the variable I. (If no element is found in the reset state, the statement is ignored.) The RESET statement functions similarly.

A process may suspend execution until a basic or derived signal is set or reset via WAIT or QUEUE statements. Execution of one of these statements is called signal selection; processes suspended while waiting for a signal to change state are called selectors of that signal. Those processes which selected the signal via wait statements all are activated (placed in ready state) when the signal changes state. Of those processes which selected the signal via queue statements, only one is activated when the signal state change occurs. This one is chosen on the basis of priority; among equal priority selectors, the first to enter the queue is chosen. Signal selections may be a mixture of wait and queue selections; when the signal changes to the selected state, all waiting selectors and one queued selector are activated.

When a process executes a set or reset statement, it is placed on the ready list; any wait selectors of the signal are placed on the ready list next, followed by the queued selector (if one was activated). The next process to execute is then selected from the ready list on the basis of priority, as described earlier. If a process executes a wait statement and the selected signal already is in the specified state, it continues in execution. If it executes a queue statement and the selected signal already is in the specified state, it continues in execution only if there are no higher-priority processes queued on that state of the signal; otherwise, it is suspended and enqueued.

A process may select the I<sup>th</sup> element of a basic or derived signal set S by selection statements such as WAIT(S(I)) or QUEUE( $\neg$ S(I)); such signal set element selections are processed identically to simple signal selections. It is also possible to select the set itself. Associated with each signal set is a signal of the same name representing the state of the set; by definition, the state of a set is the logical sum of the states of its elements. Thus,

$$S=S(1)|S(2)|\dots|S(n)$$

and

$$\neg S=\neg S(1)\&\neg S(2)\&\dots\&\neg S(n)$$

For a signal set S, the statement WAIT(S) causes a selector to be suspended until some element of S becomes set; the statement WAIT( $\neg$ S) causes a selector to be suspended until all elements of S are reset. Queue selections function similarly. Selection statements of the form WAIT(S,I) can be used to obtain the index of the element whose state change caused the selector to be returned to execution.

## SIGNAL EXPRESSIONS

A derived signal definition defines a signal (simple, set, or set element) in terms of a signal expression. The signals

in this expression may themselves be derived, so signals of arbitrary complexity may be constructed. Signal expressions take the logical sum-of-products form; parenthetical sub-expressions are not permitted, and operators are restricted to '&' ('and') and '|' ('or'). This choice of signal expression form was based on two considerations; representational efficiency and simulation efficiency. The applications of SIML/I in hardware-oriented modeling often include control mechanisms, but rarely go beyond that. For example, it may be desired to model the ingating to an adder, but simulation of the adder itself is not likely to be required. A study of control logic in various systems of interest indicated that the need for parenthetical sub-expressions and other operators (even exclusive or) arose infrequently. Restricting signal expressions to the sum-of-products form greatly expedited SIML/I implementation and permitted a very efficient structure for propogating signal state changes.

A derived signal is called a sink signal, and the signals on which it is defined are called source signals. Both sink and source signals may be either simple signals or signal sets: the various combinations govern the mapping between source and sink. Some examples of source/sink mappings are diagrammed in Figure 1; these diagrams show the mappings resulting from the following signal declarations:

SIGNAL A,B,C(2),D(3);

(a) SIGNAL W(3): W(1)=A, W(2)=C(1), W(3)=D(1);

(b) SIGNAL X=D|B&C;

(c) SIGNAL Y(3)=C&D;

When the sink signal is a single element (either a simple signal or a signal set element) and a source signal also is a single element, sink and source signals are directly mapped, as shown in Figure 1a. When the sink signal is a single

element and a source signal is a set, the source signal (by definition) is taken to be the signal representing the set, and the mapping illustrated in Figure 1b results. When sink and source signals both are sets, they are mapped element-by-element up to the dimension of each set, as shown in Figure 1c. When the sink signal is a set and the source signal is a single element, the latter is mapped to each element of the set.

Sink/source mappings for single elements are determined by the axioms of logical arithmetic. Mappings involving sets were, to some extent, chosen on consideration of the functions needed to simply construct hardware, firmware, and software control structures for various systems. One missing capability which appears desirable is source signal set concatenation (currently, this can be effected only by writing a term-by-term definition for the sink signal).

APPLICATIONS

While the signal facilities of SIML/I were designed to extend system simulation capabilities nearer to the hardware realm, they provide a general means of process coordination, and support models over a range of levels of abstraction. In current applications, signal representations range from logic gates to complete CPUs. The following declarations represent the control logic shown in Figure 2.

SIGNAL TR\_ENABLE

=ENABLE&RTR|ENABLE&WTR|ENABLE&HTR;

SIGNAL TR\_GATE=TR\_ENABLE&CLOCK;

Figure 3 shows a block diagram of a queueing network model of a computer system; a SIML/I simulation program

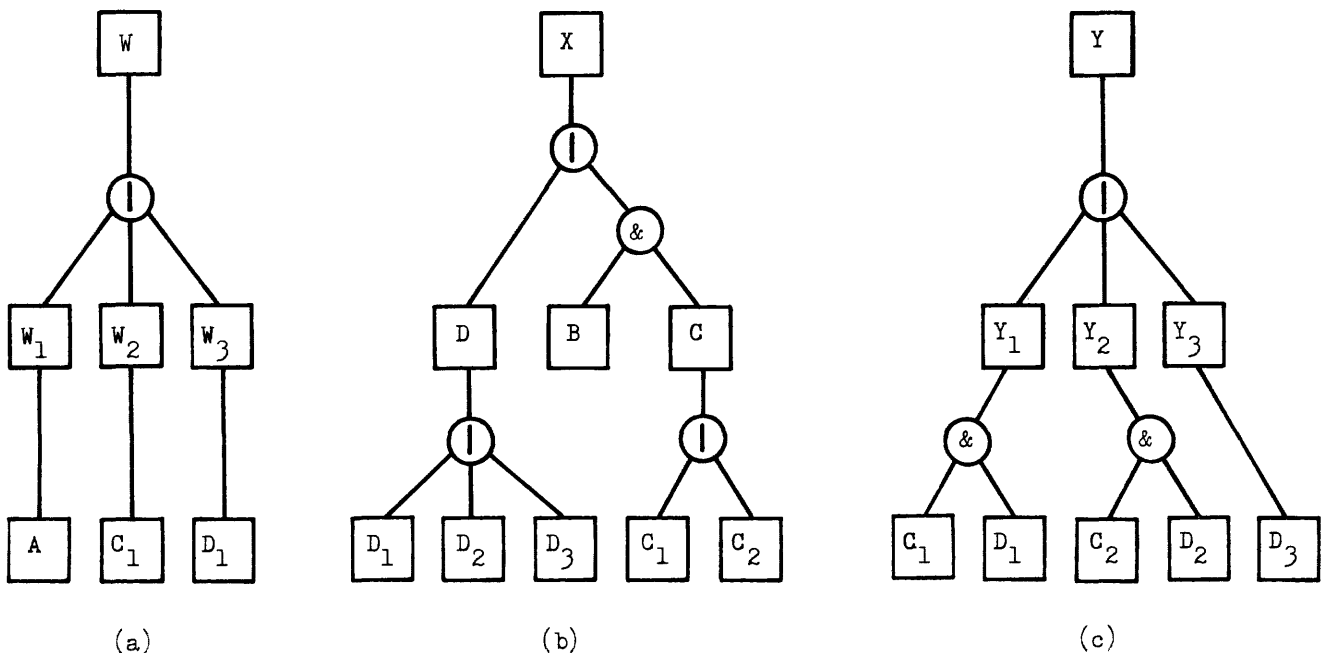

Figure 1—Sink/source signal mapping examples.

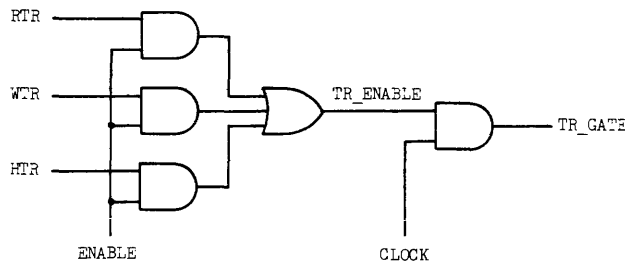

Figure 2—Control logic modeling with signals.

for this network is as follows:

```

MODEL QNM;
  SIGNAL CPU(2) INITIALLY SET, IO(8) INITIALLY
  SET;
  DO I=1,32;
    INITIATE JOB;
  END;
  HOLD(5000.);
  TERMINATE;
  PROCESS JOB;
  DO WHILE(TIME<5000.);
    QUEUE(CPU,I); RESET(CPU(I));
    HOLD(1.);
    SET(CPU(I));
    J=IRANDOM(1.8);
    QUEUE(IO(J)); RESET(IO(J));
    HOLD(EXPNTL(5.));
    SET(IO(J));
  END;
  END PROCESS JOB;
END MODEL QNM;

```

In the foregoing example, there are 32 jobs circulating in the

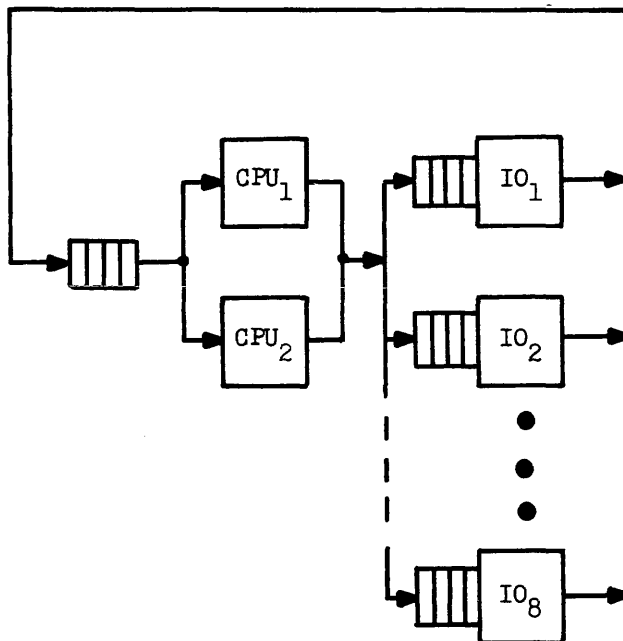

Figure 3—Queuing network model.

system. Job CPU times are constant and equal to one time unit, while I/O service times are exponentially distributed with a mean of 5 time units. When a job completes CPU service, it selects an I/O device and queues for it; when it completes I/O service, it queues for the set of CPUs. The set state of the CPU and I/O signals in this model corresponds to the nonbusy state.

Signal definitions are used to vary the level of detail of model components. The declarations below illustrate a signal defined at three different levels of detail.

- (1) SIGNAL INTERRUPT;
- (2) SIGNAL IO, FAULT, CHECK, TIMER;  
SIGNAL  
INTERRUPT=IO|FAULT|CHECK|TIMER;
- (3) SIGNAL END\_RD(8), END\_WR(8),  
RD\_FAULT, WR\_FAULT;  
SIGNAL IO=END\_RD|END\_WR,  
FAULT=RD\_FAULT|WR\_FAULT;  
SIGNAL CHECK, TIMER;  
SIGNAL  
INTERRUPT=IO|FAULT|CHECK|TIMER;

Definition expansions of this form provide part of the mechanism for the vertical communication between components of different levels of detail in a multi-level model.

As an incidental note, SIML/I does not use the PL/I multi-tasking and event facilities for process and signal control: these functions are performed by the SIML/I run-time system.

## ACKNOWLEDGMENTS

The author would like to acknowledge the fine work of Carol Realini and Allan Rhodes in developing the SIML/I language processor, and of Scott Spadafore in developing the interface between the SIML/I and PL/I run-time systems.

# Mix-dependent job scheduling— An application of hybrid simulation

by STEVE TOLOPKA and HERB SCHWETMAN

Purdue University  
West Lafayette, Indiana

## JOB SCHEDULING

In a computer system, scheduling occurs whenever the next-task-to-receive-service is selected from a queue of waiting tasks.<sup>5</sup> This paper considers the scheduling of jobs which will become active; that is, which will begin to compete for use of the system processors. Jobs waiting to be activated may be scheduled by referring to properties of the job such as priority or total resource usage.<sup>4,7</sup> It is also possible to examine some feature of the jobs already activated (i.e., the jobs in the multiprogramming mix) in order to determine a suitable candidate for admission to the mix. This is called mix-dependent scheduling. Here, we prefer to examine some intrinsic property of the jobs rather than an external one. The property we have chosen to investigate is the rate of processor (CPU or I/O) usage.

In order to quantify what we mean by rate of processor usage, we define a *CPU usage index*,  $K$ , for each job as

$$K = \frac{C_t}{C_t + I_t} * 6 + 1$$

where

$C_t$  = CPU time used by the job, and

$I_t$  = I/O time used by the job.

Notice that  $K$  ranges between 1 and 7, with the lower value denoting a totally I/O-bound job, and the upper value denoting a totally CPU-bound job. The scaling for  $K$  is arbitrary; the range 1 to 7 was chosen because our operating system at Purdue uses a similar index.

Assuming that this usage index is computed for each job (active or waiting) in a system, it is then necessary to devise scheduling algorithms which utilize this index and to evaluate the effects. The classical approach is to admit equal numbers of CPU- and I/O-bound jobs in the hope that all resources in the system will be fully utilized. However, other algorithms can be devised which may show better performance. The goal of this paper is to use a system model to evaluate job schedulers and to verify the merits of mix-dependent scheduling algorithms.

## HYBRID MODEL

An experimental technique is used in this study. A realistic system model is constructed so that different job scheduling strategies can be evaluated. Figure 1 is a schematic of this model. As can be seen, there is a queue for arriving jobs which are waiting to enter the active phase. The active phase consists of the processors (CPU and I/O) which are required by each job. As is typical in real systems, the number of available positions for jobs in the active phase is limited. Thus, the job scheduler is responsible for filling empty positions as they occur. For purposes of simplification, the number of positions (also called the maximum level of multiprogramming) is eight. Also, memory constraints are omitted, since the emphasis of these tests is to evaluate scheduling techniques for improving processor usage, not memory scheduling. In the model, every job arrives with a class designator and the amount of processing it will require. As previously indicated, an arriving job joins a queue of jobs waiting to be scheduled. There can be a separate queue for each class. The job scheduler, using one of several selectable strategies, then activates jobs as positions in the mix of active jobs become available.

A hybrid simulation technique has been developed which appears to satisfy the needs of this study. While the technique has been described in detail before,<sup>8,6</sup> it is briefly presented here.

In a hybrid model, discrete-event simulation models the arrival of jobs and job scheduling. Then an analytic modeling technique is used to estimate the processing time for each job in the active phase. The current experiment uses the central server model<sup>2,3</sup> to model resource consumption by jobs in the active phase. This part of the model consists of a CPU station and three disk stations, as shown in Figure 2. There are three classes of jobs in the system:  $P_i(r)$  represents the probability that a class  $r$  job leaving the CPU will go next to station  $i$ . The mean service times,  $S_i$ , at all devices are the same for all job classes, and the queueing discipline is FCFS. Table I displays the parameters of the model.

A *cycle* through this network begins when a job first enters the CPU queue and ends after it has passed through one of the disk stations and reappeared at the CPU queue.

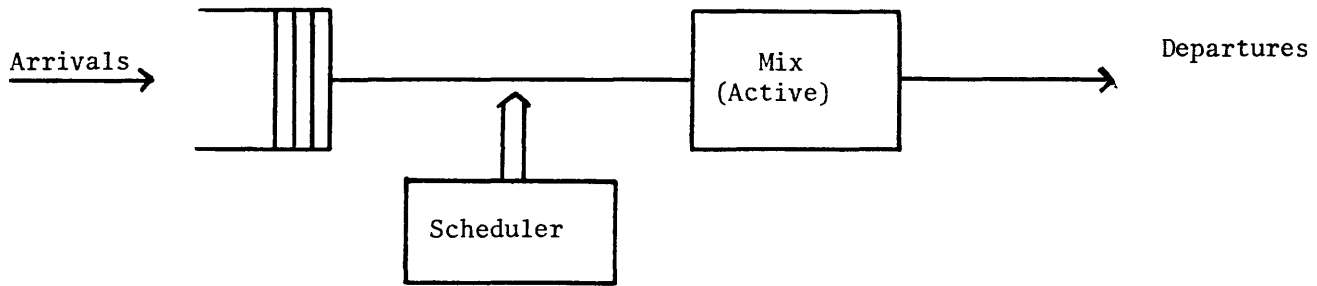

Figure 1—Schematic of system model.

Notice that a job will make one or more trips through the CPU station, and one trip through a disk station per cycle. The central server model can be solved to obtain the mean job waiting times at each device. These waiting times, together with the branching probabilities for each job, can be used to calculate the mean cycle times for each job.

In the system model, as a job joins the mix of active jobs, a new configuration of active jobs is created. The mean cycle times and the number of cycles remaining are multiplied to produce estimated completion times for each active job. If no other jobs are added to the mix, then simulated time can be advanced to the minimum of these times. In this case, the job with the shortest remaining time departs, the cycles remaining for each job are updated and the process is repeated. If another job is added to the mix before the shortest departs, then the cycles remaining for each active job are updated, the new job is added, and processing continues as just described.

This hybrid simulation has been shown to produce models which are as accurate as equivalent simulation-only models while reducing CPU processing time requirements by factors of up to 200 in some test cases.<sup>8</sup> A key feature of this model is that as more jobs are added to the mix, the time to complete each job may increase. Furthermore, the type of load imposed by jobs in each class depends on the resource usage patterns of the job. For example, a CPU-bound job can have a large impact on the active time of another CPU-

bound job, but perhaps a negligible impact on the active time of an I/O-bound job. This type of behavior coincides with commonly held views of the behavior of actual systems.

JOB CLASSES

As indicated in an earlier section, the CPU usage index,  $K$ , is a guide to the proportion of CPU time a job uses per cycle. The system model was parameterized so as to allow for three classes of jobs, with Class 1 representing I/O-bound jobs, Class 2 "balanced" jobs, and Class 3 CPU-bound jobs. This was done by adjusting the probabilities of returning to the CPU ( $P_1(r)$ ) for each class to obtain the desired behavior. Since the expected number of trips that a class  $r$  job will make through the CPU before moving to a disk is  $1/(1-P_1(r))$ , we can easily calculate the mean CPU time per cycle, and so can compute a CPU usage index,  $K$ , for each class of jobs. (See Table II.) The resulting mixture of jobs have CPU usage indices corresponding to jobs of the required types.

To help eliminate bias caused by long and short jobs, the number of cycles that a job of each class would have to complete was chosen so that the total processing time of each job was approximately constant (Table III). Prior to using the system model, the central server model was solved<sup>1</sup> for all possible triples  $(n_1, n_2, n_3)$ , where  $n_i$  represents the number of class  $i$  jobs in the system and  $n_1 + n_2 + n_3 \leq 8$  (since the level of multiprogramming will not exceed 8). There are 165 such triples for the current model. These solutions yielded the necessary mean job cycle times.

In order to evaluate the accuracy of the hybrid model, a discrete event simulation of the system model was written. Both the hybrid model and the discrete event simulation were executed using the same set of 100 jobs, equally distributed among the three classes. The mean job interarrival

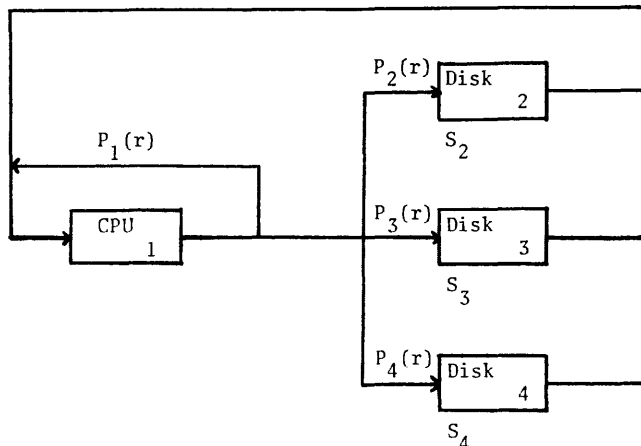

Figure 2—Central server model.

TABLE I.—Central Server Parameters

	i	S <sub>i</sub>	P <sub>i</sub> (r)		
			r=1	r=2	r=3

Disk	4	.100	.166	.034	.006

TABLE II.—CPU Usage Indices

r	CPU trips	CPU time per cycle	I/O time per cycle	K
1	2	.020	.100	2
2	10	.100	.100	4
3	50	.500	.100	6

time was 0.0 seconds; i.e., all jobs were in the queue at the start of the experiment. The level of multiprogramming was limited to eight, although no other memory constraints were imposed. The results of the two runs are compared in Table IV. Utilizations differed by at most seven percent while elapsed time and response time (whose corroboration is notoriously difficult<sup>9</sup>) disagree by only 2.5 percent. The hybrid model reduced the CPU time needed to run the model by a factor of 50, with very little (if any) resulting loss in accuracy. While these exact figures are certainly dependent upon the model parameters, other studies<sup>8</sup> have also shown that the hybrid technique works well for similar models. Thus, for a reasonable range of parameters, the hybrid model seems to provide an accurate, inexpensive way to evaluate scheduling strategies.

MIX-DEPENDENT SCHEDULING

The initial series of tests used a version of the system model with the same set of 100 jobs, all of which were present at the beginning of each test. The number of processing cycles for each job was uniformly distributed over the ranges for each class, as shown in Table V. As discussed in the previous section, these ranges yield processing times which are approximately equal for all jobs. The actual set of 100 jobs generated for each test has the properties shown in Table VI.

The basic thrust of the tests was to examine different techniques for selecting collections of jobs to be simultaneously active. The schemes that were evaluated were all variations of the following general strategies:

1. Schedule jobs from one class prior to scheduling jobs from another class (designated class-first-strategies).
2. Schedule jobs from all classes subject to class constraints (class-constrained-strategies).
3. Schedule jobs without regard for classes (ignore-class-strategies).

Within each of these general strategies there were many possible variations. For example, in the class-first-strate-

TABLE III.—Mean Processing Time Per Job

r	Cycles per job	Proc. time per cycle	Proc. time per job
1	100	.120	12.0
2	60	.200	12.0
3	20	.600	12.0

TABLE IV.—Comparing Simulation and Hybrid Models

	Hybrid	D. E. Simulation
Elapsed Time	673 sec	659 sec
Proc. time per job	11.865	11.839
Active time per job	52.466	51.284
Response time per job	298.735	297.887
Utilization		
CPU	88.9%	88.4%
Disk 1	29.1	29.4
Disk 2	29.1	31.2
Disk 3	29.1	30.5
CPU time required to run the model	1.6 sec	89.2 sec

gies, the order in which the job classes were processed could be varied. In the class-constrained-strategies, both the order of classes and the class constraints were changed.

In these tests, a strategy was judged primarily on the total elapsed time required to process the 100 test jobs—the shorter this time, the better the strategy. The elapsed times are reported without confidence intervals because the different strategies are all being evaluated on the same set of jobs. Once the set of jobs and the scheduling strategy have been chosen, the simulation is totally deterministic. Hence, the elapsed time gives us a fair comparison of the relative merits of the various scheduling strategies.

Class-first-scheduling

In class-first-scheduling, all jobs from one class are started; then as positions become available, jobs from another class are started; finally jobs from the remaining class are started. A major consequence of this strategy is that several jobs from the same class tend to be active at the same time. As will be seen, this turns out to be the worst possible configuration of active jobs.

Two tests were made with this strategy; in one, the classes were processed in the order 1,2,3; in the other, the order 3,2,1 was used. Table VII summarizes the results of these two tests.

Class-constrained-scheduling

The unbalanced scheduling should be compared with a balanced approach to see if improvements are obtainable. In a balanced strategy, the scheduler attempts to keep approximately the same number of I/O-bound and CPU-bound

	0,8,0	22.6
	8,0,0	20.2
Cyclic	3,3,2	52.3
	0,0,8	18.4
	0,4,4	16.8

jobs active. The simplest such strategy starts up jobs in a cyclic order. The results obtained using cyclic scheduling are shown in Table VIII.

Another approach to balanced scheduling is based on selecting a desirable job configuration  $(n_1, n_2, n_3)$  and then causing the scheduler to attempt to keep the current configuration  $(m_1, m_2, m_3)$  as "close" to this desired configuration as possible. This strategy was implemented by calculating the vector distance between the  $(m_1, m_2, m_3)$  obtained by tentatively adding one job to each class in succession and then selecting as the new configuration the one which was the minimum distance from  $(n_1, n_2, n_3)$ . The results of using this strategy for several different desired configurations are summarized in Table IX. In this test, the order in which jobs were considered had almost no effect on the results; hence, these cases are not included in Table IX.

While we know of no efficient technique for obtaining an optimal schedule for our model, we can point out that CPU utilizations seen in these tests were over 99 percent. This observation leads us to believe that 600 seconds is about the minimal elapsed time which can be achieved. In Table IX, it can be seen that those desired configurations having approximately equal numbers of I/O-bound and CPU-bound jobs produce near optimal results.

In trying to understand why these "balanced" configurations exhibit good performance, we can look at two additional kinds of information. One output of the model is the mean active time per job in each class. Another output is the percent of time the system was in each possible job configuration. Tables X and XI summarize these items for a 'good' schedule and a 'bad' schedule.

These data suggest that when a class is 'overloaded,' the jobs tend to interfere with each other to the point that the entire schedule can be significantly lengthened.

### Ignore classes

There are scheduling strategies based on job attributes other than processor usage which can be used. Four such strategies were evaluated as part of this test. In these tests, the length of a job is estimated by the processing time requirement (the expected cycle time with one job of the specified class active multiplied by the number of processing cycles required). The results obtained using these ignore-class strategies are summarized in Table XII.

Notice that the random and first-come, first-served strategies actually perform at a near-optimal level. We speculate that this is because of the test configuration in which the jobs are all about the same length and are equally distributed over the three classes. In this case, any strategy which tends

TABLE XII.—Ignore-Class Strategies

Strategy	Elapsed Time
Shortest job first	608.9 seconds
Longest job first	608.2
First-come, first-served	599.4
Random	600.5

TABLE XIII.—Results for 200 Jobs

	Elapsed Time
Class-first	1168.6 seconds
Cyclic	944.4
Shortest Job First	1046.9
Longest Job First	1040.9
First-come, First-served	969.4
Random	973.4

to schedule jobs from all classes simultaneously should do well. A final test used a different set of 200 jobs in the ratio of three Class 1 jobs to two Class 2 jobs to one Class 3 job. The best (cyclic) and the worst (class first) strategies as well as the four ignore-class strategies were used to verify conclusions reached in earlier tests. Table XIII summarizes these results.

## SUMMARY

Mix-dependent job scheduling has been proposed as a technique which can improve system performance. The hybrid simulation model has been used to evaluate a large number of scheduling strategies based on this technique. These tests showed that such scheduling can lead to near-optimal as well as very bad system performance. The variation between good and bad exceeded 10 percent in the test cases. These strategies all used a processor usage index to partition the jobs into classes. When the scheduler kept the number of I/O-bound and CPU-bound jobs approximately balanced, mix-dependent scheduling produced near-optimal schedules. When jobs from one class predominated, they seemed to interfere with each other, causing each job to be active for an excessively long interval, lengthening the entire schedule.

The results obtained so far are all based on the system model. A natural question is whether these results can be extended to actual computer systems. In systems, the collection of jobs is dynamic, rather than static as in the model. In the course of this project, we did use dynamic job arrivals, but saw no appreciable differences in the results. A more

fundamental question involves the accuracy of the hybrid system model—Does it accurately portray the behavior of an actual system? Some preliminary work at Purdue University<sup>9</sup> has shown that at the level of job completion times, the performance predicted by the hybrid model is within 10-15 percent of the actual system performance.

Future work for the project includes implementing some mix-dependent schedulers on an actual system to verify the performance predictions of the hybrid model. Use of the hybrid model has been crucial to the work to date, because the low operating costs allowed us to evaluate several (in excess of 20) strategies. The results for balanced class-constrained schedules and cyclic schedules suggest that near-optimal performance can be achieved. This type of job scheduling should probably be viewed as "icing on the cake." In other words, after other scheduling goals are being met, then mix-dependent scheduling can be used to improve performance a little more. However, care must be used, as some mix-dependent strategies can degrade performance significantly.

# Parametric instabilities in computer system performance prediction\*

by LAWRENCE W. DOWDY and ASHOK K. AGRAWALA

*University of Maryland*  
College Park, Maryland

## PROBLEM OVERVIEW

A typical computer system undergoes continual "upgrading." Unfortunately, this "upgrading" is not always synonymous with system improvement. For example, allowing more users to simultaneously access the system (i.e., increasing the degree of multiprogramming) increases the utilization and throughput of the computer system. However, extra system overhead (e.g., swapping) is required to properly manage the extra load. In some cases,<sup>4</sup> this overhead offsets the potential throughput improvement. Because interactions between the components of a modern computer system are so complex, there is a critical need for system models which accurately predict performance.

Consider a proposed alteration to a computer system (e.g., adding a new disc storage unit). Current predictive models of computer systems are typically constructed using the following scenario.<sup>3</sup> First, a model is constructed of the current system. Second, this model is subjected to numerous tests, and the model results are compared against the observed results obtained from the current system. If the two results are in good agreement, the model is termed "validated." Third, certain parameters of the validated model are altered to represent the proposed alteration to the real system. All unaltered parameters are typically assumed to remain constant. Fourthly, this altered (predictive) model is then subjected to tests. The test results predict what the performance of the real system would be if the proposed alteration were implemented.

This paper presents results found by applying the above scenario to a particular system, the University of Maryland Computer Center's Univac 1100/42. The results concerning the first and second scenario steps have been excellent. Models were constructed which can accurately describe the current system's behavior. However, results from applying the third and fourth scenario steps have been very disappointing. When a system change is made, the predicted

performance has, in many instances, been in error. Upon closer analysis of these instances, the scenario assumption that all unaltered parameters remain constant is found to be false.

## MODEL CONSTRUCTION

Three separate models (Models 1, 2, and 3) reflecting three successive configurations of the same basic system are constructed. The initial modeling effort is to construct a model of the Univac 1100/41 (Model 1) which consists of a single processor. Based upon this effort, performance is predicted when another processor (1100/42) is added. Our secondary modeling effort is to construct a model of the 1100/42 (Model 2) and predict performance when the system is upgraded by adding a new drum and new disc units (Model 3). The results between the predicted and actual performance, when the proposed changes are configured, are compared and analyzed.

Model 1 of the 1100/41 is the classical central server model.<sup>1</sup> The topology configuration is given in Figure 1. The assumptions of the model are 1) a fixed degree of multiprogramming (DMP), 2) exponentially distributed holding times at each queuing station,  $i$ , with parameter  $\mu(i)$ , 3) fixed branching probabilities,  $p(i)$ , which reflect the stationary probability of requiring channel service from channel  $i$ , given that some channel service is needed, and 4) first-come-first-serve and processor sharing queuing disciplines for the channel devices and the CPU, respectively. The validation criterion for the model is the utilization of all devices.

Model 2 of the 1100/42 is identical to Model 1 of the 1100/41 with the exception of the central server (CPU) complex. The 1100/41 CPU complex in Figure 1 is replaced by the CPU complex of Figure 2. Because both CPU servers are identical, they share identical service rates. The complex is modeled as a single, load-dependent server with service rate  $\mu(\text{CPU})$  when one customer is at the complex and  $2\mu(\text{CPU})$  when two or more customers are at the complex.

Model 3 of the updated 1100/42, with additional channels for a new disc subsystem and a new drum, is illustrated in Figure 3. The assumptions for all three models are identical and are as specified in the description of the 1100/41 model.

## PARAMETERIZATION

Employing this level of queuing network modeling, the utilization of any device can be specified as a function of four parameters: the number of devices, the  $\mu$ s, the  $p$ s and the DMP. The number of devices is set by the model topology (eight for the first two models—Figure 1; ten for the third model—Figure 3). The other three parameters are calculated using the Univac Software Instrumentation Package, SIP.

The  $\mu$ s, the service rates, are calculated as follows. The basic work unit (job, customer, request, run) is called a transaction. SIP records the number of transactions that each channel services in a unit of time, typically one hour. Dividing this number by the active time of the channel (also collected by SIP) yields an estimate of the channel service rate. Since it is assumed by the topology that all transactions flow through the CPU complex, the service rate of the CPU is computed by dividing the total number of transfers by the CPU's active time.

The  $p$ s, the branching probabilities, are similarly calculated. The number of transfers serviced by channel  $i$  divided by the total number of transactions serviced by all channels is taken as  $p(i)$ .

The degree of multiprogramming, DMP, cannot be calculated directly from SIP. SIP does record the average number of jobs in core memory. However, this number is an unpredictable overestimate of the DMP. Jobs may be resident in core which are waiting for activity from devices not explicitly modeled (e.g., interactive terminals). This violates a model assumption that all jobs must be either executing at, or queued for, a modeled device. The average number of jobs in core, as will become evident later, is not an accurate estimate for the DMP, and alternate methods become necessary for determining the DMP.

## EXPERIMENTAL RESULTS

Once all the model parameters are obtained, standard queuing theoretical solution techniques are applied.<sup>2</sup> These techniques assume that DMP is integral. The SIP estimated DMP (based upon the number of jobs in core) is an average and is typically non-integral. Algorithms exist<sup>5</sup> which allow non-integral values of DMP, but at the expense of disallowing load dependent servers in the network. The topology assumed in Figure 1 is not disallowed, but the models in Figures 2 and 3 are disallowed. In this case, interpolation around integral valued degrees of multiprogramming is performed.

As an example, the parameters for the 1100/41 model (Figure 1) based upon a typical hour of SIP data are summarized in Table I. (The  $\mu$ s are measured in transactions per second.)

Using the parametric values of Table I, the modeled device utilizations are compared against the SIP observed utilizations. Table II presents the comparison results. Comparing SIP utilizations with the model-derived utilizations using the SIP estimated DMP (13.4), the error involved in

TABLE I.—Typical 1100/41 Parametric Measurement

Number of devices = 8	
SIP estimated DMP= 13.4	
u(0) = 27.00	p(0) = .247
u(1) = 40.42	p(1) = .452
u(2) = 50.10	p(2) = .005
u(3) = 600.88	p(3) = .057
u(4) = 1730.12	p(4) = .080
u(5) = 10.20	p(5) = .014
u(6) = 33.71	p(6) = .145
u(CPU) 68.17	

each component is about seven percent. However, it is noticed that all predicted utilizations are overestimates, indicating that DMP is incorrectly calculated. Changing the DMP to 7.5 produces a model which correctly matches the utilizations of all devices within 0.3 percent. The value, 7.5, is termed the effective DMP and is found by calibration,<sup>6</sup> by allowing the DMP to vary to a point where a modeled parameter (e.g., CPU throughput) matches the observed parameter. The effective DMP was verified by independent techniques to be the actual multiprogramming level. The system was randomly halted and the number of jobs in execution was noted. This number is less than the SIP reported number of runs in core memory because of the problems mentioned in the third section.

The three models were tested on 37 separate time periods, and the model utilizations matched the observed utilizations within one percent in all cases on all devices when the effective DMP was used. The implication is that observed performance can be accurately modeled for any given time period, provided the correct parameters are supplied. It is further indicated that the assumptions (e.g., exponentially-distributed service times) do not seriously affect the model.

We now consider the prediction of the 1100/42 performance based upon the 1100/41 Model 1, and the prediction of the upgraded 1100/42 performance based upon the 1100/42 Model 2 without the new devices. We have already established the fact that in all the various models, the actual SIP measured performance is very accurately predicted by the models, if the correct parameters are provided. It is theoretically possible to have models with differing, but offsetting, parametric values which yield a similar performance measure, such as CPU throughput. However, it is our ex-

perience that parametric prediction errors do not offset each other, but compound performance prediction errors. Therefore, it suffices to present the results only for the parametric prediction.

Table III gives the results of predicting the 1100/42 parameters from 1100/41 observed data. The parameters used for the prediction were averages from several hours of observed data of the 1100/41. All parameters were assumed to remain the same, except for the service rate of CPU 1 which was predicted to equal the service rate of CPU 0. The actual parameters are likewise averages from several hours of observed data of the 1100/42.

Table IV gives the corresponding results of predicting the parameters of the 1100/42 with the new drum and disc units (Model 3) from the observed data of the 1100/42 without the new units (Model 2). The parameters are predicted to be

identical to those observed in Model 2 (Table III, Column 3) with the following additions. The predicted service rate of the new drum is set equal to the observed service rate of the existing drum unit. The predicted service rate for the new disc channel is 76.92 transfers per second. This value is based upon the hardware specifications for the new disc units and upon the predicted number of words per transfer. The number of words per transfer is predicted to be identical to that observed from the existing disc units. The motivation behind acquiring the new drum and the new disc systems is to lighten the loads on channels 1 and 0, respectively. Therefore, the existing load placed on the drum is predicted to be evenly divided between the two drums in the new system,

Figure 5—P(3) hourly variability.

i.e.,  $p(1)$  is predicted to equal  $p(7)$  where the sum of  $p(1)$  and  $p(7)$  in Model 3 equals the observed  $p(1)$  in Model 2. Likewise for the disc systems,  $p(0)$  is predicted to equal  $p(8)$  where the sum of  $p(0)$  and  $p(8)$  in Model 3 equals the observed  $p(0)$  in Model 2.

To investigate the source of the poor results of predicting the model parameters (Tables III and IV), we analyze the degree of parametric change observed on an hour-by-hour basis for the three system models. Figures 4 to 7 give the SIP observed results for four of the parameters. The remaining parameters possess similar results.

### CONCLUSIONS AND IMPLICATIONS

We have been successful in constructing accurate models of specific computer systems. Given the correct model parameters, the system performance from the model closely matches the actual system observed performance. However, the major application of system modeling is the prediction of performance when the system configuration is altered. The prediction results presented are disappointing but useful. We have been unable to satisfactorily predict system performance even on an hour-by-hour basis, where parameters from one hour are used to predict performance of the following hour. Using larger time intervals for prediction yields poorer results. The major problem is traced to para-

Figure 6— $\mu(6)$  hourly variability.

Figure 7— $\mu(\text{CPU0})$  hourly variability.

metric instabilities. As evidenced by Figures 4-7, parametric variations of 20 to 30 percent on an hourly basis are not uncommon. The usefulness of these results is to alert system analysts to these instabilities, even when the model structure is correct.

The model parameters are a function of the total demands placed on the system resources. Clearly these demands in-

clude both the user processing requests and the system overhead activities. In addition, the parametric values depend upon the device hardware characteristics. The interactions between the user demands, overhead activities and device characteristics must be considered in developing useful system models. The results presented in this paper represent some of our initial findings from applying traditional modeling techniques to real systems.

# Aids to the development of network simulators

by IMRICH CHLAMTAC and W. R. FRANTA

University of Minnesota  
Minneapolis, Minnesota

## INTRODUCTION

In this paper we describe the features of a program designed to simulate computer networks. The networks are assumed to consist of hosts attached to one or more network nodes (communication units) which in turn communicate with one another via one or more communication channels. The program accounts for user-host, host-node, node-node, node-host, and host-user protocols, as well as network topology and hardware characteristics. As reported in a later section, the program has been primarily used to conduct simulations to ascertain the performance (in terms of message or packet throughput and delay) for a variety of node-node channel access protocols, for nodes connected to a single common communication medium (e.g. a multi-drop cable or radio channel). It is, however, possible to accommodate networks in which nodes may be connected to several separate communication channels. Further, it is possible to simulate the behavior of store-end-forward networks as they can be viewed as a network in which the nodes are connected to multiple communication links. For either class of network the program can be used to verify protocol correctness or to assess network performance.

## MODEL PROGRAM FEATURES

The model program is designed (layered) to account for interactions at the user-host, host-node, node-node interface levels. The model program is constructed in a highly modular manner, so that alterations at one interaction level can easily be made without affecting the other layers. That is, the program is designed to accommodate alterations for the inclusion of additional or altered features. The program was developed along modular lines so as to make it more receptive to the inclusion of new protocols, buffering strategies, etc. Its basic organization accommodates the following characteristics.

*Host-User Characteristics*—Including message inter-generation and length modules, specification of the node or nodes to which a host is attached, and modules to handle the host-node message transfer mechanisms, including considerations of available buffer storage in both the host and node, and message addressing.

*Node-Characteristics*—Including queues and buffers for outgoing messages and message reassembly (from packets), buffers for retransmission of packets (messages) and acknowledgments.

- Additionally, node modules characterize the channel access protocol, i.e., node-node interactions (discussed later) and node-host interfaces including message addressing and reassembly issues. Finally, modules are included to accommodate channel-error characteristics (due to noise) and error-handling procedures (for errors resulting from noise or message collision, as applicable).

*Measures*—The model program modules currently collect data to provide estimates, where applicable, on:

1. Channel throughput.
2. Average node dependent transmission delays (message or packet).
3. The total offered channel traffic.
4. The expected length of the various node queues.
5. The number of doubly-received packets (messages).
6. The number of packet collisions.
7. Graphs for delay/throughput and delay/offered traffic.

Additionally, the modules will produce a full trace for each message that enters the network, from which additional information can be abstracted.

## NODE-NODE CHANNEL ACCESS PROTOCOLS

We have stated that, on the one hand, the model program is constructed in a highly modular fashion to mitigate the process of altering one or more levels of protocol. We have, on the other hand, also attempted to make the extant modules general so that changes can be accomplished by varying module parameters rather than module structure. It is possible, for example, to characterize seemingly unrelated channel access protocols via *scheduling functions* and the notion of *node-groupings*, and to capture the essence of network topology in the *connectivity* or *distance-control* matrix.

Figure 1a—Sample network, where H=host: N=node: The set of *host+communication subnetwork=computer communication network* solid lines between a pair of nodes implies they are within range and in LOS of each other. Subscripts identify the corresponding node sites.

To explain these notions we must imagine the  $K$  nodes to be mapped by a grouping function  $g(i)$ , into  $m$ ,  $1 \leq m \leq k$ , groups such that each node with index- $i$  is a member of one and only one group. For purposes of scheduling transmission times a node assumes the group identity, i.e., its identifier becomes the index of the group of which it is a member. The LOS (line-of-sight) matrix,  $X$ , for a network is  $K \times K$  and has entries  $x_{ij}$ , such that:

$$x_{ij} = \begin{cases} 1 & \text{node-}i \leftrightarrow \text{node-}j^* \\ 0 & \text{node-}i \nleftrightarrow \text{node-}j \end{cases}$$

where  $\leftrightarrow$  denotes the presence of a direct point-to-point channel (not necessarily dedicated) between *node- $i$*  and *node- $j$* , and  $\nleftrightarrow$  its absence. Using  $X$ , the connectivity matrix DCM (distance control matrix) can be constructed.<sup>3</sup> The

DCM matrix has entries  $d_{ij}$  such that:

$$|d_{ij}| = \text{minimum number of node-node transmissions required for a packet (message) to propagate from node-}i \text{ to node-}j.$$

The value of  $\text{sign}(d_{ij})$  can be used for secondary purposes and an example will be given below. Thus a DCM can be established to represent, for example, a star or loop network, a network organized around a multiple drop cable, a network based upon a radio channel with an arbitrary dispersion of hidden nodes, or even a store and forward network. A sample network is shown in Figure 1a, and its corresponding DCM matrix is given in Figure 1b.

Using the grouping function,  $g$ , the connectivity matrix, DCM, and the scheduling function a wide variety of network configurations and transmission protocols are easily represented. To so demonstrate, we must first define the sched-

\* Note that this definition reverses a definition given in Reference 9.

Figure 1b—DCM matrix for network of Figure 1a.

uling function. To determine the next potential time at which it may transmit, a ready node with *index-k*, uses the scheduling function  $SF(i, j)$ , where  $g(k)=i$  and  $j=g(1)$  if *node-1* transmitted last, in the algorithm which appears below. That is each ready node can be thought to execute Algorithm A.

#### Algorithm A

1. Determine,  $T$ , the next *scheduling period* leading edge.
2. Compute the next potential transmission time (for the ready node with *index-i*) by  $t_i = T + SF(g(i), j)$ , with  $j$  the group identification of the node which successfully transmitted last.
3. At time,  $t_i$ , if the channel is sensed idle (as determined by the LOS relationships given by the DCM) then transmit; otherwise return to Step 1.

The value of the scheduling period leading edge,  $T$ , is usually given by the trailing edge of a transmission (successful or not), or by the value of a counter which is zeroed and begins to increment at the termination of every transmission (used in the case where nodes approach an idle channel). Details on the determination of  $T$  can be found in References 1 and 3.

The expressive power of Algorithm A together with  $g(\cdot)$ ,  $SF(\cdot)$  and the DCM is demonstrated by Figure 2, wherein networks with a wide variety of channel access protocols are characterized by various configurations of  $g$ ,  $SF$ , and DCM values. Descriptions of the protocols mentioned in Figure 2 can be found in Reference 7 (ALOHA, CSMA variants, TDMA), Reference 8 (MSAP), Reference 1 (BRAM), Reference 2 (parametric BRAM), and Reference 3 (SUPBRAM).

Some are applicable to a cable or radio channel (e.g., CSMA, BRAM) or to radio channels with a network containing hidden nodes (e.g., BRAM, SUPBRAM, etc). In the case of BRAM or SUPBRAM operating in a radio network with hidden nodes, the DCM sign is used to convey additional message routing information. A sample DCM with

routine information is given in Figure 1b, and Reference 3 should be consulted for details.

Other protocols can also be captured by the structures, and to imagine doing so the reader must bear in mind that while certain protocols may not be realized by these constructs (in an actual system) they can be represented by them for simulation.

#### FORMAL VALIDATION OF MODELS

Typically a simulation model program is validated employing pilot runs and statistical tests. It is possible, however, to formally validate the model program's input/output behavior against the actual system. Such validation can thus serve as a kind of "proof of correctness" of the model program. The methodology employed is described in Reference 10 and in this section, for demonstration, we apply it to a simple network model which employs a slotted ALOHA transmission protocol. The reader should be assured, however, that the technique is applicable to any model program (configuration, protocol, etc.) constructed.

The methodology is based on the notions of base model, an experimental frame and a lumped model. In summary (consult Reference 10 for details), a *base model* is a model capable of accounting for all the input/output behavior of the actual system. As a consequence it must be faithful, detailed and consequentially complex representation of the system.

An *experimental frame* characterizes a limited set of circumstances under which the actual system is to be observed. Thus the experimental frame serves to define the subset of allowable input/output behaviors which are of interest.

The *lumped model* results from a process of abstraction by taking the base model and simplifying it (by grouping or lumping components, etc.) so that it accounts for the input/output behaviors specified by the given experimental frame, but not necessarily others.

The validation involves establishing a structural homomorphism between the base model and the lumped model as determined by the well defined experimental frame. In the network context, the base model is required to account for all network nodes, queues, protocols, etc. as encountered in the actual system.

To establish a homomorphism between the base and lumped models a formal machinery is necessary. The methodology of Reference 10 proceeds by first generating an informal description of the models in terms of system *components*, *descriptive variables* (descriptive of the components) and *component interaction* rules. From the informal description a formal discrete event system specification (DEVS) springs. The formal description is given in terms of:

$$\begin{aligned} \alpha_1, \alpha_2, \dots, \alpha_n & \text{—The input variables,} \\ \beta_1, \beta_2, \dots, \beta_m & \text{—The state variables, and} \\ \delta_1, \delta_2, \dots, \delta_n & \text{—The output variables,} \end{aligned}$$

with the cross product of the ranges of these variables giving the set of INPUTS, STATES, and OUTPUTS of the system.

Protocol name	SF(i,j)=	g(i)=	LOS/ DCM
ALOHA [7,9]	0	1	$d_{ij} = y \neg \text{LOS}$ $x_{ij} = 1 \text{ LOS}$
1 - persistent CSMA p - persistent CSMA [7]	0	1	$x_{ij} = Y$
non-persistent case CSMA [7]	0	1	$x_{ij} = y$
prioritized CSMA see [4]	i	i	$x_{ij} = 0$
TDMA (time division multiple access) [7,9]	i packet transmission time	i	$x_{ij} = 1$
MSAP see [8]	$(i-j+k) \bmod k$ if $i \neq j$ 0 if $i = j$	i	$x_{ij} = 0$
BRAM or centralized polling [1]	$(i-j+m) \bmod m$ if $i \neq j$ m if $i = j$	$1 \leq g(i) \leq m$ $1 \leq m \leq k$	$x_{ij} = 0, \text{LOS case}$ $d_{ij} = y, \neg \text{LOS case}$
SUPBRAM [3]	See [3]	$1 \leq g(i) \leq m$ $1 \leq m \leq k$	arbitrary, $d_{ij}$ see [3]

Figure 2—Protocols currently captured by  $g(\cdot)$ , SF( $\cdot$ ) and DCM configurations.  $k$ =number of nodes in network;  $y$ =topology-dependent value; LOS $\Rightarrow$ within line of sight and range.

To account for the discrete time points at which events (inputs, outputs, state changes) occur, the notion of a *hatching time* is introduced, to specify the times at which events occur. The next hatching time is specified by examination of a non-ordered set of linearly *decreasing* variables,  $T_1, T_2, \dots, T_k$ , (a kind of sequencing set) such that at time  $t_i$ , the *next* event time (hatching time) is given by  $\dagger(s) = t_i + \min\{T_1, T_2, \dots, T_k\}$  where  $s$  refers to the state variables. The formalism is completed by specifying first:

$$\delta\phi: \text{STATES} \rightarrow \text{STATES}$$

which describes the internal or endogenous *state transition* that occurs in traversing from time  $t_i$  to time  $t_i + \dagger(s)$ , specifying second:

$$\delta ex: Q \times \text{INPUTS} \rightarrow \text{STATES}$$

which characterizes the transitions brought about by externally-generated events, with  $Q$  denoting the set of pairs  $(s, e)$  where  $s$  denotes system state (as before) and  $e \in R [0, \dagger(s)]$  (i.e., a real number in the range  $(0, \dagger(s, e))$ ), and finally specifying:

$$\lambda: Q \rightarrow \text{OUTPUT}$$

the *output function*. Taken together, the set  $\langle \text{INPUTS}, \text{STATES}, \text{OUTPUTS}, \delta\phi, \delta ex, \lambda, \dagger \rangle$  constitutes the DEVS for the model (lumped or basic).\*\*

To apply the methodology we must first develop a DEVS for the base model, then determine the experimental frame from which the lumped model and its DEVS can be derived.

Owing to limitations of space, we will not present the

\*\* Additional discussion can be found in Reference 10.

DEVS for the base model, but instead, we will first informally describe how our sample lumped model results from the base model; second, we give the DEVS for the lumped model; and finally informally establish the *required* homomorphism, and hence the validation of the lumped model.

To proceed, an experimental frame must be specified, and for simplicity we assume the experimental frame as given by the single variable which gives channel utilization (under the assumption of a slotted ALOHA protocol as assumed earlier). The lumped model then results in:

1. Omitting in the lumped model variables, components, and interactions which account for user $\leftrightarrow$ host $\leftrightarrow$ node relationships.
2. Accounting for the omissions of (1) by replacing certain deterministic variables having to do with packet length, etc. by variates drawn from distributions determined appropriate by examination of the omissions.
3. Coarsening in the lumped model the range of certain descriptive variables in the base model (e.g., packet identification in the lumped model need only specify the associated source node, while in the base model packet identification must include source node identification, destination, node identification, sequence number within a message, message number, etc.) and eliminating several queues.

#### *The network lumped model informal description*

Under the assumptions given above the lumped model consists of components, descriptive variables and interactions as given next.

**Components**—Source, packet-queue, retransmission-queue, channel, with their obvious interpretations.

**Descriptive Variables**—For the source we have (the variable) NEW PACKET which can assume values  $X$ , with

Further, using the state variables given in the informal description, we obtain:

$$s \in \text{STATES} = \left\{ \begin{array}{l} \text{RETR. TIME. SEED, PACKET. QUEUE}_1, \text{RETR. QUEUE}_1, \text{CHANNEL}_1 \\ \text{PACKET. QUEUE}_2, \text{RETR. QUEUE}_2, \text{CHANNEL}_2 \\ \vdots \\ \text{PACKET. QUEUE}_K, \text{RETR. QUEUE}_K, \text{CHANNEL}_K \end{array} \right\}$$

$$= \left\{ \begin{array}{l} r_1, y_1, (Z_1, T_1), \sigma_1 \\ y_2, (Z_2, T_2), \sigma_2 \\ \vdots \\ y_K, (Z_K, T_K), \sigma_K \end{array} \right\}$$

The time advance function becomes:

$$t(s) = \min\{\sigma_1, \sigma_2, \dots, \sigma_K, T_1, \dots, T_K\}$$

and for simultaneous events we choose the tie-breaking rule function:

$$\begin{aligned} & \text{SELECT} (\{\text{TRANSM. TIME. LEFT, SCHEDULED. TRANS. TIME}\}) \\ & = \text{TRANSM. TIME. LEFT} \\ & \text{otherwise: SELECT} (\{X\}) = X \text{ (in the absence of simultaneous} \\ & \text{events)} \end{aligned}$$

range  $\chi \in \{0, 1, 2, \dots, K\}$ . This specification is compactly written as:

$$\begin{aligned} & \text{NEW.PACKET: } \chi \in \{0, 1, 2, \dots, K\} \\ & \text{for a } K \text{ node network. Additionally we have,} \\ & \text{PACKET.QUEUE: } y_i \in \mathcal{Z}^+ \end{aligned}$$

where  $y_i$  gives the length of the queue at node  $i$ , and

$$\text{RETR.QUEUE: } (Z_i, T_i) \in \mathcal{Z}^+ \times \mathcal{R}$$

with  $Z_i$  denoting the length of the retransmission queue at node  $i$  and  $T_i$  giving the scheduled retransmission time with  $T_i$  a variable drawn from a retransmission time generator with seed  $r_i \in [0, 1]$ . For the channel we have  $\text{TRANS. TIME. LEFT } i = \sigma_i \in [0, \text{Packet transmission time}]$  with  $K$ , packet transmission time (PTT), and the retransmission time ( $\text{SCHEDULED. TRANS. TIME}$ ) distribution established parameters.

**Component Interactions**—Component interactions are specified by noting that a newly-arrived packet joins  $\text{PACKET.QUEUE}$ , according to  $X$ , the value assigned  $\text{NEW.PACKET}$ , causing  $Z_i$  to be incremented. If  $Y_i = 1$  the node proceeds to transmit by increasing  $\sigma_i$  to the value packet transmission time. If  $Y_i > 1$ , a transmission is scheduled for the time when  $\sigma_i$  becomes zero. If  $\sigma_i$  is reset while another  $\sigma_j, j \neq i$ , is non-zero a retransmission time is drawn and  $Z_i$ , and  $T_i$  are adjusted.

#### *Formal lumped model description*

The formal description constitutes the DEVS for the lumped model and contains the input variable  $\text{NEW.PACKET}$  such that:

$$\text{INPUTS} = \{\phi, 1, 2, \dots, K\}$$

The next hatching time will therefore be given by:  
 $t_{i+1} = t_i + \min(\sigma_i, T_i)$ .

If we let  $T_l = \min T_i$ , and  $\sigma_l = \min \sigma_i$ , then  $\delta\phi$  is given by:

if  $T_l < \sigma_l$

$$\text{and if } \sigma_l = 0 \quad S = \begin{pmatrix} \Gamma(r_1), y_1, (\overline{\overline{Z_1, T_1 - T_l}}), \sigma_1 - T_l \\ \vdots \\ y_l, (\overline{\overline{Z_l, -1, 0}}), \sigma_l + PTT \\ \vdots \\ y_\kappa, (\overline{\overline{Z_\kappa, T_\kappa - T_l}}), \sigma_\kappa - T_l \end{pmatrix}$$

$$\text{and if } \sigma_l > 0 \quad S = \begin{pmatrix} r_1, y_1, (\overline{\overline{Z_1, T_1 + \sigma_l - T_l}}), \sigma_1 - T_l \\ \vdots \\ y_\kappa, (\overline{\overline{Z_\kappa, T_\kappa + \sigma_l - T_l}}), \sigma_\kappa - T_l \end{pmatrix}$$

if  $T_l > \sigma_l$

$$\text{and if } y_l \neq 0 \quad S = \begin{pmatrix} r_1, \overline{y_1}, (\overline{\overline{Z_1, T_1 - \sigma_l}}), \sigma_1 - \sigma_l \\ \vdots \\ \overline{y_l - 1}, \vdots, 0 \\ \vdots \\ \overline{y_\kappa}, (\overline{\overline{Z_\kappa, T_\kappa - \sigma_l}}), \sigma_\kappa - \sigma_l \end{pmatrix}$$

$$\text{and if } y_l = 0 \quad S = \begin{pmatrix} r_1, y_1, (\overline{\overline{Z_1, T_1 - \sigma_l}}), \sigma_1 - \sigma_l \\ \vdots \\ y_l, (\overline{\overline{Z_l + 1, T_l - \sigma_l}}), 0 \\ \vdots \\ \overline{y_\kappa}, (\overline{\overline{Z_\kappa, T_\kappa - \sigma_l}}), \sigma_\kappa - \sigma_l \end{pmatrix}$$

where  $X = \begin{cases} -\infty & x < 0 \\ x & x \geq 0 \end{cases}$ ,  $X = \begin{cases} 0 & x < 0 \\ x & x \geq 0 \end{cases}$ , and  $\Gamma(r_i)$  denotes a drawing from a stream with seed  $r_i$ , and initially  $\sigma_i = T_i = 0$ , and  $T_i = -\infty$  if  $t_i > T_i$ . In the absence of external events, i.e., when SOURCE =  $\Phi$ , the next hatching time,  $t_{i+1}$ , is given by  $t_{i+1} = t_i + \min(\sigma_l, T_l)$ . For times,  $t$ , at which SOURCE  $\leftarrow m$ ,  $l \leq m \leq \kappa$ , the state at time  $t_i + t$  is given by:

$$\delta_{ex}(s, t, m) = \begin{cases} r_1, y_1, (Z_1, T_1 - t), \sigma_1 - t \\ y_{m+1}, \vdots, \vdots \\ y_\kappa, (Z_\kappa, T_\kappa - t), \sigma_\kappa - t \end{cases}$$

Finally using the experimental frame which characterizes channel utilization, the output function becomes:

$$\lambda(S) = \begin{cases} \text{YES} & \text{if } \exists m \ni \sigma_m \neq 0 \wedge \sum_{\substack{i=0 \\ i \neq m}}^{\kappa} \sigma_i = 0 \\ \text{NO} & \text{otherwise,} \end{cases}$$

as for  $\sigma_i \neq 0$  for multiple  $i$  values collision results. From  $\lambda(s)$  channel utilization is trivially obtained.

#### Lumped model validation

Recall that our purpose is to validate the lumped model for the given experimental frame by using the DEVS of the base and lumped models. This validation is done by showing the existence of a homomorphism between the base and lumped models. That is, a valid lumped model has the same input/output behavior as the base model for the given experimental frame.

The homomorphism is established by proving the existence of a mapping  $h$ ,  $h$ : (base model states) onto (lumped model states), which preserves the time advance, transition and output functions. To formally establish the mapping requires a formal DEVS for the base model which we have not supplied. We proceed informally, therefore, by suggesting that  $h$  has the form shown in Table I, wherein grouped states of the base model correspond to states of the lumped model (assuming both models initialized identically).

As a result the states have been grouped (or lumped) from many to four. It is important to note that the mapping,  $h$ , must be onto so that each component interaction in the base model is a member of only one group in the lumped model. Having suggested a viable homomorphism,  $h$ , we can proceed to establish the preservation of the input/output time advance and transition functions.

#### Time advance preservation

For both base and lumped models the next hatching time for a channel event is determined by the end of a transmission or retransmission. Denoting the columns of the grouped base states by  $g_1, \dots, g_4$  (from Table I) and the columns of the lumped states by  $S_1, \dots, S_4$ , then  $\#(s) = \min(\sigma_i, T_i)$  for the lumped model, and  $\#(g) = \min(\sigma_i, T_i)$  for the base model. Since we have assumed identical initial conditions for the two models, we have:

$$\begin{array}{ccc} g = (g_1, \dots, g_4) \#(g) & & \\ \downarrow h & \searrow & \min(\sigma_i, T_i) \\ s = (s_1, \dots, s_4) \#(s) & \nearrow & \end{array}$$

which guarantees the preservation of the time advance function.

#### Transition function preservation

To formally prove transition function preservation we have to show that given initial correspondence between the states of the two models, that any (group  $\rightarrow$  group or state  $\rightarrow$  state) transition brings both models into corresponding states. Specifically, we have to show that:  $h(\delta\phi(g)) \rightarrow \delta\phi(s)$ , i.e., for the columns  $g_1, g_2, g_3, g_4$  we obtain by the  $h$  mapping the corresponding states  $S_1, \dots, S_4$  for the columns of the lumped model.

Additionally, we must show that  $s_i$  represents  $g_i$  following

TABLE I—Suggested Homomorphism between Grouped Base Model States and Lumped Model States

GROUPED BASE MODEL STATES "BECOME" LUMPED MODEL STATES	
1. User $\rightarrow$ host $\rightarrow$ node $\rightarrow$ packet queue;	packet queue
2. Control unit $\rightarrow$ transmission buffer $\rightarrow$ channel	channel
3. Receiver buffer retransmission queue	retransmission queue
4. Retransmission seed	retransmission seed

all state transitions. Although our ability is limited here due to not having a DEVS for the base model, we can still show the preservation by basic observation. We begin by recalling that the lumped model states are in fact representatives of "groups" of base model states. We further note that we assume all transitions within a group of base model states to be zero time transitions that do not affect  $\sigma_i, T_i$ . Thus only transitions among states from different groups have to be observed—and this is done by observing the state changes in the corresponding states of the base model. Because of this special relationship between base and lumped model structures, the transition function preservation can be justified without use of DEVS.

**Output function preservation**

In this case preservation dictates that corresponding states (in the two models) have to provide the same output. In the lumped model a YES period is recorded for those cases where a single transmitter has a non zero  $\sigma_m$  value. In the base model a receiving controller records correct reception, i.e., a YES period if and only if the channel is busy with only one transmission. It is easily seen that the two YES periods correspond so that  $\lambda(\text{lumped model}) = \lambda(\text{base model})$ , since in the base model we record YES if:

$$\sum_{\substack{i=1 \\ i \neq m}}^K \sigma_i = 0 \wedge \exists \sigma_m \neq 0.$$

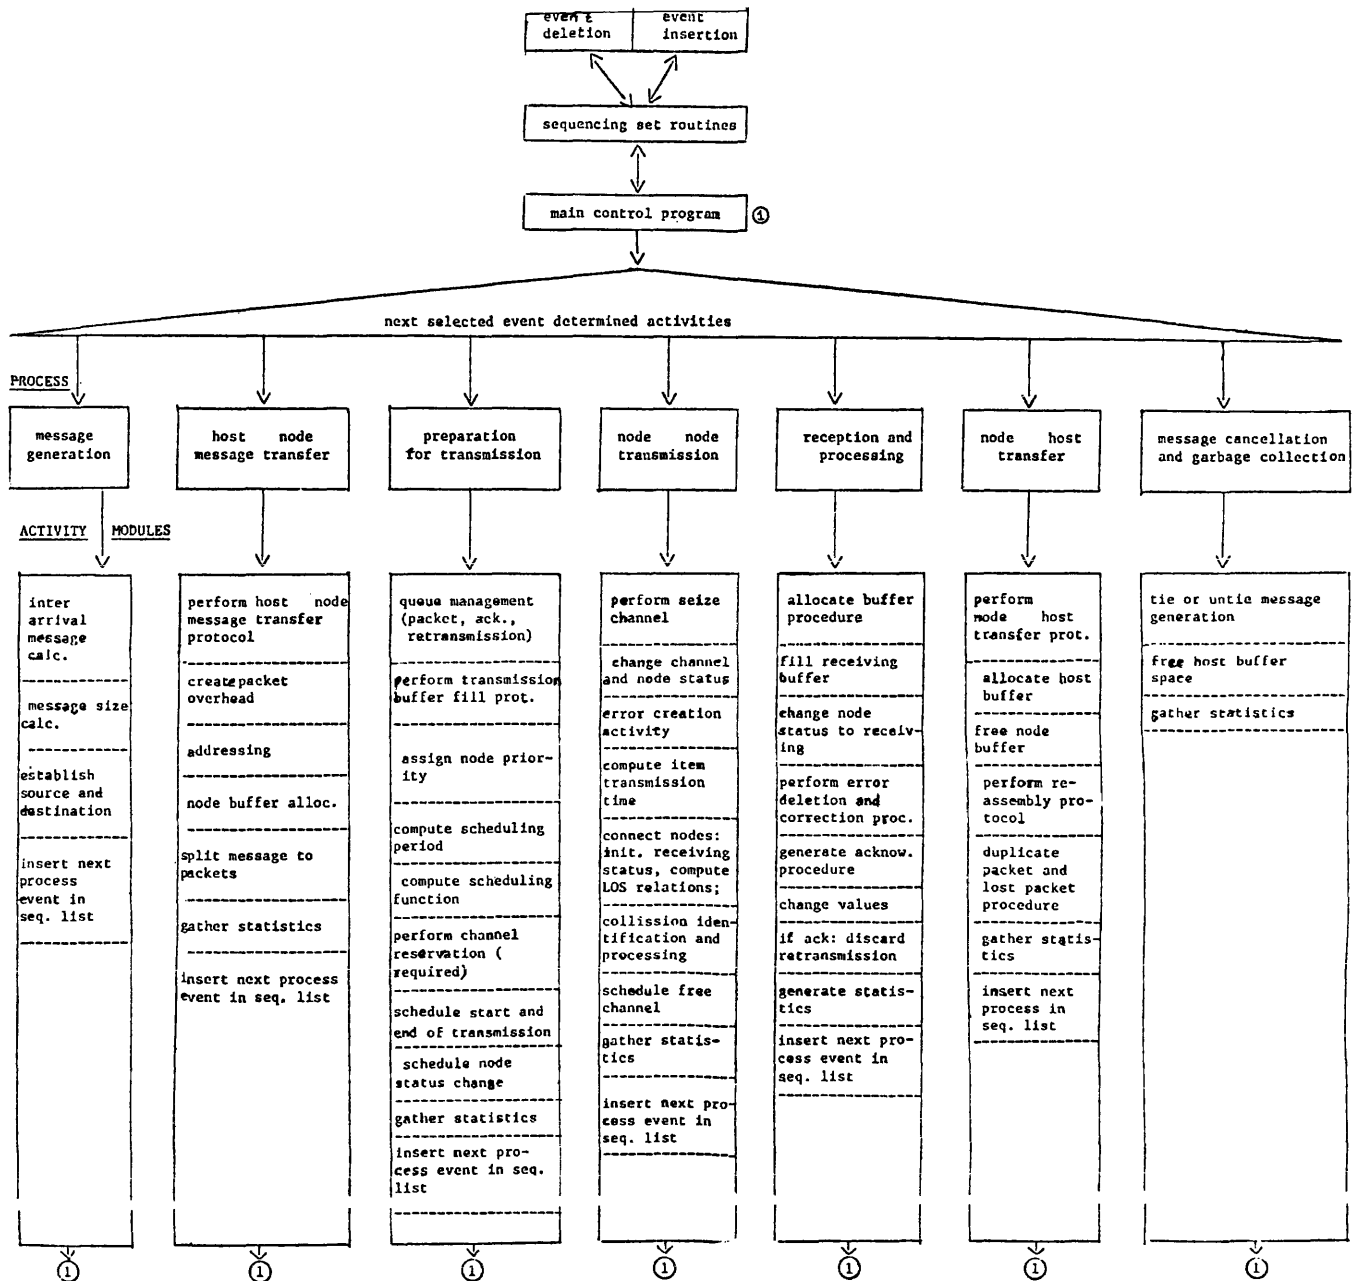

Figure 3—Model program structure.

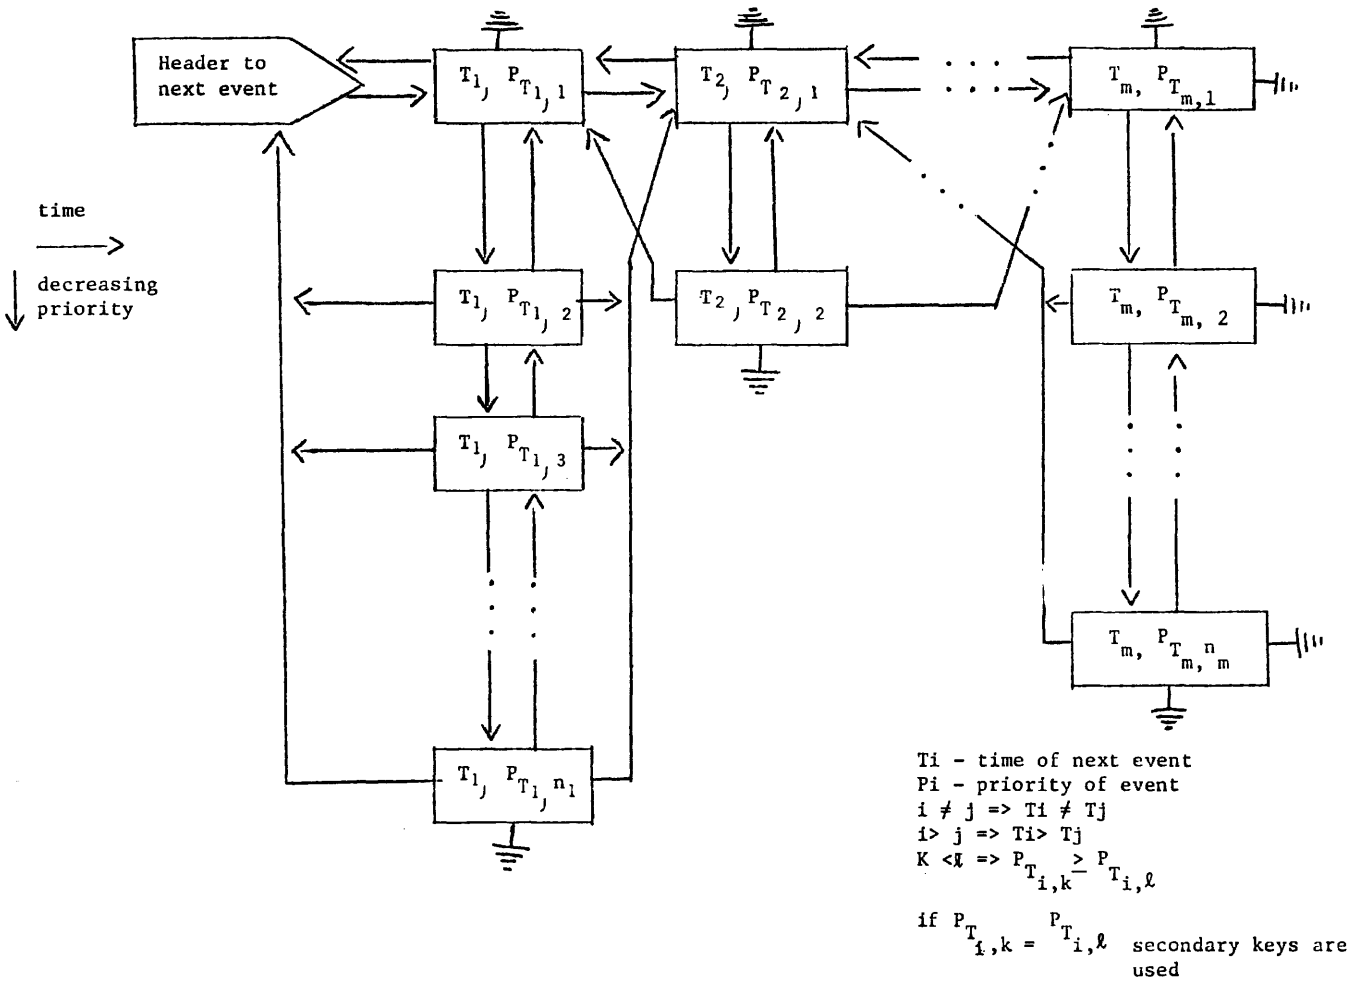

Figure 4—Model program sequencing set structure.

**Commentary on validation approach**

Our purpose has been to demonstrate a formal approach to the validation of a simulation model. Our example was purposely chosen to be simple, where complexity of the lumped model is dependent upon the experimental frame and actual system. For an experimental frame addressing only channel utilization only four-state descriptions were necessary. Quite obviously, as the experimental frame complexity becomes more comprehensive, the lumped model approaches the base model in complexity, and Reference 10 should be consulted for additional details.

We find the approach helpful in structuring network model programs (configurations, protocols, etc.) even when applied with no more rigor than was used in the example. Specifically, its use promotes the same forethought and structuring exercises for simulation programs as do verification and specification techniques for programming generally.

We believe errors have been avoided and more highly structured lumped models produced in reasonable times as

a result of only informal use of the methodology. In any case it serves as a guide to the abstraction process (always difficult), is consistent with the view of simulation we believe most natural,<sup>5</sup> and so represents a formal approach to the art of modeling (model development), and several variants of the network model program were informally validated using the approach.

**MODEL PROGRAM IMPLEMENTATION CONSIDERATIONS**

Guided by the validation procedure of the fourth section, and the scheduling function,  $SF(\cdot)$ , grouping function,  $g(\cdot)$ , and distance control matrix, DCM, as given in the third section, the model program is organized according to the modular structure shown in Figure 3. The program is written in FORTRAN (for efficiency, universality, and sequencing set structural reasons) and consists (for most variants) of around 3500 lines, which compile into approximately 62000 octal words of executable code on a CYBER 74.

Sequencing set considerations

The model program structure shown in Figure 3 is designed, of course, to promote the alterability of the program. That is, for example, all issues concerned with addressing at the *host*→*node* interaction level are contained in a single module so that addressing functions can be identified and altered (replaced) without affecting the remaining program. While serving the primary function of flexibility the structure causes certain potential overheads at execution time. Specifically because of the structure, i.e., the columns in Figure 3, it becomes necessary for activities at time  $t_i$  to schedule multiple other actions for time  $t_i$ . Moreover, to maintain the rectitude of the model the multiplicity of events scheduled for a given  $t_i$  must occur in a specified order. The use of conventional sequencing set structuring techniques, e.g., the linear list, (see Reference 6), causes considerable overhead in the insertion or deletion of event notices when there are multiple events scheduled for a given event time. Furthermore, these structures do not give particular attention to our paramount requirements on the ordering of the execution of these simultaneous events. The nature of our model program suggests use of the two-dimensional sequencing structure shown in Figure 4, wherein each activity scheduling notice contains not only a primary key giving time of occurrence,  $T_i$ , but also a secondary key  $P_{T_i,j}$  which reflects the activities assigned priority (which determines its placement among the collection of events scheduled for  $T_i$ ). Note further that the priority value assigned a scheduled event cannot be static (i.e., cannot be assigned *a priori* to the

activity) but rather must be assigned *dynamically* when the activity is given an occurrence time, with assignment based on the state of the system (the collection of events scheduled) when the scheduling occurs. For example, the order of handling the simultaneous events "set node busy status," "set channel busy status" occur in different orders dependent upon whether the system state is node transmission or node reception.

The two-dimensional structure, Figure 4, aids the assignment of activity priorities as well as the insertion and deletion of notices by reducing the number of scans (of notices) necessary to a more acceptable level than would be possible with conventionally used sequencing set structures. The structure thus allows use of the modular structure without the penalty in model program execution speed which would be incurred with conventional sequencing sets.

Input traffic generators

A large number of network simulations are conducted assuming that message intergeneration (arrival for transmission) times at *node-i* obey a Poisson process with parameter  $\lambda_i$ .

Typically a simulation program responds to this assumption by scheduling an activity "arrival" for each of the  $K$  nodes in the network. For large  $K$  this adds significantly to the number of event notices present in the sequencing set, and hence degrades notice insertion deletion operations. A cleaner more efficient approach is given by forming

$$\lambda = \sum_{i=1}^K \lambda_i \text{ and scheduling a single event with inter-event}$$

PROTOCOL	centralized star network	distributed network	node priority assignment	availability of slotted or unslotted model	centralized or distributed control	protocol dependant variants	separate Ack. channel or incorporated ack. channel	LOS/non LOS coverage
ALOHA	✓	✓	✓	Both	no control	existence of special file transfer protocol	both possibilities exist	non-significant
CSMA	✓		✓	Both	Both	l-pers., pers. CSMA p-pers., prioritized CSMA Pers. = Persistent	separate zero time	Both

TDMA	✓	✓	✓	non-significant	---	-----	"	non-significant

Figure 5—Networks simulated to date.

times drawn from the exponential distribution with parameter  $\lambda$ . Each occurrence of the event signals "arrival" and the "cumulative distribution" of the  $\lambda_i$ , can be used to determine the node to which the message has arrived. Specifically if a random number  $U$  is drawn and  $(1/\lambda) \sum_{i=1}^{j-1} \lambda_i <$

$u \leq \frac{1}{\lambda} \sum_{i=1}^j \lambda_i$ , the message is declared to have arrived at node-

$j$ . The procedure works due to the ability to split a Poisson stream into multiple streams via a multibranch Bernoulli trial, and serves to insure that a single, rather than  $K \gg 1$ , notice is in the sequencing set to signal message arrivals.

## CONCLUSION

In this paper we have examined a number of techniques designed to aid our development of a modular network simulator designed to serve as a research tool. We believe the aids have contributed to our ability to easily simulate a variety of network topologies and access protocols. In Figure 5 we summarize the uses of the simulator to date. The uses shown by Figure 5 reflect our current interests rather than the limitations of the model.

## INTRODUCTION

This paper is concerned with the development of a fixed price, supply/demand market model which can be used to predict demand for customer premises telephone equipment. A state space approach is used to model system dynamics and a Kalman filter is used for estimation. The model is nonlinear, and provides for nonstationary statistical characterization of the elements. The formulation indicates theoretically that, given perfect input (driving force) data, predictions could be highly inaccurate using linear models (even if they are dynamic) or nonlinear models which assume stationary statistics. The conceptual framework afforded by state space provides a vehicle for structuring more accurate models to predict product demand than do conventional approaches. Finally, the general model is suitable for predicting product demand in a wide range of markets.

## DESCRIPTION OF THE PROBLEM

Recent legal developments in the telecommunications industry have necessitated the re-evaluation and consequent revision of the existing market philosophy. Emphasis has been on the need for accurate prediction of product demand, as opposed to the naively formulated forecasts of the past. This problem must be faced in total by the manufacturing branch of the industry which must anticipate the demand for the individual telephone companies and long lines division. This demand is a derived version of actual demand generated by the ultimate consumers of the various final products.

The extremely large number of products to be forecast together with a multiplicity of causal relationships on demand necessitate the development of general forecasting models to optimize the accuracy of prediction. Much of the work done in the area of estimating demand functions has been accomplished using statistically stationary processes with estimates provided only in the steady state. In some

instances such methodology may be sufficient in the sense of providing an adequate level of accuracy of prediction. However, if any one of the assumptions (i.e. steady-state *vs* dynamic, linear *vs* nonlinear, stationary *vs* nonstationary statistics) is violated, then these methods can be relatively inaccurate. A method for achieving significant improvement in accuracy encompasses the development of dynamic models in state space.

To obtain a grasp of the many facets of the prediction problem, it is necessary to have an understanding of the overall operating perspective. There are approximately 500,000 manufactured items (of which about 14,000 are actively tracked), divided into nine product lines. Each product line is broken down as indicated in Figure 1.

The MFLs (Master Forecast Lists) are group configurations depicting a structure of individual items, defined as key or non-key, selected for the purpose of capturing a certain percentage of sales. Key items are components that are required solely for a particular product to function. These items are frequently options or ancillary items essential for capturing the target total dollar sales for the MFL. The MFL is the level of aggregation for which accuracy of prediction is not only desired but necessary for future planning.

Current policy dictates that forecasts be made both on a short and long term basis. Short term forecasts are made three times a year projecting six quarters ahead. Long term forecasts involve projections for the next five years, revising figures as additional information becomes available.

The product line under investigation is station equipment, the family is residential systems, the groups are various categories of telephones, i.e., rotary, touch-tone, and the MFLs are a narrow category such as wall rotary. The intention is to develop models that will encompass the items contained within an MFL to forecast the latter.

As an additional consideration, predictions are needed at various levels of aggregation, such as by region (seven regions) or by telephone company (twenty companies), as well

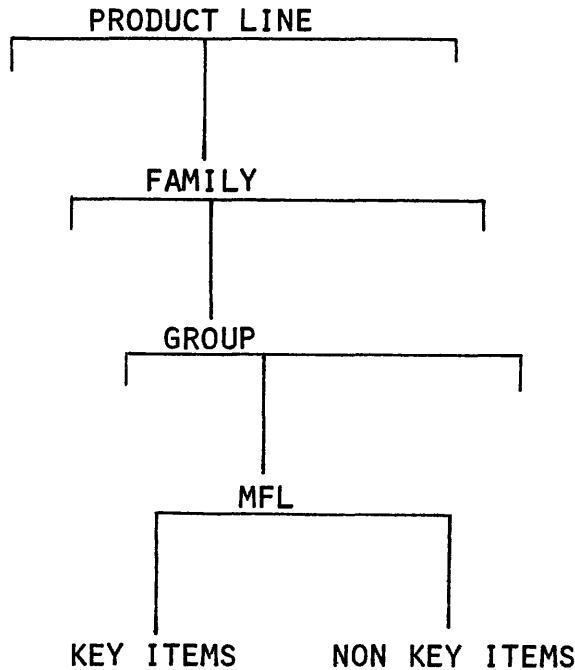

Figure 1—Product line hierarchy.

as a national total. Thus, the model must provide for isolation of regional demand functions and the special driving forces which affect them.

In summary, the basic problem is to predict the volume of demand for a "canonical" set of MFL items  $T_p$  periods into the future. The volume of demand for other MFL items can then be related to demand for the canonical items on a linear stationary basis.

#### DEFINING VOLUME OF DEMAND

In this paper, volume of demand is defined by the area under a "demand function" curve, wherein the "demand function" represents the number of items which buyers (ready, willing, and able) will pay for at the maximum price. This general demand function differs from demand curves commonly used in economics as explained in Appendix A. Referring to Figure 2,  $q(p, t)$  is the general demand function, and allows improved conceptual representation of demand under a free or multiple price structure. If the product is supplied at fixed price  $P_s$ , then volume of demand is given by the area under the demand curve from  $P_s$  to the cutoff price  $P_c$  beyond which there is no demand.

$$A(t) = \int_{P_s}^{P_c} q(p, t) dp \quad (1)$$

Supply at a given price is represented by a Dirac delta function,

$$Q_s(t) = \delta(p - p_s)$$

wherein  $Q_s(t)$ , the area or "height" of the delta function, represents the quantity on hand at time  $t$ . Although multiple

Figure 2—Demand function characterization.

pricing, e.g. discounting, is not treated here, it can be modeled using an extension of the basic approach.

We note that it is not economically feasible to directly measure  $q(p, t)$  or  $Q_s(t)$ . Thus, we look to estimate these quantities based on directly observable quantities, e.g. *orders* and *shipments*. The precision applied to approximating the demand function  $q(p, t)$  in the interval of interest  $[P_s, P_c]$  can in general affect the accuracy of prediction. However, for predicting volume demand at a fixed price, the quantity of interest is the area,  $A(t)$ , and any representation which accurately characterizes this area is suitable. In the case that price changes are being considered, a more accurate characterization of the demand function can be accomplished using the previous formulation.

#### PREDICTION OF DEMAND

Before proceeding, we note the following. The competitive business enterprise is concerned with production scheduling to satisfy demand in a way which maximizes profits, subject to various social and economic constraints. This problem can be treated as an optimal control problem. If one is concerned with maintaining market share, it is not sufficient to "track" demand. Rather, one must also be able to predict changes in demand in order to maximize utilization of resources. This problem is different from that normally found in engineering applications wherein the driving forces are either random or controlled. In the competitive environment, one must determine an optimal trajectory when the driving forces, the model of the system, and the terminal state rapidly become more uncertain as we move into the future.\* Control systems for solving this type of problem will only be as good as the imbedded prediction system for estimating trajectories into the future.

The development of an accurate prediction system requires three ingredients. These are an accurate model of the system, an accurate quantification of the forces which drive the system, and an accurate prediction algorithm. These elements are described in the following sections as they relate to predicting product demand.

\* Refer to Reference 1 for definitions of "optimal trajectory" and "terminal state."

DRIVING FORCE CHARACTERIZATION

Change in demand over the interval  $[T, T+1]$  due to various driving forces observed at  $T$  can be expressed as

$$D(T+1) = d_1[u_1(T)] + d_2[u_2(T)] + \dots + d_i[u_i(T)] \quad (2)$$

where the  $d_i$ s are functions of the driving forces  $u_i(T)$ . These functions can represent nonlinear, time-variant transformations. For example, consider a continuous or smoothed state variable  $x_1(t)$  which represents change in demand at time  $t$  due to  $u_1$ , sampled at time  $t_0$  in the past. If the effect of  $u_1$  on  $x_1(t)$  approximates a simple damped response, then it might be characterized by

$$x_1(t) = u_1(t_0) \cdot e^{-(t-t_0)/\tau} \cdot U(t-t_0)$$

where  $U(t-t_0)$  is the unit step function,<sup>2</sup> and  $\tau$  is the time constant. Converting to discrete form using a Taylor series approximation,

$$x_1(T+1) = K(\tau)x_1(T) + u_1(T+1) = d_1(x_1, T) \quad (3)$$

where

$$K(\tau) = 1 - \frac{1}{\tau} + \frac{1}{2!\tau^2} - \frac{1}{3!\tau^3} \dots$$

is truncated to yield the desired accuracy (refer to Figure 3). If, in addition, the relationship between  $x_1$  and  $u_1$  is nonlinear, this can also be taken into account in  $d_1$ . For example, if the demand,  $A$ , saturated as  $d_1$  increased, this could be represented by a describing function of  $A$ , (refer to Figure 4). Examples of driving forces which must be characterized as described above are number of new building permits (linear) and advertising budgets (nonlinear).

MODEL OF SYSTEM DYNAMICS

In this section we offer, with rationale, a simplified example of a deterministic model of the dynamics of the system which generates demand for new telephone installations. The effects of uncertainty are added in the next section to produce a stochastic model.

Our objective is to accurately predict the area  $A(T+1)$  under the demand curve, Figure 2,  $T_p$  time steps into the future. The demand for new installations,  $A_n$ , at  $T+1$  can be expressed as

$$A_n(T+1) = A_n(T) + D_n(T+1) - Q_n(T+1) \quad (4)$$

where  $D_n(T+1)$  is a function of the form  $D(T+1)$  given by Equation 1. The individual  $d_i$ s can be nonlinear functions of  $A_n(T+1)$ , as shown in Figure 4. Such effects, commonly due to saturation, can occur with advertising or similar forces driving market demand.  $Q_n(T+1)$  is the number of new installations during  $[T, T+1]$  and is given by

$$Q_n(T+1) = \alpha(Q) \cdot [O_n(T) + \gamma_n(A_n(T+1) - A_n(T))] \quad (5)$$

where  $O_n(T)$  is total outstanding orders for equipment installation, and  $\alpha(Q)$  is a nonlinear coefficient depending on  $Q_n(T+1)$  characterizing inventory levels. (In a more complete control model,  $\alpha$  can depend on the value of inventory.)  $\gamma_n$  is a coefficient representing the efficiency of converting demand to orders. Total outstanding orders at time  $T+1$  is given by

$$O_n(T+1) = O_n(T) + \gamma_n[A_n(T+1) - A_n(T)] - Q_n(T+1) \quad (6)$$

Because outstanding orders at the end of a period may be small in relation to orders filled during the period, it is more accurate to use orders filled as an observable. Total orders filled during  $[T, T+1]$  is given by

$$O_f(T+1) = O_n(T+1) - O_n(T) \quad (7)$$

To convert this problem to state space notation, we define the state vector  $x$  as

$$x(T) = \begin{bmatrix} x_1(T) \\ x_2(T) \\ x_3(T) \end{bmatrix} = \begin{bmatrix} A_n(T) \\ Q_n(T) \\ O_n(T) \end{bmatrix}$$

and the observation vector as

$$z(T) = \begin{bmatrix} z_1(T) \\ z_2(T) \end{bmatrix} = \begin{bmatrix} O_f(T) \\ O_n(T) \end{bmatrix}$$

The previous simplified model typifies more complete

Figure 3—Example of damped response to driving force impulse.

Figure 4—Nonlinear effects, e.g. caused by saturation.

models of the generalized form

$$\underline{x}(T+1) = \underline{f}(\underline{x}(T+1), \underline{x}(T), \underline{u}(T), T) \quad (8)$$

$$\underline{z}(T) = \underline{h}(\underline{x}(T), T) \quad (9)$$

where  $\underline{x}$ ,  $\underline{z}$ ,  $\underline{u}$ ,  $\underline{f}$  and  $\underline{h}$  are vector quantities.

Through linearization over the interval  $[T, T+1]$ , these equations can be rewritten as

$$\underline{x}(T+1) = \Phi(T) \cdot \underline{x}(T) + B(T) \cdot \underline{u}(T) \quad (10)$$

$$\underline{z}(T) = H(T) \cdot \underline{x}(T) \quad (11)$$

The transformations of  $\underline{f}$  to matrices  $\Phi$  and  $B$ , and  $\underline{h}$  to matrix  $H$  can be accomplished using describing functions or other linearization methods. Refer to Reference 3.

## STOCHASTIC MODEL

We recall that certain unobservable state variables, e.g. demand, were selected to provide a conceptual representation of what are believed to be the dynamics of the system. We therefore look to estimate the state  $\hat{\underline{x}}$  from observations of  $\underline{z}$ , and to predict  $\hat{\underline{z}}$  based on estimated system dynamics.

Due to uncertainty of the model and observations, the stochastic representation of the system is

$$\hat{\underline{x}}(T+1) = \Phi(T)\hat{\underline{x}}(T) + B(T)\underline{u}(T) + \underline{w}(T) \quad (12)$$

$$\hat{\underline{z}}(T) = H(T)\hat{\underline{x}}(T) + \underline{v}(T) \quad (13)$$

where  $\underline{w}(t)$  represents uncertainty in the model, and  $\underline{v}(t)$  uncertainty in the observations. If we compute the estimate  $\hat{\underline{x}}(T+T_p)$  from Equation 12, prior to observing  $\underline{z}$ , we can then estimate future values of  $\hat{\underline{z}}(T+T_p)$  based on Equation 13.

If a model could be constructed which was precise for all  $T$ , i.e.,  $\underline{w}(T)$  and  $\underline{v}(T)=0$  for all  $T$ , then estimates would be identical to actual values. Because precise models and measurements are not possible, predictions must be made in terms of probability density functions of the estimated values. Thus, given a model of the system, and a characteri-

zation of the observable driving forces, it remains to produce estimates of the probability density functions which describe the predicted trajectories  $\hat{\underline{z}}(T)$  and  $\hat{\underline{x}}(T)$  over  $[T, T+T_p]$ .

## ESTIMATION PROCEDURE

If the probability density functions are characterized by means and variances which are derived from the error residuals

$$\delta = \hat{\underline{z}} - \underline{z}$$

then accuracy of prediction can be considered to be inversely proportional to the variance of the propagated density functions. Using this measure of accuracy, we seek minimum variance estimates conditioned on all available information. Kalman<sup>4</sup> described such an estimator, and many authors, e.g. References 5 and 6, have subsequently expanded the base of knowledge on similar estimation procedures, all convenient to state space modeling.

The Kalman Filter, as it is widely known, provides minimum variance Bayesian estimates of both the state of the dynamic system and the observation vector as described in (12) and (13). The basic algorithms can be modified to estimate nonlinear systems, such as described by (8) and (9), as well as systems whose statistics are non-stationary. To summarize the estimation procedure, one must identify the statistics of the uncertainty elements  $\underline{w}$  and  $\underline{v}$ . It is assumed that these can be characterized as normally distributed white processes with zero mean, and covariance matrices given by

$$Q = E[\underline{w} \cdot \underline{w}^T]$$

$$R = E[\underline{v} \cdot \underline{v}^T]$$

(Refer to Reference 6 for a discussion of items to be considered when trying to characterize uncertainty.) Our problem is to estimate future states of the system given a starting state estimate and a statistical characterization of the uncertainty. This can be restated as follows. Given an estimate of  $\underline{x}$  and a measurement of  $\underline{z}$  at time  $T$ , we seek to propagate moments which describe the probabilities of the values of  $\underline{x}$  and  $\underline{z}$  at time  $T+T_p$  in the future. This is accomplished by computing the estimates  $\hat{\underline{x}}$  and  $\hat{\underline{z}}$ , and their corresponding error covariance matrices via the recursive Kalman filter algorithm.<sup>4</sup>

## NUMERICAL METHODS

Given the model, driving force characterization, and estimation algorithms, we must now come up with maximum accuracy predictions of future demand and corresponding orders. To do this we must determine numerical values for the unknown coefficients in the model, including those in the driving force characterization, which maximize prediction accuracy. From a practical standpoint, this model identification process is the most difficult part of the problem. In general terms, one seeks values of coefficients in the

system equations which will maximize some predetermined measure of accuracy. This model identification process must be accomplished using numerical optimization. If the system equations are nonlinear, then the optimization algorithms must be capable of seeking the global maximum. If the statistics are nonstationary, adaptive algorithms must be devised for updating the covariance matrices,  $R$  and  $Q$ , based on most recent history. Finally, methods are needed to test for the presence of non-white noise components in the error residuals which can be further characterized as driving forces or model elements.

Two systems have been used which remove most of the burden associated with accomplishing the above. These are the General Stochastic Analysis (GSA) and General Stochastic Modeling (GSM) systems. GSM provides the user with a high level stochastic modeling language which affords a direct description of the problem as described above. It also provides for tabularized input of describing functions, and nonlinear optimization algorithms for model identification. GSA provides for interactive input of vector time-series data, statistical testing, and plotting and report generation.

To describe a state space model in the GSM language, the user writes FORTRAN like expressions for each state equation, e.g. Equations 4 through 7 and observation equation. GSM scans these equations, which can contain  $X(T+1)$  terms and describing functions on the right-hand side, and generates optimal sparse matrix solutions. These are then linked to a table look-up method for solving the nonlinear equations at each time-step. The user can also write any valid FORTRAN expression for inequality constraints as well as a function to be maximized (or minimized). For model identification, the user need only specify range limits on the unknown parameters. Starting solutions are unnecessary. Using the GSM language, the person doing the modeling is left to concentrate on the development of intelligent model structures and characterization of driving forces to improve prediction accuracy.

## SUMMARY OF RESULTS

Before comparing results of different modeling techniques, it should be noted that, given any modeling technique it is possible to take alternative approaches to constructing the model. Thus, it is possible for two people to obtain different results using the same technique. This is particularly true when the modeling tools being used provide a wide range of capabilities as well as a high degree of flexibility. The authors view the modeling process as a continual refinement process, and therefore consider their results for each technique subject to further improvement.

A brief summary of results using other conventional techniques versus a simplified version of the model presented is as follows. Deviation error is defined as

$$\text{Deviation Error} = \frac{|\text{Actual} - \text{Predicted}|}{\text{Actual}} (\%).$$

For the most accurate conventional approach used to date,

the average deviation error over a 22 time-step trajectory was 18 percent compared to 13 percent for the model presented. Maximum deviation over the trajectory was 60 percent for the conventional approach versus 30 percent for the model presented. As indicated, the authors believe that improvements can be made in all techniques investigated and are presently designing improved experiments to further validate model comparisons.

## CONCLUSIONS

A general approach for developing more accurate predictions of telephone product demand has been described. This approach is based on a state space framework which provides for maximum use of human judgment in structuring models to represent market dynamics. The models which have been structured are generally nonlinear, and methods have been devised for identification of statistically nonstationary parameters. When structuring intelligent models of the type presented, it is apparent that numerical solutions are heavily dependent upon the use of highly sophisticated software, and the ease with which it can be used.

## APPENDIX A

Consider the demand curve in Figure 5a with  $Q$  as total quantity of demand at price  $p$ . Except for the interchange of ordinate and abscissa this is the curve normally referenced in economics, with total quantity of demand decreasing as price increases.

Figure 5b represents a general demand function as used in this paper, and described in Figure 2, where  $q$  represents

Figure 5a—Normal economic demand curve.

Figure 5b—General demand function.

the demanded quantity at a *maximum* price which buyers will pay. Total quantity of demand using this function is defined by the integral, Equation 1, with  $P_s$  replaced by the general price variable  $p$ . Since this integral evaluated at the

upper limit is always zero, the general demand function can be related to the demand curve (Figure 5a) as

$$q(p) = - \frac{d}{dp} [Q(p)].$$

## INTRODUCTION

The widespread use of microprocessor-based systems has made the problems of development time and development cost most urgent. With the increasing complexity of recent systems, there has come a great need for powerful and adaptive development tools.

The Bus Link is a development tool for the MC<sup>2</sup> processor system, which was developed along with the microprocessor chip. The Bus-Link can be used throughout the development cycle of any MC<sup>2</sup>-controlled system to solve either hardware or software problems. This tool is not restricted to any particular system configuration and can operate with the maximum allowable processor speed (see Figure 1).

## SYSTEM DESCRIPTION

The Bus Link hardware can be partitioned into two parts—the controller and the Unit Under Test (UUT) interface (see Figure 2).

The controller consists of a microprocessor and 8K × 16 bit words of memory. In addition, the controller contains a serial data interface port (UART) and an IEEE standard 488 interface port. Since the only front panel controls are the POWER ON switch and a RESET button, the user interacts exclusively from the CRT terminal connected to the serial data port. The terminal also contains a dual cartridge tape unit which can be used to load programs to or from the UUT memory. Since most of the hardware (including the dual comparators) is software controlled, the user can add and modify the entire system by loading new routines from the cartridge tape unit.

The UUT interface consists of the following parts:

1. The dual comparator unit with an ALU.

2. The trace buffer unit.
3. The UUT bus interface.
4. The bus synchronizer unit.

Each one of the above units is a separate entity, and the connection between them is done under the user's supervision.

## MODES OF OPERATION

The Bus Link can operate in two modes:

1. Management Mode.
2. Monitor Mode.

### *Management Mode*

In the Management Mode of operation the user enters commands from the CRT keyboard. The commands can be entered at any time even while the UUT is executing programs. The following capabilities are provided:

- a. Load and Store Programs—User programs are loaded from UUT memory to the cartridge tape unit or vice versa.
- b. Display and Modify UUT memory, registers and I/O.
- c. Display Trace—The specified number of entries in the Trace Buffer is displayed.
- d. Run, Halt and Single Step user programs.
- e. Interrupt UUT—A forced hardware interrupt.
- f. Reset the UUT system.
- g. Force Handshake—The Bus Link records initiation and completion of handshaking activities (either Memory or I/O) on the UUT Bus. When this command is executed, the Bus Link senses the incompleting handshake activity and simulates its completion so that UUT may resume execution.

\* This work was compiled while employed by Hewlett-Packard Co. Data System Division, Cupertino, California.

Figure 1—Bus link development system.

- h. Add Command—The user can enhance the capabilities of the Bus Link with additional commands which can be loaded into the Bus Link's memory from the system's cartridge tape unit.

#### Monitor Mode

Once the user issues the RUN command, control is passed to the UUT and the Bus Link enters the Monitor Mode. In this mode the Bus Link is monitoring a continuous process on the UUT. All 43 UUT bus lines (16 address, 16 data, 11 control) are continuously sampled.

A Bus Event occurs whenever a preprogrammed set of specifications describing conditions on the MC<sup>2</sup> bus has occurred. The occurrence of an event is a result of two individual comparisons being processed by an ALU unit and a delay counter (see Figure 3). Each comparator samples an actual condition on the UUT bus and compares it with an expected condition. Each one of the two comparators consists of three independent field comparators for the data field, address field and control field with a choice of: >, <, ≥, ≤, =, ≠, and bit mask on each field along with AND operation of all three fields (refer to Figure 3). Altogether we should have six comparator circuits (2 × data, address, control) and their associated masking registers. However, no physical comparators can be found in the Bus Link since the entire task is performed by software, a technique that will be discussed later. Each of the two comparators is connected to the ALU unit and a delay counter to provide the desired event pulse. The event pulse is used to start or stop the trace buffer or to halt the execution of a program. While in Monitor Mode, the static condition on the UUT

may be loaded into a local memory (64 words × 43 bits) called the Trace Buffer. The Trace Buffer may be started with an immediate command or following an occurrence of an event. Similarly, the Trace Buffer may be stopped by a command or following an event. The Trace Buffer may be loaded continuously, may be examined at any time, and may be stopped once the Buffer has been filled up.

The UUT may be programmed to halt under a certain set of conditions. When the condition occurs, the UUT is halted and control is passed to the user at the terminal. The UUT internal register values are updated on the screen and the instruction register is automatically disassembled. A UUT HALT condition can be set to follow an event condition or when the Trace Buffer is Full (see Figure 4).

#### THEORY OF OPERATION

The main building block of any microprocessor development system is the comparator circuits. There are two popular ways of implementing this block; the first one is by using SSI gates (see Figure 5a) and second one is by using MSI circuits (see Figure 5b). When using only SSI circuits, the expected response is stored in the data register and the DON'T CARE (X) bits are stored in the mask register. The sampled data is stored into the input register and compared with the expected data stored in the data register. The result is then ANDed with the bit pattern stored in the mask register, before it is being ORed to provide a compare signal (see Figure 5a). Another common way of implementing the same block is by using an MSI comparator which can provide not only the compare signal (−), but also greater than (>) or less than (<) signals.

Figure 4—Bus link screen format.

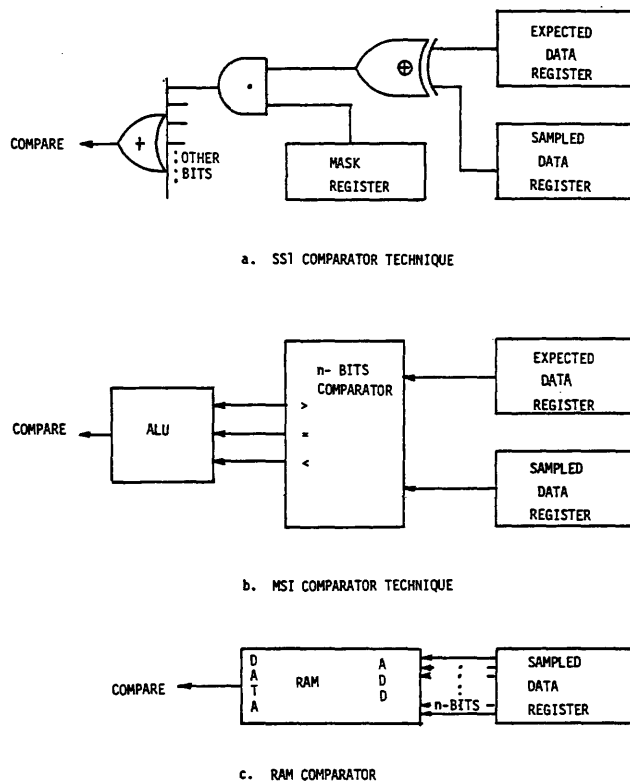

Figure 5—Digital comparison techniques.

The conventional techniques just described have three major disadvantages:

- Expensive—Both circuits require a large amount of integrated circuits and also require a large P.C. Board since many traces must be routed between the components.
- Incomplete—Comparing the sampled data with an expected response to determine a greater than ( $>$ ) or a less than ( $<$ ) equality while some of the bits are masked can't be implemented with the above circuits.
- Inflexible—Changes of existing design are hard to implement.

The comparator circuit can also be implemented with Random Access Memories (RAMs), and such implementation contains none of the disadvantages described earlier (see Figure 5c). The Bus Link is only one of many development tools in which the comparators are designed by utilizing RAMs. This concept will be explained with examples in the next paragraphs.

- Comparing single breakpoint with single RAM*—Let's assume that we want to compare an  $n$ -bit word with another  $n$ -bit word (expected response vs. actual response). If an  $n$ -word  $\times$  1 bit RAM is available, and it is possible to store the data (1-bit word) in each location ( $n$ -bits address), the comparison process can be prepared by software and can be exercised by the RAM.

The software routine stores a "1" in the  $K$ th word where the address of  $K$  is equal to the bit pattern we want to compare with (see Figure 6a).

$K$ th word address = expected response of  $n$ -bit word. The software also stores a "0" anywhere else in the memory. Now the RAM is ready to compare any actual data sampled on the UUT bus. The sampled data word is connected to the address field of the RAM. The RAM is read continuously by the processor which can now determine the result of the comparison. If the data word read (one bit) is found to be a "0," it implies that the expected  $n$ -bit pattern is not equal to the actual one. If the data word is found to be a "1," a match between the expected data and the actual one exists.

- Comparing Multiple breakpoint with single RAM*—Multiple breakpoints comparison can be performed with the same hardware, only the software routine must be modified. Let's keep the same definition of the  $K$ th word. Again— $K$ th word address = expected response of  $n$ -bits word; we can deduct the following:
  - To compare  $\neq$  not equal, store in the  $K$ th word a "0" and store a "1" anywhere else in the memory space. (See Figure 6b.)
  - To compare  $<$ , less than (or  $\leq$ ) store a "1" in the memory space from location 0 to (inclusive) the  $K$ th address and a "1" from the  $K$ th address and on. (See Figure 6c.)
  - To compare  $>$ , greater than (or  $\geq$ ), use the 2b algorithm with a complemented data word. (See Figure 6d.)
- Handling masked (Don't Care-X) bits with single RAM*—Masked bits (X) can be easily processed by the same algorithm, with minor modification. A masked bit is essentially a multiple compare situation; each masked bit doubles the number of words to be compared with since  $X = 1$  and also  $X = 0$  (see Figure 6e). No mask registers or AND gates are needed.
- Comparing multiple breakpoints with more than a single RAM*—The Bus Link was designed as a development tool for the MC<sup>2</sup> microprocessor. As mentioned earlier the MC<sup>2</sup> has 16 bits of data word, 16 bits of address word and 11 bits of control word. If a RAM is to be used as a comparator, it must contain at least  $2^{16} \times 1$  bit words (64K words). With an additional data bit, every single RAM can be divided down into smaller RAM units which may be cascaded to any arbitrary length. The additional bit is a dependency bit (carry bit) which enables the comparison of lower-order bits. In the example described in Figure 7, the 16-bit word comparator is implemented with two  $256 \times 2$  bit words RAM. A comparison is always started with the high-order bits (byte) and carried to the lower-order byte only if it is needed. The software processes the expected data word format and determines whether a carry bit should be entered. This example can be carried further if either a larger than 16-bit word is to be compared or if the RAMs are to be partitioned to smaller units (for economic reasons).

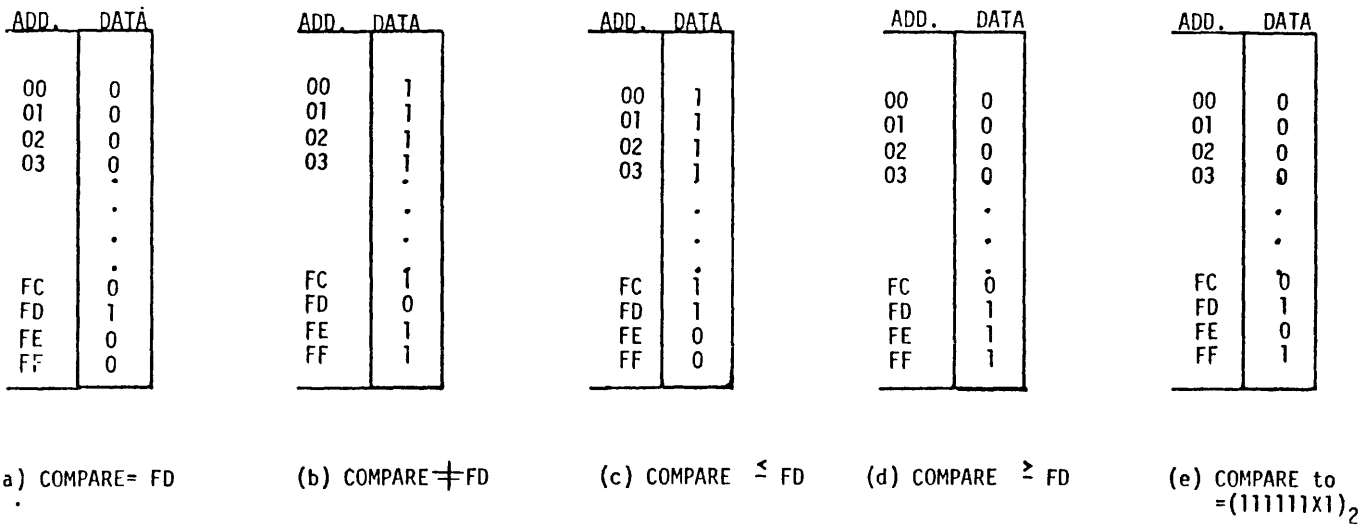

Figure 6—Examples of comparing with a single RAM. Addresses are expressed in hexadecimal notation.

e. *Multiple comparison of multiple breakpoints with more than a single RAM*—Most development tools available today offer only a single comparator, which is adequate for most applications. But a single comparator isn't effective if complicated software routines or complicated I/O ports are to be developed. For example, an

address space can be bounded to be greater than a minimum value AND less than another maximum value—upper bound  $\geq$  address  $\geq$  lower bound. If a hardware comparator (with SSI or MSI devices) is used, a second comparator almost doubles the amount of hardware. In using RAMs, only the RAM size (and some logic) is doubled which yields much greater price/performance ratio. As shown in Figure 7, the additional comparator function is added with almost no additional cost since the standard 256 word RAMs are four bits wide anyway. More comparators can be added to the circuit without much difficulty. The software prepares the data for each comparator separately and then concatenates the corresponding data words to form a single block before writing the entire block into each RAM.

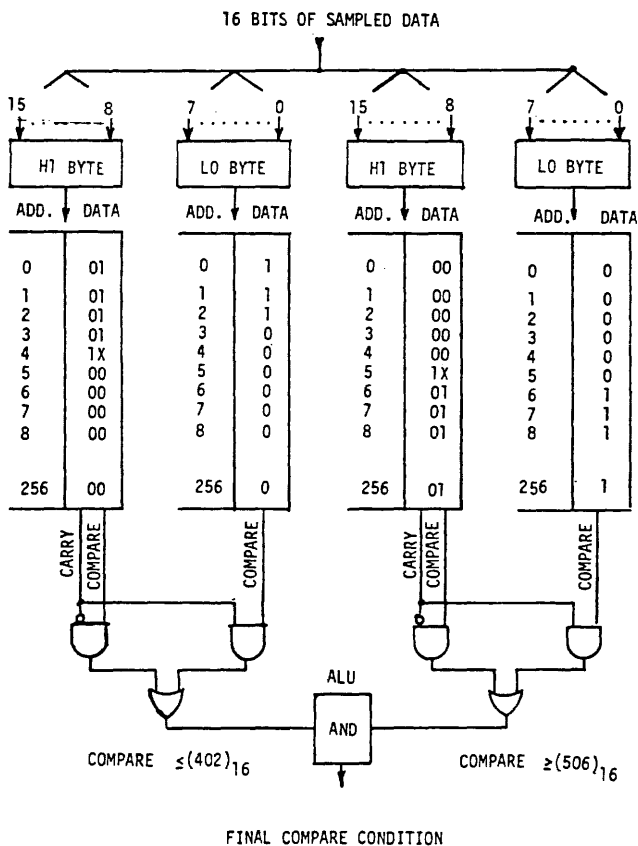

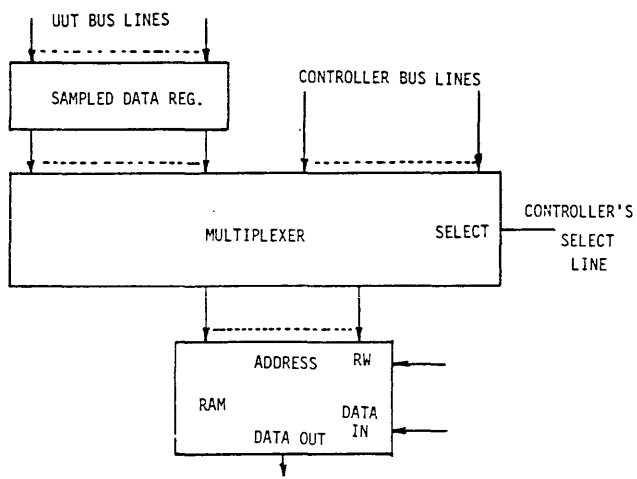

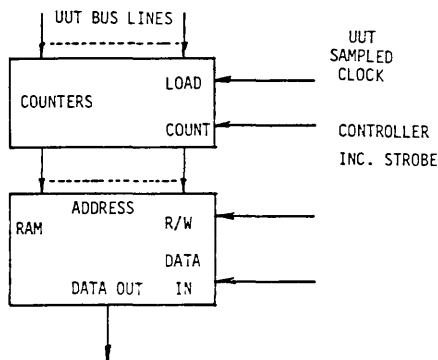

Figure 7—Dual comparison of multiple breakpoint with two 256 × 4 RAMs.

f. *Do without multiplexers*—The address for the RAMs is provided from two sources—the UUT and the controller. When the controller writes the data into the RAMs it must provide the address field, but when the actual comparison is performed, the address field must be connected to the UUT bus. Multiplexing 43 lines between the controller and the UUT bus to the RAMs address field requires many multiplexers and consumes much of the PC Board area due to the large number of traces. Since the software prepares the data in blocks, multiplexing is not required, synchronous counters can be used instead. As shown in Figure 8, when the controller writes the information into the RAMs, the counters are automatically incremented and the processor only provides the data word to be written. When the actual comparison is to be made, the counters are used as registers where the count pulse is disabled and the load pulse is connected to the UUT clock.

g. *Single multitask sequential control circuit—the Hardware Subroutine*—In the management mode of operation, the user can enter one of many optional functions. The common method of designing the control logic is to implement each sequential logic (in a minimized

(a) CONVENTIONAL MULTIPLEXING SCHEME

(b) COUNTERS- MULTIPLEXING SCHEME

Figure 8—Conventional vs. counter multiplexing scheme.

form) of every function separately, and to attach a selector unit to activate each one of the functions separately (as shown in Figure 9). Further study of all the control functions revealed three important facts:

1. The functions are similar to each other.
2. Only one function can be active at any single time.
3. The functions are not time-sensitive.

Taking the previous facts into consideration and deviating from the standard approach, a new design method has resulted:

1. Find the largest common denominator among the functions. Simple functions can be made to act like complicated ones by adding redundant states.
2. Use a selector device to demultiplex the selected set of inputs (qualifiers) into the general sequential circuit block.
3. Use a demultiplexer to select one set of outputs from the sequential circuit block.

Since this method resembles the activity of writing a general-

purpose subroutine, it is called The Hardware Subroutine. A minimum of 3:1 reduction in components count was achieved utilizing this approach.

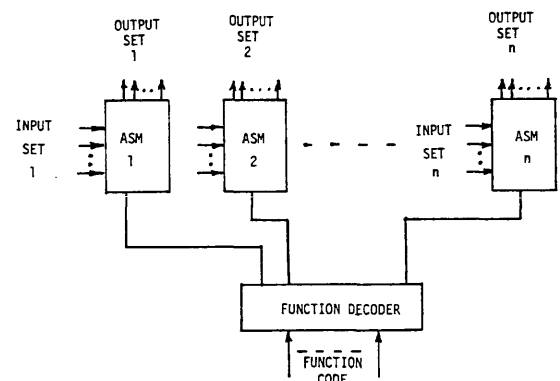

### SOFTWARE DESCRIPTION

The operation of the Bus Link is controlled by the software, which resides in 8K words of RAM. The software can be partitioned into three main blocks:

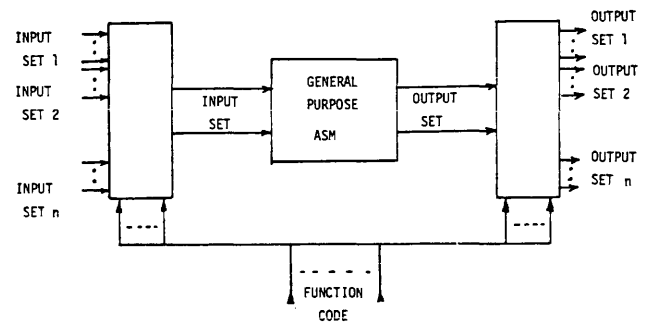

- a. Terminal handler.
- b. Controller.
- c. Comparator processor.

### Terminal Handler

The terminal screen is partitioned into two areas (see Figure 4)—the dynamic and the static area. The static area is used to display the status of the processor and the status of the Bus Link. Commands are entered by the user in a form-fill-out fashion and interpreted only when the user exits this area. The dynamic area can be used for all control

(a) CONVENTIONAL IMPLEMENTATION OF MULTIFUNCTION SEQUENTIAL LOGIC

(b) THE HARDWARE SUBROUTINE

Figure 9—The hardware subroutine vs. conventional implementation. "ASM" stands for, Algorithmic State Machine.<sup>3</sup>

commands, for displaying the status of memory and registers, and for the content of the trace buffer. The terminal handler routine also loads and stores programs in the cartridge tape unit.

### Controller

The controller part is the supervisor of the entire system. It is composed of interrupt-driven routines which answer demands from either the terminal or the various hardware blocks in their assigned priorities. The controller is also capable of self-diagnosing the system once a failure is suspected.

### Comparator Processor

As described earlier, the preparation of the data to be stored in the comparator RAMs is done by the software. Since setting a breakpoint could be done while the UUT processor is running, a powerful algorithm was developed to minimize the required time to process the breakpoint data. The algorithm can be described as follows:

1. Retrieve the breakpoint word.
2. Form a mask word which is a copy of the breakpoint word after all the don't care bits (x) are marked as "0"s, and all the actual bits ("1" or "0") are marked as "1"s.
3. Form a compare word which is a copy of the breakpoint word when all the don't care bits are modified to "0"s and the actual bits are left unchanged.
4. Prepare a table in which the address of the table corresponds to an identical breakpoint word (256 entries for eight-bit word) and the content of each address carries the following data—0: =(equal), 1: >(greater than), 2: <(less than).
5. Each address of the table must be ANDed with the mask word and compared with the compare word. The data of each address reflects the result of the comparison 1, 0 or 2 (stands for =, >, <).
6. For the high byte RAM refer to Table I. Select the desired row for the condition specified (=, ≠, <, >, <=, >=) and change each entry of the table prepared in (5) to the corresponding bit format described in Table I (word-by-word table lookup).

TABLE I.—Lookup Table for the Comparator's RAM Data

Condition	Hi Byte			Low Byte		
	=, 0	<, 2	>, 1	=, 0	<, 2	>, 1
1. =	1	0	0	2	0	0
2. ≠	1	2	2	0	2	2
3. <	1	2	0	0	2	0
4. < =	1	2	0	2	2	0
5. >	1	0	2	0	0	2
6. > =	1	0	2	2	0	2

2 = compare; 1 = carry; 0 = doesn't compare

7. Store the new table in the high byte comparator RAM.
8. Repeat Steps 2 through 6 for the low byte RAM and use Table I for the same task.

9. Store the new table in the low byte comparator RAM.

The following is an example of using the previous algorithm for preparing the data for a four-bit compare word (see also Table I).

Step 1—Compare to  $\geq 10X0$

Step 2—Mask word: 1101

Step 3—Compare word: 1000

Steps 4,5—

table word address	masked mask word address	masked word address	compare word	comparison result	table data
0000	. 1101	0000	1000	2	0

1111	. 1101	1101	1000	1	2

Step #6—Compare with low byte of Table I, condition 6. Table data is shown on last column of previous step.

### CONCLUSIONS

Four unique design contributions in the Bus Link have been presented in detail—RAM comparator unit, counter multiplexing logic, multitask sequential control circuit and a powerful algorithm to compute breakpoints. The above features when used together enable the designers to construct a very powerful development tool which is useful throughout the development cycle of any microprocessor-based system. The Bus Link is adaptive and can be easily modified to accommodate different systems. Each one of the previous features can also be used separately for different design applications to improve the cost-performance ratio.

The Bus Link and the associated products are currently being used in many applications with great success.

### ACKNOWLEDGMENTS

The authors would like to thank Janelle Bedke for her help in defining the project and Larry Lopp for his support throughout the development phase. Special thanks are due to Kim Leeper who wrote many of the software routines and Helen Azadkhanian for typing the paper.

# A computer analysis tool for structural decomposition using entropy metrics

by AARON N. SILVER

*Martin-Marietta Corporation*  
Denver, Colorado

## INTRODUCTION AND BACKGROUND

The decomposition of a metric space into successive subregions exhibiting distinctive characteristics is a problem of broad application. In pattern classification, the object is to partition the space such that pattern classes are easily separable; that is, so that each subregion of the partition contains predominantly samples of only one class. In piece-wise-constant approximation the decompositions produced contain samples whose values are sufficiently close to allow approximation with a specified degree of accuracy. In defining software it is quite often necessary to derive a structural model of a computer program which contains modules, i.e., partitions exhibiting the flow relations or connectivities among the elements (statements) in a program. The subsequent analysis and manipulation of the structural model produces useful design alternatives that enhance the operational qualities of the software generated in terms of program control, logic paths, data transfer and other relevant software issues. The basic feasibility of this approach has been demonstrated by numerous investigators.<sup>1-5</sup> However, the analytical and diagnostic tools for performing structural decompositions require further refinement and development. For example, the metrics usually used<sup>6,7</sup> for defining the topology of a given software structure are primarily single attribute measures. Although the entropy metric proposed in this paper is metrizable in terms of its hypergraph representation,<sup>8</sup> the extension to a multi-attribute unique formulation is, as yet, elusive. This is because an all-purpose problem-independent metric space places unrealizable constraints on the structure it proposes to define. Thus, as Koontz et al.<sup>9</sup> point out, even when a metric is given and a structure well known, the notion of neighboring points can not be rigorously defined for finite point sets from a computational point of view, since the simplest Euclidean distance measure must be scaled by a factor indicating its own respective distance to the nearest neighbor in order to avoid overlapping and ambiguous regions. Although conceptually, the construction of a neighborhood and the determination of the limit point of a sequence of real numbers is a widely used idea, a more fundamental requirement for metrizable hyper-spaces is that of specifying the existence of a limit point of a set. The resultant necessary and sufficient conditions for identifying

metrizable spaces is given by Hausdorff.<sup>10</sup> However, equivalent normalizations and the use of discrete semi-metrics over a restricted space have precluded some of these inherent problems in the quest for such a unique, multi-attribute metric. Thus, the primary emphasis is to obtain realizable decompositions using readily-implementable metrics, as well as focus upon suitable partitioning alternatives in terms of identifying mathematically consistent criteria for structural decompositions.

Figure 1 indicates the application of several useful metrics to well defined problem areas. In this respect, it should be observed that the determination of the "correct" metric properties to be abstracted is largely an experimental process. This process involves two broad and interrelated questions. The first of these concerns the investigation and classification of the various concrete realizations, or models, which one may encounter. This entails the recognition of equivalent models, as is done for isomorphic groups, graphs, or congruent geometric figures, for example. In turn, this equivalence of models is usually defined in terms of a one-to-one reversible transformation of one model onto a metric space. This equivalence transformation is so chosen as to leave invariant the fundamental properties of the models. Typical examples are the rigid motions in geometry, the isomorphisms in group theory, etc. At the extreme end of the spectrum, Figure 1 includes the non-metric measures of a Calhoun distance as discussed by Bartels et al.<sup>11</sup> This distance measure utilizes only the ordering of points along each dimension of the space. The basic concept for measuring the distance between two points is to imagine them as opposite vertices of a hypervolume whose sides are parallel to the axes of the space. The distance is basically the fraction of all points which fall into this hypervolume and its extensions. The Calhoun distance is invariant to transformations which preserve the order of the points along the measurement axes. One kind of transformation to which the Calhoun distance is not invariant is an orthogonal rotation. Still another non-metric measure is the Lance and Williams<sup>12</sup> ratio, which was developed as a generalization of the Czekanowski or Dice coefficient measure.

The second broad question in studying structural decom-

Figure 1—Application of metric spaces to graphs.

position as exemplified by topologized sets involves consideration of transformations more general than one-to-one equivalence transformation. The condition that the transformation be one-to-one and reversible is dropped and one retains only the requirement that the basic structure is to be preserved. The homomorphisms in group theory illustrate this situation. In topology, the corresponding transformations are those that preserve limit points.

#### METRIC SPACES, ENTROPY FUNCTIONS AND GRAPHS

It is convenient to establish a mathematical basis for mapping a structure, i.e., graph representation onto a metric space (particularly an entropy metric space), so that subsequent decompositions may be rigorously analyzed. The following concept of a metric space and its associated topology enables the investigator to identify a potential metric-based decomposition strategy, as well as formulate effective

quality measures for the overall structure based upon a metrizable function; i.e., in this case the entropy function.

#### Metric spaces

A set  $X$  of elements  $x, y, z, \dots$  is called a metric space if each pair  $x, y$  in  $X$  is assigned a non-negative number  $d(x, y)$  (called the distance from  $x$  to  $y$ ), satisfying the following conditions:

1. (identity axiom)  $d(x, y) = 0$ , if  $x = y$ ; otherwise  $d(x, y) > 0$
2. (symmetry axiom)  $d(x, y) = d(y, x)$
3. (triangle axiom)  $d(x, y) + d(y, z) \geq d(x, z)$

It is clear that  $d(x, y)$  is a function of  $s, y$ ; it is called the metric in  $X$ . A function having Properties 1 and 2 but not Property 3 is called a "semi-metric." If Property 3 is replaced by

- 3'.  $\text{Max}\{d(s, y), d(y, z)\} \geq d(x, z)$

then a function with Properties 1, 2 and 3 and 3' is called an "ultra-metric," since 3' is considerably stronger than 3.

A topology may be introduced in the metric space X by taking the neighborhood basis of the point  $x_0 \in X$  to be the set of all open spheres with center  $x_0$ . It is easily verified that Axioms 1-3, for a neighborhood basis and the separation axiom (i.e., every pair of distinct points in X have disjoint neighborhoods) are satisfied so that X is indeed a Hausdorff topological space. In this case, the topology in X is defined by the metric  $d(x, y)$ . Thus, a topological space is said to be "metrizable" if a metric can be introduced in X which defines a topology in X, coinciding with the initial topology. Furthermore, a mapping of a metric space X into the metric space X' is said to be isometric if it preserves distances, i.e., if the distance  $d(x, y)$  between any two points  $x, y \in X$  equals the distance  $d(x', y')$  between their images in X'. Clearly, an isometric mapping is a homeomorphism. Two metric spaces X, X' are said to be isometric if there exists an isometric mapping of X onto X'. Obviously, isometric spaces are homeomorphic. From the viewpoint of metric space theory, two isometric spaces are considered to be essentially the same.

*Entropy functions*

Consider the sequence  $Z = \{Z_1, Z_2, \dots, Z_n\}$  of random variables defined on some metric space, i.e., a probability metric space with measure P. Let the entropy function  $H(Z)$  be denoted by

$$H(Z_1, Z_2, \dots, Z_n) = \sum P(Z) \log_2 P(Z)$$

and let  $p_i$  equal the values assumed by the random variables. Thus,

$$H(p_1, p_2, \dots, p_n) = -\sum_{i=1}^n p_i \log_2 p_i$$

Let the set  $z = \{1, \dots, n\}$  be partitioned into two disjoint subsets  $\{i_1, i_2, \dots, i_k\} = \{\zeta_n\}$  and  $\{j_1, j_2, \dots, j_{n-k}\} = \{\theta_n\}$

For simplicity

let  $X = X\{\zeta_n\} = \{X_{i_1}, X_{i_2}, \dots, X_{i_k}\}$   
 and  $Y = Y\{\theta_n\} = \{Y_{j_1}, Y_{j_2}, \dots, Y_{j_{n-k}}\}$

also let  $x$  and  $y$  be the values assumed by the random variables X and Y.

Thus, X and Y are finite non-empty sets such that  $\{S\} \subseteq X \times Y$ , and

$$S_x: \{y | (x, y) \in S\} \text{ for } x \in X$$

and

$$S_y: \{x | (x, y) \in S\} \text{ for } y \in Y$$

**Property 1**—The conditional entropy is non-negative

$$H(x | y) \geq 0, \text{ or } H(y | x) \geq 0$$

**Property 2**—The joint entropy is given by

$$H(x, y) = H(x) + H(y)$$

**Property 3**—Combining 1 and 2 above

$$\begin{aligned} H(x, y) &= H(x) + H(y | x) = H(x) + H_x(y) \\ &= H(y) + H(x | y) = H(y) + H_y(x) \end{aligned}$$

where

$$H(x | y) = H_y(x) \text{ and } H(y | x) = H_x(y)$$

These three properties satisfy the conditions for a metric stated in the previous section.

*Graph structures*

A graph  $G = (V, E)$  consists of finite set of vertices V, and a finite set of edges E (adjacency) which is symmetric and irreflexive.

$G = (V_1, E_1)$  is a subgraph of G if  $V_1 \subseteq V$  and  $E_1$  is the restriction of E to  $E_1$  (some authors call  $G_1$  a vertex-generated subgraph). The complement of G is a graph  $G^c = (V, E^c)$  with the same vertex and adjacency defined: for  $x, y \in V$  and  $x \neq y$ , then  $x \in E^c \iff \sim x \in E \iff y$  (any pair of distinct vertices are adjacent in exactly one of G and  $G^c$ ).

A path  $v_1$  to  $v_n$  is a sequence of edges  $(v_1, v_2), (v_2, v_3), \dots, (v_{n-1}, v_n)$ . If all vertices  $v_i, 1 \leq i \leq n$  are distinct, the path is simple. A graph is connected if there is a path between any two distinct vertices. A bridge is an edge  $(v, e)$  that is in every path for  $v$  to  $e$ .

A tree is a connected graph, where any two distinct vertices are joined by a unique simple path. A spanning tree of G is a subgraph containing all vertices of G.

In a weighted graph, every edge  $e$  has a number  $W(e)$  called its weight. If T is a set of edges such as a spanning tree, the weight of T is  $\sum_{e \in T} W(e)$ .

Using the preceding three sections dealing with metric spaces, entropy functions and graph structures, a hypergraph<sup>13</sup> may be defined on an entropy metric as follows:

Denote the hypergraph by  $G_H = (X, \Theta)$  such that

$$\Theta = \{E_y | y \in Y, Y \text{ is a finite set } S_y\}$$

and

$$\cup_{y \in Y} \{E_y\} = X, X \text{ is a finite set } S_x$$

Then for  $G_H$ ,  $f(H)$  is given by

$$f(H) = \sum_{i, j \in Y} \left\{ |E_i \cap E_j| \log_2 \frac{|X|}{|E_i \cap E_j|} \right\}$$

where  $E_i \cap E_j \neq \emptyset$

or

$$H(X, Y) = - \sum_{i \in Y} \left\{ \frac{E_y}{X} \log_2 \frac{E_y}{X} \right\}$$

Here  $|X|$  denotes the number of vertices in the metric space, while the connectivities (if they exist) are given by  $|E_i \cap E_j|$ . Thus the hypergraph  $G_H$  is defined on the metric H.

DERIVATION OF THE DECOMPOSITION CRITERION

Consider an arbitrary partition of the space {S} into subsets {S<sub>1</sub>, S<sub>2</sub>, . . . , S<sub>n</sub>} such that {S<sub>i</sub>} ∩ {S<sub>j</sub>} = 0, and ∪<sub>n</sub> {S<sub>i</sub>} = {S}. Let the information contained in {S} be represented by the entropy function H{S} as previously defined. Thus, the information or entropy contained in {S<sub>i</sub>} taken separately is Σ {H{S<sub>i</sub>}}. Except in the case where there is no interaction at all between the subregions (i.e., statistical independence) the expression Σ H{S<sub>i</sub>} will be larger than H{S} only because some information (entropies) will be counted more than once. This difference is commonly called the "redundancy" and is given by the difference between the two expressions: Σ {H{S<sub>i</sub>}} - H{S}. It is a measure of the *strength* of the connectivities. Thus, one may write for two subregions x and y

$$H(x:y) = H_{\max}(x, y) - H(x, y)$$

As the space is partitioned into another subregion denoted by w, expressions for the redundancies may be easily obtained as follows:

$$\begin{aligned} H(y:w, x) &= H(y:x) + H_x(y:w) \\ H(y:w, x) &= H(y:w) + H_w(y:x) \end{aligned}$$

By adding ±H(y:x) and regrouping terms

$$H(y:w, x) = H(y:w) + H(y:w) + H(wxy)$$

where H(wxy) = H<sub>w</sub>(y:x) - H(y:x) is a composite entropy term. As the space is partitioned further into n regions, the

Figure 2—Decomposition using entropy metrics.

general expression for the redundancy criterion becomes

$$\begin{aligned} &H(y_1, y_2, \dots, Y_n; X_1, x_2, \dots, x_n) \\ &- H(y_1: y_2: \dots, y_n) \\ &- H(x_1: x_2: \dots, x_n) \end{aligned}$$

The minimization of this expression constitutes the decomposition criterion. Of course, each of the terms in the previous equation can be expanded to examine individually all of the simple redundancy terms, plus the various composite terms. To extremize these equations constitutes a formidable task mathematically, i.e., analytically, since the functional forms must be explicitly stated and may involve complex expressions. However, some heuristics concerning feasible alternative metrics are under consideration, utilizing

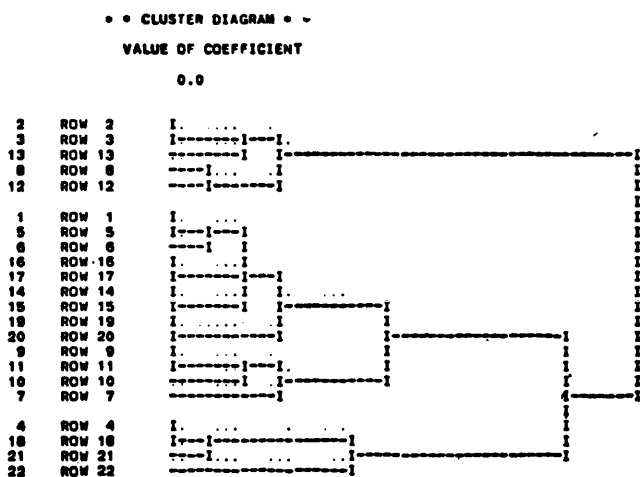

Figure 3—Hierarchical recombination.

partially-ordered binary data sets, corresponding to reduced subgraphs of adjacency matrices. For some limited cases of almost trivial consequences it appears technically feasible to obtain decompositions which are both analytically elegant and computationally executable.

RESULTS OBTAINED

The computer program used in this investigation for obtaining partitions based on the entropy metric is a modified combination of the hierarchical decomposition scheme given in Reference 14 and the recent work of Andreu<sup>15</sup> at MIT. Figure 2 shows a non-trivial sample problem suggested by Andreu, with the super-imposed disjunctive and non-disjunctive solutions. Figure 3 represents the corresponding hierarchical recombination. The subgraph "strength" is a function of the ratio of connectivities that do exist to those that can exist. This parameter is controlled by the investigator, and thus the decompositions produced yield couplings which are problem-dependent. Heuristically, this amounts to picking a suitable a priori ratio without specifying whether it interacts with other nodes.

SILVER PROB. - MULTI ATTRIBUTE COMBINED METRIC (WEIGHTED)  
 THE DISTANCE-FUNCTION MATRIX IS FORMED  
 DIAGONAL ELEMENTS ARE UNALTERED  
 NO ROTATION IS PERFORMED

Figure 5—Agglomerative clustering solution (Silver problem—semi/metric).

An independent solution, using agglomerative clustering, is given in Figure 4.<sup>16</sup> The solution was obtained using the matrix of "core sets" given by Andreu.

The use of a multi-attribute semi-metric is illustrated in Figure 5. Here, selected segments of rows and columns in the distance adjacency matrix were constructed and the dendrogram drawn based upon the polythetic clustering algorithms. At this point, no attempt was made to analyze in detail the particular structure of the various solutions obtained.

However, some general observations may be made. For example, weighting the variables by the variance accounted for resulted in a rather sharp delineation of the clusters when the distance function is used as the basis for grouping. The utilization of correlation matrices had the effect of producing larger, but fewer overall clusters. In both cases the varimax rotation produced the "best" parsimonious solution in terms of simple structure taxa. From empirical results the covarimin criterion was found to produce primary factors which were highly correlated; the bi-quartimin is an intermediate position but tending toward the lower correlations. (See References 17-26).

The conclusions emanating from this study will be deferred to a more comprehensive paper<sup>27</sup> dealing with the details of the methodology. The intent of this investigation is to lay the foundation for decomposition using entropy metrics, without resorting to excessive rigor, while at the same time report some interesting results.

#### ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. C. E. Velez, Manager, Software Research, the Martin Marietta Corporation, for initially suggesting the problem, as well as for his many helpful insights and discussions concerning the uses and application of metric spaces. A special note of thanks is due to Mrs. Rose Lemieux for her painstaking efforts in the preparation of the manuscript.

# Interactive modeling systems for managers—Semantic models should underlie quantitative models

by RAND B. KRUMLAND

Baylor College of Medicine  
Houston, Texas

## INTRODUCTION

This paper is concerned with helping managers build and use quantitative models in problem-solving, especially models that are built and used on on-line, interactive computer systems. Quantitative models play a large part in many of the activities of managers of a wide variety of organizations. Indeed, several companies currently find it profitable to provide managers with the service of access to models and modeling systems which have increasing levels of sophistication.<sup>2,8</sup> However, such models are not used as widely as they could be.<sup>6</sup> Certain concepts are beginning to emerge which will hasten the development and deployment of more sophisticated interactive modeling systems which may improve this situation. Here we define one such concept—that of a *semantic model*—and discuss its place in an advanced interactive modeling system.

## THE CONCEPT OF A SEMANTIC MODEL

Neither a semantic model nor the facilities for constructing one exist in any modeling system available today for general use. The proposition that a semantic model would be a useful adjunct to a modeling system rests on new ideas about the process of creating quantitative models.<sup>1,4,5</sup> Consider the following simple description of a business situation:

U. S. Robot is a corporation which produces and sells robots. Robots are produced out of bodies and central processing units. The bodies are fabricated out of sheet metal and rivets, and the central processing units are purchased from Texas Instrument. In 1977 sales of robots were 17 million dollars. It is expected that sales this year will increase by 12 percent, direct costs will increase by 10 percent, and overhead will increase by six percent.

Suppose that the president of U. S. Robot would like to know what profits will be in 1978 in light of the expectations that are given. The following quantitative model would help

him answer that question:

$$\begin{aligned}\text{PROFIT}(1978) &= \text{SALES}(1978) - \text{COSTS}(1978) \\ \text{SALES}(1978) &= \text{SALES}(1977) * 1.12 \\ \text{COSTS}(1978) &= \text{DIRECT-} \\ &\quad \text{COSTS}(1978) + \text{OVERHEAD}(1978) \\ \text{DIRECT-COSTS}(1978) &= \text{DIRECT-COSTS}(1977) * 1.10 \\ \text{OVERHEAD}(1978) &= \text{OVERHEAD}(1977) * 1.06\end{aligned}$$

Although this is a simple model, an analysis of what underlies its production can yield important insights.

Let us presume that a consultant has produced this model for the president, has implemented it as a computer program and stands ready to use it to answer the president's question. What must be true of the consultant and what must he have done to have produced the model? First, he must obviously know many things—most importantly, he must know something about business in general and about manufacturing firms and processes in particular; he must know how business activities are measured and characterized; and he must know how to structure sets of algebraic equations into a useful model. Second, he must have learned the information that is given in the brief description of U. S. Robot. Third, he must know how to apply elements of the first set of knowledge to what he learned about U.S. Robot. In addition, of course, the consultant must know much more—many “common sense” things, natural language, how to write or type, etc.—but we have enough to work with for the moment.

A diagram of what the consultant knows is shown in Figure 1. Of everything the consultant knows—of his entire *knowledge base*—only the quantitative model is ever made known to the computer. Yet it is those other things that the consultant knows that have allowed him to be successful in formulating the model of his client. This brings us to the first major point of our argument—if the power of the computer is to be brought to bear on the model building task, then it will have to contain more elements analogous to those that make up the consultant's knowledge base than it currently does. If the computer is to act more like the con-

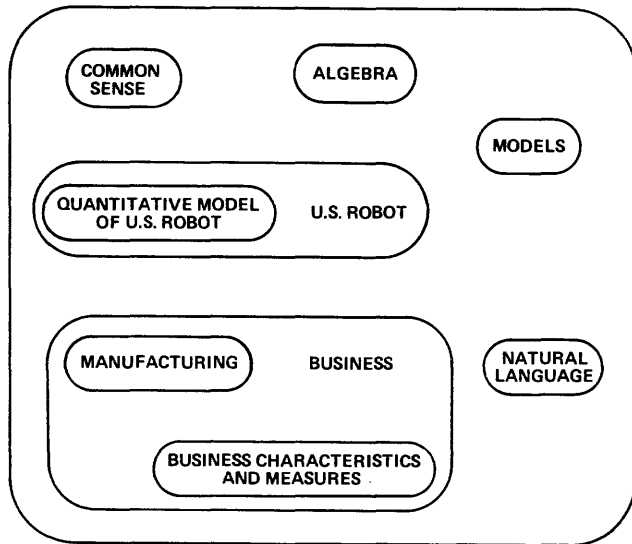

Figure 1—What the consultant must know in order to construct the quantitative model.

sultant, it will have to “know” about more things than simply the quantitative model.

If we want to build such additional knowledge into a computer system, where do we start? More common sense would certainly be a candidate as would a natural language facility. However, the diagram of the consultant’s knowledge points to a different answer—the quantitative model that the consultant built is part of his knowledge about U.S. Robot. That model is obviously linked in many ways with the other knowledge about U.S. Robot; in fact, it is an abstraction of other parts of that knowledge. This brings us to the second major point of our argument—based on our observations, that other knowledge about the current situation—about U.S. Robot—would be extremely useful to have inside the computer and the capability to capture and use it is the best next thing to try to add to a modeling system for a manager. So in terms of the diagram in Figure 1, if the current boundary of a computer’s knowledge is congruent with the circle delineating the quantitative model, then we would like to push that boundary out to encompass more knowledge about the current situation.

A semantic model is just that knowledge of the current situation; it includes the quantitative model plus other quantitative and non-quantitative information. For the consultant it is everything he knows about the current situation; for a computer system then, a semantic model is the quantitative model plus other information that the system obtains and stores that is not necessarily part of the quantitative model but that represents parts of the situation for which that model is built.

We have stressed the static relationships between semantic models and other knowledge; the place of semantic models in the modeling process is important to understand as well. Any model is an abstraction of the things that it models, a representation of them in some other terms. In the process of formulating the quantitative model, the con-

sultant first constructed his semantic representation, and then through abstraction processes he derived the quantitative model from it, as depicted in Figure 2. Thus, if the computer is going to aid substantially in the task of formulating a quantitative model, it, too, will have to have the semantic model as a basis for its actions.

It is not uncommon for users of computer systems to wish that those systems were smarter, more intelligent, or “not so stupid.” Minsky argues that one hallmark of an intelligent system is that it contains “internal models” of its environment and of the various objects, including itself, within that environment.<sup>13</sup> Our semantic models could serve as more effective internal models for quantitative modeling systems and therefore form the basis for more intelligent action in general part of which could be improved modeling capabilities.

### BUILDING A SEMANTIC MODEL

A semantic model is a representation of something in the real world and as such it needs a representational system. Researchers in the fields of artificial intelligence and knowledge-based systems have developed methods to represent knowledge in computer systems—these include production systems, semantic nets, frames, conceptual dependency structures, etc. No single best way to represent knowledge has been found, but there are clearly several facilities that a representation system must provide and many problems that it must deal with. To be a useful basis for a quantitative model for a manager, a semantic model will at least have to contain representations of entities, actions, events, values and relationships in a business environment. Thus we would expect to be able to represent such things as a corporation, company or other business entity, the products or services that a company produces or provides, the different functional and organizational parts of a company such as a division or the marketing department, activities that the organization engages in such as selling, employing, producing and advertising, characteristics that a business entity uses to measure its activities such as sales, costs, prices and wages, etc. In addition, a representational system will need to deal with relationships that link these entities, actions and characteristics together.

A simple example of a representation will illustrate some of these concepts. Figure 3 illustrates part of an encoding of the description of U.S. Robot in a diagram rendering of a frame system, i.e., a system which uses the ideas of frame theory for representation. The diagrams are similar to those used by Winston in explaining frames.<sup>18</sup> In Figure 4 an

Figure 2—The model building process.

encoding is given in a version of a knowledge representation scheme called OWL which is under development at MIT's Laboratory for Computer Science.<sup>17,10</sup>

In spite of the simplicity of this description, it presents some difficult problems in representation. For instance, there are two activities that U.S. Robot engages in—producing robots and selling robots—and a natural presumption is that the robots they sell are the same ones that they produce. Also, note that the quantity “sales of robots” is a measure of the selling robots activity. Such links must be encoded in the semantic model and the representation scheme must therefore provide ways to handle them.

The nature of the representations given point to many aspects of a semantic modeling system which have not been addressed. First, semantic models are not very useful without programs which “know” how to use them to help in modeling. In fact, the knowledge that such programs effectively contain must be part of any semantic modeling system. Second, a semantic model is realized as a set of links and pointers to a larger structure within the system. For instance, the fact that U.S. Robot is a CORPORATION cannot be represented unless the concept CORPORATION has been previously defined in some way to the system. In addition, the fact is not useful unless some other general facts about CORPORATIONS are known which can be used to help understand and deal with this particular corporation. The concepts and links that make up the semantic model of the current user's situation are really only the tip of an iceberg, or rather the tip of a much larger knowledge base. A semantic modeling system that rests on only a limited knowledge base could be useful, but a larger knowledge base will provide greater power, flexibility and increased usefulness for the quantitative modeling task.

## USING A SEMANTIC MODEL

A semantic model serves as the repository for information that the user has transmitted to the system. Thus, for the quantitative modeling system it provides a focal point for interaction with the user; it provides a means for the system to “remember” what it has learned and it serves as the “raw” data from which the parts of the quantitative model can be constructed or parameterized. In a future modeling system quantitative models could be more automatically constructed from semantic models; however, the current genre of interactive modeling systems could also benefit by the incorporation of semantic models.

Techniques have been developed for automatically formulating appropriate quantitative expressions and relations from semantic structures.<sup>1,4,9,5</sup> For example, in our sample of a semantic model given previously the English language phrase

*U.S. Robot's profit in 1978 will be 12 percent greater than in 1977*

if rendered in a semantic model as

```

[[ (BE (GREATER-THAN
  [PROFIT-US-ROBOT-1977
  = ((PROFIT US-ROBOT)
    (TIME (YEAR 1977))))))
  [PROFIT-US-ROBOT-78
  = ((PROFIT US-ROBOT)
    (TIME (YEAR 1978))))]]
  
```

can be translated automatically into an equation such as

$$profit(1978) = profit(1977) * 1.12$$

For a more difficult example, consider generating an equation for the quantity "cost of producing robots" which decomposes that cost into other costs. Cost is a measure of a process here that has an output, two inputs—CPUs and bodies—and undoubtedly involves some direct labor and overhead. Therefore the cost equation must be generated from the semantic descriptions of the process, of the descriptions of the inputs and outputs and other information that must be gleaned about labor quantities and rates as well as overhead and overhead allocation procedures.

Individual terms and equations is the easy part of automatic model generation; producing a model that is complete, well formed and which addresses the manager's problem is significantly harder. General mechanisms have been identified which make up any procedure for producing an entire model.<sup>5</sup> They include *concept production*, or finding parts of the semantic model to be recast for the quantitative model, *integration* or *fitting*, or completing concepts so that they correctly reflect the user's current situation and *equation generation*, or generating variables and the appropriate set of algebraic connectors and relations for a well formed equation. A modeling system that is at all automatic will incorporate these mechanisms to a degree.

Semantic models would also be useful adjuncts to existing modeling systems. They could be used to enable more natural command languages, to allow more flexible command structures, to provide for more intelligent and intelligible prompts for data acquisition and model parameterization, to satisfy a broader spectrum of naive and sophisticated users, etc. For instance, when a system prompts for and receives the value of a variable, a semantic model would provide a general place to store it allowing it to be more readily accessed by other parts of the system. Or, a semantic model could allow model variables to be more readily related to the manager's meaning for them; if there is a variable "SLS(77)" in the quantitative model and the user refers to it as "our sales in 1977," through the use of a semantic model the system could "understand" the reference. A semantic model is a tool that could facilitate the addition of many important features to a modeling system which would make it much more useable and used.

## CONCLUSION

We have discussed the notion of a semantic model as an emerging concept in the design and construction of interactive modeling systems for managers. In fact, a semantic model will underlie any interactive system which is intended to have users who are not obliged to program the computer at a low level. A detailed discussion of how to build a more general semantic modeling facility and how to integrate it with a quantitative modeling system must be deferred until better examples of such systems have been constructed and tested in use. Progress in this area will depend on progress in the relevant areas of AI and on the ability of builders of practical systems to take the work and results from that field and develop them for practical use. In the meantime systems

like Management Decision System's EXPRESS and Meador's PROJECTOR remain the most advanced practical systems in this regard<sup>8,11</sup> and Malhotra's work on a prototypical system demonstrates many things that can be done.<sup>7</sup> The primary utility of a semantic model for current system builders is as an organizing concept and a conceptual focal point for design considerations that to date has been lacking.

## ACKNOWLEDGMENT

This work is based on thesis research which was supported in part by the Advanced Projects Research Agency of the Department of Defense and was monitored by the Office of Naval Research under contract number N00014-75-C-0661. I want to thank Bill Martin and Tony Gorry for significant contributions to the ideas presented here.

# Modeling regular, process-structured networks\*

by BRUCE W. ARDEN and HIKYU LEE

Princeton University  
Princeton, New Jersey

## INTRODUCTION

An interesting strategy to exploit micro-technology is to interconnect microcomputers (i.e., microprocessor with local memory) in a regular dataflow network of low degree. The network is regular so that each computer is a similar "building block" with regard to the number of connecting data buses. The number of buses is small not only because microcomputers are inherently limited in their bus capacity but also because many incident buses lead to switching and "memory port" complexity, which is difficult to handle by micro-circuits. Such complexity is one of the reasons why shared memory "mainframe" computers are relatively expensive. In essence, the low-degree, regular network approach replaces the hard-wired switching with programmed message-passing. Since the processor node will not be fully utilized by productive computing, some of the capacity can profitably be used for such message-handling.

This paper is concerned with an illustrative comparison of performance of two such data flow networks. The first is not regular and it models a particular process structure in which all messages are passed to the intended destination within a single step. For convenience, we call this network a *process network*. In the second, the same process structure is mapped onto a *regular network* (of degree 3) with the result that a number of multi-step message paths are introduced. The comparison shows the effects on system utilization and response time of the additional message handling overhead introduced in the regular network.

## PROCESS STRUCTURE

Current multiprogrammed systems are usually described as *process-structured*. The processes that are enabled for execution are assigned system resources on the basis of some scheduling procedure. An alternative architecture, which arises from the development and low cost of microcomputers, is to assign each system and user process to a microcomputer (which may have attached I/O devices) for the entire life of the process. The use of a process becomes a matter of sending data to the appropriate process node,

and ultimately, receiving the response. This is a data flow network in the sense that the messages enable the resident processes to carry out their specific computation. It is not unreasonable to think about networks of hundreds of microcomputers but, of course, the geometry of a regular network and the mapping of the process structure onto the regular network become important considerations.<sup>1</sup>

In a system of processes, some are *autonomous* and some are *subordinate*. That is, some spontaneously generate a message and others are passive in the sense that they only react to the receipt of a message and are otherwise idle. Clearly, *user* processes are in the first category and most, but not all, of *system* processes are in the second. For example, system processes such as archiving, and spooling routines can act autonomously.

Each autonomous process and the subordinate processes with which it communicates and for which it provides a workload comprise a *chain* with one circulating message. It is assumed that chains, even if they are indistinguishable with respect to their workload demands, cannot be combined in the process system, since they cannot be correspondingly combined in the regular system due to the distinct locations of each autonomous processes resulting from the 1-1 mapping of the process structure onto the regular network. Hence, the number of chains is equal to the number of autonomous processes and each chain contains one circulating message. This situation is quite different from the models of conventional, tightly-coupled systems where the number of processes is generally larger than the number of processors.

In the language of queueing theory, the circulating entities are usually called *customers* and a specific *customer class* is identified by the distinguishing workload it presents at each service center. To preserve the data flow orientation, this concept is here called *message class*. Circulating messages are *processed* at each node in the process system. In the regular system, they are, in addition, simply *retransmitted* at some nodes without being processed locally.

## UNDERLYING MODEL FOR PROCESS SYSTEM

As the preceding suggests, the underlying model for the process system is a closed network of queues model with multiple chains and different classes of messages. There is

\* This work has been supported by NSF Grant DCR 74-18655.

a finite number of processors indexed  $1, 2, \dots, M$  and a finite number of circulating messages numbered  $1, 2, \dots, N$ , where  $N$  is equal to the number of autonomous processes in the system. Obviously, we have  $N < M$ . Since each autonomous process defines a chain, we assume that there is a finite number of different classes of messages  $1, 2, \dots, R$ , where  $R$  is equal to the number of autonomous processes, i.e.,  $R = N$ . Let  $N_i$  denote the number of messages in chain  $i$  ( $i = 1, 2, \dots, R$ ), which is equal to one for each chain  $i$ . Assuming that the messages in chain  $i$  are of class  $i$ ,  $N_i$  also denotes the number of class  $i$  messages in the system.

The behavior of circulating messages is determined by its service time distribution at each service center and transition pattern through the network. The service time distribution of messages is assumed to be general with rational Laplace transformation<sup>6</sup> and the queuing discipline at each service center is assumed to be LCFS-PR (Last Come First Served-Preemptive Resume). The transition of circulating messages is described by the transition probability matrix  $Q = \{q_{irjs}\}$ , where  $q_{irjs}$  denotes the probability that a class  $r$  message completing its service at service center  $i$  will require its next service at service center  $j$  in message class  $s$ . Since class  $r$  messages are confined in chain  $r$ , we have

$$q_{irjs} = 0 \quad \text{if } r \neq s (r, s = 1, 2, \dots, R)$$

We define the state of the model for the process system as the number of messages in each class at each service center. Thus, the state  $S$  is written as

$$S = (y_1, y_2, \dots, y_M),$$

where

$$y_i = (n_{i1}, n_{i2}, \dots, n_{iR}).$$

Then a feasible state of the model satisfies

$$\tilde{N} = (N_1, N_2, \dots, N_R) = \sum_{i=1}^M y_i,$$

where

$$N_j = \sum_{i=1}^M n_{ij} = 1 \quad (j = 1, 2, \dots, R)$$

and

$$N = \sum_{i=1}^R N_i = \text{constant}.$$

The  $n_{ir}$  denotes the number of class  $r$  messages at service center  $i$ .

#### UNDERLYING MODEL FOR REGULAR SYSTEM

The regular system is obtained from the process system by mapping the process structure onto a regular network. Hence, as in the process system, there are  $M$  processors and  $N$  circulating messages in the system. We assume that a specific network geometry and the mapping for the regular system are given.

Since the adjacency relationship between processes in the process system is not, in general, preserved due to the mapping, transition of class  $r$  messages from service center  $i$  to an adjacent service center  $j$  in the process system might take a multi-step path in the corresponding regular system. We add  $R$  new message classes  $\bar{1}, \bar{2}, \dots, \bar{R}$  to our model for the regular system to distinguish messages being retransmitted, i.e., if a class  $r$  message at service center  $i$  makes a multi-step transition to service center  $j$  for the next service request, then we assume that there exists class  $\bar{r}$  message arrival at each intermediate service centers along the path. Hence, each service center in the regular system is presumed to execute a local, system or user process (which may involve the support of a connected I/O device) as well as simple message-passing task for inter-node communications.

We assume that the shortest path between service center  $i$  and service center  $j$  in the regular system is used for the inter-node communication. Furthermore, if there exists more than one such path, then each shortest path is used with equal probability. For convenience, we call this routing scheme as SPEP (Shortest Path with Equal Probability) routing scheme.

The service time distribution of messages is assumed to be general with rational Laplace transformation and the queuing discipline at each service center is assumed to be LCFS-PR (Last Come First Served-Preemptive Resume).

The transition probability matrix  $P = \{p_{i\alpha j\beta}\}$  ( $\alpha, \beta = 1, 2, \dots, R, \bar{1}, \bar{2}, \dots, \bar{R}$ ) describes transition of messages and can be derived for the regular system from the transition probabilities given in the process system as follows. Let  $\lambda_{i\alpha j\beta}$  denote the relative rate of class  $\beta$  message arrival at node  $j$  from node  $i$  and class  $\alpha$ .  $\lambda_{i\alpha j\beta}$  corresponds to the average number of times a class  $\alpha$  message at node  $i$  visits link  $(i, j)$  to become a class  $\beta$  message at node  $j$ . Let  $e_{ir}$  denote the relative arrival rate of class  $r$  messages at service center  $i$  in the process system, where  $i = 1, 2, \dots, M$  and  $r = 1, 2, \dots, R$ . The  $e_{ir}$  are obtained up to multiplicative constant from the following set of linear equations:

$$e_{js} = \sum_{i=1}^M \sum_{r=1}^R e_{ir} q_{irjs},$$

where  $j = 1, 2, \dots, M$  and  $s = 1, 2, \dots, R$ . Then, for each node pair  $(x, y)$  in the process system such that  $e_{xr} > 0$  and  $q_{xryr} > 0$  for some  $r$  ( $r = 1, 2, \dots, R$ ), the total relative arrival of messages at node  $y$  from node  $x$  in the regular system is  $e_{xr} q_{xryr}$  and the fraction which passes through an edge  $(i, j)$  in the set of edges of the shortest paths from node  $x$  to node  $y$  is given by

$$e_{xr} q_{xryr} P(x, i; x, y) P(i, j; x, y),$$

where  $P(x, i; x, y)$  denotes the probability that a message, which has completed a local service at node  $x$  and is making a multi-step transition to node  $y$  for the next local service request, will pass through node  $i$ . and  $P(i, j; x, y)$  denotes the probability that the message which is passing through node  $i$  will make a transition to an adjacent node  $j$  under SPEP routing scheme. Note that  $P(x, i; x, y)$  and  $P(i, j; x, y)$ .

$y$ ) are given by

$$P(x, i; x, y) = \frac{\# \text{ of shortest paths from } n_x \text{ to } n_y \text{ which include } n_i}{\text{total } \# \text{ of shortest paths from } n_x \text{ to } n_y}$$

and

$$P(i, j; x, y) = \frac{\# \text{ of shortest paths from } n_j \text{ to } n_y}{\# \text{ of shortest paths from } n_i \text{ to } n_y}.$$

For the special case of fixed routing, where a specific single path is used for the inter-node communication between node  $x$  and node  $y$ , we have

$$P(x, i; x, y) = P(i, j; x, y) = \begin{cases} 1 & \text{if } n_i \text{ and } n_j \text{ are on the path.} \\ 0 & \text{otherwise.} \end{cases}$$

Considering all the node pairs  $(x, y)$  ( $x, y=1, 2, \dots, M$ ) in the process system such that  $e_{xr} > 0$  and  $q_{xrr} > 0$  for  $r=1, 2, \dots, R$ , we get  $\lambda_{i\alpha j\beta}$  ( $i, j=1, 2, \dots, M$  and  $\alpha, \beta=1, 2, \dots, R, \bar{1}, \bar{2}, \dots, \bar{R}$ ) for the regular system. Then, the transition probability matrix  $P = \{p_{i\alpha j\beta}\}$  is obtained from:

$$P_{i\alpha j\beta} = \lambda_{i\alpha j\beta} / \sum_{k=1}^M (\lambda_{i\alpha kr} + \lambda_{i\alpha k\bar{r}}),$$

where  $\alpha, \beta=r$  or  $\bar{r}$ ,  $r=1, 2, \dots, R$  and  $i, j=1, 2, \dots, M$ . We also get  $\lambda_{i\alpha}$ , the relative arrival rate of class  $\alpha$  messages at service center  $i$  in the regular system from:

$$\lambda_{i\alpha} = \sum_{k=1}^M (\lambda_{kri\alpha} + \lambda_{k\bar{r}i\alpha}),$$

where  $\alpha=r$  or  $\bar{r}$  and  $r=1, 2, \dots, R$ . Since each chain  $r$  has two different message classes, i.e., class  $r$  and class  $\bar{r}$ , we denote the number of class  $r$  messages in chain  $r$  as  $N_{rr}$  and class  $\bar{r}$  as  $N_{r\bar{r}}$ . Then, for each chain  $r$ , we have

$$N_r = N_{rr} + N_{r\bar{r}} = 1.$$

The state of the model for the regular system is defined as

$$S = (y_1, y_2, \dots, y_M),$$

where  $y_i = (n_{i1}, n_{i2}, \dots, n_{iR}, n_{i\bar{1}}, n_{i\bar{2}}, \dots, n_{i\bar{R}})$ . Then a feasible state of the model satisfies

$$\tilde{N} = (N_1, N_2, \dots, N_R) = \sum_{i=1}^M \hat{y}_i,$$

where

$$N_j = N_{j\bar{j}} + N_{jj} = \sum_{i=1}^M (n_{ij} + n_{i\bar{j}}) = 1 \quad (j=1, 2, \dots, R),$$

$$N = \sum_{i=1}^R N_i = \text{constant}$$

and

$$\hat{y}_i = (n_{i1} + n_{i\bar{1}}, n_{i2} + n_{i\bar{2}}, \dots, n_{iR} + n_{i\bar{R}}).$$

## PERFORMANCE MEASURES

The underlying models for both process and regular system are, in essence, special cases of the general queueing network model developed by Baskett et al.,<sup>3</sup> where the equilibrium state probabilities are shown to have the following product form:

$$P(S) = C(\tilde{N}) \prod_{i=1}^M f_i(y_i),$$

where

$$f_i(y_i) = \begin{cases} n_i! \prod_{r=1}^R \frac{1}{n_{ir}!} \left[ \frac{e_{ir}}{\mu_{ir}} \right]^{n_{ir}} & \text{for process system} \\ n_i! \prod_{r=1}^R \frac{1}{n_{ir}!} \left[ \frac{\lambda_{ir}}{\mu_{ir}} \right]^{n_{ir}} \prod_{\bar{r}=1}^R \frac{1}{n_{i\bar{r}}!} \left[ \frac{\lambda_{i\bar{r}}}{\mu_{i\bar{r}}} \right]^{n_{i\bar{r}}} & \text{for regular system} \end{cases}$$

The normalization constant  $C(\tilde{N})$  is obtained by equating the sum of these products, over all states, to unity, i.e.,

$$C(\tilde{N})^{-1} = \sum_{\substack{\text{all feasible} \\ \text{states}}} \prod_{i=1}^M f_i(y_i).$$

The direct approach to compute the normalization constant yields exponential growth in the number of algebraic operations. However, efficient computational techniques have been developed by several authors,<sup>2,9</sup> which are, in essence, generalizations of Buzen's result.<sup>5</sup>

Let  $P_i(y_i)$  denote the marginal probability that the service center  $i$  is in state  $y_i$ , where  $y_i = (n_{i1}, \dots, n_{iR})$  for the process system and  $(n_{i1}, \dots, n_{iR}, n_{i\bar{1}}, \dots, n_{i\bar{R}})$  for the regular system. Then, we have

$$P_i(y_i) = \sum_{\substack{\text{all states} \\ \text{s.t. node } i \\ \text{is in state } y_i}} P(y_1, y_2, \dots, y_M)$$

The mean number of class  $\theta$  messages at service center  $i$ ,  $E(n_{i\theta})$  is given by

$$E(n_{i\theta}) = \sum_{k=1}^{N_\theta} \left\{ \sum_{\substack{\text{all states } y_i \\ \text{s.t. } n_{i\theta}=k}} P_i(y_i) \right\} k,$$

where  $\theta=1, 2, \dots, R$  for the process system and  $1, 2, \dots, R, \bar{1}, \bar{2}, \dots, \bar{R}$  for the regular system.

The utilization of service center  $i$  by class  $\theta$  messages,  $\rho_{i\theta}$  is obtained from:

$$\rho_{i\theta} = \sum_{\substack{\text{all} \\ \text{states } y_i}} P_i(y_i) \frac{n_{i\theta}}{n_i}$$

We define the mean response time of class  $r$  ( $r=1, 2, \dots, R$ ) messages,  $T_r$  as the time for the class  $r$  message leaving an autonomous node in chain  $r$  after finishing its local service request to revisit the autonomous node in class  $r$  after finishing its service requirements in the rest of the system. Assuming that node  $i$  is the autonomous node in

chain  $r$ , the total number of the messages in the rest of the system is  $N_r - E(n_{ir})$ . Applying Little's result<sup>7</sup> to the rest of the system, we have

$$T_r = \frac{N_r - E(n_{ir})}{v_{ir}}$$

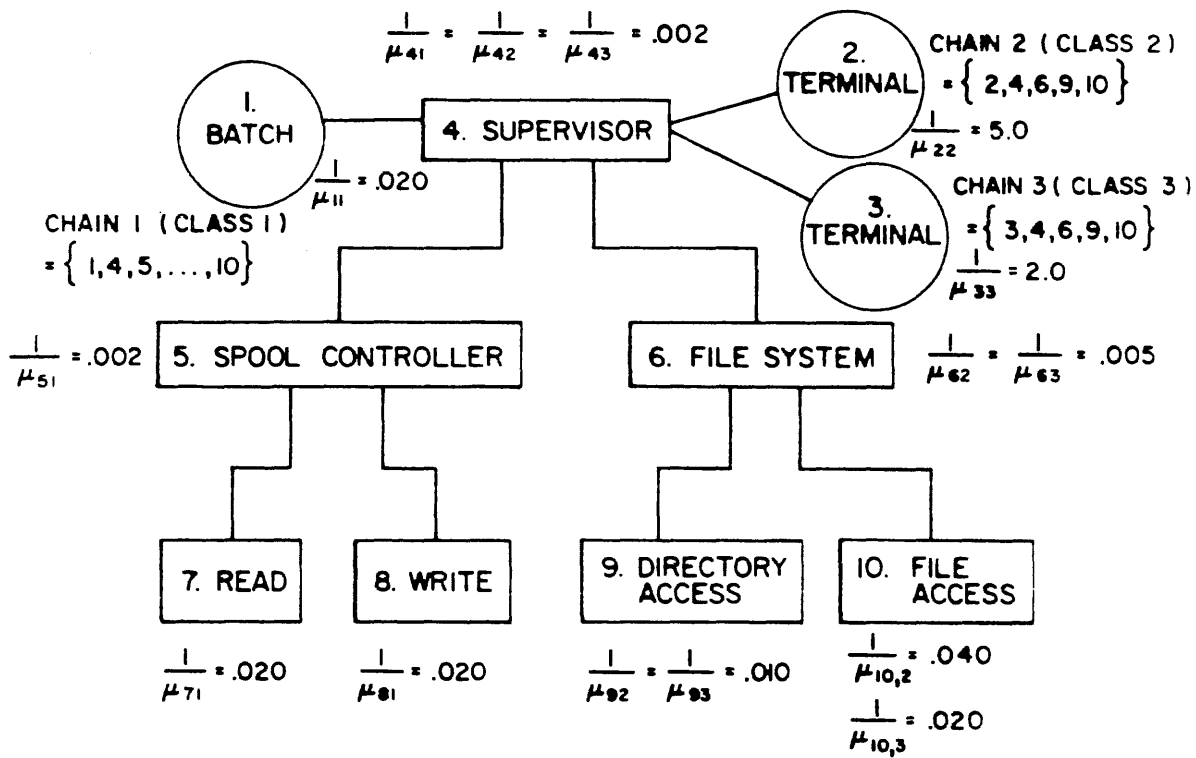

where  $v_{ir}$  is the mean departure rate of class  $r$  messages at service center  $i$ .

EXAMPLE

A 10-node example of process system with necessary parameter values is shown in Figure 1. There are three autonomous nodes, 1, 2 and 3, each of which comprises a chain.

This example, though not based on an actual system, is intended to represent a simple hierarchical operating system structure with different types of task requirements. Chain 1 represents compute-bound batch processing. Node 1 reads a program either in card image format via spool controller or from disk file via file system. Similarly, it produces output to spool controller or for storage in the disk file. Chain 2 and Chain 3 both represent interactive processing of high-level file operations, where Node 2 and Node 3 represent rather long file operation compared to Chain 3.

The regular system, onto which the process structure in Figure 1 is mapped, is shown in Figure 2. Transition prob-

TRANSITION PROBABILITIES

$q_{4111} = .50$	$q_{6141} = .40$	$q_{4222} = .05$	$q_{4333} = .05$		
$q_{4151} = .40$	$q_{6191} = .30$	$q_{4262} = .95$	$q_{4363} = .95$		
$q_{4161} = .10$	$q_{6210} = .30$	$q_{6242} = .40$	$q_{6343} = .40$		
$q_{5141} = .50$		$q_{6292} = .30$	$q_{6393} = .30$		
$q_{5171} = .25$		$q_{62102} = .30$	$q_{63103} = .30$		
$q_{5181} = .25$					

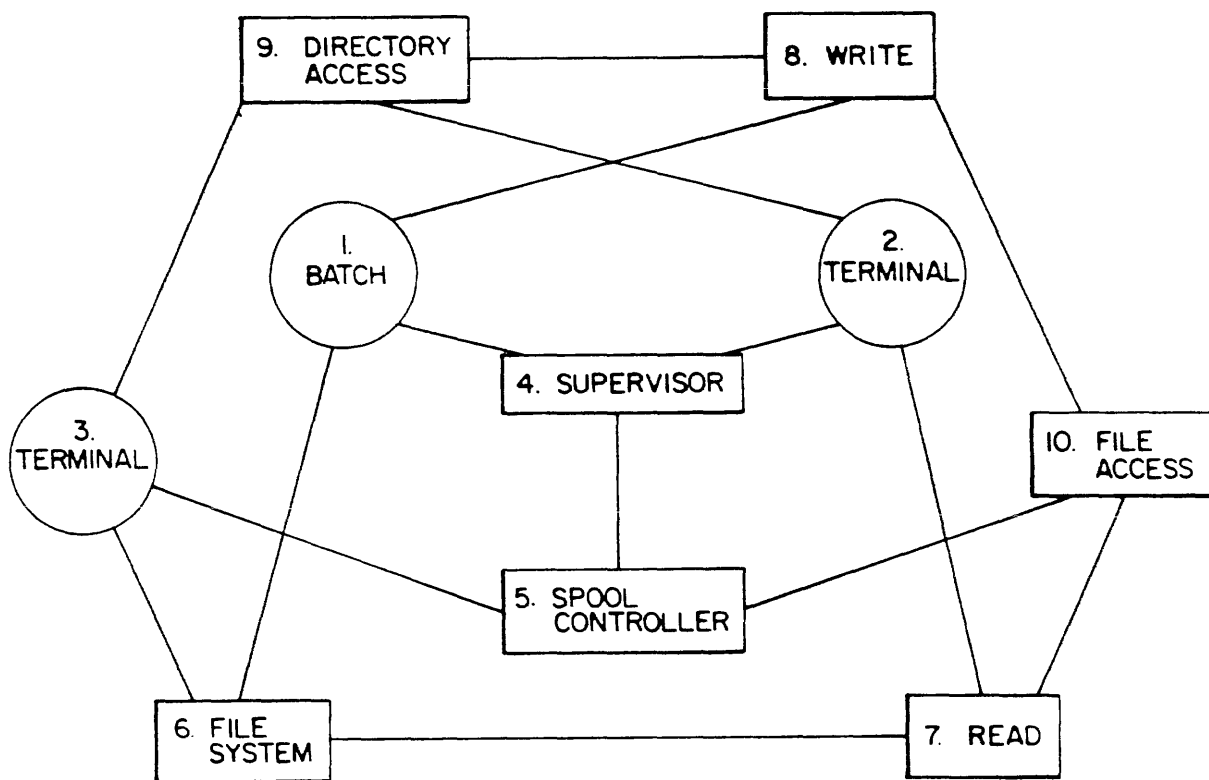

Figure 1—Process system.

abilities obtained by the method explained in the preceding section are also shown for Chain 2 as an illustration. In the network shown, there is a unique shortest path for each pair of nodes. This particular geometry is known as a (3,2) Moore graph,<sup>1</sup> which is also called a Peterson graph. In this case, the mapping is intentionally non-optimal so that appreciable message-passing overhead is introduced. In an optimal assignment, the process network adjacency would be preserved to the greatest extent possible. The mean service time of messages in Classes  $\bar{1}$ ,  $\bar{2}$  and  $\bar{3}$  is assumed to be equal at each service center and is given by:

$$\frac{1}{\mu_{i\bar{1}}} = \frac{1}{\mu_{i\bar{3}}} = .001\gamma \text{ sec} \quad \text{and} \quad \frac{1}{\mu_{i\bar{2}}} = .002\gamma \text{ sec},$$

where  $i=1, 2, \dots, 10$  and  $\gamma$  is a multiplication factor. The statistics obtained on performance measures for the process system is shown in Table I. Table II shows corresponding statistics for the regular system with  $\gamma=1$ . Comparison of the result shows the effects of message-passing overhead on service center utilizations and mean response time of the system. For example, the productive utilization of Service Center 1 is decreased by  $\approx 7$  percent, while overall utilization is increased by  $\approx 1.5$  percent, and the mean response time is increased by  $\approx 12$  to  $\approx 25$  percent for each chain due to the message-passing overhead.

Figures 3 and 4 show the effects of changing the mean service time for the messages in class  $\bar{1}$ ,  $\bar{2}$  and  $\bar{3}$  on service center utilization and mean service time of the system.

$$\frac{1}{\mu_{i\bar{1}}} = \frac{1}{\mu_{i\bar{3}}} = .001\gamma \text{ sec} \quad \frac{1}{\mu_{i\bar{2}}} = .002\gamma \text{ sec} \quad i = 1, 2, \dots, 10$$

CONCLUSION

A network of queues model for process-structured systems is discussed and analyzed by using solution techniques recently developed. The comparison of process system and regular system shows the effects on system performance measures of the message-passing overhead introduced when the process system is mapped onto the regular system.

Although the issues concerning the mapping of a process system to a regular system and specific geometry for a regular network of low degree are not covered in this paper, they are vital considerations in considering the effects on system performance of the message-passing overhead.

The analysis technique presented could be used to design networks to meet specific performance requirements. Given a particular geometry for the regular system, for instance, the analysis technique can be used as a tool to determine a mapping which gives preference to a certain set of autonomous processes in terms of the mean response time or other performance measures.

# The City of New York's integrated financial management system—From mandate to working system in 18 months

by SALLY J. RUPERT

*Office of Computer Plans and Controls  
New York, New York*

The development and implementation of New York City's Integrated Financial Management System (IFMS) is precedent-setting in both its scope and its purpose. It is an excellent example of the successful implementation of a large-scale computer system, a 20-million-dollar investment using the combined efforts of five consulting firms, into a complex organization, a municipal bureaucracy with 250,000 employees in 109 agencies and with a constantly shifting executive management. This paper describes how it was accomplished in terms of the development philosophy, the building of the system and, finally, the post-implementation environment.

Before beginning the presentation of how IFMS was implemented, a little history lesson seems in order. In 1975, when the fiscal crisis was a full-blown reality, the Federal and State governments issued a mandate that, unless New York City could put its financial reporting house in order and establish sufficient spending controls, no further monies would flow from their coffers to those of the City. It was from this mandate that the project named IFMS sprung. It was to be managed by two co-directors, David Woodbridge representing the then Mayor, Abraham Beame, and Steven Clifford representing the Comptroller, Harrison Goldin. The co-directors were given support and backing and authority which crossed both mayoral- and comptroller-directed functions and agencies. The City also made a substantial budget commitment to the project. The co-directors were charged with the awesome task of establishing standard municipal accounting practice throughout the City, creating entirely new central and line agency financial reporting procedures, establishing City-wide training programs, designing and implementing a fourth-generation computer system which would fully integrate the Budget, Accounting and Payroll activities of the City of New York and creating a line agency to operate, maintain and further develop the new computer system. They had exactly 18 months in which to complete the project.

And so began the creation of IFMS.

## THE PROJECT DEVELOPMENT PHILOSOPHY

Large-scale projects setting a new direction and involving many designers and decision-makers tend to get bogged

down in bureaucratic red tape and development indecision. In order to alleviate this major stumbling block to successful implementation, the co-directors of IFMS developed a philosophy for getting the job done rapidly and correctly, then implemented it and stuck with it throughout the project life. That philosophy consisted of the following three premises.

The first premise said that today's business world, in both the private and the public sector, is changing with such rapidity that, if a project is not completed within a relatively short time span, it is outdated before it is implemented. That includes not only the method of doing business, but also the data processing tools to be used and the decision-makers who would use them. Therefore, no project should have a life cycle of more than 24 months. It is not worth doing if it will take longer, no matter what the size of the effort. The longer the project takes the higher the risk of obsolescence as it nears completion. And so, IFMS was planned for 18 months.

A second premise was that different methods of management and control should be used as a project progresses in its life. During the developmental portion of the project the "czar" approach was used; that is, the co-directors had final say in all decisions needed to be made by the City. This alleviated the bottleneck of soliciting decisions from various managers, sometimes with digressant goals. As the project drew close to implementation the management control expanded to a task force including members from all developmental areas, but, with the co-directors still holding final vote and veto power. Then, after the implementation, the project was placed under standard project control for maintenance. In terms of how management knew what they were controlling, here also a methodology was applied that was suited to the stage in development. Progress was monitored in two ways, deliverables and status reporting. The latter, status reporting, forced the interdependencies among all participants in the project to be addressed and honored.

The third premise said that the project could only succeed through the intelligent use of people. High-level technical people with functional and hardware/software computer specialties were dedicated to the General Design phase, at which time the project strategy was set. That strategy included not only the functional aspects of the design but also the high-order technical concept. Throughout the project,

resources were allocated to get a specific portion of the job done. No matter what may have occurred in one area of the project, resources allocated to other portions were left in place. That kept the project moving while outside resources were brought in to shore up the limping portion.

## THE BUILDING OF IFMS

IFMS was constructed and implemented through the efforts of over 200 people, including not only City personnel but also five consulting firms working under the direction of the IFMS co-directors, David Woodbridge and Steven Clifford. Each consultant performed a specific function during the development and all were brought together in a single effort during the final testing and implementation. American Management Systems designed and programmed the Budget, Encumbrance Control and Accounting subsystems. Bradford National Corporation designed and programmed the Payroll subsystem. Ernst and Ernst were the developers of line agency procedures to be used in accordance with the new Charter requirements implemented through IFMS. Touche Ross set the new accounting principals and developed central agency organizations and procedures for operation under the new Budgeting, Accounting and Payroll methods. And finally, the Urban Academy developed operations manuals explaining how to complete input forms and forms flows, then trained City personnel in the use of the new system. Training for IFMS was and is still being done by the Urban Academy and consists of budget, accounting and payroll manual procedures, budget and accounting management, data analysis and on-line inquiry system use.

As work on IFMS began, project personnel worked concurrently to develop both the computerized portion of the system as well as all the attendant procedures and processes. Design efforts and all other efforts were coordinated, to ensure that all development was consistent, through the co-directors and their staffs and, as implementation drew near, a task force composed of members of each consulting firm as well as members of New York City's Office of Management and Budget, Comptroller's Office and Department of Personnel. It was chaired by the IFMS co-directors. The task force was embodied with decision-making powers which were to be exercised whenever design or procedural criteria was to be determined. Without the co-directors and the task force with authority concept, IFMS could never have been implemented in those 18 months. In an organization as complex and bureaucratic as New York's municipal government, decentralized development and decision-making would have made the decision-making process impossible. The single goal of the co-directors was to implement IFMS. The common goal of the task force was implement IFMS.

Let us now turn our attention to the building of each component of the system. The systems design for the computerized budget and accounting portion of IFMS took ten months with a team of 10-40 analysts working, at times, around the clock. The general design document totalled 32

volumes, covering only the budget and accounting subsystem in detail and giving a specification only for the Payroll subsystem. A decision was made to phase Payroll in at a later date because the risk management factor was far greater than the other two subsystems. The Payroll subsystem design consisted of 17 volumes and was produced by seven analysts. Based on this design, which was approved by the co-directors and their staffs, programming began. Throughout the programming stage of development, approximately 30 analysts and programmers contributed to the effort. Structured programming techniques were used to build the thousands of modules which comprise the system. Each program was walked through both at the unit level then again at the integration level.

Large-scale use of macros and common modules added speed to the implementation and centralized all common functions, thereby making maintenance easier. Master Tables were developed for all variable non-data base information. A complete subsystem was built to support the maintenance of these tables and common entry routines were built to access them from application programs.

Even before applications programs and technical support software were being created, another technical team was about the task of selecting the hardware configuration upon which the system would operate. The initial hardware configuration was in place in time for program unit testing. That configuration consisted of fourth-generation IBM hardware and a terminal network to support remote testing. Two CPUs were devoted to budget and accounting development while the Payroll subsystem was built on one CPU.

The software configuration consisted of IBMs—IMS used to manage IFMS's data bases, VS1 as an operating system, Data Analyzer to support report generation, and ROSCOE to support on-line testing.

IMS was chosen because it provided the speed in development needed to support the extremely tight project schedules. VS1 gave IFMS a stable proven operating system.

While system design and programming efforts were going forward, two other teams were about the task of defining central and line agency procedures and organizations. Both procedures and organizations were built to interact with the IFMS computer system. At this point in the development, communication flowed across teams from the technicians to the procedural analysts and back.

Once procedures were defined and inputs and outputs had been designed, work commenced on the development of procedures manuals and management manuals. So, another team, the manual procedures analysts, was added to the horizontal communications process.

Also, during development a team of consultants defined the agency which would be responsible for the operation of IFMS. This definition included the organization and its basic operating procedures. Approximately seven months before implementation, this agency, the Financial Information Services Agency (FISA), was formed and its managers selected. These managers, with the aid of the consultants, then commenced to hire and have trained both the technical and the operations personnel that would man the agency.

As IFMS was nearing the final stages of program testing, the task force formed an implementation group to coordinate the systems test and to make last-minute decisions.

Six weeks before July 1, 1977, the officially committed implementation day, a final integrated test began. The test consisted of two parts, a structured test with pre-determined test cases, from which agency personnel coded input, and an unstructured test in which situations were defined and central and line agency personnel interpreted the new procedures and submitted input accordingly. During the unstructured test, members of the task force were invited to submit their own test situations and input. The test was designed to exercise all newly developed procedures, manuals, organizations and of course, the computer system. FISA, the IFMS operating agency, acted in its full capacity during the test, thereby checking out its operating procedures, even including such things as courier routes and pickup and delivery points. A test coordinator was named who became the central focus for problem reports, which were completed by personnel finding errors in any of the processes, procedures, or the computer output. The test coordinator monitored problem resolution and reported to the task force at its weekly meetings. In this final step before implementation, line and central agency personnel became directly involved with the system so that on day one they were prepared to face the system, thus alleviating some of the trauma of an entirely new operating process.

As stated earlier in this paper, the Payroll subsystem implementation lagged the balance of IFMS implementation by about one year. And so, the system which went live on July 1, 1977 contained an interim computerized Payroll interface. When the Payroll subsystem began implementation in March 1978, it followed much the same process as the rest of IFMS. There was one major difference, however, in the implementation method; Budget and Accounting went live with all City agencies at once while Payroll was implemented on a phased basis, a few Agencies at a time.

#### POST-IMPLEMENTATION—THE OPERATIONAL ENVIRONMENT

As soon as implementation of the basic system was completed, IFMS moved to an operational status. FISA, the agency created to operate IFMS, took control gradually over the first year of operation. First, the day-to-day document processing, then job running, then job integration and production linking and library functions moved to City control. Concurrently with the operations shift, the FISA programming staff was walking through and accepting responsibility for the applications programs. Finally, the data bases and technical software were turned over to the FISA data base and systems programming area. The transition was gradual and the consultants remained in place until City personnel felt comfortable with their ability to maintain and operate this very large and complex computer system.

In order to support this system, FISA has employed over 200 data entry, operations, systems, programming and an-

alytical personnel. With the planned growth for IFMS to incorporate other Funds and other financial applications that number will increase again before another year passes.

IFMS has indeed accomplished its primary objectives, to provide the City of New York with single-source financial reporting, to provide an auditable record of every transaction processed by it, to incorporate Charter revisions into the City's financial processes, to increase the credibility of its financial information.

Agency personnel learned very quickly to complete input forms with very low error rates. Forms continued to flow and financial functions improved. The City's personnel were indeed capable of being completely retrained in a short time frame, a task thought insurmountable by many of the system's early skeptics.

The system has expanded steadily since its implementation. New development demands have been high. The communications network has grown substantially. Inquiry processing alone has multiplied to at least ten times its start volume with a weekly inquiry rate of 60,000 transactions. Two million-plus documents will flow through IFMS operations area this year. Requests for new information from the system outstrip available resources. If use of a system is a determinant of the success of the system, then IFMS was a roaring success.

To support the rapid growth of IFMS, FISA's director has had to reconfigure the hardware environment to higher-powered CPUs, substantially more disk space, and higher-speed, added capability, printing hardware. The network has grown to over 400 on-line terminals. FISA has also installed a large tape library controlled by Tape Management System to facilitate its large volume of tape-stored data and its export data subsystem which interfaces with other City computer systems. Disk storage expands again and again to support the data availability requirements of the City. Central agencies have demanded on-line availability of historical information about every document processed during a fiscal year and even beyond in many cases. FISA's hardware/software specialists continually review new products in the marketplace in order to keep FISA and consequently the City of New York at the forefront in latest generation equipment.

#### AND IN CONCLUSION. . .

In conclusion I would like to state again those premises which drove the method of development and implementation of IFMS and those elements of sponsor support which, when combined, made the Integrated Financial Management System of The City of New York a successful large scale computer system running in a complex organization.

#### *Premises applied*

- The world is changing so rapidly that projects not completed in a relatively short time span are obsolete before

implementation. Therefore, no project should go over two years in development.

- Different methods of management should be used at different points in the project progress, from "czar" in the beginning to task force in the end.
- Projects can only succeed through the intelligent use of people.

*Action taken*

- Project functional and technical concept were set early in the General design.
- Hardware configuration and operations support func-

tions were established during the General design phase so that the operating environment was ready when testing commenced.

- Both developers and sponsors took part in design evaluation.
- Both developers and users performed final testing.
- Sponsors provided almost unlimited financial support and waived decision-making to IFMS co-directors.

Obviously the Federal and State governments' mandates added additional impetus to getting the job done, but, in the end, it was the method, not the mandate, that put IFMS on the air.

# Recurrent dilemmas of computer use in complex organizations

by ROB KLING and WALT SCACCHI

University of California, Irvine  
Irvine, California

## COMPUTER SYSTEMS AS TOOLS

Computer technology is usually spoken of as a problem-solving tool,<sup>33,36</sup> a helpful device used to ease the burdens and expand the flexibility of information processing. In this narrow sense, computer technologies have in fact increased the capabilities of people and organizations to carry out complex calculations, manipulate large sets of data and access data from geographically remote locations.

These capabilities generate a corresponding and sometimes unexpected set of problems for many computer users. People who use computer systems for a variety of daily tasks must adjust to changes in computer systems, vie for adequate priority for their computing jobs, develop backup procedures when automated systems fail and periodically search for skilled programming staff. As a result, the very technology which was supposed to be an unobtrusive aid and time-saver can become very attention-demanding and a source of continual low-level conflicts. The "problem solving instrument" is capable of generating its own special problems.

Easing problems of computer use has been a traditional concern of computer scientists and many solutions have been suggested and tested. Most of these solutions, however, have assumed that computing is a fairly straightforward dialogue between a hypothetical user and a machine. Focus may rest on one party or another. Thus, hardware-based solutions which focus on expanding the flexibility and reliability of the machines emphasize components such as new peripheral devices, distributed computing, microprocessing, operating systems protection schemes or computer graphics. Likewise, software-based solutions which focus on easing the cognitive burdens of the user include new programming languages, data base manipulators, or more "natural" interfaces. Lastly, managerial solutions emphasize the organizational arrangements within which computer based-services are developed and provided. Involving users in systems design, for example, is often recommended to ensure that system specifications are appropriately developed.<sup>16,21,27</sup>

Analysts can suggest sensible solutions to difficulties that computer users face in dealing with computing by segmenting the world into manageable chunks. Named topics such

as "ease of access," "software reliability" and "resource allocation" are well known labels for identified problems. This is the traditional "divide and conquer" strategy of the engineering disciplines and helps make complex production problems *manageable*. Solutions to these identified problems, however, reduce only a selected portion of the burdens faced by computer users. As computing use grows in complexity, and the number of identified "problems" and "effective solutions" increases, the likelihood that they can all be well handled by any group of service providers or instrumental users diminishes.

The routine use of computer-based services increasingly brings people in computer-using organizations into a complex set of dealings with the technology, its providers and other actors. These social relationships are both a source of service for computer users and a locus of difficulty. Factoring these relations into independent "problem areas," each with its own technical and managerial strategies for solutions, doesn't help a user comprehend the way in which computing is often *problematic*. First, no profession or service provider is usually capable of meeting all the needs and wants of its clientele. Secondly, the problematic aspects of computing arrangements often *interact*. Problems are best factored when their components interact weakly. In the case of computing, choices of which technology to use, who to staff it with, how to maintain it, and how to pay for it are often highly coupled. These are clearly social decisions as much as they are technical decisions. The social aspects of computer use are commonplace, but nevertheless they are *poorly* understood.

Our studies of computer use in a variety of settings<sup>16-24</sup> indicate that many users often have recurrent problems in obtaining computer services smoothly. Management analysts are quick to suggest that when users have difficulties, there must be a clearly identifiable management problem which needs a systematic solution.<sup>7,9</sup> In most of the organizations we have studied, managers and staff have developed sensible strategies for dealing with many aspects of computing; but problems still recur. It is easy to blame recurrent problems on "poor managers," "stupid users" and "inadequate technology." Such sentiments are too loaded with blame and faith in simple solutions (i.e., "education," "more core") and too short on analysis to be uniformly

convincing. Simply identifying new "problems" and suggesting new, independent "solutions" may even add to the burdens of attention faced by computer users. We suggest a new approach to help understand why computer use is often problematic.

We find it helpful to expand the traditional view of computing from that of a "tool" to that of a "package." The tool metaphor, which is very appropriate for simple, individually controllable devices, such as hammers and pocket calculators, suggests that the item denoted may be used with few attendant problems. Of course, some tools may be more graceful, effective and reliable than others; but in most cases one can safely focus on the device to understand its use and operation.

In contrast, the package metaphor describes a technology which is something more than the physical device. In the case of computing, the package includes not only hardware and software facilities, but also a diverse set of skills, organizational units to supply and maintain computer-based services and data and sets of beliefs about what computing is good for and how it may be used efficaciously. Many of the difficulties that users face in exploiting computer-based systems lie in the way in which the technology is embedded in a complex set of social relationships.

Not only are most computer systems shared with other users, but programs and data are provided through several different social networks which often entail contact with different social groups.<sup>20,26</sup> This complex social setting in which computing is embedded makes computing a social object, and the use of computer-based services a social act.

The primary thrust of this paper is to identify the recurrent aspects of the social world of computer users which are problematic for people who use computing to serve other ends. We have expanded our conception of computing as a potentially problematic "tool" to computing as a social object. We will now explore some more specific consequences that this expansion reveals. We would caution that while we list a set of issues which are problematic for computer users and computer specialists, and advance some hypotheses as to their relative and absolute costs and importance, we intend this discussion to be an introduction to the bundle of issues which warrant further investigation, articulation and conceptualization.

## THE SOCIAL CHARACTER OF COMPUTING

Our analyses of computer use are based upon several empirical observations and theoretical claims:

1. Many people (*instrumental users*) who use computing hope it will help them be more effective in their work. The substance of that work may have little connection with computing; computer use is a means to further some other end.
2. In many important situations in which computing is used there may be many different people who are interested in utilizing the same computer-based data or reports. These people can have different understand-

ings as to the capabilities of computing and indicate different interests in the uses of computer-based analyses.

3. Much modern computing and most important automated information systems are supported in settings in which several specialized groups provide the requisite computing services and data.<sup>6,14,19,21,26</sup> Automated information systems serve managers and organizational people who have little time or skill to carry out the full range of computational tasks to support their data use. Even skilled programmers rarely design, implement, test and maintain all the software they use while carrying out their work.
4. Users of computer-based services frequently report an array of difficulties in computer use.<sup>22</sup> Complaints usually focus upon aspects of computer use which are byproducts of the social arrangements in which computer-based systems are conceptualized, developed, provided and maintained. These problems rarely focus upon computing hardware, except when users believe there is too little of it or when some party allegedly chose less suitable equipment than might be available in the market.
5. Computer-based services and information processing tasks are organized in vast array of distinctly different arrangements within and between organizations. Smooth computing use often entails the cooperation of distinct organizational groups and interests.<sup>19,26</sup>
6. We view organizations as patterned arenas for conflicting and cooperating interests.<sup>8,35</sup> We note there are often conflicts between the interests of participants who identify primarily with computing as their profession or career interest, and those who identify with some other social world in which computer use is primarily an instrumentality.<sup>23</sup> These extremes are, of course, simplified since many participants align themselves as specialists who mix computing and other substantive interests. But the grounds for conflict of interests remain similar.

These observations encourage us to view much of computer use as a complex social phenomenon in which hardware and software plays an essential, but partial role. In fact, computer use can be expected to be particularly problematic as the milieu in which it is embedded increases in *social complexity*.

## ISSUES IN INSTRUMENTAL COMPUTER USE

Computing services are produced and consumed in *work settings* in which the participants take on specialized roles. The demands that instrumental users and computer specialists make upon each other and of the technology hinge, in part, on their *understandings* of the appropriate *role, capabilities* and *limitations of computing*. Typically, relations between service providers and their clients is problematic. Few service providers can meet all the wants of their clients or of the organizational participants to whom they are ac-

countable. Few clients have sufficient skill and interest to deal with technically skilled service providers on their own terms.

Application development *changes* procedures and processes for users at various intervals which may be either relatively benign or disruptive. When instrumental users rely upon automated data systems, *ensuring* that the *data* provided is of high *quality* (i.e., accurate and timely) is particularly sensitive. Part of the social interaction around computing involves establishing and maintaining *control* over the various computing resources within the organization.

Both specialists and users depend on the current state of *software development practices* to help construct reliable programs which are easy to operate and maintain. Similarly, computing creates special demands for the *time* and *attention* of users. The social aspects of computer work and computer use play a large role in shaping each computing milieu, as does the particular technology in use.

In Table I, we list the array of representative issues which we have clustered under the categories emphasized in the preceding three paragraphs. This set of issues has been selected because they appear problematic to instrumental users in studies we conducted in a variety of settings.<sup>16-24</sup> Some of the specific issues indicated in Table I are important to computer users in many settings; others occur infrequently. Most of these issues should be easily recognizable since they are common in settings where there is extensive computer use. These issues are briefly examined in Appendix A to indicate how each one is a byproduct of the social elements of the computing package and how it can effect the quality of computer-based services.

These issues do not exhaust those raised by the social nature of computing. But they do represent those social aspects of computing which strongly influence the patterns of computer use adopted by instrumental users. The relative importance of any of these issues is also dependent on the organizational setting where computing occurs.

## THE ORGANIZATIONAL CONTEXT OF COMPUTER USE

The actual difficulties experienced in using computing depend upon the *interplay* between both technical and organizational arrangements. Consider, for example, the different impacts of data base management systems (DBMS) on the time to produce a program for a user in scientific and commercial settings.

Computer specialists may assume that a scientist utilizing a DBMS will either carry out his own programming or employ a skilled research assistant who is under his supervision. This is a result of the work organization of scientific laboratories in which each research team has dedicated research assistants to help carry out a variety of laboratory chores including data collection, reduction and analysis. If the scientist desires to change schedules or priorities in his use of the DBMS, he normally faces no bottlenecks in the process except the limitation on his own or assistant's time. Since he can regulate these alterations of priority, he is at most buffered by one queue from access to programming.

A different situation faces the instrumental computer user in a commercial firm. In commercial firms, it is rare for staff to have their own programming assistants. Programmers are usually centralized in a pool, even in user departments and scheduled through a supervisor. The commercial user may thus be further buffered from the access to computing. He may have to negotiate with a supervisor, a special committee or a review board to achieve changes in schedules or priorities in dealing with a DBMS. Each of these parties has a separate queue of requests and demands with their attendant delays. Each such queue creates additional delays for the commercial user in gaining access to programming assistance. In practice, a person may wait much longer to get on the queue of a programmer than it takes to do the work.

Even if a DBMS reduces the time required for a *programmer* to write a given program, the time it takes for *users* to

TABLE I.—Common Issues in Instrumental Computer Use

get a given computing task completed depends upon organizational arrangements. This example illustrates the way in which the social setting of computer use may influence users more than the technology in use.

## STRATEGIES AND RESOURCES

The issues identified in this paper are representative of those that arise for many instrumental users and computer specialists in their daily encounters with computing. Improving the grace or ease with which computing is used hinges on coming to grips with these issues. This requires recognizing computing as a social object as much as it depends upon developing new software and new hardware. In addition, a major impact on groups using computing is the increased attention to information processing—its management and conflicts—that negotiating these issues demands. People's time, skills and organizational resources are involved in attending to these negotiations. The negotiation costs, in time, money, skills, foregone opportunities, and sentiment borne by instrumental users may become a substantial fraction (if not the largest) of the cost of a system during its life cycle.

Computer specialists have been sensitive to some of the difficulties of computer use raised here: after all, they are commonplace. And computer scientists have been particularly adept at providing technical solutions for some of these difficulties. Generally, those technologies that diminish the "social size" of the computing package by decoupling instrumental users from some of the groups upon which they depend may alleviate some of the burdens of computing. Thus, acquiring a minicomputer may insulate a group of instrumental users from demands for machine resources made by other groups. However, it doesn't diminish the difficulties of managing data and may even increase the difficulties instrumental users face in managing skilled staff.

"Turnkey" installation of applications and hardware may reduce the instability of computing development. However, other technical improvements are more problematic from the perspective developed here. While advocates of data base management systems have stated objectives of making the development of *ad hoc* analyses easier for instrumental users,<sup>28,29</sup> the social complexity of the computing milieu should increase since new specialists (such as data base administrators) are often employed. It is empirically open whether the overall environment of data base management is easier or more difficult for instrumental users to negotiate. Similarly, software engineers often propose that development aids such as test data generators would help insure the correctness of programs. From our perspective, a test data generator, however carefully crafted, is another package subject to the recurrent social histories of computing packages.

Management and social analysts who identify difficulties of computing in the social milieu often propose organizational reforms such as new pricing schemes or design disciplines that emphasize user involvement.<sup>16,21,27</sup> Such strategies often resolve particular dilemmas of computer use in

a specific setting, but they do not deal directly with the large, diffuse social elements that pervade the computing package.

Our own field work in several large private firms and research laboratories indicates that effective strategies often entail large commitments of organizational resources. Chains of liaisons between instrumental users and computing service providers facilitate multiple lines of communication and smooth tensions between conflicting groups. Regular meetings and redundant forms of communication ease coordination and minimize the likelihood of major slippages between the service providers and their clients.

Technology-based strategies often require large resource commitments. We have seen, for example, one engineering firm which uses a large-scale computer for production applications, and a similarly large computer devoted solely to software development so routine operations are unlikely to be interrupted. The point is that mitigating strategies which add more machine or staffing resources can add to the existing complexity of a computing setting thereby potentially displacing one set of problems with another set of problems.

In summary, technology-based strategies often miss major portions of the computing package that include important social relations and contingencies. In addition, the best mix of technology-based strategies and socially-oriented strategies for graceful computing can consume large resources, time and money. Since most computer using groups have limited resources, one should expect "budget strategies" to be the rule rather than the exception. Given constrained resources, some interests will be better served than others and some parties should be expected to face computing dilemmas routinely. The empirical prediction would be that any problem (such as data quality, response time, appropriate consulting or adequate documentation) should be troublesome for some minority of instrumental users in even the best managed setting of computer use.<sup>22</sup>

## CONCLUSION

Much of our account has focused upon the problems attendant in routine computer use. This is not because we believe that computing is a wholly troublesome technology. On the contrary, we believe that computer use often increases the information processing effectiveness and eases the work of many instrumental users.<sup>22</sup> However, these gains often do not come gracefully or easily. Computer use is most troublesome when the necessary social resources (such as technical expertise, demands for time and attention, staff sentiment and control over computing services) are slighted or ignored when new computing arrangements are to be provided.

From the analysis of the recurrent dilemmas of computer use presented in this paper, we draw the following conclusions:

1. The computing tool metaphor displaces attention from the social dilemmas of computing by tacitly identifying advances in computing with advances in the technical

sophistication of the equipment used. Moreover, many of the attendant difficulties in computing are *not well predicted or understood* by employing the tool metaphor.

2. Problems of computing vary with the particular computing technology in use and the organizational arrangements through which computing services are produced and used. Hardware reliability is usually more salient in on-line systems than with batch systems. Allocation of machines and staff are typically most contentious when control over each resource is centralized. Staff highly sophisticated in computing may provide the best technical assistance, but they are also the most difficult to interest in routine applications.
3. Many of the problems experienced by computer users develop from their relationships within the "computing world." The computing world is highly differentiated into specialty interests<sup>24</sup> and organized to routinize the movement of innovations from producers, through service providers to instrumental users.<sup>23</sup> Instrumental users face markedly more complex issues when they split their computing activities across equipment supplied from different "vendor worlds." Also, they often have little control over the pace at which small enhancements or alterations are made in supporting software supplied by groups outside their organization.
4. As technical advances in computer hardware and software simplify the technical problems of computer use faced by users, the social problems of computer use will become relatively dominant. Each of these problems has associated costs. These costs are poorly understood and have yet to appear in the figures cited for total systems costs.<sup>3,13,25,38</sup>
5. The social elements of computing are typically underestimated in proposals for new computing arrangements. Social resources such as time, attention, skills, information and inclination can be costly to acquire, utilize and maintain, but discounting their role in computing results in displaced organizational costs. For example, expert consultants and good system training aids are costly to provide. But when instrumental users cannot obtain needed assistance, they recurrently find computing use to be troublesome and uncertain.
6. The package view implies that successful computer use depends on the organizational distribution of social *and* technological resources and how they are allocated or acquired. Successful computer-using organizations balance their technological investments with explicit investments in the social elements of the computing package.
7. Currently, there are no simple or uniform solutions. Alternative computing arrangements which are proposed to solve certain individual problems can exacerbate or manifest others if the social character of computing is disregarded.

Computing is a problematic technology for many instrumental users, in part, because it raises *so many social issues* which continually demand attention. We suggest that instru-

mental users and specialists alike use the list of issues presented in Table I as a diagnostic guide for assessing the impact of existing or proposed computing arrangements. As a checklist, Table I can help an analyst decide which activities a new "solution" may alter, and which it may leave untouched. Table I can also help an analyst make explicit the rich set of social features which characterize the social milieu of complex organizations.

#### ACKNOWLEDGMENT

Elihu Gerson, Sharon Price, and Harold Sackman provided helpful comments on an earlier draft of this paper. Philip Crabtree helped develop some of the ideas presented here. This work was supported by NSF Grant MCS77-20831.

#### APPENDIX A—COMMON ISSUES IN INSTRUMENTAL COMPUTER USE

##### *The work setting of computer use*

**The concepts users and computer specialists have of their own work and the role of computing in it.** Specialists and users have different concepts of how central computing is, should and could be to the successful performance of their jobs. To specialists, computing can be everything. Instrumental users, however, often view computers simply as a means to achieve some other ends. This difference of focus has substantial repercussions for the amount of effort people of each orientation are willing to spend learning and adapting to new computer system developments.

**The mutual perceptions of computer specialists and users.** Specialists can influence the involvement of users in the computing process. Shared perceptions may be important to the specialist in determining how users should be educated or to what extent users should be involved in the design, implementation and maintenance of particular systems.

**Differing responsibilities among computer specialists.** As an organizational unit grows and expands, the jobs within it often become more narrowly defined and specialized.<sup>2</sup> The resulting division of responsibilities and skills may increase the difficulties faced by clients of the unit when they seek a service which requires several specialists. For example, an instrumental user may find that to change an inquiry program, he or she must coordinate efforts with those of a programmer, a systems analyst, a data base manager and a teleprocessing specialist. Increasing the technical sophistication of a system often leads users to interactions with more specialists.

**Doing a "good job" and being rewarded for it.** People often differ on which aspects of a job are important for satisfactory performance. Some programmers emphasize satisfying user demands, while other programmers emphasize elegant code.

Despite these individual interpretations of what constitutes doing a "good job," the organizational structure may impose a reward system on specialists which emphasizes

different activities.<sup>16</sup> The rewards may be for meeting schedules, for the number of coding lines produced or for getting to work on time. Whatever reward system exists in an organization for computing specialists, it may conflict with what specialists perceive to be important measures of job performance.<sup>21</sup>

**Maintaining career mobility.** Specialists appear no different than any other employees in being concerned about job security and career development. Specialists may feel that a strong position in the marketplace depends on one's experience with the latest technological innovations. Consequently, specialists may influence their organization to continually acquire state-of-the-art hardware and software packages.<sup>23</sup>

### *Understanding the capabilities of computing*

**Learning about computing—What computers are good for, how their particular machine might be used, etc.** Beliefs about the appropriate role and capabilities of computing vary considerably. Those who work closely with the technology often view computing as a special-purpose device which is best suited for applications something like their own. Thus accountants often view computers as "accounting engines," while urban planners may view them as statistical calculators.

Coupled with beliefs about appropriate tasks for automation are beliefs about the ease of applying computing. Computer specialists often view the technology as speedy and convenient. However, programmers (like planners, designers, managers and other professionals), can underestimate the time required to develop and implement new projects.

**Getting a computational task successfully completed.** When a problem can be solved with the existing computing system, users may find themselves facing a procrustean software system.<sup>33</sup> Rigid system designs add to the complexity which users must overcome to compute a solution to their problem. In theory, computing may be both technically and organizationally complex. In fact, it is also complicated.\* Most software packages, however simple or complex, usually have idiosyncratic conventions\*\* which arise from problems in implementation, compatibility with odd features of related systems, or simply through "poor" design. Nevertheless, an instrumental user must master and remember these conventions to utilize a software system.

In addition, the elapsed time to complete a computational task, from the point of view of an instrumental user, begins

when the task is conceived and ends when the computed job is translated into a usable form. This time frame is larger than that of the computer specialist who counts from the time that a task is well specified until a product is delivered to the user. And it is still longer than the time to complete a computational job as viewed by the computer operators. This usually equals the time to complete a job once it is being executed by a digital computer. Despite these obvious observations, the time to complete computing tasks are usually conceptualized in time frames closer to those of machine execution than to those of instrumental users.

**Dealing with computing/systems jargon.** Specialized languages enable work groups to communicate about their work compactly and to maintain a definition of "insiders" and "outsiders." "Jargon" is thus an inevitable element of worklife in specialized occupations. Smooth expert-client relations in computing milieus require that either one participant know the technical vocabularies and rationales of both computing and the occupational world to which it is applied, or that one of the parties be skilled at developing communicative bridges between computing and another world of discourse. If both parties possess either skill, so much the better.

Purposive use of jargon enables an actor to structure situations to her or his advantage by "snowing" the other parties in an encounter. When the legitimacy or competence of a computer specialist is brought into question, confident explanations couched in complex technical rationalities are difficult for most people to penetrate. Purposive use of jargon helps a specialist save face and protect his autonomy.

**Getting adequate documentation for computer-based systems.** Both computer users and specialists rely upon a variety of documents to learn the capabilities of and precise incantations for using particular system features. Different users of a given system may desire either a tutorial manual or a reference manual, although both rarely co-exist for any computer-based system. In fact, one dominant feature of computer settings is the extent to which participants depend upon clear and accurate documents to select, use and maintain computer systems, and the relative paucity of appropriate high-quality documents. Documents, like any other computing product, are produced within a social order of computer specialists, service providers, and clients. The difficulties of documentation are more those of the priorities within the computing world rather than the technical difficulties of writing.<sup>30</sup>

### *Changing computing arrangements*

**Loci of change.** Most computer applications evolve gradually. However, changing an application often results in altering the routine procedures for many different people who use it. New features are usually negotiated between some mix of instrumental users, computer specialists, important actors in the computer using organization, computer vendors, and outside consultants.

Computing personnel often have more requests, demands and self-initiated ideas for changes than their staffing per-

\* Complexity refers to substantive logic-mathematical interrelations and difficulties: complications can arise in almost any arrangement of facts, concepts and thoughts. Complication is an undesirable characteristic of any construct: complexity may be an inherent feature.<sup>6</sup>

\*\* For example, program runs may begin with an incantation such as //JOB=. Variables may be restricted to six alphanumeric characters and begin with a letter. Or once a file is processed, it may not be reprocessed until a special routine is executed. Most computer users learn to use the technology despite dozens of similarly idiosyncratic conventions. However, they add undue complication to a complex technology.

mits. Thus, they can usually select certain alterations from the larger set of requested or required alterations. While many changes in computer applications or their supporting systems are requested or "needed" by some users, certain users appear better served than others. In addition, most users must expend personal and organizational resources to ensure that changes which they desire are actually implemented. The actual dynamics of these negotiations, the resources they consume and their repercussions for both computer users and computer specialists are poorly understood.

**Scope and rate of change.** Changes in the computing milieu vary in frequency and scope. While it is easy to assume that low rates of change are easier for users to adapt to, that hypothesis is oversimplified. Infrequent changes of wide scope, such as changing the formats for large sets of data, may disrupt a class of users regardless of frequency. Upward compatible features which are transparent to most users may be introduced into many systems and processors with relative impunity for most users.

On the other hand, certain users often seek specific changes in both applications and support software. However, in *shared systems*, changes developed for one party are typically imposed upon all users of the same computational resources. Many technical changes that benefit one party may benefit others as well. However, there are also common conflicts between the technical needs of different users. It is an empirically open question as to how frequently technical changes are either "pareto optimal" or indicate a redistribution of computational resources. Thus, the advocacy and implementation of changes has a strong political content above and beyond the resources required to implement the change.

**Formalizing change procedures.** Large software systems are often used to support organizational activities. Since these systems operate in a production environment, any alteration to such a system is usually scrutinized to assure that it doesn't cause disastrous effects. Many organizations have thus instituted a series of bureaucratic procedures to be followed prior to the actual alteration of a system. These procedures can be cumbersome in certain organizational structures.

The ability of an organization group to get a particular set of changes implemented may require interaction with, and the approval of, a number of intervening individuals or committees. If there are a large number of system change requests pending, then some prioritization scheme may exist. The group seeking system changes may now have to rely on its members' negotiating skills to assure a suitable priority.

#### *Data quality*

**Collecting input data.** Many contingencies structure the situations in which one party collects data about the activities of a second group from a third group for use by a fourth group. Some extreme situations include those in which (a) the groups are all the same or (b) all groups are aware of each other and share information with mutual consent and are all jointly concerned that the data be accurate. The latter case might occur with bank records, for example. In cases

of high mutual commitment, data capture may be smooth and subject primarily to errors in data entry.

However, in some important situations conflicts of interest or priority can arise among the various groups. If the data is to be used to assist the fourth party to control some activities of the data subjects (as in tax reports) there is some incentive for incomplete or inaccurate reporting.<sup>17</sup> When several organizations share information systems, providing high quality and complete information may be more important to some participants than to others.<sup>18</sup> Thus the quality of data collected is influenced by the patterns of interest cooperation within the social order surrounding the information systems.

**Ensuring the correctness of processed data.** It is common to believe that once data is accurately captured by a computer-based system it will remain accurate. There are at least two conditions under which this assumption can be problematic. Sometimes data is aggregated or reorganized to be used in an analysis. As the complexity and number of the data manipulation steps increases, programmers, operators or the application system itself may introduce difficult to detect errors in the transformed data set. Since data do not reorganize themselves in useful ways without personal intervention, data analysts are an essential part of many policy analysis units, survey research centers, etc. Secondly, in some systems which are shared by many users, particularly simulations, important parameters may be changed by one party without the cognizance of other users. Digital computers are particularly useful as calculating engines when the computations are too complex, tedious, or time-consuming for hand calculation. However, it is just in such cases that verifying the validity (or stability) of the results obtained is the most difficult. While such events are rare, their dynamics are instructive.

#### *Control over computing*

**Control over the technology.** Maintaining effective control over computing resources is a central issue for many computer users in an organization. In addition, some higher-level administrators who are not computer users, simply view computing as an expensive line-item to be kept in check.

Since computing and information are rich organizational resources, issues over contention for control are naturally commonplace. Like other social aspects of computing, negotiations over control of specific computing resources (e.g. data, programmers, budgets, I/O devices) take time and absorb organizational resources.

**Access to and control over expertise.** Computing is a complex process. In spite of its complexity, its use by a variety of people is becoming widespread. Many people do not take the time or interest to learn a great deal about it. Therefore, they must rely on others to help utilize computing effectively and to handle problems and unanticipated situations. There is increasing evidence that when users have easy access to expert assistance, the computer-based systems are better accepted than in those situations where access is more difficult.<sup>27</sup>

**Controlling the kinds of demands made by users.** Whenever a personal service is provided, the stage is set of its consumers and providers to continually negotiate the kinds of service each would most prefer. In this way, computing is little different from other personal services such as legal advice, financial counseling, or medical care.

Computer specialists develop strategies for managing the behavior of their clients to help serve their own ends and make their organizational life tractable. Since they usually work as salaried employees with little freedom to negotiate a higher wage for difficult projects or those that incur an unacceptable level of dirty work, the strategies usually entail claims about organizational contingencies. Users may be told their requests are more expensive to fulfill, will take longer time to complete or entail unexpected technical complexity (such as system redesigns) to help displace less desirable work. Since computer specialists often have a relative monopoly on the expertise essential for judging the complexity of different requests, specialists' work-moderating strategies are difficult for instrumental users to easily counter.

**The "values" sought by those individuals and organizations which promote applications development.** Often computing systems are developed and installed when a specific person or small group of individuals actively promotes computing within an organization.<sup>21,26</sup> New computer applications are usually costly: promoters who want resources allocated to their project must often first obtain sanctions from other organizational members. Since different actors become involved in acquiring computing resources, computing will often serve many ends. For example, some actors may be seeking to enhance their administrative control, others seeking to cut costs, still others may be seeking to make their jobs easier or more interesting. Few applications can be designed to serve many different interests well. Some users of computing often face difficulties which derive from the way in which their system is "optimized" to serve the interests of some other group.

**Political support within the organization.** Politics deals with the allocation of goods, services, symbols and values. The distribution of computing resources is often the focus of conflicts over budgets, staff and domain. This is not incidental. Rather, it is an *intrinsic* aspect of computer use. To the extent computing resources are valued by different actors in an organization, they will seek access to them. The resulting contention with its usual conflicts, bargaining and subterfuges is similar to other kinds of organizational politics.

Some actors seek control over computing resources simply because it provides a relatively large, growing staff and consequently a growing budget. There is also some evidence that overall computing arrangements can be more strongly influenced by the political access of key actors than by the technical soundness of their preferences.<sup>31</sup>

#### *Software development practices*

**Programming and design practices.** Since the development of software has become a major expense of computing for

most organizations, considerable attention has been focused on improving software design and programming productivity. New techniques<sup>12</sup> and tools have been developed to assist specialists with their various tasks. Structured programming<sup>10,11,39</sup> is currently emphasized to aid specialists, as well as Chief Programmer Teams<sup>1</sup> and automated design aids.<sup>4,5</sup>

While these techniques and aids may be beneficial for the organization, they may be problematic and disruptive for specialists. They may actually make the specialists' jobs more difficult and attention-demanding. They may create changes which are frustrating for specialists accustomed to previously established procedures.

Most modern programming practices and tools are yet to be widely adopted in computing settings outside of where they were developed. Reasons for this are unclear, but we suspect that organizational contingencies (such as meeting schedule deadlines, budgetary constraints or personnel training costs) in a computing setting tend to shape the adoption and incorporation of such tools and techniques.

**Program testing.** In theory, one would like to be able to automatically generate a sufficient set of test data necessary to demonstrate the probable correctness of a robust class of programs. However, for programs of moderate complexity, the set of test data to exercise all paths through a program is infeasibly large.<sup>15</sup> Nevertheless, some promising research is proceeding on various schemes to automate tests for special program conditions.<sup>5,32</sup> In contrast to the research on new tools for program testing, the state of current practice does not rely upon much automation at all. Test data, for example, are usually selected manually by a programmer or a knowledgeable user.

**Software maintenance.** Maintenance is often considered to be everything that happens to software after user acceptance. Maintenance can range from "bug fixes" through complete redesign and redevelopment of a delivered system. Often, the people who develop the system are not the same as those who maintain it. Given that different specialists are involved in system development and maintenance, finding those people (users or specialists) with dependable understandings of a system operation can be quite salient in determining the ease, timeliness and reliable execution of maintenance tasks.

Most programming work is in maintenance, not development. However, maintenance entails ongoing interaction between users, programmers, managers, vendor representatives, etc. While current software system life-cycle costs reflect the high cost of maintenance,<sup>3,5</sup> the available figures do not distinguish the costs of program alteration work from the time, skill and attention required by specialists to successfully interact with those people requesting alterations. The extent to which these interactions are negotiated and completed with ease or difficulty, may better account for the variation in minimizing or exacerbating the costs of "routine" maintenance tasks.

**Software documentation.** Adequate and up-to-date software documentation is continually a weak feature of most software systems. Poor documentation is not usually a result of some software development practice. We note that while

many software system manuals can be measured in inches, their adequacy and currency vary. However, reasons for the variable quality of documentation appear not to be due to the unavailability of suitable documentation support aids or deficient programmer practices. Rather, updating documentation demands time, skills in clear and concise writing and attention. Given that specialists face some number of competing demands for their services, their ability or desire to maintain documentation competes with other work demands whose completion may be more highly rewarded.

### Attention

**The kinds of attention demanded by computing.** Computing may appear to some users and specialists as a technology that requires a person learn a great deal to effectively utilize it. Many users must (or are at least led to believe they must) use the computer efficiently because it is a scarce resource. However, the time required by a user to prepare and successfully execute (after "debugging" runs) efficient programs often displaces any net savings in terms of completing the task at hand. Concern for minimal computer resource usage versus concern for minimizing the time to complete a work task often lead to conflicting demands for the user's attention.

**The precision and detail demanded by computing.** As a tool, the computer is a fairly exacting device. It demands that procedures be followed explicitly. It does not allow loose or *ad hoc* procedures in handling transactions as might exist in a manual or more informal information system.

At times, users complain that their jobs are actually more difficult or less interesting with computing than they had been previous to computing. Specialists complain that it takes a special person, like a "hacker," to be truly satisfied with the detail demanded by systems and application programming.<sup>37</sup>

# Project management through the Accomplishment Value Procedure (AVP)

by DONALD J. AHARONIAN

Digital Equipment Corporation  
Maynard, Massachusetts

## INTRODUCTION

This paper describes a technique called the Accomplishment Value Procedure, AVP, which accurately measures the status of and provides visibility to an information systems development project. It builds upon the foundation of two of R. I. Benjamin's axioms:<sup>1</sup>

*Axiom #10*—"The great leap forward is best accomplished in short, comfortable hops; if there is a 'Golden Rule' in information systems development, this is it."

*Axiom #14*—"If you can't plan it, you can't do it."

to which I add my own corollary:

"If you don't schedule it, it won't get done."

A persistent problem of project management has been to relate resources budgeted with work accomplished after the project begins.<sup>2</sup> AVP bridges that gap. As a tool of project management, AVP:

1. Provides the means to schedule, monitor and control a project after it has passed the planning phase.
2. Enforces a discipline for resource estimating and time scheduling that focuses on the completion of tasks.
3. Provides a method to handle changes to schedules and to resources which can be documented and displayed simply and clearly.
4. Provides a method for summarizing overall status of projects by management responsibility.

AVP does all this by focusing on the gathering of data that is plotted on a Project Visibility Chart for an individual project and a Summary Visibility Chart for a group of projects.

In doing so, AVP communicates with all levels of an organization in a consistent manner:

1. Top management sees a snapshot of the overall status of development projects.
2. Middle management sees a snapshot of individual projects.

3. Project leaders can monitor performance and compare it to schedules and estimates which point to areas of potential problems that might require management analysis.
4. Project team members can see the status of the projects they are working on.

The remainder of this paper deals with (1) a discussion of *Background: AVP in the Perspective of Project Management*, (2) a description of the *Accomplishment Value Procedure*, (3) a description of an *Example of the AVP Process*, (4) a description of *How AVP Handles Changes* in schedules and estimates, (5) a description of the *AVP Summary Process* and (6) a *Summary* section that includes conclusions and observations regarding the applicability of AVP.

## BACKGROUND—AVP IN THE PERSPECTIVE OF PROJECT MANAGEMENT

Project management usually means different things to each of us. A major reason is that a project is a unique effort marshalling resources to solve a unique problem. The uniqueness has attracted special management techniques which, according to Murdick and Ross<sup>3</sup> include "outstanding characteristics," such as:

1. *Work breakdown structuring* which is a method that decomposes the project end result, level-by-level, all the way down to something called the work package, the lowest identifiable element of work to be done.
2. *Network definition* which describes task relationships in a project and which is usually associated with PERT/CPM activities.
3. The *integration of performance/cost/time* for project planning and control.

You can locate AVP in the perspective of project management by relating the outstanding characteristics to the three basic managerial functions required as defined by Paulson<sup>4</sup> as follows:

- *Planning*—" . . . the various tasks . . . must be performed to complete the project . . . involves approxi-

TABLE I.—Project Management Matrix

		Outstanding Characteristics <sup>3</sup>		
		Work Breakdown Structuring	Network	Integration of Performance/ Cost/Time
Management Functions <sup>4</sup>	Planning			
	Scheduling			AVP
	Control			AVP

mate requirements for material, equipment and manpower . . .”

- *Scheduling*—“. . . the feasible start and completion dates for each activity . . .”
- *Control*—“. . . monitoring actual performance and comparing it to that which was anticipated from the schedule. The essence of control lies in recognizing differences when they occur, determining reasons for them, and promptly evaluating effects on the schedule.”

In terms of the three “outstanding characteristics,” AVP assumes that (1) formal, or informal work breakdown structuring exists with or without a standard work breakdown

structure being built, and (2) that the relationships and dependencies among tasks are understood with or without a network being drafted. It is the third characteristic dealing with performance, cost, and time to which AVP applies—with one distinction. The distinction is that AVP takes place after planning is completed.

The matrix in Table I shows where AVP fits in the relationships between Outstanding Characteristics and Managerial Functions of Project Management. AVP addresses itself to the articulation of accomplishment (performance) and manpower (cost) related to (integrated with) time. By displaying accomplishment and manpower at points in time, AVP provides a visibility that communicates the schedule and supports control.

The quantification of the value of accomplishing each task is crucial to AVP. As each task is completed, the project is credited with the value of the task. There is no credit for a partial completion; thus the notion of “percentage complete” is avoided. The expression of percentage complete has traditionally been difficult in its execution, arbitrary in its determination and misleading in its interpretation.<sup>2</sup> How often has one heard the response that a project is “x percent complete?” In fact, projects have been known to be “90 percent” complete for months.

THE ACCOMPLISHMENT VALUE PROCEDURE

The mechanics of the procedure result in the creation and update of the Project Visibility Chart. The vehicle for this

Figure 1—Blank Project Visibility Chart and Estimating and Scheduling Form (Parts A-E).

procedure is the Estimating and Scheduling Form. The form integrates the key steps of the procedure and flows through to provide the data for the Project Visibility Chart. The form is a composite of five parts, referred to as Parts A through E. Figure 1 shows all parts in the relative positions of the flow of data and information, i.e., from A to B to E and from A to C to D.

Part A is where you would insert descriptive data about each task (milestone) deliverable. The procedure assumes a documentation standard and just about any version would do. Further, the procedure amplifies the doctrine espoused by *ADP Analyzer*,<sup>5</sup> which says "... documentation be completed by the end of each phase and each review period. If the documentation has not been completed, then the phase has not been completed—and the next phase cannot begin." AVP accepts any documentation standard and encourages even finer breakouts or subsets.

Part B is where you would enter the estimates of resources committed to each task/milestone/deliverable by time period (usually a month, but the procedure can handle weekly and daily). We focused on manhours because it is the key resource and it is easier to collect data regarding manpower on a timely basis.

Part C is where you enter the time span for each task/milestone/deliverable further annotated with the "value" calculated for each.

Part D is a table which is built on the accumulation of data concerning accomplishment units scheduled and actual for each time period and accumulated by the end of each time period.

Part E is a table which is built on the accumulation of data concerning manhours estimated and actual for each time period and accumulated by the end of each time period. For convenience in preparation and for easy reference and analysis, Parts D and E are physically part of the Project Visibility Chart.

In Figure 2 is an example of a Project Visibility Chart for a completed project showing in the top portion, the Cumulative Accomplishment Values, Scheduled vs. Actual and in the bottom portion, the Cumulative Manhours (resources), Estimated vs. Actual, for the history of a project. The Chart displays the status of the project expressed in Accomplishment Units as well as the expenditure of Manhours, both over the life of the project. Notice that the points plotted on each Chart are derived from the data tables, Part D and Part E, contiguous with each. The data tables are built as a result of the process previously described.

EXAMPLE OF THE AVP PROCESS

The Accomplishment Value Procedure (AVP) highlights actual completion of milestones and ignores partial comple-

ESTIMATING AND SCHEDULING

PART B

Figure 3—Example of Parts A-B and A-C filled out at the beginning of the AVP process.

tion. It provides the mechanism for identifying those milestones in the development process that have specific deliverable documents which signal the completion of a milestone.

Once the milestones are identified and resource *estimates* are associated with each, the sequence of events can be *scheduled*. Next is the calculation of the "value" of each milestone. For our purposes, value is based on the establishment of an arbitrary denomination of units which reflect the relative estimated manhour resource for each milestone/deliverable.

The Accomplishment Value is the focal point for the project as it moves to completion. The Accomplishment Value is plotted monthly on the graph along with the resources. In this example, 20 manhours was selected as equal to one Accomplishment Value. Thus, if the milestone/deliverable is estimated to need 160 manhours of resources, then its Accomplishment Value is eight.

See Figure 3, Key I, which is the Estimating and Scheduling Form—Part A filled out with the Accomplishment Values for each milestone/deliverable and represents the beginning of the process.

Having completed Part A, you can proceed to Part B where the loading of the resources over the course of the project is entered. This loading then becomes the estimated manhours (resources) for the life of the project. See Figure 3, Key II, which shows the manhour loading or MONTH EST (estimate) by month for each task/milestone/deliverable and the total MONTH EST (Estimate) for each month.

For each milestone/deliverable that you have associated with a Scheduled Start and Completion date, you can enter the 0—symbol for the start in the week in which the effort for that milestone/deliverable will begin and a □ in the week that it is scheduled to be completed and delivered.

In the square for the ending week, you can enter the Accomplishment Value. Next, add up the Accomplishment Values for each month. See Figure 3, Key III.

The values of each milestone/deliverable are combined to roll up to the total value of the project. In the course of completing the project and as each milestone/deliverable is achieved, the value of each milestone is credited toward project completion, and a measure of project status is established. Credit is given only to those milestone/deliverables that are completed; resources expended on an incomplete deliverable are given *no* credit. This criteria forces attention to establishing as many milestones as is logical and manageable—a basic rule in successful project management. As a corollary, a specific deliverable could be segmented with each segment becoming a separate milestone/deliverable that would be scheduled, estimated and accomplishment valued.

Next, you build the data tables in Parts D and E that will be the plots for curves on the Project Visibility Chart. See Figure 4.

The MONTHLY SCHEDULE Accomplishment Value in Part D is simply a posting of the totals from the bottom of Part C and from which the CUMULATIVE SCHEDULE Accomplishment Value data is calculated.

The MONTHLY EST (Estimate) manhours data in Part

Figure 4—Project Visibility at end of April.

E is simply a posting of the totals from the bottom of Part B and from which the CUMULATIVE EST (Estimate) is calculated.

The CUMULATIVE SCHEDULE Accomplishment Value and the CUMULATIVE EST (Estimate) manhours are the plots by month on the Project Visibility Chart in Figure 4.

As the project develops, Actual Data is collected for Manhours and Accomplishment Values. In our example you can see the data recorded through April, the fourth month.

The Project Visibility Chart representing the status of the Sample Project through April would be as in Figure 4. An analysis of the charts and the data in the table above and below the charts (which are Parts D and E of the Estimating and Scheduling Form) shows that the Project fell behind the Scheduled Accomplishment during March but that we caught up during April. The recovery, however, seems to be costly since we have exceeded our estimated manhours

by nearly 200 manhours. If the trend continues, the project could get into a serious over-budget situation. This situation would require further analysis.

HOW AVP HANDLES CHANGES

The technique lends itself to a procedure for changing schedules and estimates based on changes in project scope or in availability of resources, etc. If for example, at the end of April it was determined that the project's schedule could be shortened by infusion of additional available resources, (while it may violate Brooks' Law<sup>6</sup> it is optimistically espoused here for illustration purposes) then the Estimating and Scheduling Form—Parts B, C, D, and E—should be modified to reflect this change and to show the impact on the bar chart schedules. The impact of the revision with the new manpower estimate, and the Accomplishment Value Units, for May and June is readily shown in the Project Visibility Chart, Figure 5, which shows a new chart with the scheduled and estimated lines shifted upward for both Accomplishment Values and Manhours. This representation is significant since it provides visibility for changes in estimates and schedules.

THE AVP SUMMARY PROCESS

AVP further lends itself to summarizing groups of projects by management responsibility such as those of an individual cost center. A collection of Project Visibility data from several projects can be aggregated to provide visibility. By focusing on an individual fiscal month, you can display Scheduled and Estimated data for its development projects at the beginning of the month. At the end of the month, you can then aggregate the Actual data for Accomplishment and Manhours.

On the right side of Figure 6 is a Summary Visibility Chart completed for a development cost center for the month of October 1978. The Bar Graphs show the Scheduled Accomplishment Units next to the Actual Accomplishment Units in the top portion with the Estimated Manhours next to the Actual Manhours in the bottom portion.

On the left hand side of Figure 6 is the AVP Log which is the vehicle for the Summary Process. The Log provides space for recording the Schedules and Estimates for each of a group of projects at the beginning of a time period (usually Fiscal Month) and for their Actual Data at the end of the period.

While transferring Accomplishment Values from the Part Ds you have to make certain that the Unit of Measure (U/M) is consistent. If 20 manhours were used as the U/M for the Summary Process, then the procedure is to divide the U/M of each project by 20 and then to multiply the resulting fraction by the Accomplishment Value Units associated with the project. For example, if a project had scheduled 72 units with a U/M of 10, then to convert—divide 10 by 20 which results in 1/2; then multiply 1/2 by 72 which results in the

Figure 5—Project Visibility Chart showing impact of revision at end of April.

conversion of 36 Accomplishment Units. It is the latter number that you post to the Summary AVP Log.

Six projects are posted on the Summary AVP Log with a total Accomplishment Value of 120 (based on a unit of measure of 20 manhours per each Accomplishment Unit) and 2,600 manhours are estimated (and committed) to be used in the process of doing project work. At the end of the month, the actual data are posted totaling 100 Accomplishment Value Units and 3,000 manhours respectively. It is the data from the totals column that is used as a basis for constructing the bar chart.

SUMMARY

This paper has introduced the Accomplishment Value Procedure (AVP) by first discussing where it fits in the background perspective of Project Management. Then, the paper

# SUMMARY VISIBILITY CHART

Figure 6—Summary Visibility for one month.

described the steps in the AVP process which lead up to the creation of and provides the basis for updating the Project Visibility Chart. Included in the description was an illustration of how changes in resources or in time would be shown on the Project Visibility Chart. Finally, there was a description of the AVP Summary Process which provides for tracking and displaying groups of projects of a functional organization by aggregating their Visibility Data.

AVP is currently in place in the Customer Service Operations Development (C.S.O.D.) Department which is the internal ADP/MIS systems development and computer operations organization at the Field Service Headquarters of Digital Equipment Corporation, Maynard, Mass. C.S.O.D. provides system development and computer-based support

to headquarters functions in worldwide logistics, financial control and product engineering and centralized design and development of distributed systems for decentralized implementation at 15 data centers worldwide.

The benefits of its application revolve around the simplicity of how well it can be understood by project team members and how effective it is in relating (communicating) status to users and to management.

In addition, individual project team members reach a "comfort" level with the graphical representation of the project status and spend their time with greater attention to the objectives of the project.

There are other benefits. AVP highlights the viability of resource estimates and schedules at the onset of the devel-

opment cycle and the resource consumption and accomplishment achievement during the development cycle by the smoothness or lack of smoothness of the curve on the Project Visibility Chart.

The discipline of the Accomplishment Value Procedure lends itself to contracting applications development to a vendor. By focusing on specific deliverables you could contract for progress payments synchronized with each deliverable under either a cost re-imbursable basis or a fixed-price basis.

At project completion, final payment could be held back until a reasonable warranty period has passed. Moreover, there can be variations that would provide incentives to a contractor. For example, a progress payment or a fixed-price commitment for a deliverable by a certain date would pay  $X$  dollars to the vendor but delivery one month earlier

would pay 120 percent of  $X$  dollars where the incremental 20 percent would serve as an incentive to the contractor.

# Textfax—Principle for new tools in the office of the future

by WOLFGANG HORAK and WALTER WOBORSCHIL

Siemens Central Research Laboratory  
Munich, Germany

## INTRODUCTION

By taking a closer look at today's office, we observe the following trend: The conventional typewriter is gradually being replaced by word-processors. These may merely be electric typewriters with a storage added or they may take on the form of highly sophisticated CRT workstations featuring screens carrying an entire standard size page and exchangeable storage media. These systems, which originally had been intended for local word-processing, are now increasingly being supplemented by communication functions, permitting direct text communication from one's own buffer to that of a business partner—i.e. to his electronic "mailbox." Whenever desired, the recipient can then call up the text from the buffer for reading or, if necessary, for editing and subsequent filing or forwarding. These functions can be summed up under the catchword "electronic mail."

First experiments on this have been performed especially in the United States, like those of the Citibank.<sup>1</sup> To permit not only internal, but also public text communication, national and international standards still have to be elaborated, ensuring compatibility of the various products.

Further important elements in today's office, besides text systems, are the numerous copiers and—to the extent to which international standardization progresses—also remote copiers, i.e. facsimile equipment. Copiers and remote copiers are required to duplicate or transmit documents consisting of text *and* graphics. Here, too, a fusion of individual functions can be observed, as is the case with the remote copier with local copying operation.

Let us enter an office handling, for example, quotations for technical products. In this office, the quotation texts can be generated on the text system, perhaps by using stored text segments. However, the data sheet with photos, diagrams, etc., must be prepared at the printer's in the various versions and kept in conventional files in the office. To mail the quotation copy and the data sheet to the customer, there are two possibilities. Either text and data sheet are jointly enveloped and mailed or, in case the customer happens to have a remote copier of the same type, both can be scanned and transmitted successively by the remote copier. During this process, the text is treated like a graphic and—compared with alphanumerical coding—is transmitted with unnecessary redundancy, i.e. involving too much time.

The previous example shows that, in today's office, it is still not possible to jointly

- Collect
- Process
- File
- Output as hard and soft copy
- Effectively transmit

text *and* image at the same workstation by using the same hardware and software components.

To be able to do so, new office tools are required. The underlying principle we call Textfax.<sup>2</sup> On the road toward a largely "paperless" office, we have done some research to work out this principle, trying to specify the functions of these tools and to study ways and means of implementing them.

Developments in the direction of Textfax are

- The printer plotters, where the same matrix printer is used for text and facsimile printout.
- The image processing systems for computer-aided processing of TV images.
- The system named Electronic Darkroom<sup>3,4</sup> developed since 1970 at the MIT for Associated Press for editing, filing and transmitting of press photos.
- The large printing facilities for electronic photocomposition, enabling above all combined text and graphic processing for ad offices.
- The initial proposals<sup>5</sup> for transmission procedures permitting combined transmission of alphanumerically coded text and coded facsimiles.
- The experimental Soft Display Word Processor from Xerox,<sup>6</sup> which has a facsimile graphic generator to produce business forms or other graphics, that can be overlaid with text from the character generator.

In the following, the performance features of Textfax will first be specified more closely to subsequently go into the first results from two processing runs carried out on an experimental workstation.

## PERFORMANCE FEATURES OF INTEGRATED TEXT AND FACSIMILE PROCESSING AND COMMUNICATION

### Data entry

Figure 1 illustrates the various possibilities of entering text, handwriting and hand drawings and collecting mixed text/graphic material on paper or microfilm.

The *tablet* is used for inserting hand drawings to be copied into mixed text/image documents. During copying, a separate positioning step is required which is not necessary when writing directly in the softcopy with a light pen or on a touch-sensitive device (TSD) attached to the screen. This way handwritten comments, corrections and signatures can be applied to documents.

In the case of a boss/secretary workstation, e.g., the secretary has a complete system while the boss merely has a tiltable full-page screen with a TSD for handwriting and function selection. The boss can thus apply corrections to the text typed by his secretary and circulars and other sorted mail received electronically can be marked with comments before it is passed on, for example.

The *facsimile scanner* has the same resolution as defined in CCITT recommendation T.4 for Group 3 facsimile apparatus. As a compromise between facsimile quality and data quantity this resolution should suffice for most office applications and represents the standard according to which the documents are processed, filed, output and transmitted at a Textfax station. With a scanning window of approx.

215×297 mm, a page (size DIN A4=210 mm, ×297 mm, U.S. standard=215 mm×280 mm) in the form of a loose-leaf, a book or a magazine page, is scanned with a horizontal resolution of 1728 pixels per line, and a vertical resolution of 7.7 lines/min. Scanning time per page of about 10 sec. is possible. Mixed documents are entered with 4 to 8 bits per pixel, with grayscale portions after rastering being passed on for further processing with one bit per pixel just like text, graphic and handwritten portions after passing a black-and-white threshold.

On workstations having to cope with large text volumes of existing documents, *character recognition circuits* can be connected to the scanner. This way texts can be entered with low redundancy and alphanumeric coding, and not as facsimiles, i.e. in raster reproduction. In the case of mixed documents, texts in strange fonts, graphics, handwritings and grayscale images can be either masked via programmable masks or, like unrecognized characters, be entered as facsimiles. In the latter case, undesirable portions of a document to be entered can only be erased afterwards by marking the corresponding spaces in the softcopy with the cursor. In the same manner, unrecognized characters can be replaced subsequently via the keyboard by alphanumerically coded ones. The most frequently occurring fonts, such as OCR-B, letter gothic and pica, should be recognizable.

Via *video camera*, sections from leaf and book material can be entered quickly and conveniently. For example, via function keyboard and screen monitoring, the camera is positioned over the material, and the size of the section determined with the motor zoom. Thus, it is possible to enter details with a resolution larger than the standard resolution. Furthermore, construction permitting, images of three-dimensional objects and persons (e.g. photos of authors) can be entered with one and the same camera. Microfiches are either scanned at the workstation, using a suitable frontal attachment to the above camera, or with the scanner of a central microfilm file containing standard graphic segments, for example.

Figure 1—Entry.

### Hardcopy and softcopy

The softcopy on the screen is required for monitoring input and text/facsimile editing. To feature a full page flickerless with Group 3 resolution, a video monitor with approx. 2,300 visible lines at 60 Hz frame frequency would be required. Depending on the size of image and line return, this corresponds to a beam dwell of less than four ns per pixel, and an output rate of more than 240 Mbit/s. Obtaining such data entails technological problems, above all concerning the picture tube. It is therefore recommended to instead make use of a monitor with approximately 1,200 visible lines and a 60 Hz frame. Selecting vertical format and a 44 cm screen diagonal, a full page with half the standard resolution, i.e. 3.85 lines/mm (=Group 2 resolution) can be shown flickerless in original size with black text on white background.

If half the standard resolution is insufficient, e.g. when editing smaller details, switching to full resolution is possible. In this mode only one-quarter of a vertical format page enlarged by the factor two can be represented. However,

the window, i.e. the quarter section, can be shifted over the entire page, both horizontally and vertically. The video monitor is accompanied by a refresh memory of four Mbit capacity. This corresponds to the number of black-and-white pixels of a complete page scanned with Group 3 resolution.

Hardcopies are produced with a matrix plotter. It should output the mixed text/image documents in standard resolution on regular paper DIN A4 sheets within about 10 sec. per page. As required, a processor-controlled device will cut the sheets from a paper reel of 210 or 215 mm width. Like entering, outputting and processing can be handled simultaneously.

The plotter and facsimile scanner, or videocamera or microfilm scanner can be operated concurrently in the local copying mode. Enlarging or reducing is done via software. The local copy renders text duplication by way of an impact printer's carbon copy superfluous. However, since local copying by coupling scanner and plotter via the processor loses in resolution over conventional office copiers relying on xerographic techniques, a combination of copier and facsimile scanner in one and the same device would be desirable. With local copying, the original is reproduced on the copying paper on a 1:1 scale, whereas entering calls for the original to be reproduced—e.g. on a line-by-line basis on a small CCD line.

### *Processing*

The known functions of text editing and processing are to be supplemented by the functions of facsimile processing, to the effect that mixed text/image material can be edited just as well.

Texts are edited in alphanumeric coding, in the form entered via keyboard or character recognition circuits. Only for outputting on the screen or the plotter, and perhaps for transmitting, the text is converted into a facsimile and combined with the image information. However, as the plotter is restricted only in resolution with regard to reproducible type faces, and since the reproduction scale of the characters permits ample variations, the text editing software must allow for corresponding variables. Individual type appearance is thus ensured, right up to text graphics, without the limitations inherent in a printer's type set. Furthermore, the coordinates of facsimile fields must be taken into account in the case of automatic line wraparound and margin adjust of mixed documents.

Compared to conventional text systems, where forms can be filled out only by way of complicated screen masks, filling out forms is considerably facilitated. The actual combination of text and form is now left to the printer's hardcopy. In the case of Textfax, writing can be done on the true-to-original form featured on the screen with signets and preprinted matter. The form can be signed without bothering about the softcopy paper. The forms are stored as facsimiles in the image file from where they are called up if needed. Figure 2 presents an outline of possible functions of a modular editor for integrated text and facsimile processing.

### *Filing*

Digitalized images involve large data volumes. While a DIN A4 page with text, alphanumerically coded, requires approx. 1.5 Kbytes, approx. 0.5 Mbytes are needed for a non-compressed DIN A4 page scanned with Group 3 resolution. On a double-density floppy disk for writing on both sides, roughly 600 text pages could be accommodated, but only two image pages. The previous figures could be increased roughly 10 times by taking recourse to single disk systems tailored to local office implementation. It is therefore necessary to develop efficient compression codes, for filing both black and white images and rastered grayscale images. Depending on image content, compression factors around 10 should be expected. Viewed from this angle, too, the floppy disk and the disk seem to be suitable for short-term filing of facsimiles only. For long-range image filing, one therefore has to avail oneself of either central image data bases with magnetic disk, magnetic tape and microfilm, or develop new image mass storage for local use at the workstation. The videotape might be one way to solve the problem. A two-hour tape should accommodate some 10,000 Group 3 facsimiles. Another way is the optical data disk for  $10^{10}$  bit from Philips, which is capable of storing at least 2,500 Group 3 facsimiles.<sup>7</sup>

In the text file, e.g. on floppy disk, so-called document heads of images and mixed text/image documents are stored. They are prepared and managed like texts. The document head contains a list indicating the files in which the various component parts of the document are stored. Text and image shares can be stored in different media.

### *Transmission*

The text/image documents prepared at a Textfax workstation can simply be transmitted as Group 3 facsimiles. To this end—as is the case with the softcopy—text components are converted into a facsimile and combined with the image components to form a full-page facsimile of approximately four million pixels. Implementation of the transmission procedure and the compression code (modified Huffman run-length code) in compliance with CCITT Standards T.30 and T.4 is the precondition for international transmission of text/image documents via telephone network to all Group 3 remote copiers, and their true-to-original output.

Due to the standardized scan/plot speed of max. 1 line/5ms a maximum transmission rate of  $1728 \text{ bits}/8 \times 5 \text{ ms} \approx 44 \text{ kbit/s}$  with an assumed mean compression factor 8 is possible in traffic with Group 3 facsimile equipment without full-page buffer. However, over analog lines of the telephone network, transmission can be done at a rate of 4.8 kbits/s only, or 9.6 kbits/s at most. Depending on content, the transmission of a page thus takes approximately 1 minute. Transmission via data networks or future digital telephone networks at a signal transmission rate of 48 kbits/s would result in a transmission time of approximately 10 s, which would be in keeping with the maximum plotter speed.

If a text page is not transmitted as a facsimile, but alphanumerically coded, only approximately 3 s. are needed

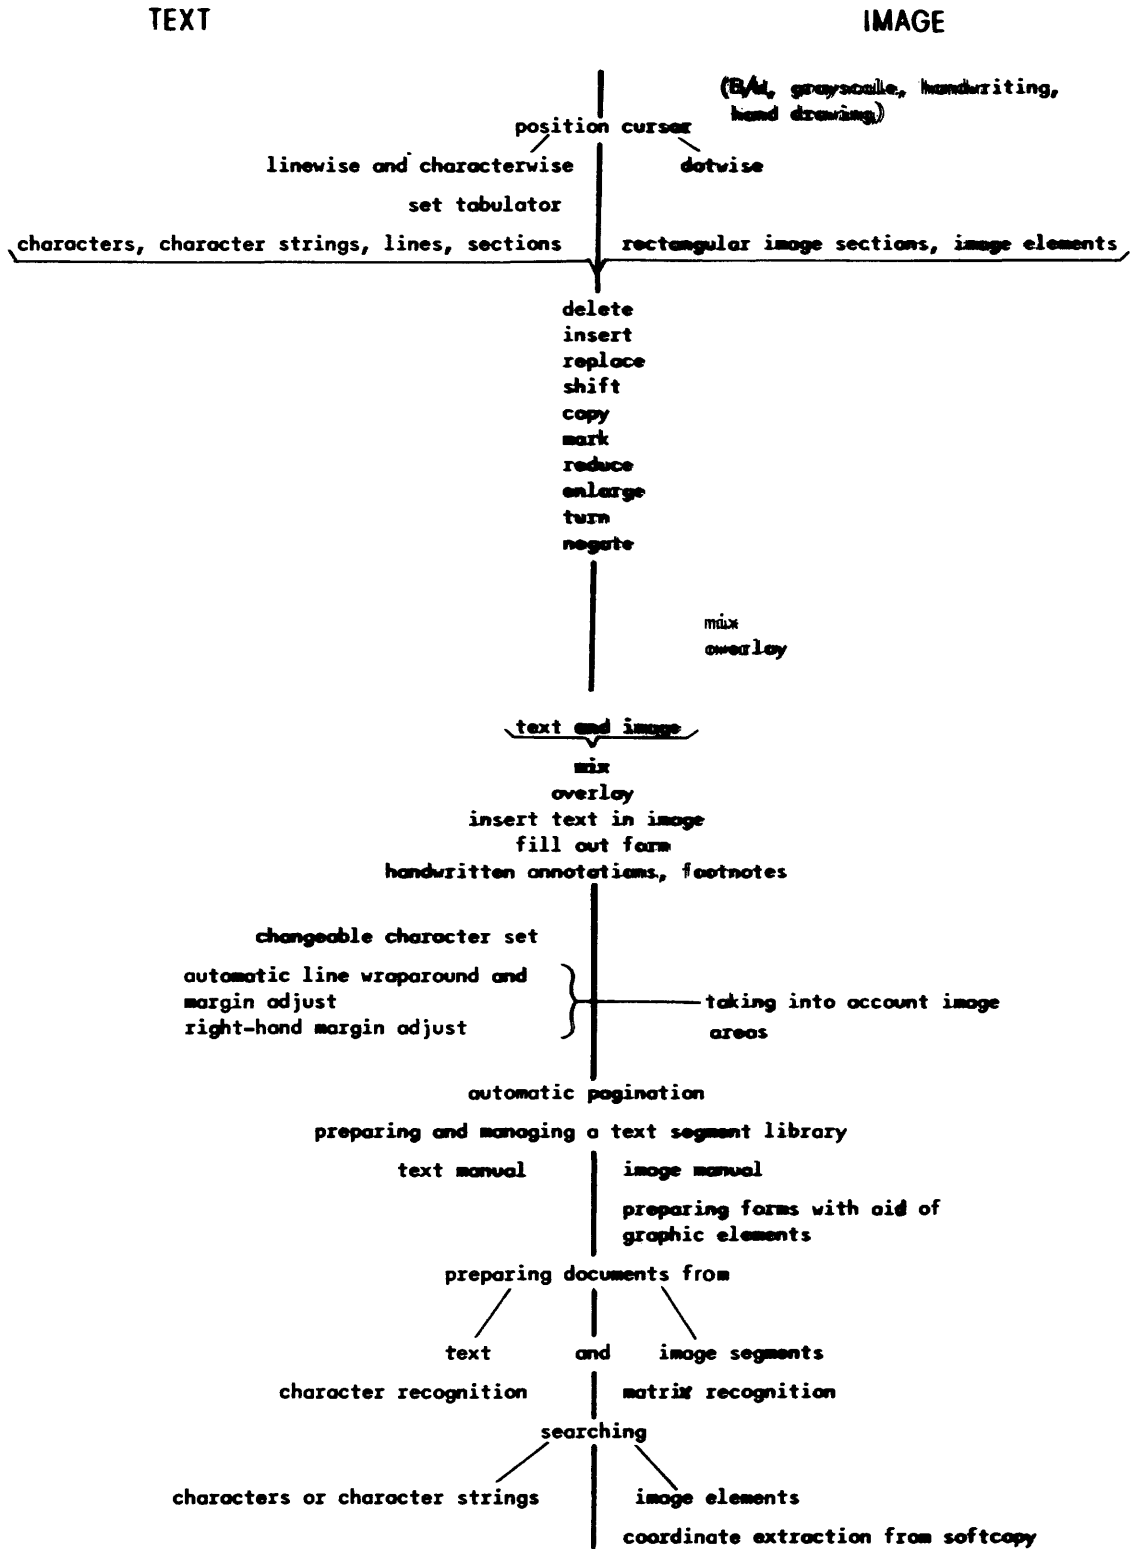

Figure 2—Processing.

## TEXT

- Alphanumerically coded
  - Compatible with text stations
  - 96-character set (national)
- Character set for Latin alphabets taken from a basic table (international alphabet No. 5) and an extension table with special characters and letters
- ISO 7-bit code
  - Free text formatting on standard size longitudinal and transverse
  - Arbitrary margins, exponents, indexes, single, 1,5 and double line spacing
  - Standard 1/10 inch character spacing
  - Variable character size
  - Variable font

## IMAGE

- Pixel lines compressed with modified Huffman run length code
- Compatible with CCITT T.30
- Vertical resolution 7.7 or 3.8 lines/mm
- Horizontal resolution 1728 pixels/215mm
- Any image position

- Automatic textfax switchover
- HDLC protocol
- 7 logical transmission levels
- No transmission in the opposite direction on the same circuit

Either

- Transmission on request, addressing in document header (send control protocol)
- Document header contains answerback code, phone number, distribution, date, Re:, etc
- unmanned, automatic connection setup and transmission from send to receive buffer (mailbox) with automatic dialing and automatic retry parallel to local processing
- manned transmission setup with telephone and manual switchover between voice and textfax transmission
- manned and unmanned reception with either automatic storage and indication of "incoming mail" or automatic hardcopy
- Recall of texts from the incoming mail buffer to the screen for further processing (delete, hardcopy, file edit, handwritten comments, forwarding)
- Virtual image transmission
- Automatic journaling with document headers

Figure 3—Transmission.

instead of one minute at 4.8 kbits/s, thus entailing substantial savings in transmission costs.

To be able to transmit and receive simultaneously with local processing without interrupting either process, one would ideally need a multipage send or receive buffer. Among the eight CCITT test documents the modified Huffmann Code has the lowest compression factor with 5.2 with document No. 7.<sup>8</sup> Correspondingly, the buffers would have to have a capacity of  $n \times 0.8$  Mbits.

It is thus obvious that for reasons of economy—i.e. to operate with minimum transmission times and small buffer storages—care must be taken in transmission of mixed text/image documents that text components are transmitted in alphanumerical coding, if possible. Depending on the content of the document, switching between text and facsimile mode must therefore be possible during transmission. The most economical buffer storage capacity has still to be found by way of statistical analyses of the documents arising at the office. Assuming a *one*-page buffer for a mixed document consisting of text and image at a 50:50 ratio, we would thus arrive at a capacity of about 6 kbits+0.4 Mbits, i.e. approx. 0.4 Mbits. A page having been sent, sending can only be

continued after the receiver has confirmed the empty state of the one-page buffer.

To facilitate text transmission between Textfax and text stations, such as memory typewriters which are mapped out for communication, one should rely on the transmission standard for text stations during the text transmission phase. Corresponding international standards have not been established as yet, but they can be expected within the next few years.

Concerning transmission, seven logical levels which will be outlined by the following can be distinguished.

- The physical level with interface to the transmission equipment with signal and signalling lines for connection setup and clear-down in manned and unmanned operation. If Textfax station and telephone are connected to the same telephone line, signalling during connection setup is required to distinguish between language and non-language transmission (corresponding to the data tone). Also, in the case of conversation-interrupting transmission, the receiver must be signalled the

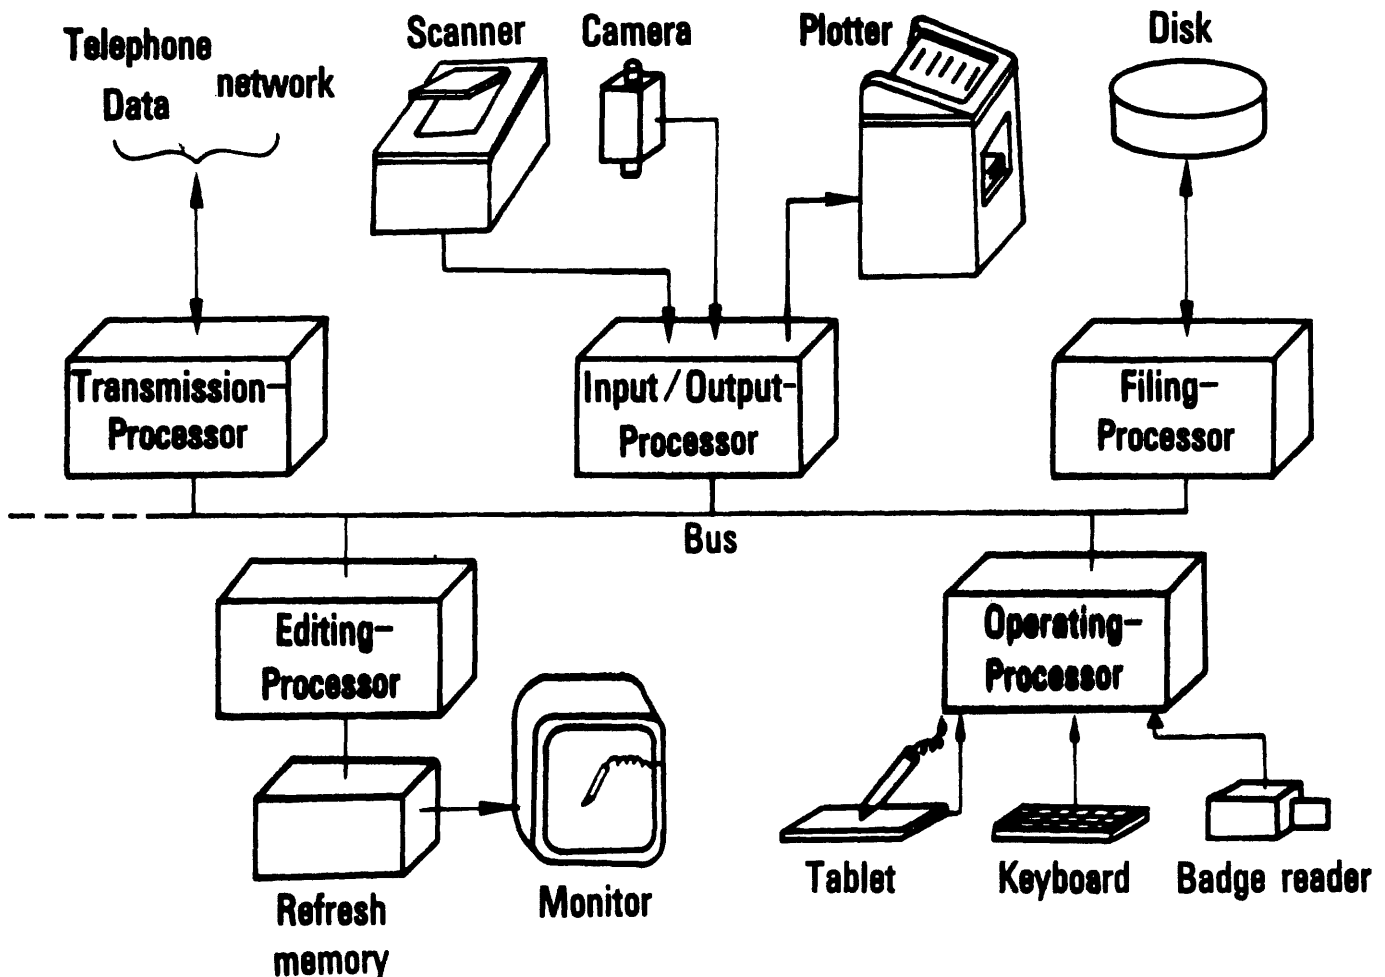

Figure 4—Multiprocessor structure of the experimental workstation.

end of Textfax transmission. Basic CCITT standards for Level 1 are

- Standards V.26 and V.27ter for modems, and V.25 for automatic calling equipment, in the case of transmission via the analog telephone network.
  - Standard X.21 in the case of transmission via data networks or digital telephone networks.
  - Standard X.21 as a subset of X.25 in the case of packet switching networks.
- The link level with the code-transparent, full-duplex HDLC protocol for protected transmission of text and facsimile blocks.
  - The packet level which is required only in case transmission is to be made via a packet switching network.
  - Level 4, which initiates the specific terminal and user-related control procedures for which no standards exist so far. For this control level, control characters must be defined to identify the further transmission procedure as text transmission, Group 3 facsimile transmission or combined text facsimile transmission.
  - Level 5 with which the end-to-end logs start out. This level provides for mutual identification of the stations according to duplex capability, character supply (alphabet, font), resolution, compression code, automatic multi-page reception, etc.
  - Level 6 as the user level. It comprises password check, format selection, form number, beginning and end of a

page, if necessary change of transmission direction, etc.

- Level 7 encompasses terminal control functions contained in the transmission code, such as control characters for text formatting (beginning of line, line spacing), change of font, change of character size, image position, text/fax switchover control characters, interrupt signals, etc.

In Figure 3 possible features of transmission services of future Textfax stations are listed. In traffic between business partners using the same forms, preprints, etc., "virtual image transmission" is important. A form, for example, is transmitted only as a name under which it is stored in the sender's and the receiver's image files, together with text and position specifications for combined copying of text and form at the place of reception.

## FIRST RESULTS

### *Textfax experimental workstation*

After this look into the future, let us now turn to the present state of our research work. In order to determine how the functions of Textfax can be implemented and how they will be accepted by the user, an experimental workstation designed in modular multiprocessor technique, which will incorporate the previously-mentioned performance

Figure 5—Initial configuration of the experimental workstation.

Figure 6

characteristics, is to be set up in the research laboratory of Siemens AG. The multiprocessor structure is shown in Figure 4. The first stage of this experimental workstation was essentially the configuration shown in Figure 5, which was used to carry out the processing activities described in the next section.

The configuration in Figure 5 is based on the Siemens microcomputer SME 800 with a 64 kB internal memory and two 250 kB floppy disk drives. Text entry and operation of the workstation are handled by a control terminal. Actual text and facsimile processing is performed on a per window basis on a 512×512 dot plasma display showing approximately one fourth of a standard size page in Group 2 resolution. The Group 2 remote copier HF 1048, attached via a digital interface, serves for data entry, hardcopy output and transmission of text/image documents. The graphics tablet can be used to insert handwritten drawings or comments in the softcopy. This configuration may be viewed as an expansion of the remote copier to include local processing functions for text and image.

An editor permitting the elementary functions listed in Figure 2 to be used on black and white images and rastered grayscale images was prepared for processing and mixing text and facsimile. Images are rastered according to the method illustrated in Reference 9, where different grayscale levels are represented by different dot densities. A special redundancy reduction method was developed offering storage economy combined with a low compute time requirement.

Figure 8

#### *Processing examples*

Example 1 in Figure 6 shows an order form filled out at the Textfax workstation. The form, which previously has been scanned via the remote copier and stored in a forms file, is displayed on the screen where it is filled with text in a window-by-window fashion. The start of the text line is marked by the cursor which may be positioned to any dot. Font and character size may be changed even within a line. When the text has been entered in the form, the drawing is recalled from the image file and copied into the order form using the cursor for positioning. The order is now ready for approval. After this, it is transmitted as a facsimile from the buffer of the employee's Textfax station to the station of the

purchasing manager, who signs the softcopy before sending the order on to the remote copier station of the supplier.

Example 2 shows processing of a rastered grayscale image. A photo was scanned by the remote copier, the resultant analog information was digitized with 4 bits per pixel and rastered using a 4×4 dot Dither matrix. Figure 7 illustrates the softcopy of the raster image on the plasma display. The black and white image can now be processed. Figure 8 shows the same head done up with glasses, moustache, data relating to the individual, and the signature. The same procedures may be used for producing wanted persons pictures (composite drawings) on a police workstation.

# Microcomputer programming skills

by C. WRANDLE BARTH

Goddard Space Flight Center—NASA  
Greenbelt, Maryland

One of the most overwhelming aspects of the microcomputer revolution has been the speed with which hardware costs have plummeted. The software versus hardware costs ratio which prompted much of the interest in software engineering in recent years has grown dramatically as the parallel development of the microprocessors pushed down the cost of computer systems and their proliferation fueled software demand. This is increasing the need for skilled programmers for microsystems, part of which will be met by programmers currently working on big systems. In this paper we will examine some of the differences in skills and techniques that one can expect to encounter in the transition from programmer to microprogrammer. (The terms *microprogram*, *microprogrammer*, and *microprogramming* are frequently used in reference to the firmware or microcode of large machines. We will be using such terms only with reference to microprocessors.)

## THE CONVERSION FROM PROGRAMMER TO MICROPROGRAMMER

Microprocessors are being used in a wide variety of applications. The programmer whose previous experience is with large batch systems may find that microprogramming for some of these applications requires a number of new skills. The hardware architecture, which high-level languages and operating systems have kept hidden from him on the big computers, may now be the primary thing with which he is working. Even the systems programmer who is accustomed to working at the level of assembly language and the machine architecture may find he must dig another level deeper, down to the logic diagrams and gates of the system. The *ands* and *ors* may have a familiar ring, but there are new things to unravel. If the application includes hardware development, signal timing diagrams will have to be read and understood to ensure the equipment being developed will work together; and testing and debugging now require oscilloscopes and probes as well as the more common traces and dumps.

These new skills are of particular importance when developing special-purpose systems that include microprocessors. When the hardware is being developed along with the software like this, one of the most important aspects of the work is the hardware/software tradeoff. Many of the func-

tions to be developed can be accomplished in either hardware or software, or a combination of the two. The greater the designer's understanding of both areas, the more valuable he becomes in being able to create an optimal system.

If one is writing programs for micros in EDP, the changes in skills and techniques are much less pronounced. It will still be necessary to be more familiar with the hardware than would be required on large systems (although not to the degree needed in systems involving dedicated microprocessors). This is mostly prompted by the limited number of sophisticated tools currently available. Even though this is certain to become less of a problem as the necessary tools are produced, the EDP microprogrammer will have to bridge the gap for some time to come.

Tumbling costs are also making real-time EDP systems more viable. Programmers of such systems may have fewer hardware concerns than those programming dedicated microprocessors; but the interfacing is certainly much harder than for the batch-style EDP systems to which their experience may have been limited.

Many of the skills and techniques required in programming microprocessors are dependent on whether the micro is part of a dedicated, general-purpose batch, or general-purpose real-time system. These distinctions, in fact, are often overlooked in the presence of the much more obvious, but somewhat more superficial transition from maxi to micro. Although much of our discussion will apply to all areas of microprogramming, parts will be appropriate only to certain applications. We will attempt to distinguish among these areas in the topics that follow.

## THE CONVERSION TO PROGRAMMING DEDICATED APPLICATIONS

With each new decrease in the cost of computers, new applications for their dedicated use have become economically justifiable. The maxis were limited to the really huge projects—defense, space and production control for large factories and utilities. The minis brought computer power to the smaller factories and research laboratories. And now the micros are making computers a part of everything from cash registers to video games. Those who are new to programming-dedicated microcomputers will not only need to learn techniques they never used in batch work, but they may

also find themselves using some techniques different from those of the traditional real-time programmer as well. The old ponderous real-time applications were frequently of a nature so large or critical that the only reasonable testing approach was simulation. With the smaller systems, it is more common to be able to test directly on a working prototype, using hardware test equipment instead of simulation.

As we have already noted, the knowledge of hardware/software tradeoffs is particularly important in projects in which both are being developed together. But such tradeoffs are not easily assessed. The cost of things accomplished in hardware recurs with every copy; the software costs occur only once. Thus there is a tendency to make the hardware "weak" for economic reasons. But this pushes more and more complexity into the software while trimming the hardware capability to a bare minimum. And when the application requires every last ounce of hardware power available, other things may have to be sacrificed. Such things as the use of high-level languages, various structured programming techniques, and the avoidance of coding tricks quickly fall prey to such an environment. Building systems that are friendly to the ultimate user requires resources that may be viewed as luxuries that cannot be afforded. Even high reliability or high programmer productivity can be lost when developing in a minimal hardware system.

#### THOSE PAINFULLY PINCHING SHOES

Developing programs in a minimal environment has always been burdensome. Dijkstra spoke of the earliest computers that were slow and whose memories were too small as "painfully pinching shoes."<sup>1</sup> He said that the first programmers were pushed into coding tricks in the machine language and that they viewed programming primarily as the process of optimizing the efficiency of the computational process. Now, close to three decades later, we are faced with a brand new shoe of the very latest style, but one that is just as pinching as ever.

Many programmers view the microprocessor's relatively slow speed as immediately ruling out the use of high-level languages, regardless of the application. Optimization becomes glorified again, even optimization for its own sake. We know that optimization during coding is very error-prone. And with a dedicated computer, cycles saved on non-critical paths cannot even be made available to "other users." The use of programming tricks makes software even more unstable in these environments. (I should mention that I am not talking about programming idioms—such things as subtracting a register from itself to clear it—that become the universally acceptable way of accomplishing a task. It is the perversion of an operation code into a meaning unclear to other humans that often leads to errors.) In general, the smaller the excess hardware capacity over that minimally required, the harder our systems will be to program; the more the we will be pushed into poor programming practices; and the less reliable the end product will be.

But these are not the only aspects of machine smallness that the new microprogrammer faces. An easily overlooked

difference is that less help is available from the operating system. In many cases, there is no operating system at all; just a bare bones machine. But even where some services are available, they are far removed from the facilities that were taken for granted on the maxis. The programmer cannot count on a supervisor fixing up a division by zero, or recovering from an input error. His code must do more checking and correcting for itself.

#### STRUCTURED PROGRAMMING ON MICROSYSTEMS

Structured programming has always required a healthy helping of common sense. The programming manager who decrees that "all programs shall be structured" is quick to discover that really terrible programs can be written without a sign of a **goto** and with no module exceeding 50 lines. Structured programming is not a blindly mechanical process, nor is it a panacea. The more demanding the external constraints, the more that sound judgment is required in applying the principles of structured programming; but also the more that the discipline will pay off.

Some people question whether structured programs are sufficiently efficient for use on micros. Of course, many of the techniques that have been loosely grouped under the name "structured programming" really have no bearing on efficiency at all. And while I've already indicated that I feel optimization is sometimes overemphasized, there is no doubt that certain constraints must be met, particularly in programming real-time applications (either dedicated or general-purpose). It is true that some structures which frequently turn up are inefficient. Redundant tests occur when using only standard control structures. Branch instructions whose targets are other branch instructions may be generated by high-level languages or assembly macros for some of the standard control structures. And numerous short subroutines can add substantial calling overhead to a program. Some of these problems can be overcome; others cannot.

Of major interest is the use of structured programming in high-level languages. As new languages are developed with the structured programming techniques in mind, we may find that better code is generated than would be for the current high-level languages. For example, optimizers can work better on structured code. Even our best current optimizers must abandon much of the optimization in program segments where a rat's nest of **gotos** prevents their deducing the flow of control. The optimizer for a structured programming language, however, could optimize every loop in the program since each begins with one of a small number of specific keywords. Furthermore, such optimizers could convert procedures that are called from only a single place in the program text into in-line code, thus cutting down on the calling overhead. But all of this is only what *could be*. What about what *is*? How should programs be written with the tools we have available now?

We know that most programs spend the majority of their time in a minority of their code. Even real-time programs are often time critical in relatively few places. These facts can allow us to take advantage of structured programming

techniques in our program development and then go back to post-optimize in those places where it is really critical. This also allows us to isolate our thinking about optimization from our thinking about the programming of the algorithm. Many of the techniques we use when optimizing are based on assumptions about the data of the program's variables. If we optimize as we code, it is particularly easy to make false assumptions that get violated as we also optimize other parts of the program. Post-optimization is both easier and surer since all of the parts of the puzzle are present, allowing us to completely verify any assumptions we must make. We can attack the problem piecemeal, assuring each change is valid before making another. And most importantly, we can direct our efforts to those parts of the program that are most apt to be worthwhile.

Other software engineering techniques can provide efficiency payoffs. The use of functional cohesion and decoupling<sup>2</sup> aid the complete replacement of algorithms with better ones. In a poorly modularized program, the code implementing an algorithm may be sprinkled about in such a way that it is impossible to change even when a better method is found. And replacing a poor algorithm with a better one can frequently yield a much higher optimization factor than can a ton of coding tricks.

The most important realization is that efficiency is a very relative thing. On a microprocessor dedicated to a single activity (whether used in a dedicated hardware system or in a general-purpose single-task system), wasting CPU time is of no concern if we are totally I/O bound and there is nothing else to do. Wasting memory is unimportant until it crosses a quantum boundary; and as chips become bigger and cheaper, the size of that quantum keeps increasing. Even when poor efficiency causes the system to be slower, it may be preferable. Efficiency considerations must be weighed against reliability considerations. Up to a point, a slow system that works is preferable to a fast one that fails (although a sufficiently slow system may be a failure by definition). A latent bug can be costly in any system, but particularly in a commercial device.

## A NEW COMMUNITY OF USERS

One of the biggest changes that the microprogrammer faces is the new user community he serves. As a programmer of large systems, the "unsophisticated user" was a manager, a data entry clerk, a scientist, an engineer; with the micros it may well include a non-professional, an office clerk, a sales clerk, a houseperson, or a blue-collar worker. This is particularly true with programming for dedicated micros, somewhat less for real-time EDP, and least for batch EDP. However, even in this last case, the operator of such a system might well be the owner of a small business rather than a computer professional. The human interface of programs must take on a new aspect. These people will find words like "input," "record," or "string" strange or understand them differently and they are not accustomed to learning jargon. Moreover, they may not be just "down the hall" where they can ask you about some strange message

they receive when trying to run your program. They are going to put commas in their numbers and type the letter "I" when they mean the digit "1." And they expect "end" and "END" and " end" to all be the same—except when they want them to be different! But most important, they expect programs to work—and work right every time.

## RELIABILITY

Consumers expect high reliability of the things they buy. No one expects to go to the store and find release 21.8 of a microwave oven! The closest things to "program fixes" that most consumers see are automobile company recalls. But if such recalls can hurt the images of the auto giants, think of what such bad public relations could do to a struggling company producing microcomputer-based systems.

And yet the overwhelming majority of programs are marketed while still sadly undertested. They are, in fact, so bad that it has become common to talk of buying program "maintenance." But programs don't break down; so what people are really buying is not maintenance at all, but a warranty. The programs are effectively guaranteed not to work as advertised; the "maintenance" assures that they will be fixed up when they inevitably fail. This viewpoint is well understood by people that have been dealing with computers every day, for they know that much software is quite bad. But the consumers are only starting to find out. This is not just limited to consumer-oriented systems, either. Customers have little sympathy for merchants whose real-time systems are down and prevent them from transacting business.

Is there a way to avoid bad software? There are some aids, for sure. Program certification (mathematical proof of correctness) offers the best hope, but is still far from practical for most programs. However, the more critical the application, the more certification may be justified, even if only on a limited basis. Certainly programs that are a part of automotive systems are going to require higher reliability as they take over more crucial functions in those systems. For the time being, the best insurance for most non-critical software is probably the peer program walk-through. Such walk-throughs will frequently turn up bugs faster and better than testing methods will, and they have the additional advantage of being educational. One of the biggest problems that is overlooked by many is how *will* field upgrades be dealt with, particularly the inevitable fixes. For in spite of all their preventive measures, if the handling of the correction of a bug that slips through is mismanaged, a company's whole reputation may go down the drain.

## OLD LESSONS TO BE RELEARNED

There are a number of lessons that we have learned over the years that apply as much as ever to the micros or even more. To make sure we do not lose sight of them, we will review some here.

Use of high-level languages must be emphasized wherever

possible. Of course, there will be areas where the overhead is just too great and we must turn to assembly languages. But we must weigh this alternative carefully on a case-by-case basis. We know we can turn out better software faster using high-level languages. Even our "superprogrammers" can (and we all like to think of ourselves as superprogrammers). But if we expect to keep up with the growing software need, we must use the better tools whenever possible.

The same argument applies to using modularity. The general-purpose routine seldom takes much longer to write than a very special-purpose routine. And although it probably won't be quite as efficient, it can save programming time over and over if we can use it in future projects rather than reinventing the wheel.

The biggest cost in changing hardware is changing software. The big boys learned it when they were repeatedly cursed with "downward" (backward?) compatibility. In microcomputing hardware, six months is forever. The more a given system is tied to a given architecture, the more that system is going to become obsolete with the hardware. This may be fine for dedicated use in a consumer product where the time frame during which we plan on being in production matches the expected availability of the component hardware. But for general-purpose programs, software compatibility will be the key to longevity. This adds another reason in favor of using high-level languages. Even though different compilers for the same high-level language may require some changes in our programs, assemblers for different architectures will require even more.

One of the biggest differences between good programs and so-so programs is human engineering. This is all the more important when we consider our new user community. Programs should be written to be helpful and friendly to the user. In many cases he will be communicating in an alien environment and will not appreciate contorting himself to a system with a thousand rules he can't remember. Sometimes it requires a major increase in effort to build systems that are well engineered; but frequently simple changes can provide great conveniences to the users as well as providing additional selling points in a competitive market.

Patching is one programming technique that was falling into disrepute on the larger machines and is now making a reappearance. Patching object code rather than fixing the source is sometimes required as a temporary measure when testing micro software, particularly where the turnaround time to recompile the program is long. The key to avoiding errors when patching is maintaining the discipline of keeping

track of all such changes and assuring that they get back into the source. There is actually a greater problem than this type of patching, and it is still seen regularly in all phases of programming. That is the patching of source code contrary to the program's design. Sometimes such a patch is, in fact, the only reasonable way to fix a design bug—particularly the last bug in a large design. If the time to correct the error at the design level and then "recode" is too long, then the source patch is just as reasonable as was the object patch. And just as for the object patch, the documentation should include complete information regarding the error for future reference. But we should not be too quick to write off such errors as unfixable at their true source. If any further use is to be made of the program, it is all the more desirable to correct the design error. And in well structured programs, corrections in the design should be able to be sifted down into the code fairly straightforwardly, allowing the number of final modules that must actually be recoded to be quite small.

## CONCLUSIONS

The need for programmers for microcomputers is great and will draw people from many disciplines. Professional programmers for large machines can expect to have a big head start if they move to micros and there will not be as many differences ahead as they might think. Most of the techniques that were applicable on the big machines are at least worthy of consideration for the micros, although the actual application may require some changes. The biggest differences, however, will stem more from the differences in applications than from differences in machine size. The change to real-time programming is the most important of these differences (particularly on dedicated microprocessors) and may entail dealing with hardware and machine architecture to a greater depth. The other primary difference is programming with a more computer-naive user in mind, and dealing with his limitations and expectations.

# Program conversion—One successful paradigm

by CHARLES LYNN, JR., JEAN RISLEY and ROBERT WELLS

*Bolt Beranek and Newman, Inc.*  
Cambridge, Massachusetts

The continuing rapid development of computer hardware over the years has been both a blessing to the user who sees his computing power increase and cost decrease over time, and a disappointment to those who have found that the cost of converting existing software outweighs the advantages of the new machines. For any proposed change of hardware, there are at least three options whose cost the user must carefully weigh—(1) the option of remaining with older hardware, (2) the option of completely redesigning/rewriting existent software and (3) the option of converting those portions of the existing software which are portable and rewriting the rest.

At BBN we have recently carried out the transfer of a large body of programs from one hardware environment to another. In the process of this task, we have developed an analytical approach to the problem of conversion of programs written in a partially independent higher-level language. Our technique consists of several distinct phases:

1. Identification of the programs to be converted and the environment in which they will be run.
2. Isolation and analysis of those language features which are not portable and of those features of the hardware and system environment which were used.
3. Design and implementation of a mechanical conversion process.
4. Creation and use of a procedure for giving human attention to special or difficult areas.
5. Conversion and debugging of the programs including definition and use of standards for debugging and program testing.
6. Creation of the operational environment under which the programs will be run.
7. Parallel operation of both systems with extensive comparison of their respective results.
8. Operational use of the converted system and the archiving of material from the old system.

Dividing the problem in this way makes it possible to keep control of the progress of the conversion effort. Also, performing a complete analysis before actually beginning to convert and run programs provides a better grasp of the scope of the work and tends to minimize surprises later in the project.

## THE PROBLEM

Our specific problem was to move all of the current Management Information Services (MIS) functions of the company from the GE Timesharing Service\* to an in-house DECSYSTEM-2020. Our primary motive was the reduction of the continually growing hardware cost in terms of machine time and storage charges. Those costs were much higher than those projected for the in-house machine, and the prohibitive cost of increasing service and development of new software effectively precluded major improvements. We were also constrained by the absolute requirement for continuity of performance—the change of environment had to be transparent to the company.

Throughout the conversion project, there were a few basic policies. The primary constraint was that the converted system behave “exactly” like the old one. This provided a strict guideline on program rewrites—nothing was to be rewritten if it could be done in the old way.

The body of programs comprising the MIS system to be converted consisted of approximately 450 source program files (70,000 source lines of code) written in three different dialects of FORTRAN (\$FORTY\$,<sup>1</sup> FIV<sup>2</sup> and F77<sup>4</sup>). There were both batch and interactive processes, and 15 hierarchical data bases with a total of 65 record types were used by the programs. The system was developed almost entirely by internal BBN MIS development personnel over several years, with some support software such as the data base management system provided by the time-sharing vendor. Program documentation was generally limited or out of date, with most documentation consisting primarily of user instruction memos.

## ANALYSIS

During the analysis phase of the conversion, we divided the potential language and environmental conversion problems into specific analysis areas, with responsibility for one or more areas assumed by each member of the team. The main areas were (1) character and string handling data types

\* GE is a trademark of General Electric Company; DEC, DECSYSTEM-10, and DECSYSTEM-20 are trademarks of Digital Equipment Corporation; System 1022 is a trademark of Software House.

and features present in each of the GE FORTRAN dialects but absent from the DEC FORTRAN;<sup>3</sup> (2) data base issues (HISAM hierarchical data bases on GE,<sup>7</sup> relational data-bases provided by System 1022<sup>10</sup> on DEC); (3) input/output and file handling language features; (4) system-provided features (subroutine packages, monitor commands, SORT/MERGEs, interrupt error handling, etc.); (5) other language feature incompatibilities (ENCODE/DECODE, initialization statements, structured programming features, etc.); and (6) other facilities used, such as the data base report and batch stream command languages.

All the source code files were initially transported to the DEC system where they were kept on-line continuously. During the analysis phase we used the vendor-supplied manuals to locate potential incompatibilities in the languages, and then searched the existing on-line sources for actual occurrences of any potentially troublesome syntax.

We specifically designed a search program to accept a set of search patterns and a set of exclusion patterns, specified as regular expressions, and scan a specified group of files for line matches, which were then listed with their locations. Exclusion patterns were used to eliminate non-interesting matches, such as those found within comments. This search program and all the programs used to mechanically translate the FORTRAN sources were written in FASBOL,<sup>9</sup> a compiled dialect of SNOBOL for the DECSYSTEM-10 and DECSYSTEM-20 systems. SNOBOL<sup>5</sup> is a powerful string processing language, and it proved ideal for the rapid development of these conversion programs.

The information collected during the analysis phase was circulated within the whole MIS group by an on-line message system (HERMES<sup>6</sup>). This was useful both for communication of specific points ("NAMELIST I/O is never used," "there is a lot of EQUIVALENCE with character data variables," etc.), and to provide on-line hard copy of problem areas by topic as a guide for later phases. There were group reviews and discussion sessions on the findings in each area based on the collection of messages. This information was also circulated to the development group so that they would be aware of language features that should be avoided in their development work.

## MECHANICAL CONVERSION

The design of the mechanical conversion itself began with listing, by area, the specific mappings of syntax which would change a feature in one of the GE FORTRANs to acceptable DEC FORTRAN. For example, in an unformatted read, map 'READ. . .' to 'ACCEPT \*.. .'; or in a type statement with initialization values, 'remove the initialization values and create a DATA statement for the variable.' Specific translations were grouped into 17 processes, each of which became a FASBOL program.

Each conversion process was conceived as a filter, taking an input file and applying a set of translations to it. The intermediate forms between these processes were not, in general, legal FORTRAN programs; for example, one of the initial filters concatenated continuation lines together to

make lines hundreds of characters long so that later filters would not have to be concerned with continuation lines. Another filter analyzed each routine to develop symbol table information about the variables used, then distributed this information as control character sequences to all occurrences of the variables. This allowed later filters to trivially determine such information as the type and dimensionality of any variable. The last FASBOL filters in the sequence removed such alterations to produce valid FORTRAN programs. Due to the largely unstructured nature of SNOBOL programs, we felt it would have been much more difficult to develop only one large SNOBOL program to perform all the translations; most of our filter programs were under three pages long and understandable as a whole.

The ordering requirements of the translation processes, shown in the graph of Figure 1, evolved based on special requirements of the processes themselves. For instance, the process to reconcile OPEN, CLOSE and unit assignments (OPCLOS) needed to occur before the one resolving problems of format modes and expressions in I/O lists (IOLIST) in order to locate FORMAT statement numbers in the READs and WRITEs. Figure 1 also shows, for example, that the relative order in which SHORT and STATE were executed does not matter, but both require LINES to have been run and both must be run before any of the other routines (DBCALL, IOTRIV, or ENVIR) may be run. The execution order which was actually used for the 17 modules is indicated by the numbers in the upper left corner of the boxes in Figure 1.

For many features, a choice had to be made between conversion to acceptable DEC forms and emulation of the GE-provided features. In most cases we favored conversion, since we hoped to minimize long-term maintenance problems caused by the holdover of alien conventions. However, the use of the HISAM data base calls and the representation of character data in strings was so difficult to convert to DEC that it was decided to emulate these functions in the converted system.

The HISAM hierarchical data base structure so dominated the logical structure of the programs that conversion of the programs to make optimal use of the System 1022 relational data base facilities would have required almost total restructuring and rewriting. We therefore decided to emulate the HISAM data base routines where possible rather than undertake extensive rewriting. The HISAM emulation consists of 14 external routines and several internal routines, comprising 1700 lines of source code. The package was written in RATFOR,<sup>8</sup> a structured FORTRAN pre-processor, because of the readability and cleanliness of the structural statements it provided.

Character processing in all the FORTRAN dialects, including the target DEC language, is very dependent on the number of characters that fit into single- and double-word variables. The GE code was firmly based on four characters per word and could not be practically mapped into the five-character words that are used for literals and support routine calls on DEC. We therefore provided a minimal preprocessor (MISFOR) for long-term maintenance of the code. This

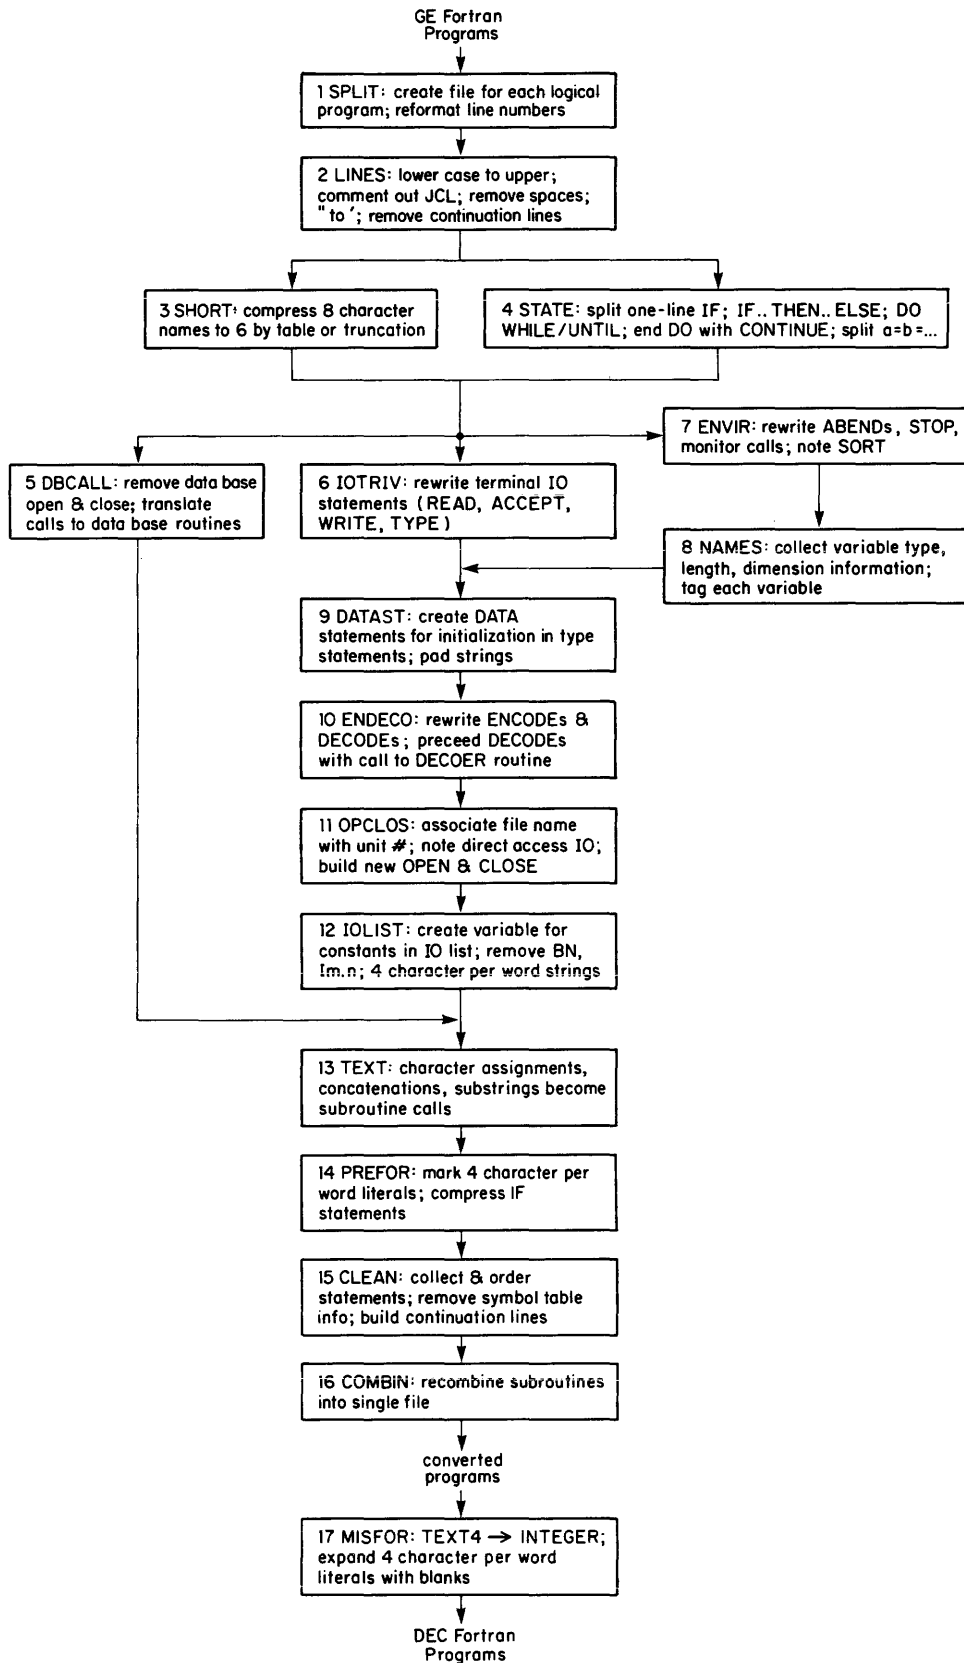

Figure 1—Execution precedence graph of translation processes.

preprocessor trivially translates a data type declaration line (TEXT4 to INTEGER) for variables containing four character/word data and translates syntactically-marked literals by inserting a blank every four characters so that DEC FORTRAN will effectively store four characters per word. Support routines have also been provided to convert four-character-per-word strings to the five-character-per-word strings needed for interfacing with DEC system routines.

Many capabilities that were language features on the GE system became calls to subroutines from the newly-created support library for the converted code. For example, the error return on DECODE, character assignment and comparison statements, and the INQUIRE for file status all became subroutine calls during the mechanical conversion.

## MANUAL CONVERSION

Once the mechanical translation had been completely specified and developed, there remained a list of problems that required manual intervention. These included cases of more complicated syntax which were not used often enough to justify complete treatment in the translation programs, as well as issues such as changing file name conventions or sort command syntax which were not simply decidable. The mechanical translation both listed these troublesome items and placed a comment before them in the source program.

For the programmer performing the manual checking and editing there were a number of reference materials and memory aids. First, there was search program output with line number locations of specific potential problems, (SORT, overlays, possible bit fields, PROCEDURE calls, monitor calls, etc.). Second, there was the output of the mechanical phase with error messages marking possible problems. Third, there was a summary document and a complete specification of subroutines in the support library with calling conventions. Finally, there was a step-by-step document listing all issues expected to arise during the manual conversion. These reference materials were the primary force for completeness and consistency during the manual conversion, and they made it possible for each team member to recreate the conversion environment even when there had been distractions to other tasks.

## PROGRAM CONVERSION AND DEBUGGING

For conversion, the program set was divided into subgroups of 10 to 30 programs each, usually by similarity of function or access to the same data sets. These subgroups were generally subsets of the functional groups defined by the operational system. The fact that most of the programs are organized around file input and output made it relatively straightforward to isolate each program. The actual conversion of programs tended to consist of four steps—(1) a preliminary (sometimes optional) manual edit, (2) the mechanical conversion, (3) a finalizing manual edit and (4) extensive debugging and testing. In general, each person tended to convert 10 to 20 related programs at once, moving a whole

group of programs through all of the steps. There was specialization within each group, with particular project members being most expert at understanding the complexities of sort conversion, data base usage, or data base report language usage. However, each member was responsible for conversion of groups of programs from beginning to end, with consultation if needed with the appropriate specialist.

During the manual conversion we discovered that some repeated sections of code occurred sufficiently often to merit inclusion in the support library. The requests for interactive input (TYPE, FORMAT, ACCEPT, FORMAT) were so frequent that we created functions to receive literal messages and return a value of the appropriate type. Similarly, a function was added to locate and format the date for use in many of the programs. In general, however, we tried to minimize the number of subroutines introduced so that our efforts in the conversion phase could be concentrated on conversion rather than tool development.

While most of the actual program conversion was straightforward, a few problem areas were encountered. Some of the programs required history or parameter files which had not been transferred to the new system; short files were usually re-entered manually while longer ones were transferred via tape. The time-sharing system used for the first part of the conversion (before our own DECSYSTEM-20 arrived) crashed frequently; usually only a few minutes work was lost although at one point it crashed, was down for a week, and somehow managed to lose several additional days work.

The most troublesome problems involved the parallel modification of programs. One situation involved GE programs which were modified between the time they were transferred to the new machine and the time they were actually converted; checking the dates on which the programs were last modified immediately before beginning to convert a group of programs prevented conversion of outdated modules. A second situation involved GE programs which were modified after they were converted. When this happened, the modified program was either again transported to the new system where it was mechanically compared to the earlier version, or else the development personnel making the GE modifications also modified the DEC version. The latter procedure, when not carefully controlled, led to a third situation—two people modified a converted program at the "same" time. This problem was later avoided by making each program the responsibility of one individual and making sure that no one else modified it without first checking with the program's nominal owner.

As each program was converted it was debugged. Debugging generally began with synthetic input and then proceeded with copies of actual input from the running system. The use of synthetic data made testing of programs which performed input validation and editing operations much easier since the actual input data was voluminous and would rarely, if ever, contain all possible errors. The use of large amounts of actual input from the running system made validation of the computations performed by the programs easy to check since the correct answers were already available.

It should be noted that when a discrepancy was found, it was not always because the converted program was wrong; we found several bugs in the running system. The action to be taken in such cases required careful consideration. Repairing the operational system was not always desirable—in one case it required that many people change the way values were interpreted. Therefore, the converted program was modified to run in a "simulate-the-bug" mode. In cases where numbers which were printed on reports were truncated (without any indication by the GE system) the field widths were increased. Since the data in the reports was not generally re-entered into the system, these differences did not lead to further discrepancies. In several cases, bugs in the operational system were fixed.

A disturbingly large portion of the debugging time was consumed by bugs, some amounting to a comedy of errors, which were not related to the conversion. Bugs in the DEC SORT utility provide many examples. One of its numerous errors was traced to a record in a sorted file whose record length was changed by the sort. After a couple days we were told that the bug would be fixed in the next software release. We could get it shortly but it required the next monitor release because it used new monitor calls to parse the new command string format. However, that version of the monitor was not scheduled for release for two months. Thus, all the calls to the sort utility had to be found and changed to conform to the new syntax and a routine had to be written to emulate those functions of the new monitor which the new sort used.

#### BATCH STREAM DEVELOPMENT

Most jobs on the GE system were run in overnight batch mode. The control file was built and submitted by a program which used a prototype and operator responses to simulated program queries. In addition to running programs, the streams created temporary backup copies of some files (it was too expensive to backup all of the files and data bases) and performed other file maintenance operations. The command language made built-in recovery mechanisms so hard to implement that none were used. Development personnel were frequently required to perform manual recovery operations when a service interrupt occurred during a job since time did not permit restoration of files from the normal GE dumps (that would require waiting until the next night). The batch streams were totally rewritten because of the large differences in the command languages and operating environments and because of the desire to improve error detection and recovery mechanisms.

The operations environment we developed on the DEC system is similar to the GE system in many ways. Batch control files are built from prototypes and operator responses; specially marked strings in the prototype, the questions, are replaced by the responses. Several advantages have resulted from running all programs from batch streams: the operations staff is free to use their terminals for other tasks, a log is automatically created for each job, and the running environment is consistently defined. Since space is

available, all major files and databases which are to be modified by a job are first copied; "deleted" files are only logically deleted. All intermediate steps are saved on the daily dump tapes before being physically deleted from the system. In the event of a crash or other large error it is relatively easy to backup to any specified point.

#### PARALLEL OPERATION

The validation of the system by running in parallel was a formidable task. The operational system worked under tight time constraints for data input processing and report distributions. Originally, the system had a fairly large component of interactive data entry and report request and retrieval. We made a few operational changes preparatory to running in parallel, replacing interactive data entry with batch entry, in order to get better control over input and changes to the system.

The parallel operation phase evolved into two parts. During the first part all inputs to the operational system, usually in the form of card decks, were collected and transferred via magtape to the new system. Every half-month (the company business cycle) the operational data bases and transaction files were dumped to tape and loaded onto the parallel system. About one day was required to read the tapes (11 2400-foot reels) and build the binary transaction files and System 1022 data bases. Batch control files were then generated from the stream prototypes based on the GE operations log and then run (overnight) in the same order as they had been run on the actual system. This operation, in addition to testing the individual programs, tested the batch streams, their interaction with the programs (mostly file management), and our ability to recover and backup to any specified point. While some bugs were found, most required excessive amounts of time to locate since the actual bug could have occurred anywhere within the simulated bimonthly period.

These problems led to a second mode of parallel operation during which the parallel system was run as close to the operational system as possible (typically within a day) with the reports being checked line-by-line (rounding differences of one cent were usually ignored). In order to isolate differences in data files as quickly as possible, two techniques were developed. The first was a detailed RECAP program, used on both systems, which calculated transaction file summaries. After a job stream was run, RECAP was used on the modified files: comparison of the outputs quickly isolated the differing transactions. The second technique was a complete record-by-record match of the contents of all modified data bases and some transaction files performed by a set of batch jobs and programs to sort and run file comparisons. A match was run weekly during full parallel operation.

Many of the differences encountered during the parallel operation were of a mechanical nature. Getting the same input data for both machines was a significant problem. The problem of dates had been foreseen and a modification to the DEC system date routine was made to allow the date to be pre-set. This was not sufficient, however, during the

latter stages of the parallel operation when the parallel system was run ahead of the operational one. Date discrepancies in runs made before or after midnight were common. This later resulted in several comparison mismatches which required further manual investigation to ascertain that the differences were only due to the differing dates.

Card input was also a problem. Before the card reader for the DECSYSTEM-20 arrived (about five months late) card decks were sent to a service bureau for transfer to tape. Cards were occasionally lost or out of order. Later, a program was written to allow direct inter-machine transfer of ASCII files. Its 300-baud transfer rate was satisfactory for small card decks but was too time-consuming for larger ones. When the card reader finally did arrive, the data became worse since dark spots on the backs of cards were interpreted as punched holes by GE's card reader but not by DEC's. Correcting the consequences of these differences was time-consuming and frequently led to the necessity of additional correction runs. These, in turn, led to comparison differences caused by differences in the unique batch number assigned to each run. This problem was solved by writing programs to selectively zero-specified fields in the files before the comparisons were made.

From the inception of parallel running the original operational personnel played an increasingly important role in the conversion, advising us on how to make the system easier to use, identifying problems in the parallel runs, and, during the second part, conducting the parallel runs. Their enthusiastic cooperation in the conversion was invaluable both in the technical side of the conversion, and in familiarizing them with the new system in advance of the actual switch to it.

## PERSONNEL AND SCHEDULING

Our conversion team consisted primarily of four people full-time for 12 months, with expert consultations by several people including one of the original authors and one of the current operators of the system. None of the conversion team had significant previous MIS or business programming experience, but came from scientific, communications, or systems programming backgrounds.

In selection and support of personnel for a conversion project, our experience shows that a careful separation between conversion and development teams is very important. Some interaction is necessary to avoid conversion of obsolete segments and to understand more obscure sections, but, in general, keeping the conversion team separate from design issues permits complete concentration on reproducing the current functions. This tended to prevent a distraction into the history of the code, an involvement with all of the things the code could or should have been made to do, and any dependence on unverified premises about how portions of the code ought to interact.

We had two major overall design and scheduling checkpoints, one before actual conversion began and one half-way through the conversion effort. We decided initially to spend half of the time (six months) in analysis, approach

design, tool building and experimentation using one of the functional groups of the system, and at the end of that period the conversion procedure was essentially complete. The second half was originally scheduled to convert all the programs in three months, and run in parallel for three months. Actually we converted about  $\frac{2}{3}$  of the programs in three months and did both conversion and running in parallel in the final three months. Converting programs, even with mechanical aids, was made more difficult by having to switch between conversion and other support tasks such as installing system software on the new machine or transporting test data and new source files to the new machine.

## RESULTS

When the switch to operational use of the new system occurred, all of the regularly-scheduled programs and batch streams were operational. A few quarterly reports and reports which run irregularly on a demand basis had not been converted. A request for one of these reports caused it to be placed at the top of the queue of programs to be converted.

The conversion was essentially transparent to users of the new reports; except for the addition of report numbers and/or page numbers the actual reports are identical. The conversion was not as transparent to those who distribute the reports for mechanical reasons. Since the old system printed several reports interspersed with the batch log they were partially identified by their position in the printout. On the new system each report is printed separately so the report numbers must be used. This was initially a problem since reports which differed by either paging, sort order, class inclusion or exclusion, or run date had been given the same report number; addition of version numbers to these reports solved the problem.

The conversion was least transparent to those people, such as the contract and personnel administrators, who had performed interactive data base updating under the old system. During the parallel operation phase all updates were batched and performed by the operations staff. This method of operation has been retained, at least initially, under the new system until the scheduling and security requirements are resolved. In addition, several people had interactively requested reports under the old system; they must now request the operations staff to run these reports.

For the operations staff the day-to-day running of the system is structurally quite similar to the old system—only a few of the names have changed. The biggest difference involves having to run and distribute both those reports which were formerly requested interactively and the batched update results. The latter must be carefully scheduled since they have to be verified, and frequently corrected and re-submitted, by the people who are responsible for the data.

It is difficult to make direct comparisons of execution times or costs between the two systems due to a large number of unknown factors. The old system provided the user with two quantities—time of day, in hours and minutes, and "cost." The cost is an undisclosed function of at least

CPU, memory and I/O usage. The new system also provides the user with two quantities—elapsed time and run-time, both expressed in hundredths of seconds. The direct and secondary effects of multiple users in a time-sharing environment cause these quantities to increase with load but correction factors are not known. In general, the overnight runs on the old system required less wall clock time than the corresponding overnight run on the new system but the difference does not seem to be "significant" in the operations environment. This relationship can be reversed under appropriate loading conditions caused by additional users.

A complete cost analysis of the conversion project is difficult because many costs cannot be directly compared and several are not readily quantifiable. New development on the GE system directly increased costs; on the DEC system it only increases overall machine usage. The 4800-baud remote station was critical for the GE system and communication difficulties frequently delayed operations. After a service interrupt there was no way to quickly catch up. The DEC system does not require remote communications. After an interruption of service the operations staff can preempt the development group until things are back on schedule. Things can be scheduled more efficiently on the DEC system as system loading is more predictable.

Ignoring the factors mentioned in the last paragraph, a rough estimate of the cost of the GE services was about \$26,000 per month. This includes subscription fees, job and storage charges, communication costs, remote station lease and maintenance, shipping charges, etc. The costs associated with the DEC system are about \$13,000 per month. This figure includes two full-time operators, system hardware (appropriately depreciated) and software (including the SORT and System 1022 data base packages), maintenance, disks, tapes, cabinets, power and space. The one-time costs of the conversion from GE were about four person-years of labor and \$65,000 for computer usage (additional GE usage due to the conversion and portions of the initial mechanical conversion which occurred before the DECSYSTEM-20 was delivered). It is estimated that the conversion will pay for itself within three years.

## CONCLUSIONS

We found that only a very few programs actually needed extensive rewrites. Some rewriting was required, for example, when either there were not enough I/O channels to access files in the same order as before, or because the emulation routines were prohibitively slow for the reorganization of some data bases.

The creation of standards for those aspects of the programs which can change is a process which has continued throughout the conversion. We found that the creation of interactive entry conventions applied consistently made the programs easier to read and debug without changing actual user interaction. Conventions for file and program names, once created and consistently applied, made program and data grouping more reasonable. Conventions and routines for accessing and processing dates, for example, provided

a basic consistency between programs that made functional differences easier to understand. In deciding to institute each of these standardizations, there was a careful weighing of alternatives in which the additional cost of implementation had to be shown to be negligible and the benefit to be considerably positive.

If we were to begin the project again, there are a few improvements we would make in the procedure. Attention would be given to the final operations environment before report naming and identification conventions were established. The HISAM emulation would have been written so that data base extensions could be made without having to modify the emulation package and recompile all programs using it. Time should have been spent to develop an efficient, reliable method of inter-machine data transfer. The tools to compare binary files, data bases and reports allowing error tolerances to be specified should have been developed sooner. Finally, ample time should have been allowed for the "unexpected"; about one-quarter of our time was devoted to finding bugs in purchased software, installation of new releases, delays in delivery, finding ways around problems which could not be readily fixed and system crashes.

The overall policy for a system which is undergoing conversion should be to restrain new development as much as possible until the conversion is finished. Even fixing bugs in the old system can be a problem for conversion if the fixes are not made to the converted programs as well. Any new development brings up a number of difficult issues such as whether to develop on the old or new machine, when to convert if developed on the old machine and how to run operationally on the new machine before conversion is done. We have been only partially successful in avoiding these problems, but without a deliberate management policy of only allowing the most essential changes, the conversion would have been made more difficult if not impossible.

Based on our experience, the reliable conversion of a large body of code from one hardware environment to another is possible with a detailed analytical approach. We hope that as a result of our experience others will find conversion to be less of an intimidating, uncontrolled process and more of a task for which some reasonable, effective procedures exist. Conversion may be both expensive and difficult, but it is possible.

# A generalized zooming technique for pictorial database systems

by S. K. CHANG, B. S. LIN and R. WALSER

University of Illinois  
Chicago, Illinois

## INTRODUCTION

Pictorial information processing relies heavily on the establishment of an efficient pictorial database system. Present-day database management systems are designed primarily for efficient storage, retrieval and manipulation of alphanumeric data. Until very recently, little attention has been paid to the storage, retrieval and manipulation of non-alphanumeric information such as digitized images which require a large amount of storage even for pictures of average complexity. With the growing list of new applications in picture processing, such as geographic data processing, demographic data processing, computed tomography, whole-body scanner, earth resources survey satellite (LANDSAT) image processing, regional economic and health data processing, cartographic and mapping applications, etc., the problem of efficient, economical storage, retrieval and manipulation of vast amounts of pictorial information becomes more important and requires careful considerations.

Two problems can be distinguished in designing pictorial databases—the storage, retrieval and manipulation of a large number of pictures, and the storage, retrieval and manipulation of pictures of great complexity. Traditionally, researchers in image processing have concentrated on working with a few pictures. However, the new applications for pictorial information systems generally require that the systems be capable of handling a large number of pictures, some of which are also very complex. Consequently, new techniques must be investigated for the efficient, flexible retrieval of pictorial information from large pictorial databases.

In Reference 2, an approach to designing an integrated database system for tabular data, graphical data, and image data is described. It is based upon generalizations of the relational approach to database design.<sup>5</sup> The main idea is to represent pictorial information by both logical pictures and physical pictures. A logical picture can be regarded as a model of the real image. It is defined as a hierarchically-structured collection of picture objects. The logical picture can thus be stored as relational tables in a relational database and manipulated using a relational database manipulation language. Inquiries concerning the attributes of picture objects can also be handled by this relational database man-

agement system. Once a logical picture has been identified for retrieval, the corresponding physical picture can be generated on the output device by retrieving the physical picture from an image store which is specially designed for the storage of image data.

This paper describes a generalized zooming technique which can be used for flexible information retrieval and manipulation for pictorial database system. The design of an integrated pictorial database system to support generalized zoom is then described. This system is implemented for interactive map data retrieval and manipulation in a distributed database environment. The project, called the DIMAP (Distributed Image Management and Projection) Project, is funded by the Defense Advanced Research Projects Administration.

In the following section, capabilities of the DIMAP system are described. Generalized zooming concepts, including vertical zoom, horizontal zoom and diagonal zoom, are discussed. The concept of logical pictures and physical pictures, and the correspondence of maps and *d*-maps, are discussed in the third section. The fourth section describes the image store. An example pictorial database is described in the fifth section, followed by pictorial information retrieval examples using the GRAIN language (sixth section). Dynamic zooming examples are discussed in the seventh section, and techniques for frame staging are discussed in the eighth section.

## SYSTEM CAPABILITIES

### *System overview*

The goal of the DIMAP project is to design an integrated pictorial database system which combines a relational database management system, RAIN, with an image store management system, ISMS, to enable the user to perform various zooming and panning operations, and to browse through the pictorial database. The DIMAP system provides a pictorial information retrieval language called the GRAIN language. The integrated pictorial database management system, which includes the RAIN subsystem and the ISMS subsystem, is illustrated in Figure 1.

Figure 1—An integrated pictorial database management system.

### Display terminal

The user interacts with the DIMAP system via a display terminal. The display terminal has the following features: (a) A color raster monitor with good resolution (512 by 512 pixels); (b) Two joysticks, one for panning, the other for zooming; (c) A cursor for pointing at picture objects in the window; (d) A functional keyboard.

A user views a map through a window in a CRT screen. The window size in the present system is 512 by 512, corresponding to the CRT screen size as well as the  $x$ - $y$  size of one frame buffer. In later versions, it may be possible to display more than one (variable-sized) window on the screen at a time. It's possible to view a large map by panning the window in any direction over the map using a joystick. Panning proceeds in starts and stops: smooth panning is possible over an area nine times the area covered by a single window; when panning is uni-directional there is sometimes jerkiness due to loading of frame buffers.

### Vertical zoom

By pushing a joystick forward, the user zooms (vertically) in for a more detailed view of a map. The current map is replaced by a more detailed map. Pulling the joystick back causes an outward zoom and loss of detail apparent in the current map.

Since the map set is organized hierarchically (see the next section and Figure 5), some picture objects in the current map may correspond to more detailed lower-level maps. The user can also zoom in on a single picture object, and request more detailed information on this picture object. If this picture object is indeed enlargeable, the current map will be replaced by another map corresponding to this picture object.

### Generalized zoom

Since the DIMAP system makes use of the relational database system RAIN, the user may ask questions about non-graphical attributes of picture objects appearing in a map. A list of all attributes known to the DIMAP system about a particular picture object is obtained simply by pointing at the picture object and striking a button. A menu of

attributes appears in the window near the picture object. The user may then ask questions about those attributes. The cursor could be controlled in several ways: through the keyboard, using a joystick, or via a data tablet pen. A light pen could also serve the same function.

With the relational database system RAIN, the DIMAP system can provide generalized zoom capabilities to retrieve picture objects based upon their logical attributes. The concept of *horizontal zoom* (H-zoom) is illustrated in Figure 2. A *zoom window* is first displayed on the CRT screen, whose vertical axis corresponds to various picture objects in a picture file, and whose horizontal axis corresponds to a user-supplied *selection index* (which is obtained either by direct computation, or by table look-up). For example, one selection index could be the degree of similarity of a picture object with a given reference picture object. The *zoom line* can then be moved to set a threshold for selection of picture objects for display. If the zoom line is moved to the left, more picture objects will be selected. Thus, we are having a wide-angle view of the picture file. If the zoom line is moved to the right, fewer picture objects will be selected, meaning a close-up (telephoto) view of the picture file. This type of zoom is called horizontal zoom, because we are zooming in on subsets of picture objects belonging to a picture file. The traditional *vertical zoom* (V-zoom), on the other hand, provides close-up or wide-angle views of a single picture.

Once the zoom line is set, the *view line* can be moved to select a picture object for display. The corresponding picture then appears in the display window. In later versions, more than one viewing window may be provided.

Using functional keys, it may be possible to compute characteristics for a set of picture objects thus selected using the zoom line. We may sketch typical picture objects and atypical picture objects of the picture object set, and display their attributes. In case of raster images, an average picture object (in the sense of averaging the gray levels), can be painted, and its average attribute values displayed. We may also obtain a variable-valued logical description of the picture object set using VVL reduction techniques, extract additional features from the picture object set using pattern recognition techniques, and obtain structural information from the picture object set using syntactic parsing tech-

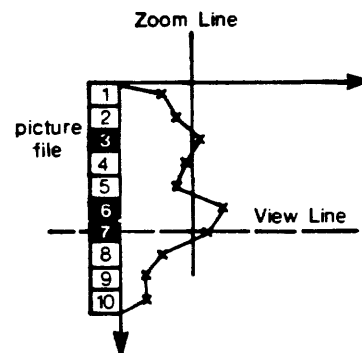

Figure 2—Horizontal zoom (H-zoom).

niques.<sup>6</sup> Attribute values and texts associated with picture objects can also be displayed.

Figure 3 illustrates picture retrieval by successive horizontal zooms. By moving the view line from one position to another and striking a function key, all picture objects between these limits having selection index above the zoom threshold will be selected. A reduced picture file can then be constructed. The zoom line can again be used to further reduce the picture object set, perhaps using a different (user-supplied) selection index. Finally, by striking another function key, the view line is set in the automatic mode, and pictures appear one by one in the viewing window in rapid succession. If these pictures are successive frames ordered chronologically, a movie is produced.

The concept of horizontal zoom can be further generalized to provide correlation capabilities among picture files. This is called *diagonal zoom* (D-zoom), as illustrated in Figure 4. Suppose picture files A and B are to be correlated, based upon a (user-defined) relation among picture objects. For example, picture file A may consist of prototypes of various types of tanks, and picture file B consists of picture objects to be classified. The user may first select a subset from file A by setting zoom line A. All picture objects in file B related to picture objects in this subset of file A can be selected (using the correlation matrix as shown in Figure 4). The user

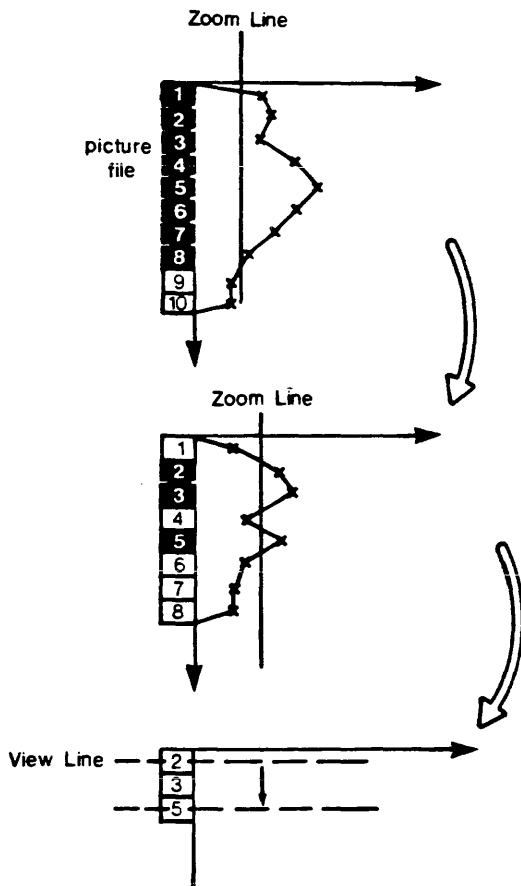

Figure 3—Successive horizontal zooms.

Figure 4—Diagonal zoom (D-zoom).

may further prune the resulting set using zoom line B. The final subset of selected picture objects in file B can then be displayed.

To summarize, V-zoom and H-zoom can be used to select a subset of picture objects from a single picture file. D-zoom can be regarded as generalized H-zoom and can be used to select a related subset of picture objects from multiple picture files.

*Map overlay and panning*

A map is composed of a collection of *overlays* (see Figure 5), which the user may select individually. In order to concentrate on selected features, the user tunes out overlays simply by pushing buttons. A terrain map, for example, may show elevation contours, roads, vegetation and cities. These four features could be plotted separately, perhaps on clear

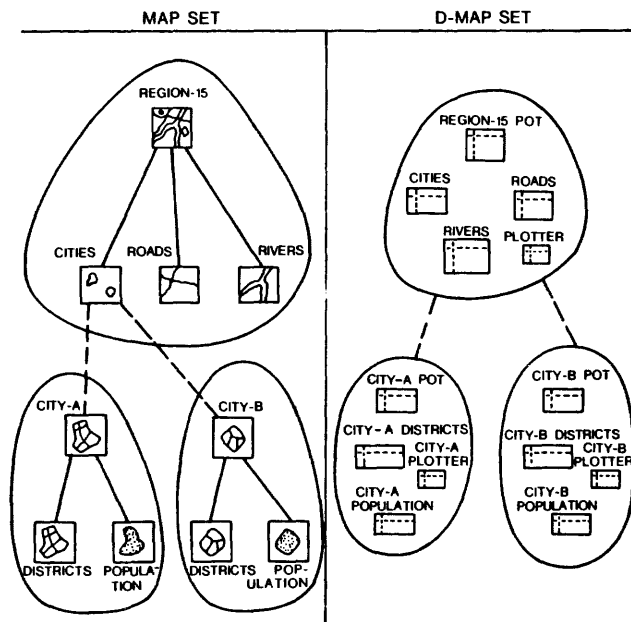

Figure 5—Correspondence of map set and d-map set.

plastic sheets. When the sheets are overlaid, a complete map is obtained.

In conventional maps, on paper, "What you see is what you get." The map reader can't tune out certain features in order to concentrate on others. There's no such constraint in the DIMAP system. At any time the user may show a single or many features in a particular region. The only restriction is that features which interfere visually with one another may not be displayed at the same time. Consider, for example, the two features "vegetation" and "political system." Assume both are area features, meaning their frames consist of colored (or shaded) regions in the viewing window. Displaying both simultaneously would produce a masking effect. The color actually seen by the user would not be the intended color of either, unless the intended color of the two areas happens to be the same; and in the latter case information would surely be distorted because there's little chance that vegetation and political system would correspond in an exact way.

The dynamic overlay capability of the DIMAP system is implemented through the use of the image planes (see the fourth section). At load time, features (picture object set) can be arbitrarily associated with a particular image plane. The user can then move the display window horizontally over an image plane from one frame to another, which is called *panning*.

### CONCEPT OF LOGICAL VS. PHYSICAL PICTURES

A map isn't stored in the relational data base in the way it appears in the window to the user. Rather, maps are generated by various processes that transform relational data into a visual form. The overall process of transforming

relational data for display is called *materialization*. Clearly, there is a close correspondence between information in the relational database and information on the display screen. In fact, it's the same information, represented in two different ways. In Reference 2, it has been proposed that only logical pictures are stored in the relational database, and physical pictures are stored in a separate image store.

To make the distinction among logical pictures and physical pictures conceptually clear, the following terminology is adopted:

- |  |  |
|--|--|
| <ul style="list-style-type: none"> <li>• Relational Database</li> <li>  d-map set</li> <li>  d-map</li> <li>  d-frame/logical</li> <li>  picture</li> <li>  relation</li> <li>  tuple</li> </ul> | <ul style="list-style-type: none"> <li>• Image Store</li> <li>  map set</li> <li>  map</li> <li>  frame/physical</li> <li>  picture/image</li> <li>  picture object</li> <li>  set/features/overlay</li> <li>  picture object/feature</li> </ul> |
|--|--|

A *map set* is a hierarchical collection of maps, whose logical representation is called a *d-map set*. A *d-map set* is the entire collection of d-map relations in the database. The correspondence of map set and d-map set is illustrated in Figure 5.

In Figure 5, the top map is REGION-15, consisting of three overlays CITIES, ROADS, and RIVERS. In the CITIES overlay, there are two enlargeable picture objects CITY-A and CITY-B, each corresponding to another map. The map CITY-A in turn consists of two overlays, DISTRICT and POPULATION.

A *map* is composed from one or many overlays, whose logical representation is called a *d-map*. A *d-map* is a set of relations in the data base, which defines a complete map. The correspondence of map and d-map is illustrated in Figure 6. In addition to the relations CITIES, ROADS and RIVERS, there are two special relations POT and PLOTTER, whose functions will be explained below.

The smallest unit for visual display is called a *frame*, whose logical representation is called a *d-frame*. A *d-frame* is a set of relations from which a single frame buffer may be loaded. Each relation in a d-frame corresponds to a group of *picture objects* (i.e. *features*) of the same class. The correspondence of frame and d-frame is illustrated in Figure 7. It should be noted that these d-frame relations are restricted relations obtained from the d-map relations.

The *physical picture* in a frame is also called an *image*. Thus, physical picture, frame and image are regarded as synonymous, whose logical representation is called a *logical picture*.

For each d-map, there is a special relation called POT (Picture Object Table), which contains detailed definitions of all the d-map relations. An example will be given in a later section.

Since all picture objects represented in a d-frame relation are of the same class, their visual interpretations are similar. The visual interpretations of tuples in the relation PEOPLE, for example, are alike insofar as they all depict a head, two arms, and two legs. We associate with each d-frame relation

Figure 6—Correspondence of map and d-map.

a graphics program that can draw a stereotypical picture object that is characteristic of the class of picture objects corresponding to the relation. The graphics program associated with PEOPLE knows, of course, how to draw people. It doesn't know, however, how to draw specific people, like "Mary Scott" or "Ray Roth." It takes the information needed to draw a specific person (assuming it's capable of drawing details about people) from the tuple corresponding to the person in question.

A typical d-frame is illustrated in Figure 7. There is a graphics program associated with every relation in the d-frame. The association is made via the special relation named PLOTTER, illustrated in detail in Figure 8. In the simplest implementation scheme, the "program" attribute in plotter takes program names as values. These are the names of graphical programs stored in regular executable UNIX files. The information the program needs to create a particular frame is found in the associated relation. This implies that the graphics program must somehow communicate with the RAIN database system.

Support for materialization, i.e. the process through which relations are given a visual interpretation, is one of DIMAP's central tasks. The problem is how to associate a d-frame with a frame buffer so that materialization may proceed as quickly as possible, leaving a pleasing visual impression with the user. This problem will be discussed in a later section.

Figure 7—Correspondence of frame and d-frame. (Note: d-frame relations are restricted relations obtained from d-map relations.)

THE IMAGE STORE

A detailed system diagram is illustrated in Figure 9. From the user's viewpoint, the DIMAP system can be used to retrieve a logical picture, called a d-frame, which is stored in relational tabular form. A logical picture, or a d-frame, consists of a number of relational tables which are retrieved from the pictorial database using GRAIN commands. The

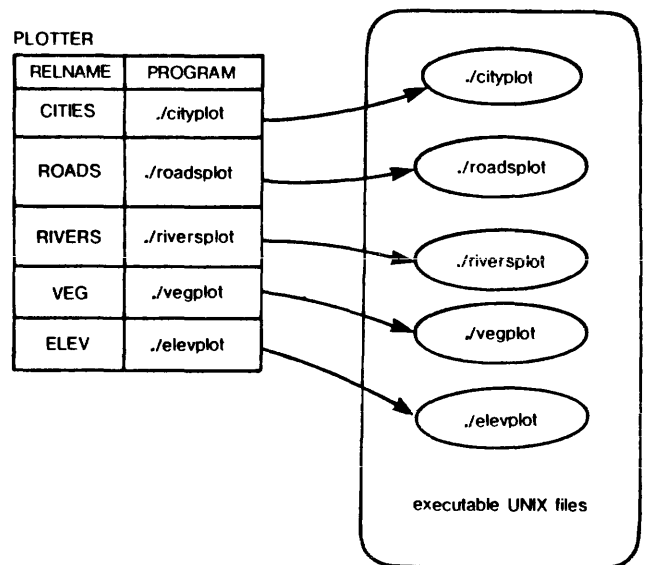

Figure 8—PLOTTER relation.

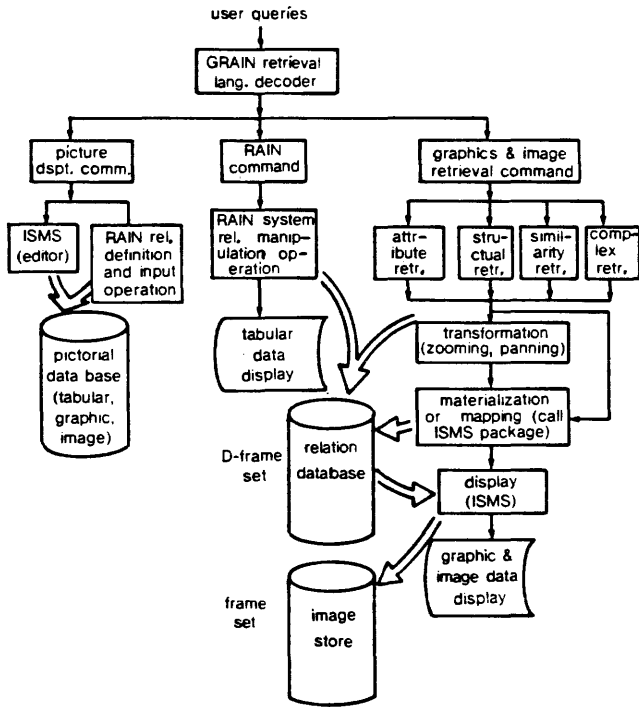

Figure 9—Detailed system diagram of DIMAP.

GRAIN commands can be used to retrieve pictorial information the user needed via attribute information, structural relationship, similarity measure, and complex image processing operations such as color level and gray level manipulation. At the bottom level, the ISMS system can be used to materialize logical pictures into physical pictures, called picture frames or simply frames. Using the display and print commands provided by the GRAIN language, the user can have flexible access to graphic, image, and tabular information. The design of the integrated pictorial database system, the relational database system RAIN, and the image store management system ISMS, can be found in References 2, 11 and 9, respectively.

The viewing window is refreshed out of the *image store*, consisting of four *image planes*, as depicted in Figure 10. The basic unit in the image store is a four-(or larger) bit register called an *image cell*. The four bits can be used to code color or gray level information. On display, the value in an image cell is interpreted visually as a point in a picture. Thus, an image store cell corresponds to a pixel. Each image plane has 2048 by 2048 memory cells, and is partitioned into nine areas, called *frame buffers*. Each frame buffer has 512 by 512 memory cells; thus, a frame buffer has the same number of memory cells as the viewing window has pixels.

Ideally, the image store would be implemented in hardware. This would be expensive in practice, however. To reduce cost, the frame buffers in the present DIMAP system are disk-resident. The result is a less expensive but slower system. The storage requirement (in UNIX blocks) of the disk-resident frame buffers is computed as follows: Since one frame buffer has  $512 \times 512 \times 4 \text{ bits} = 131,072 \text{ bytes} = 256$

UNIX blocks, and one image plane has 9 frame buffers, or  $256 \times 9 = 2304$  UNIX blocks, the total storage requirement for four image planes is 9216 UNIX blocks, which can be accommodated by a reasonably large disk system.

It's assumed that a typical digitized map is so large that it won't fit within a single viewing window, nor even within a single image plane. This means that pixels in the map greatly outnumber points on the display screen. Thus it's necessary to partition the information associated with the map. Such a partition is called a frame.

In the simplest case, a map fits entirely within one frame buffer. Thus the *x* dimension of the map is the same or less than a frame buffer's maximum width; and likewise for the map's *y* dimension and the frame buffer's maximum height. The d-map for such a map consists of just one d-frame. A frame buffer may be loaded from this single d-frame, and the map may be viewed in its entirety within the buffer, without panning.

In the worst case, the map is very large and the d-map consists of a large number of d-frames,  $DF_1, \dots, DF_n$ . Since the user can view only one frame at a time it will often be necessary to move the window from one frame to another. Using the image store, it should be possible to achieve a smooth (if slow) pan.

The panning problem, from the database point of view, is to load the frame buffers from the proper d-frames as the user moves the window over the map. It should appear to the user that he is peering down through a window that can be moved laterally in any direction.

### AN EXAMPLE PICTORIAL DATABASE

An example pictorial database will be described here, which will be used in future experiments. This database includes aerial features, linear features, and point features of a 10km by 10km area in West Germany around the city of Fulda. In order to define the pictorial database, approximately 20 elementary relations have been defined.

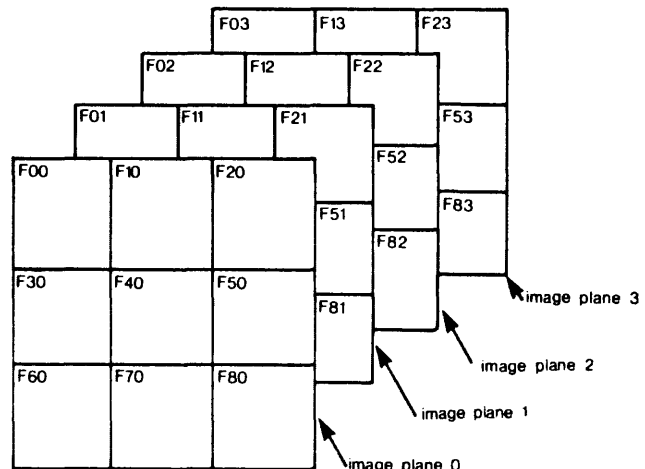

Figure 10—The image store.

Figure 11—Typical map overlays for aerial features.

There are three types of features in the example database. Bridge relation and tunnel relation are point features. Highway relation, railroad relation and waterway relation are linear features. Land use overlay consists of five land distribution relations—urban, forest, cropland, meadow and others. These are aerial features. Vegetation relation and soil type relation are also aerial features. Typical map overlays for aerial features are illustrated in Figure 11.

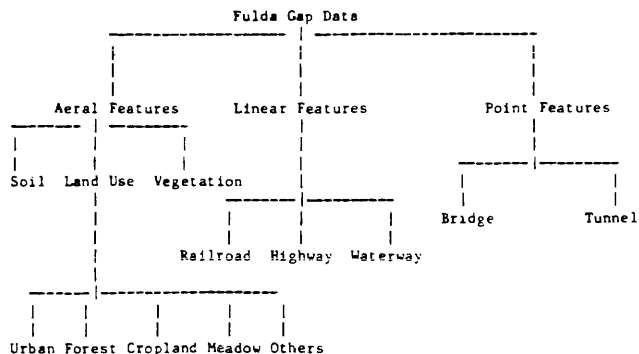

Figure 12—Fulda Gap example database structure.

The structure of the Fulda Gap example database to represent the relationship among these elementary relations is illustrated in Figure 12.

From Figure 12, we can create a relation table, called POT (picture object table), to represent this Fulda Gap example database structure. In Figure 13, the data type field value *R* means raster data format, *L* means line data format, and *P* means point data format. If two relations both have

name	oname	data type	operator	relation type	descriptor definition	no. of tuples
urban	landuse	R	+	E-	d1	400
forest	landuse	R	+	E-	d2	2000
cropland	landuse	R	+	E-	d3	1500
meadow	landuse	R	+	E-	d4	1500
others	landuse	R	+	E-	d5	1000
veget.	aeral	R	-	E-	d6	6400
soil	aeral	R	-	E-	d7	6400
landuse	aeral	R	-	C-	--	--
highway	linear	L	+	E-	d9	30
railroad	linear	L	+	E-	da	20
waterway	linear	L	+	E-	db	15
bridge	point	P	+	E-	dc	1
tunnel	point	P	+	E-	dd	1
aeral	Fulda	R	+	C-	--	--
linear	Fulda	L	+	C-	--	--
point	Fulda	P	+	C-	--	--
Fulda	---	*	*	C-	--	--

Figure 13—POT for Fulda Gap example database.

+ operators or one with + operator and the other with - operator, and with data type *L* and/or *R*, then these two relations can be combined to materialize in the same frame buffer. If two relations both have - operators, then these two relations cannot be combined to materialize in the same frame buffer.

Elementary relations are indicated by type *E* in Figure 13. A composite relation<sup>3</sup> is indicated by type *C*. The symbol "--" indicates this relation contains no picture object that can be enlarged. A "++" symbol would indicate this relation contains enlargeable picture objects. The user can then V-zoom in on such picture objects. The remaining fields of POT relation are pointers to descriptor definitions and number of tuples in a relation.

## GRAIN RETRIEVAL EXAMPLES

The syntax of GRAIN retrieval language is given in Appendix 1 of Reference 1. GRAIN also contains the RAIN language as a proper subset for manipulation of relational tables. In this section, we present some pictorial retrieval examples for DIMAP by using Fulda Gap example database. First we present several important commands of the GRAIN command language.<sup>2</sup>

1. *Display* *(frame name)*—Display the physical picture stored in frame buffer *(frame name)* on the CRT screen.
2. *Sketch* *(picture name)*—The logical picture *(picture name)* is plotted on the CRT screen as a line drawing. *(picture name)* can also be a composite picture object which is defined in terms of other picture objects. If the clause "into *(frame name)*" is added to this command, then the logical picture selected will be converted into physical picture and stored in the frame buffer called *(frame name)*.
3. *Paint* *(picture name)*—The physical picture corresponding to the logical picture called *(picture name)* is displayed on the CRT screen as a raster image or a line drawing depending on the picture data type. If the clause "into *(frame name)*" is added, the physical picture is stored in the frame buffer called *(frame name)*.
4. *Draw* *(picture name)*—The line drawing for a new picture object *(picture name)* is to be created. The draw command invokes a graphics editor, which utilizes the graphic system for interactive generation of line drawing.

These are the more important GRAIN commands. In what follows, pictorial information retrieval using the above commands will be illustrated by examples. Pictorial information retrieval can be classified into several categories: attribute retrieval, structural retrieval, similarity retrieval, and complex retrieval.

### Attribute retrieval

In attribute retrieval, pictorial objects are retrieved by their logical attributes. For example, in order to sketch the railroads, the sketch command can be used:

*sketch picture; name equal 'railroad.'*

To select certain railroads, the following command can be used:

*sketch railroad; rgage greater than '120,' or  
sketch picture; name equal 'railroad'; rgage greater than  
'120,'*

where '*rgage*' means the rail gage.

To generate urban land distribution of land use for Fulda Gap, we can say:

*paint picture; name equal 'urban.'*

### Structural retrieval

In structural retrieval, picture objects are retrieved by structural properties, such as component, container, left, right, up, down. For example, the following command sketches the picture objects having a component picture object with name 'urban':

*sketch picture; component (name equal 'urban').*

In the previous statement, a line drawing for land use will be sketched.

### Similarity retrieval

This command can be used to retrieve picture objects which are similar to a given picture using a certain similarity measure. For example, to retrieve all highways which are similar to a given highway called 'h3,' the command is:

*sketch highway; similar (highway-name equal 'h3') using  
'M1,'*

where '*M1*' is the similarity measure routine which the user supplies for testing similarity among picture objects. For raster images, the user-supplied routine may range from simple template matching to sophisticated hierarchical structural matching. If raster image data is converted into contour data, then several efficient similarity measures can be applied.

### Complex retrieval

Complex pictorial information retrieval involves the combination and processing of tabular, graphical, as well as

image data. Complex pictorial information retrieval can also be handled using GRAIN commands. For example, to paint a portion of a picture object with certain color, and paint the other portion with different color, the commands are:

```
paint picture; name equal 'urban'; with 'red'; into frame-x.
paint picture; name equal 'forest'; with 'green'; into frame-x.
display frame-x.
```

If we have a special routine to convert line segment format data to coordinate format data, then we can use the following command to check which highway passes through certain city or town or village:

```
pass=temp(*(x,y)) urban
sketch pass.
```

where the relation '*temp*' is a temporary relation to store the converted coordinate format data for highway relation. The first statement is a RAIN equi-join command.

## DYNAMIC ZOOMING EXAMPLES

As mentioned in the second section, the DIMAP system supports panning and zooming operations for pictorial information retrieval. We again use Fulda Gap database in the following examples.

### *Panning transformation*

To pan around certain portion of land occupied by forest, the statement is:

```
paint picture; name equal 'forest'; (forest-x less than or equal '40') and (forest-x greater than or equal '70') and (forest-y less than or equal '20') and (forest-y greater than or equal '30').
```

### *Zooming transformations*

Three kinds of zoom—horizontal zoom, vertical zoom and diagonal zoom are supported.

#### **Horizontal zoom (H-zoom)**

To select the land occupied by coniferous forest and mixed forest, the commands are:

```
paint picture; name equal 'forest'; forest-class greater than '1.'
```

#### **Vertical zoom (V-zoom)**

For V-zoom within a map, it is almost the same as panning transformation, except that the origin and coordinate spacing should be specified.

```
paint picture; name equal 'forest'; (forest-x greater than or equal '20') and (forest-x less than or equal '40') and (forest-y greater than or equal '10') and (forest-y less than or equal '30'); ((forest-x minus '2') mod '2') equal '0'; ((forest-y minus '4') mod '2') equal 0.
```

For V-zoom on enlargeable picture objects, we first select a picture object, and then load a new d-map corresponding to that picture object.

```
load CITY-A.
sketch picture.
```

#### **Diagonal zoom (D-zoom)**

This is the generalized H-zoom operation. This transformation finds all picture objects which are similar to a group of picture objects. For example, in order to find all highways which are similar to two highways '*h1*' or '*h2*', the command is:

```
get picture; similar (highway-name equal 'h1') or similar (highway-name equal 'h2') using 'M2'; into TEMP.
```

## TECHNIQUES FOR FRAME STAGING

In the previous cases, zoom operations are performed by dynamically constructing a d-frame using GRAIN retrieval commands. The advantage of dynamic zoom is its flexibility. The disadvantage of dynamic zoom is that it may be too time-consuming to construct d-frames dynamically. For efficiency reasons, we need also consider the problem of *staging* of d-frames.

The problem can be conceived as in Figure 14a where a window is shown over an image plane. The image plane, in turn, is (conceptually) over a d-map. Since the map is larger than the image plane, it isn't possible to have the entire map in the image plane at one time. Relations from the d-map must therefore be materialized on a selected basis into the image plane. It may appear to the user that the window may move anywhere over the map, even though, plainly, this isn't physically straightforward. We need an algorithm which will indicate which frame to load from which relation, and when.

A potential solution is depicted in Figure 14b. The image plane, consisting of nine frame buffers (shown from the "top"), is emphasized by heavy black lines. The viewing window is shown dashed, and the d-map (corresponding to a collection of d-frames in the relational database) is shown

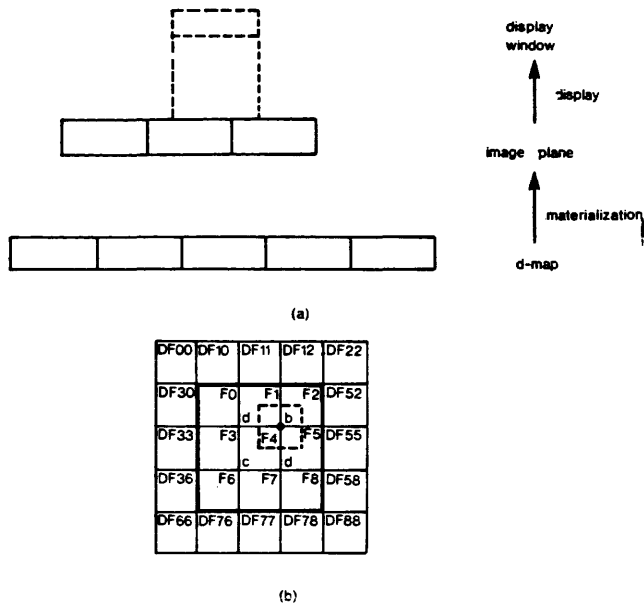

Figure 14—Frame buffer staging concepts (a) and panning of window on image plane (b).

underneath the image plane. It's helpful to notice that Figure 14b is a top view of the arrangement shown in Figure 14a.

To see the solution to the frame buffer staging problem (and, as a corollary, the panning problem) first imagine that the window (shown dashed) is positioned precisely over the central frame buffer. With the window in this position the problem is simple: just let hardware project the image in the central frame buffer up to the CRT screen. But now notice that if the user moves the viewing window at all it will partially cover not just one but four frame buffers. Precisely which four buffers are affected can be determined by noting which of the four central vertices is covered. It's easy to see that only one vertex may be covered at a time. Suppose vertex *b* is covered. This indicates that the viewing window is moving toward the upper right hand corner of the d-map. There's a strong likelihood that frames lying in that vicinity will have to be displayed. This is taken as a cue by the system to mean that the available frame buffers—F0, F3, F6, F7, and F8—are to be loaded. Assuming there are procedures for properly mapping frame buffers into the viewing window, the question is: from which d-frames should the frame buffers be loaded? A staging rule that would work in the case illustrated in Figure 14b is as follows:

If the window covers vertex *b*, then DF11 is materialized into F0, DF12 into F3, DF22 into F6, DF52 into F7 and DF55 into F8.

Other staging rules can be similarly formulated.

## IMPLEMENTATION STATUS AND DISCUSSIONS

Prototype RAIN and ISMS subsystems have already been implemented. At the Knowledge Systems Laboratory, we are currently implementing RAIN II (a better version to replace RAIN), and the DIMAP system.

The following research/development problems are currently being considered: (a) The design of a pictorial relational algebra for logical picture manipulation, which can be regarded as enhancement of the traditional relational algebra; (b) Evaluation of paging techniques for efficient storage of frames in image store,<sup>10</sup> and staging techniques for efficient retrieval of frames from d-map; (c) Evaluation of system capabilities by combining the DIMAP system with a knowledge base system to test policy analysis applications; (d) Consideration of database decomposition in a distributed database environment.

# An approach to real-time scan conversion\*

by FRANKLIN C. CROW

University of Texas  
Austin, Texas

## INTRODUCTION

Scan conversion—that is, the transformation of line segment endpoint coordinates into a collection of scanline segments suitable for raster display—is important because raster displays have many advantages over random-scan, or calligraphic, displays. The calligraphic displays require extensive special-purpose hardware to generate line segments, or “vectors,” and to drive the beam deflection circuits of the CRT. Furthermore, by its very nature, the calligraphic display is subject to damage caused by software defects; a program which directs the beam to the same portion of the CRT face for too long can damage the phosphors, creating a permanent dark spot.

On the other hand, the raster display can be driven by simple digital signals and is immune to software-induced damage. The raster display uses a technology shared by millions of television receivers around the world. This means lower costs through mass production and more flexibility through associated devices designed to store, transmit, project and make hard copies from video signals. For these same reasons, research into new displays is almost entirely concentrated on TV-compatible proposals. Thus, inexpensive displays for computer graphics are most likely to use raster displays in the future.<sup>17</sup>

There are a number of current products offering raster-graphic displays using digital image memories with a bit for every picture element of the display.<sup>1-3</sup> Such memories provide a very straightforward way to perform scan conversion and are quite appropriate for primarily static images. However, dynamic images pose difficult problems since moving portions of the image must be cleared from the memory and then re-drawn for each successive frame. Furthermore, any static portions of the image which coincide with cleared portions of the display will themselves be partially cleared, leaving unsightly gaps (Figure 1). It would be preferable to generate all dynamic lines together, in scan order, 30 to 60 times a second.

Ideally, static portions of an image should be stored in an image memory while the moving portions are dynamically scan-converted. However, there are arguments for dynamically scan-converting the entire image, assuming that scan-

conversion can be made to run fast enough. If vectors are to be colored or grayscale tricks used to smooth the lines (as discussed later in this paper) then several bits must be used to define the characteristics of each picture element. This requires a rather large amount of memory for an entire image of any worthwhile resolution (307,200 times  $N$  bits for a 640 by 480 element image).

There is a reasonably clear trade of memory size against processor power in the decision between an image memory and real-time scan conversion. The image memory needs a processor for generating vectors, etc. But, it doesn't need the power necessary for the techniques discussed here. Buying considerably more processor power could eliminate a few megabits of memory. It is not clear, given the rapid pace of development in both processor and memory systems, which alternative will be more economical ten years from now.

There are, of course, compromises. The image memory can be divided into character-sized cells and memory allocated only to those cells through which a line passes.<sup>2,10,11</sup> This would allow important savings when using color or grayscale. It is also possible to use separate image memories for static and dynamic portions of the image, allowing the dynamic portion to be cleared after every frame display. This sort of functionally-divided form of display has been used successfully with direct-view storage tubes.<sup>19</sup>

There have been at least two previous efforts to develop systems using real-time scan conversion. Cheek<sup>6</sup> reported a system in which vectors were chopped into short lengths and then grouped into horizontal strips of the display. Lindner and Tozzi<sup>14</sup> have worked on a system which takes an approach similar to that of this paper but appears much more complicated. The approach taken here is heavily influenced by experience with scan-ordered hidden-surface algorithms; similarity between adjacent scanlines is depended upon to minimize computations. The basic scan-conversion algorithm, described next, was initially used, by the author, in a software implementation at the University of Utah in 1973.

## THE BASIC SCAN CONVERSION ALGORITHM

A line segment has a great deal of “coherence.” That is, given one part of a line segment, the rest is easily extrapo-

\* This work was supported in part by The National Science Foundation under grant # MCS76-83889.

(a)

(b)

Figure 1—The effect of selective erasure using a digital image memory.

lated. Thus very simple changes suffice to update the scan segment description for a vector from one scanline to the next. Digital vector generators use this property to reduce vector drawing to a series of incremental operations.<sup>4,9,13,15,16,18</sup> The algorithms developed here differ from previously published methods in that all vectors are generated in an interleaved order dictated by the raster scan pattern. Earlier methods generate vectors individually, using the most convenient order for the algorithm involved.

The scan conversion algorithm is composed of three reasonably distinct tasks. First, lines in the display list must be sorted by the order in which they first appear in the scan. Second, for each scanline the position and length of the scan segment representing each vector crossing that scanline must be computed. Finally, the scan segments for each scanline in turn must be sent in proper order to the display.

The conversion process is spread over a pipeline consisting of a general purpose image update processor, a *Y*-sorted buffer, a microprogrammed scanline processor, an *X*-sorted scanline buffer and, finally, a hardwired picture element processor (Figure 2). The two buffers are implicitly sorted by writing into predetermined slots, one for each scanline

in the *Y*-sorted buffer and one for each picture element in the *X*-sorted buffer.

The design process was heavily influenced by the desire to use general purpose processors wherever possible in order to be in the best position to take advantage of future advances in microprocessor components. Thus, while the scanline processor could no doubt be more effectively implemented in random logic, a bit-sliced microprocessor was chosen to maximize flexibility.

Very modest design goals have been set for the first implementation, a machine capable of maintaining a few hundred vectors with no more than about 50 intersecting any one scanline. For this effort a display resolution of 320 by 240 picture elements at 60 fields per second will be used, roughly the resolution available from an inexpensive home television set. The eventual design goal is at least 1000 by 750 picture elements, or about an order of magnitude improvement. For the moment, the more modest goal allows concentrating on the algorithms and minimizes the sort of difficulties which arise from pushing digital circuitry to state-of-the-art limits.

#### THE IMAGE UPDATE PROCESSOR

At the head of the scan conversion pipeline, the image update processor is dedicated to keeping track of the vectors

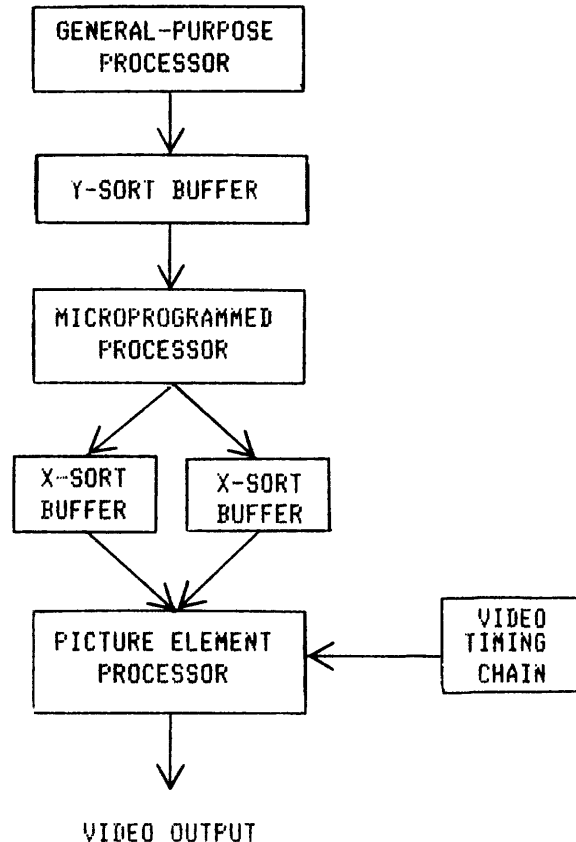

Figure 2—The basic elements of the scan conversion pipeline.

to be displayed (the "display list") and loading the *Y*-sorted buffer. The display list may be formatted to suit the application at hand, the architecture of the host computer, the architecture of the software system or whatever other constraints exist. In short, the display list organization is of no concern here. Suggestions for structuring display lists can be found in Reference 16.

The important task for scan conversion is loading the *Y*-sorted buffer. For the convenience of later, more tightly time-bound elements of the pipeline, the *Y*-sorted buffer stores vector descriptions in a different form. Only the *X*-coordinate of the higher end of the vector is stored, the *Y*-coordinate being implied by the position of the entry. An increment for the *X*-coordinate serves to define the direction of the vector since the *Y*-increment is assumed to be one. All that is left to completely define the line is a length measure. This is supplied as the number of scanlines spanned by the vector.

The calculations involved in computing the buffer entries from vector endpoint coordinates are dominated (in small processors at least) by one division step. This division is necessary to computing the increment. The upper endpoint *X*-coordinate is available directly, after a compare of the *Y*-coordinates. Nearly as simply, the number of scanlines spanned is given by the difference of the *Y*-coordinates plus one. However, the increment is the difference in *X*-coordinates divided by the number of scanlines spanned.

Updating an image consisting of 200 lines at a rate of 30 times a second allows 166 microseconds per vector. Current 16-bit microprocessors with built-in multiply and divide can execute the necessary instructions in about that same time. Since the image update rate can vary from 60 times a second down to around 20 times a second without destroying the smoothness of the motion, there is some leeway available. Use of a minicomputer or one of the more powerful 16-bit microprocessors now appearing should supply adequate power for the image update function.

THE *Y*-SORTED BUFFER

The vector entries, as produced by the image update processor are stored in the *Y*-sorted buffer in a manner which makes it easy for the scanline processor to access the information it needs. Specifically, the scanline processor must be able to readily retrieve all the vectors whose upper endpoints lie on a given scanline. Therefore, the *Y*-sorted buffer is organized as a fixed length array of list heads, each of which is either null or points into a memory containing linked lists of vector entries (Figure 3).

All unused vector entries in the buffer are similarly linked in a separate list to make allocation and deallocation of the fixed-sized vector entries a simple operation. Algorithms for this sort of memory management can be found in Knuth.<sup>12</sup>

The *Y*-sorted buffer can be used in one of two modes. If the drawing displayed is very dynamic, it is simplest to recreate the entire set of vector entries for each image update. However, for partially-static drawings and those with only translational motion, processor cycles may be saved by modifying the existing structure. Using a doubly-linked list for each scanline, a vector entry can be removed from one scanline list and appended to another. If only the position and not the direction of the vector has been changed, it suffices to change the upper end *X*-coordinate in the vector entry. All other numbers remain the same.

The latter mode, of course, involves contention for access to the buffer. Both the image update processor and the scanline processor must access the buffer. Since the scanline processor is under greater time constraints, it is given priority.

THE SCANLINE UPDATE PROCESSOR

The contents of the *Y*-sorted buffer are used to generate a set of scan segments for each scanline. The scan segments

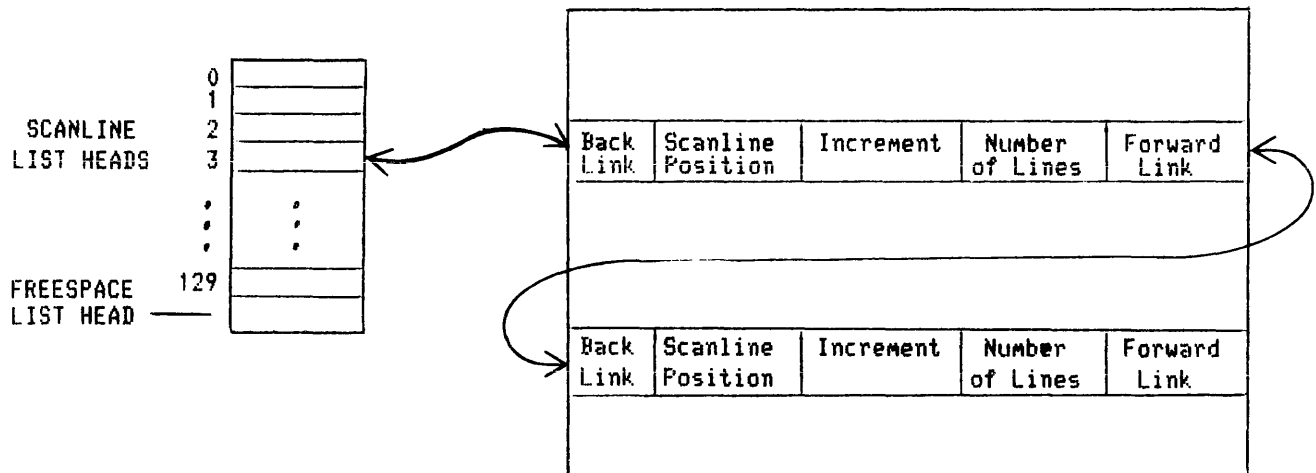

Figure 3—The *Y*-sort buffer and its data structure.

consist of a start position and a run length (the number of picture elements to intensify) for each vector which intersects a given scanline. The scanline processor generates the scan segments for each scanline in turn, moving from the top of the drawing to the bottom.

A scan segment is easily produced from the current *X*-coordinate of a vector and the increment giving the position of the vector at the next scanline. The start position is just the vector position; the run length is just the integer part of the sum of the increment and the fractional part of the vector position.

As the scanline processor works its way down the picture, a "scanline array" containing those vectors which intersect the current scanline must be maintained. As each new scanline is processed, three operations are necessary to maintain the scanline array. First, old vectors in the list which lie entirely above the current scanline must be discarded. Then, vectors which do intersect the current scanline must be updated to find the current point of intersection. Finally, new vectors whose topmost end coincides with the current scanline must be added to the array.

Recall, the *Y*-sorted buffer contains three data on each vector: (1) The horizontal position of the topmost end, (2) the increment which will give the position at the next scanline and (3) the number of scanlines spanned by the vector. Three similar quantities must be maintained by the scanline processor for all vectors intersecting the current scanline (Figure 4).

At each scanline, the scanline array is processed. For each array position with a valid entry, the increment is added to the fractional part of the vector position. The integer portion of the result is then stored in the *X*-sorted scan buffer as the run length. The increment is then added to the vector position and the result stored for use at the next scanline. The number of scanlines spanned is then decremented. If the result is zero, the entry is tagged invalid.

**Position**

	Current Position	Increment	Number of Lines Left
0	52.25	4.36	43
1	69.45	0.01	2
2	314.0	-1.23	15
3	5.0	-0.67	0
⋮		⋮	
49			

Figure 4—Information stored in the scanline processor's data memory.

New vector descriptions are inserted where invalid entries are found or created while generating a scan segment. At each such occurrence, the *Y*-sorted buffer is checked for a new vector which, if found, is then loaded into the available array position and processed to generate a scan segment.

Given the standard scan rate of 15,750 lines per second, the scanline processor has 63.5 microseconds to produce a scanline or 1270 nanoseconds per vector, assuming the initial design goal of 50 vectors per scanline. Pipelining the microinstruction fetch, a vector can be processed in six microcycles: (1) Fetch the entry, (2) sum for the run length, (3) store the run length, (4) sum for the position on the next scanline, (5) decrement the scanlines spanned and (6) store the updated entry. Adding a new entry requires two or three more cycles to transfer the entry and update a list pointer. Thus a somewhat relaxed 200-nanosecond cycle time can be used without overly specializing the processor. This is well within the capabilities of current four-bit processor slices.

**THE X-SORTED SCAN BUFFER**

The scan buffer is actually two buffers. One receives scan segments from the scanline processor while the other is read by the picture element processor. After each scanline is processed the two buffers are functionally switched (Figure 2).

The scanline processor sends a run length to be stored at an address given by the accompanying vector position (Figure 5). A read-modify-write cycle on the given address is used to fetch the previously-stored run length, compare it with the incoming run length and store the larger of the two. This process automatically resolves the problem of overlapping scan segments starting at the same picture element.

At the end of each scanline, one buffer should contain all the scan segments for the next scanline stored in *X*-sorted order while the other should be zeroed, ready to accept another set of scan segments. This implies that the picture element processor must clear the memory as it reads it. Given 320 picture elements per scanline, the buffer must cycle at around 150 nanoseconds. If the picture element processor is to clear the memory in a read-modify-write cycle, then a 70-nanosecond memory is needed. Alterna-

Figure 5—Structure of the *X*-sorted buffer.

tively, the memory can be interleaved on the least significant bit or a bulk clear executed during the beam flyback time (about ten microseconds).

### THE PICTURE ELEMENT PROCESSOR

The final element in the picture production pipeline produces a sequence of pulses which, when mixed with synchronization signals for a video monitor, result in intensified scan segments properly placed on the display. This involves reading the *X*-sorted scan buffer, setting a flip-flop at the beginning of a scan segment and resetting that flip-flop at the end of a scan segment.

A counter is used to divide the visible portion of a scanline into 320 parts and to address the *X*-sorted scan buffer. A down counter running at the same rate is used to define scan segment lengths. When the down counter is loaded, the output flip-flop is set. When the down counter reaches zero, the flip-flop is reset.

The down counter is loaded directly from the *X*-sorted scan buffer. Before loading, however, the downcounter contents are compared with the run length from the scan buffer. Only if the magnitude of the incoming run exceeds the content of the down counter is the down counter reloaded. This ensures that overlapping scan segments are properly handled. A series of overlapping segments will produce a single long intensified strip on the display.

The 150 nanoseconds allowed by the 320-element scanline is ample time to perform the compare-and-load operation. Accesses to the scanline buffer are overlapped with the compare operation using an intermediate register.

### SPEEDING UP THE IMPLEMENTATION—MORE LINES AND HIGHER RESOLUTION

It should be clear that the picture element processor is designed to handle the case where there is a new scan segment at every picture element. Therefore arbitrarily complicated drawings can be handled at the tail end of the pipeline. However, higher resolution may require producing a picture element as often as every 15 nanoseconds, requiring high-power circuitry and greater concurrency for the scanline buffer and comparator.

The word-processing industry is currently moving to high-resolution monitors in an effort to make the display look as much as possible like a standard 8½-by-11 typewritten page. Because of this, high-resolution raster monitors are now available at costs as low as a few hundred dollars. The semiconductor industry can be expected to eventually produce high-resolution versions of the display controller chips now being produced for standard-resolution monitors greatly simplifying the problems in driving the faster displays.

Current restrictions on the number of vectors which can be displayed lie in the scanline update processor. Bit-sliced microprocessors are not currently fast enough to allow more than 100 vectors or so to intersect a given scanline. The algorithm executed by the scanline processor is simple

enough to be readily translated to random logic. Estimates indicate a potential for increasing the processing rate by as much as an order of magnitude by such means. This would allow up to 1000 vectors on a scanline on a 240-line display or roughly 300 on a 750-line display. Wild guesses suggest that the chip count and cost of the scanline processor would increase by a factor of three to five. However, this violates the philosophy of minimizing special-purpose circuitry.

The other approach to speeding up the scanline processor involves running several microprocessors concurrently. Unfortunately, adequately speedy processors are not yet cheap enough that more than one or two of them can be considered economical in a supposedly low-cost terminal. If cost considerations are ignored under the supposition that the semiconductor industry will solve that sort of problem in due course, then a collection of processors could be arranged to deliver updated vector entries at a rate of one per microcycle. The processor cost and complexity could be expected to increase by a factor of five to ten.

An order of magnitude increase in performance allows a 1000 element by 750 line display with up to 300 vectors crossing any one scanline. This would allow display of roughly 60 lines of 100 or so legible characters, or (equivalently) 18,000 short vectors, or 3600 vector-inches on a 16" by 12" screen (19" diagonal). These figures are for 60 frames per second. Stroke-writing displays with equivalent or better specifications currently start at around \$20,000. The sort of display system discussed here should cost considerably less than one-half that amount. Whether it could be marketed at such a low price, however, is open to question.

### HIGHER QUALITY LINES

One good look at Figure 1 will reveal the major aesthetic problem with scan-converted vectors. They have ugly kinks which are all too evident at any but impractically high resolutions (compare with Figure 6 made on a calligraphic display). Getting rid of these kinks is a difficult, but not impossible proposition. The observer of the display can be tricked into perceiving smooth lines on the display by the judicious use of grayscale techniques.<sup>7,8</sup>

When using these techniques, the scan segments become gray-level functions instead of just run lengths. This necessitates a more complicated picture element processor. However, the scanline processor and *Y*-sorted buffer need not be changed.

Gray levels for producing any scan segment may be stored in a single table which stores the universal intensity profile for all scan segments. Any given scan segment may be produced by supplying an index into the table for the first picture element, the number of elements and the distance between table entries to be retrieved.

Therefore it becomes the job of the picture element processor to generate these numbers from the scanline position and position increment maintained by the scanline processor. The index of the first table entry is computed from the fractional part of the vector scanline position. The number of elements and the distance between table entries, in turn,

(a)

(b)

Figure 6—The pattern of Figure 1 on a calligraphic display.

must be computed from the vector position increment. The microcode for the scanline processor can easily be modified to deliver these two numbers instead of the truncated scanline position and run length.

The distance between table entries is obtained from the reciprocal of the vector position increment using a table of scaled reciprocals. The index for the first entry is given by the product of the fractional part of the vector position and the distance between table entries. The number of entries to be used is just twice the run length used previously.

Note that each scan segment must now be treated individually. The problem of overlapping scan segments becomes much more acute. Furthermore, each scan segment must now be twice as long as before. The likelihood that a number of nearly horizontal vectors will cause sufficient overlap to swamp the processor is quite high.

The gray levels of overlapping vectors must be arithmetically combined to determine the gray level for affected

picture elements. To be absolutely correct about combining the intensities of overlapping vectors, some measure of the area each vector occupies in a picture element and the area of overlap between such vectors would be necessary. Although such calculations have been used for shaded raster images,<sup>5,7</sup> the additional quality obtained isn't worth the expense in this application. Experiments indicate that a simple sum, truncated to the maximum allowable intensity where necessary, gives acceptable results.<sup>8</sup>

It appears unlikely that all this arithmetic can be performed on the fly as the line is scanned out. Therefore, a buffer is needed in which the grey levels to be displayed are stored. Two such buffers may be used. While one is providing grey levels to the display, the other may be used for building the next scanline (Figures 7,8).

The scan segment information provided by the scanline processor is acted upon by a picture element processor which loads its output into the scanline buffer via a read-sum-write cycle, accumulating intensity at a pixel until saturation. This arrangement eliminates the strict timing constraints involved in scanning directly from an *X*-sorted buffer of run lengths.

For simple images, the picture element processor should be less than three times as complex as in the initial design.

However, a high-performance implementation would require using several picture element processors in parallel.

## CONCLUSIONS

The algorithms for the approach to scan conversion presented here have been demonstrated in software. The translation to a hardware implementation for a limited number of lines and modest resolution should pose no problems. The expansion of the concept to higher resolutions and smooth vectors is expected to provide some challenge, but no insurmountable problems.

The failure modes exhibited when the scan converter is overloaded are totally different from the flicker seen on an overloaded calligraphic display system. There are two choices for a failure mode: either repeat the last scanline, or leave out some scan segments. The former method will cause noticeable stripes on the screen, the latter will cause some vectors to disappear on certain scanlines and perhaps leave other vectors out altogether.

A safer failure mode could be engineered by going to lower resolution whenever overload is detected. At a 60-hz refresh rate one slightly bad frame produced while discovering overflow would probably be acceptable. The degraded mode of operation for low-resolution (320 by 240) would provide only 120 lines vertically. Surely, most users would find this intolerable. On the other hand, a high resolution implementation might run in the degraded mode quite successfully.

A practical approach to real-time scan conversion has been described which can be implemented straightforwardly using currently widely available parts. Projected trends in LSI development indicate that high-resolution implementations competitive with low-end calligraphic displays could be produced at quite reasonable cost within a few years.

# The evolution and architecture of a high-speed workstation for interactive graphics

by WILLIAM L. PAISNER

California Computer Products, Inc.  
Anaheim, California

## INTRODUCTION

In 1975, California Computer Products, Inc. (CalComp) embarked on the design of a multi-station Interactive Graphics System. As a major part of this design effort, a fresh look was taken at the requirements for the workstation, which, after all, is the operator's sole point of contact with the system. The needs of the operator were perceived as follows:

- To examine the working drawing—any part at any magnification.
- To interact with the drawing—pointing where useful, typing where useful.  
—To perform the above rapidly so that he functions in a result-oriented rather than mechanics-oriented environment.<sup>1,3,4</sup>
- To receive prompting as necessary for complex operations.

In addition, the design goal of multiple simultaneously operating workstations added the following requirements:

- A workstation must have a substantial share of the distributed processing load so that rapid response time can be maintained at all times.
- A workstation must share major peripherals with other workstations.

The remainder of the paper illustrates the workstation design which evolved from these needs and requirements, concentrating on the architecture of an innovative high-speed graphics processor at the workstation core.

## STRUCTURE OF CALCOMP IGS 500 SYSTEM

The system is based around a CalComp 16/40 16-bit minicomputer. It incorporates from one to four large high-speed disks which contain program and drawings. The system is structured as in Figure 1, which is drawn to emphasize the workstation elements.

The requirement of speed and distributed intelligence was

satisfied by the inclusion of a "Picture Processor." The description of the architecture and capabilities of this high-speed graphics processor occupies the remaining sections of this paper.

The Alphanumeric CRT/Keyboard provides the operator with high-speed prompting (9600 baud) and allows keyboard input wherever relevant and useful. The tablet or digitizer allows the operator to point at the drawing being digitized/edited and in general allows a close interaction with the drawing through local functions supported by the Picture Processor. The tablet and keyboard can both also be used for menu selection.

A three-axis joystick allows the operator, locally supported by the Picture Processor, to pan and zoom over the *entire* drawing in real time. As will be seen in the next section, the drawing is resident in the Picture Processor for the duration of the session. The speed of the Picture Processor allows a single scan (re-display) of the drawing through the joystick-defined window in 16-200 milliseconds, depending on drawing complexity.

Vector graphics are presented on a raster scan display, operating at 60 Hz, non-interlaced. This provides a bright, flicker free display at minimum cost. An optional two-bit gray scale is available to support gridding and cursor operations.

It should be emphasized that the drawing contained in the Picture Processor memory is a working copy of the archived drawing on the disk. It is in an application-structured hierarchical form—it is in "database" coordinates, not "screen" coordinates. During the session, this is the only copy of the drawing to be modified. At the end of the session it is returned through the central minicomputer and packed onto the disk. This concept of a single resident application-structured drawing, acted upon by a local high-speed graphic processor, is the heart of the workstation and has allowed significant advances to take place in operator interaction.

## GENERAL ARCHITECTURE OF THE PICTURE PROCESSOR

The Picture Processor connects to the Host Computer, a 16-bit minicomputer, through a high-speed parallel interface.

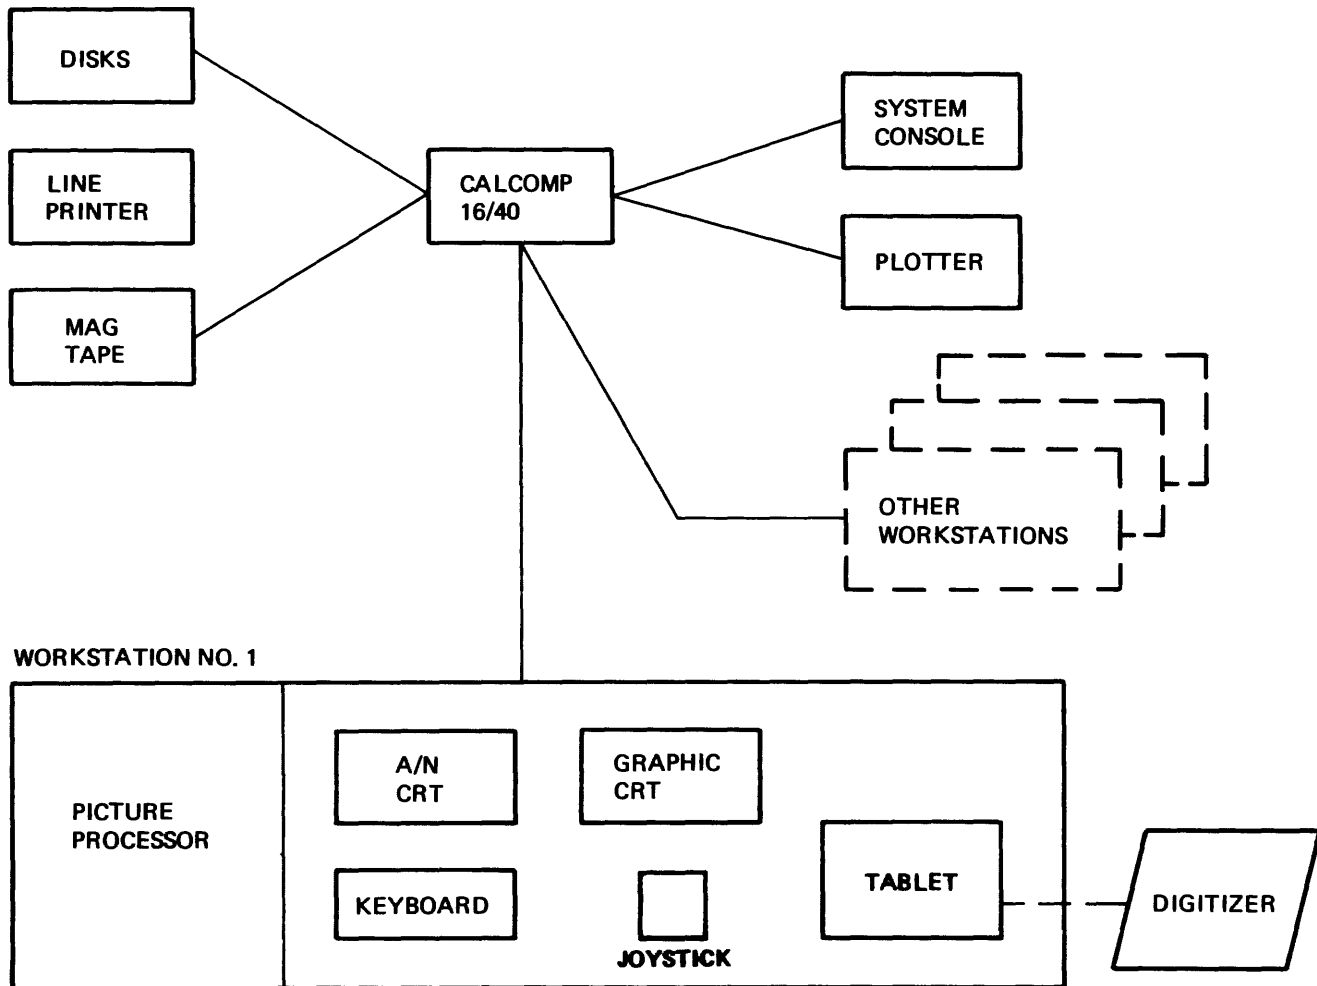

Figure 1

The interface has full handshake and is capable of speeds up to two MBYTES/second. As discussed earlier, the Picture Processor contains a large (64-256 KBYTE) Data Base Memory which holds the drawing during the interactive session. The memory is structured as 64K 32-bit words. A small area of the memory (less than 200 words) is used to pass command and outputs to and from the Host Computer, Local Function Manager, and Display Manager. (See Figure 2.)

The Data Base Memory is, in effect, shared by these three processors during the session. The Host Computer is a 16-bit general purpose minicomputer distributed and partially manufactured by CalComp under license from SEMS Corporation. Through the Host Input/Output module, it manipulates the drawing in the Data Base Memory and issues commands to the remaining two processors. The Local Function Manager is a 6800-based microcomputer which manages the joystick and tablet/digitizer and which serves as a "local" Host Computer to perform functions which reduce the load on the central minicomputer. The position of the local Function Manager within the Picture Processor architecture allows it to perform a significant number of

useful tasks. These will be described in more detail later in this paper. The Display Manager is a high-speed (200 nsec. cycle time) custom-designed microcomputer whose primary task is to scan the drawing in Data Base Memory and output vectors to a pipelined sequence of graphics processing modules which then drive the graphics CRT.

The actual pipeline is a byte-structured 10 MBYTE/second path with a FIFO at the entrance to each module. The pipeline has its own language, using control bytes and data bytes, which allows a standard interface for each processing module and supports the introduction of new ones in future designs. So that the Display Manager may make additional use of these modules, the pipeline is fed back to the Display Manager, allowing it to accept data after processing. This capability is fully exploited in the Picture Processor and is described in the next section.

The graphics CRT is a 15-inch video monitor driven through frame buffer technology. The basic workstation contains one monochrome graphic CRT, switch-selected reverse video and a resolution of 300x416 pixels. An additional frame buffer plane can be added for an optional two-bit gray scale. The Picture Processor can support up to three

additional graphics CRTs, each with optional two-bit gray scale. The 300x416 resolution was selected as the basic display because the operator's ability to rapidly pan and zoom over the drawing made it less necessary to observe larger areas of the drawing at one time. This, in turn, allowed a less expensive display system, with savings in the size (and cost) of the frame buffers and in the selection of the video monitor. At the time of submission of this paper, larger and higher resolution monochrome and color CRT display systems are under development and will be available as options.

The ability of the Picture Processor to allow rapid motion on the screen required a corresponding sophistication in the display system. The graphics CRT is actually driven by two independent frame buffers which are used in various ways during a session. While pan/zoom is taking place, the frame buffers are used as a double-buffered output system. While

one buffer is refreshing the CRT, the other is being loaded with new information from the graphics pipeline. When this loading is complete, taking one to 13 frame times, the buffers are swapped, the other buffer is cleared and loading of new data begins again. The result is a smooth, no-flicker motion of the drawing on the screen.

Another mode of frame buffer operation supports local "dragging," in which an element of the drawing is attached to the tablet stylus and moved around on the screen. In this case, the initial screen image is displayed through one frame buffer. The object to be moved is undrawn from the buffer and redrawn into the other frame buffer, thus avoiding the typical holes which are left when only one buffer is available. During this operation, the contents of both frame buffers appear on the screen but a priority logic is used to ensure that the intensity level of the object being dragged overrides that of the objects over which it passes.

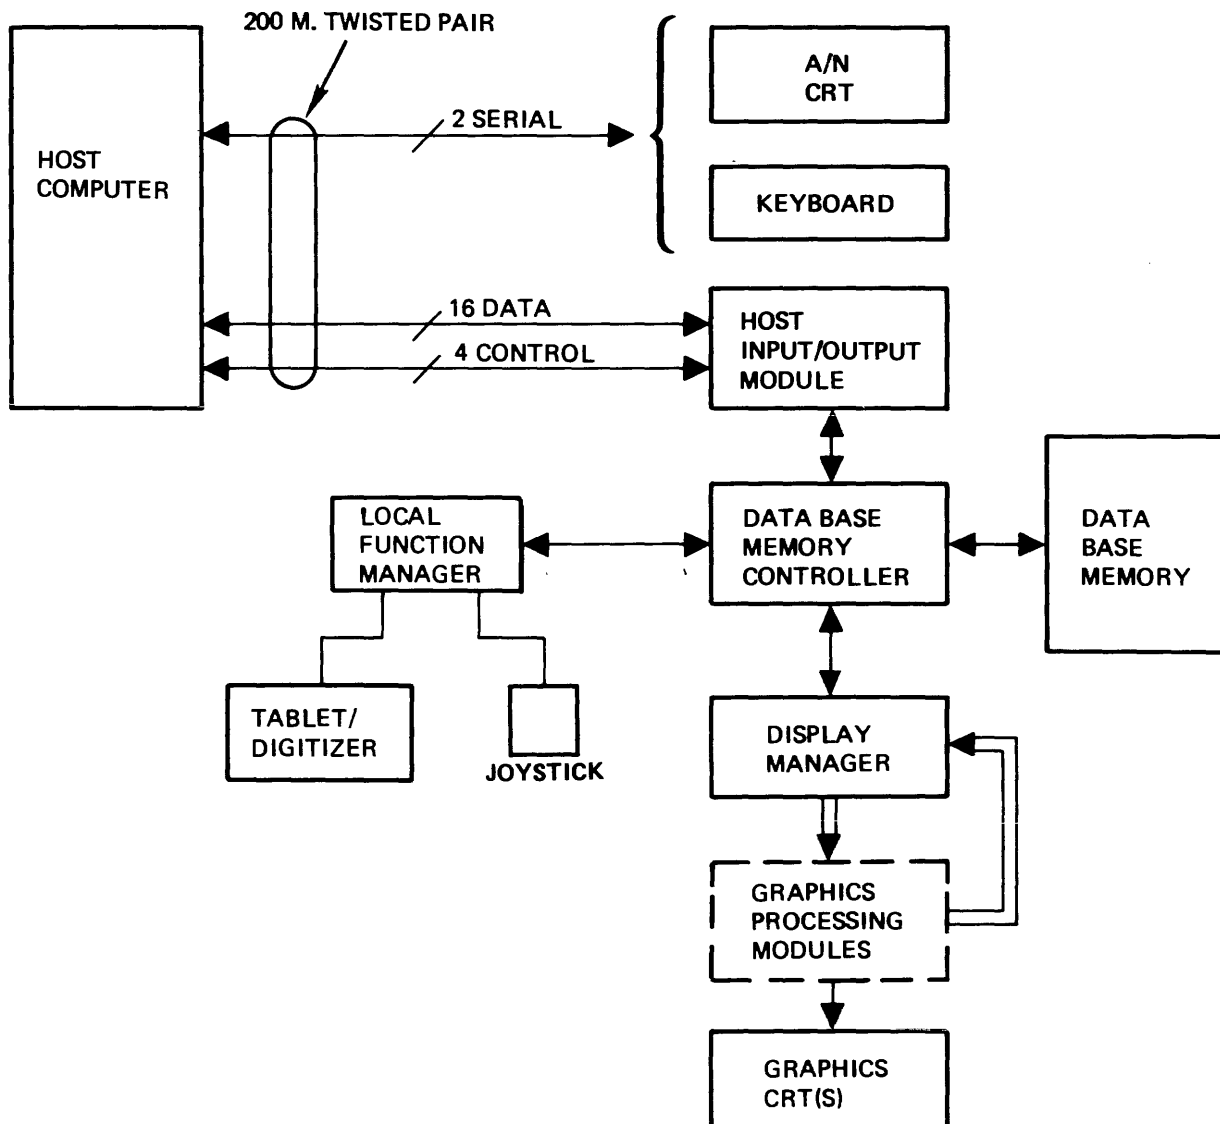

Figure 2

**INFORMATION FLOW WITHIN THE PICTURE PROCESSOR**

The functions performed by the Picture Processor fall into two major categories. The first group are those involving scan and interpretation of the drawing in Data Base Memory and are performed through the Display Manager/Graphics Processing pipeline path. The second group are those involving the joystick and tablet and the functions which involve them. These are performed by the Local Function Manager which in many cases makes use of the Display Manager/pipeline functions as part of its operation. Figure 3 illustrates the major functions in the first group. The Local Function Manager is described in the next section.

The drawing data base is fetched from disk and loaded into Data Base Memory when the operator types the drawing

name. The disk file is not accessed again for graphical information until the drawing is saved during or at the end of the session. A drawing can be loaded in a few seconds. The drawing structure in Data Base Memory consists of two "files." The Control File has fixed length entries and contains information common to all graphical objects—origin, geometry type, boxing parameters, and certain parametric information such as drawing level, subtype, and a pointer to disk-resident application-dependent properties of the object. Each Control File entry also contains a pointer to a related Geometry File entry. The Geometry File has variable length entries—the structure of each entry depends on its geometry type.

Geometry types supported by the Picture Processor are:

*Line*—A series of connected or unconnected line segments.

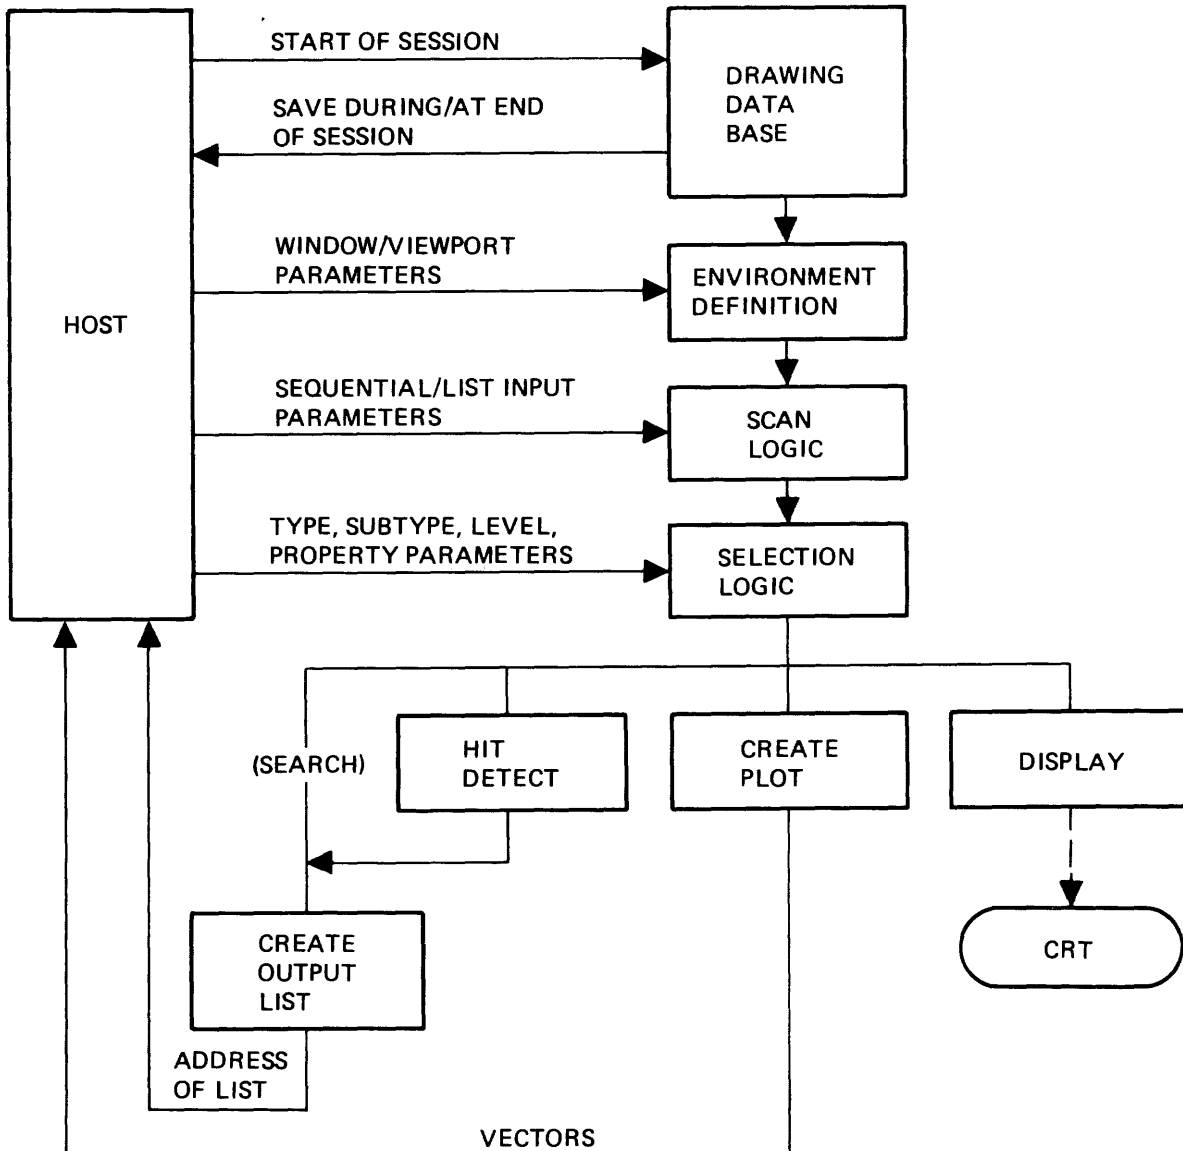

Figure 3

*Short line*—A series of short connected or unconnected line segments.

*Arc*—A circular arc, up to and including a full circle.

*Text*—A character string with optional size, rotation, and inter-character spacing. All characters come from a selection of system or user-defined fonts and are completely arbitrary. A step-and-repeat capability is provided that allows an individual character, of arbitrary structure, to be repeated in a string up to 256 times.

*Group*—A collection of any of the above entities or other groups. The collection is treated as an entity and may be scaled, rotated, and placed in multiple locations in the drawing. Independent *X, Y* scaling is provided, allowing for example, an ellipse to be generated from an Arc group member.

From this description, it can be seen that it is a hierarchical structure, and in fact most drawings contain a variety of multi-level groups. This sharing of geometries allows the data base to become extremely compact, allowing a smaller, lower cost memory to be used. The data base structure allows for 24-bit precision in all coordinates except for Short Line (12-bit) and text font construction. The Picture Processor Graphics Processing Modules, however, allow 24-bit data in window specifications and the origins of objects at the top of the hierarchy—all other coordinate information is limited to 16 bits. This decision was made to permit reasonable construction costs for the critical Picture Processor boards.

The Host computer directs the Display Manager operation by placing a command block in a reserved area of Data Base Memory. Once the command block has been placed, the Display Manager generally follows the sequence in Figure 3 and the Host is free, during this sequence, to service other workstations, plot, or do other background tasks.

Initially, the Display Manager defines the window, in data base coordinates, and the viewport, in screen coordinates, to be used for this command sequence. In some modes, namely Search and Hit Detect, only the window is defined; for simple Search, neither are defined. Next the scan parameters are examined. The Display Manager can sequentially scan the Control File within the parameter limits, or it can process only those Control File entries whose addresses appear in a list in Data Base Memory. In the latter case, only the address of the list is given as a parameter. List input is a powerful tool for the Display Manager, as it is also able to generate lists in the same format.

As each Control File entry is accessed, the Display Manager compares its level, type, subtype and property pointer against a selection block given to it as a parameter. Selection parameters can be lists or ranges and a Control File entry can be either included or excluded if it "passes" selection. The speed of the Display Manager allows an entry to be tested in microseconds. Selection serves a variety of functions for the application software: among them is the ability to avoid or reduce the "hit ambiguity" problem by allowing only certain objects to be "hit" by the user. In practice, the combination of memory-resident drawing and a very high speed processor (Display Manager) has had a synergistic

effect in the selection mechanism and new uses are still being found for this capability.

Once a Control File entry is selected, it is processed according to one of four basic modes of operation:

*Search*—No further processing is done. The address of the selected Control entry is added to a list being built in Data Base Memory. At the end of processing of the Control File, the address of this list is returned to the Host computer through Data Base Memory. Note especially that this list is in the form accepted by the Display Manager as list input and can therefore, if desired, be resubmitted to the Display Manager in a subsequent command for display or even further search operations.

*Display*—The selected Control File entries are processed to extract their coordinates. The associated Geometry File entries are located and interpreted to produce vectors. These vectors are then output to the pipeline where the Graphics Processing Modules perform the necessary transformations into screen coordinates. The end result is to load a frame buffer with the proper bits for the raster display.

*Plot*—Processing is identical to Display except that instead of the vectors being "drawn" in the frame buffer, they are returned through the pipeline (see Figure 2) back to the Display Manager which then places them in a buffer in Data Base Memory for the Host computer. In this case, the "viewport" definition is chosen so that the precision of the output vectors match the precision of the plotter to be used. The Host then queues the plot data for actual plotting. This capability allows a complete plot file to be generated in seconds with a minimum of Host computer involvement.

*Hit Detect*—In this mode, the window definition is typically (although not necessarily) a very small region in data base coordinates surrounding the data base coordinate location of the tablet/digitizer stylus. The processing of Control File and Geometry File entries proceeds as before, but for this mode, the Graphics Processing Modules are used differently. Vectors are output to the pipeline but processing terminates at the Window/Clip module (described later in this paper). The module generates for each draw vector, a 2-byte hit response word and outputs that word to the remainder of the pipeline. The Display Manager, on receiving this response word, generates an output list entry in Data Base Memory, just as in Search Mode. At the end of processing, the address of this list is returned to the Host computer, where, as before, it can be re-input to the Display Manager in a subsequent command, for example, Display (for flashing the hit object).

## THE LOCAL FUNCTION MANAGER (LFM)

As previously described, the high-speed processing capability of the Picture Processor is located in the Display Manager/Graphics Processing modules pipeline. The Display Manager receives command information from and outputs results, if any, to the Data Base Memory. Because both

the Host computer and the LFM are capable of reading and writing Data Base Memory, the full power of the pipeline is available to the LFM as well. In this mode of operation, the Host computer places command information for the LFM in Data Base Memory. Included in that information are the proper command blocks for the LFM to use when invoking the Display Manager. The flow of information is therefore as shown in Figure 4.

The variety of LFM tasks within the Picture Processor is best illustrated by describing six of the major ones:

- Panning and zooming
- Picking
- Dragging
- Flashing
- Performing application-specific functions
- Managing Picture Processor diagnostics

#### *Panning and zooming*

The LFM samples the X, Y and Z axes of the joystick 60 times a second. If a change has occurred, the values are used to modify the center and size of the window(s) given to the LFM by the Host computer when the Pan/Zoom command was issued. The LFM then, using command blocks given it by the Host, invokes the Display Manager to erase the current frame buffer, redisplay the drawing through the modified window, and swap frame buffers. This process repeats as often as possible ( $\leq 60$  times a second) while the operator is manipulating the joystick. The process of calculating the window modifications from the joystick position was subject to considerable optimization during development of the Picture Processor to improve the "feel" of the joystick. The joystick is the operator's movie camera—its operation is required to be smooth, self-evident, immediately rewarding in terms of screen motion, and, most important, to require no mental effort whatsoever from an experienced operator. The LFM modifies both the window center/size and the update rate as a table-lookup function of joystick position. Note that once the initial command was issued, all pan/zoom activity has been completely local.

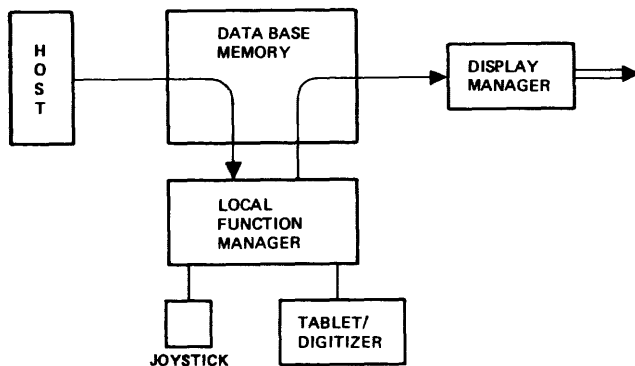

Figure 4

#### *Picking*

This is the process used by an operator to identify a particular screen object. The LFM reads the tablet stylus position in screen (tablet) coordinates. Using the viewport in which the access is made and its associated window, the LFM uses one of the Graphics Processing modules (invoked through the Display Manager) to "inverse map" the stylus coordinates into data base coordinates. A small window centered at these coordinates is created and the Display Manager used in Hit Detect mode to determine if an object is being pointed to. The LFM interrogates the list output by the Display Manager and, if null, continues to monitor the stylus until it is lifted. At this point, or if an object is "hit," the LFM quits and raises status to interrupt the Host computer. From the time that the Pick command is issued to the first hit, if any, all operation is local to the workstation.

#### *Dragging*

This capability allows the operator to "attach" an on-screen object to the tablet stylus and to literally drag it around on the screen. As part of the command, the Host has identified the object to be dragged, usually from a preceding Pick. The LFM uses the inverse mapped stylus coordinates, obtained as in the Pick operation, to update the origin of the object. The LFM then uses the Display Manager to erase the priority frame buffer and to redraw the object at its new location. This process continues as the operator moves the stylus and terminates when he lifts the stylus. An important aspect of this operation is that the updating takes place on the real drawing object in actual data base coordinates. Thus, when the operation terminates, the drawing is correctly updated and no Host involvement has taken place since the initial command was issued. Due to the high speed of the Picture Processor, objects of any complexity can be dragged in real time.

#### *Flashing*

Flashing is a simple LFM function during which an object or list of objects with appropriate Display Manager command blocks is given to the LFM by the Host. The LFM from then on, unless told to stop by the Host, periodically draws and blanks the object(s), using the Display Manager as usual.

#### *Performing application-specific functions*

In addition to PROM-resident firmware, the LFM also contains a read-write memory, most of which is available for additional firmware. The LFM contains a loader and the Host may, as part of the initialization of a given application software package, download specific functions to be executed in the LFM. Such functions can be chosen to further offload the Host or to make use of the joystick or tablet in

ways not provided by the standard LFM firmware. This is a powerful capability in its ability to support future application areas.

#### Managing Picture Processor diagnostics

When power is first applied to the workstation, the LFM performs an extensive, carefully sequenced fault detection and isolation process. It tests itself, its peripherals, its access to Data Base Memory, the memory itself, the Display Manager and each of the Graphics Processing Modules. As the tests are performed, each using only those capabilities proven by the previous test, indicator lights are decremented on the edge of the LFM board. When all tests are successful, a status line is raised to the Host computer to indicate an available workstation. If a failure occurred, the board or boards at fault can be deduced from an examination of the indicator lights. The presence of this test, together with loop-through capabilities in the Host Input/Output Module (Figure 1) provides an exceptional degree of confidence in the workstation at the start of a session.

#### GRAPHICS PROCESSING MODULES

The modules in Figure 5 perform all of the high-speed work of the Picture Processor. The architecture of the Display Manager and of the pipeline itself were described earlier in this paper. Of the remaining modules in Figure 5, all but the Video Function module are custom designed microcomputers with a cycle time of 200 nsec non-overlapped. All modules shown operate on standard 10 MHz and 5 MHz clocks generated by and distributed from a timing module, not shown here, which also generates the video sync and other timing signals.

#### Matrix transform module

The Display Manager outputs vectors for an object (Control File-Geometry File pair) which are in the local coordinate system of the object. These vectors may require scaling, rotation, and translation to transform them into true data base coordinates. The Matrix Transform module stores a working matrix,  $M_w$ , internally as

$$\begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \\ M_{31} & M_{32} \end{bmatrix}$$

As vectors are input from the pipeline, they are transformed by this matrix as follows

$$(X', Y') = (X, Y, 1) M_w$$

and output to the pipeline following the module. The matrix can be cleared to the identity by a command to the module. If nested transformations are required, as in multi-level groups or italic text, a new matrix can be sent via the pipeline to the Matrix Transform module where it will be concatenated onto the working matrix as follows:

$$M_w' = M_{input} M_w$$

It should be noted that for compatibility, a (0 0 1) column is appended to both matrices before concatenation—the resulting (0 0 1) column is then deleted before  $M_w'$  is stored. The matrix can also be output to the pipeline, back to the Display Manager, where it can be saved either in local storage or Data Base Memory. This saving (and subsequent restoring) of the matrix occurs as part of context changes during the traversal of nested groups—also in specialized areas of Text and Arc generation.

The Matrix Transform module represents all scaling and rotational terms in twos complement with 14 fractional bits. This allows the values  $\pm 1$  to be represented exactly which

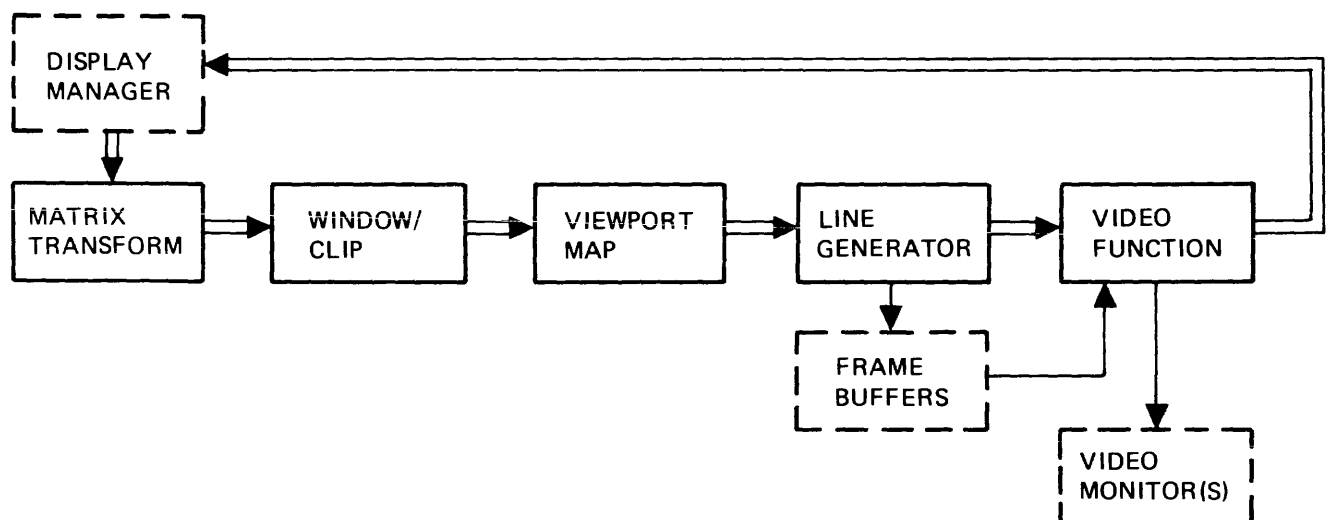

Figure 5

reduces the accumulated error present in nested transformations. In practice, visual feedback has tended to compensate for any such error and nesting levels of five or six (of a maximum of 14) are used routinely.

The Matrix Transform module performs all calculations in 16-bit two's complement fixed-point arithmetic. In vector multiplication the microprogram sequences a set of serial multipliers and adders which calculate  $X'$  and  $Y'$  simultaneously. Typical processing times are 5.8 microseconds for vector transformation and 17.4 microseconds for a full matrix concatenation.

#### Window/Clip module

During the Environment Definition phase of operation (see Figure 3), the Display Manager has output the current window size to this module. As each top-level object in the hierarchy is output, the difference between its 24-bit origin and the 24-bit window center, called the "offset," is calculated by the Display Manager and output to the Window/Clip module. Using this information, the module then performs a clipping algorithm on incoming vectors, and in Display and Plot modes, outputs the clipped vectors, if any, to the pipeline. In Hit Detect mode, only a result code is output. Vectors entering the Window/Clip module are in an "object-centered" data base coordinate system. When they leave, they have been clipped to the window edges and translated so that they are in a window-centered data base coordinate system.

The algorithm used is a modified version of the Clipping Divider.<sup>2</sup> The hardware operates in 18-bit precision and, using essentially two microprocessors operating from the same microprogram, performs  $X$  and  $Y$  clipping simultaneously. Typical clipping times range from five to 20 microseconds per vector.

#### Viewport map module

During the Environment Definition phase, the Display Manager has output the current window size, viewport size, and viewport center to this module. Since the incoming vectors to this module are in window-centered data base coordinates, a simple linear transformation turns them into screen coordinates as follows:

$$X_s = X_w(VXSIZE/WXSIZE) + VXCTR$$

$$Y_s = Y_w(VYSIZE/WYSIZE) + VYCTR$$

where

- $(X_w, Y_w)$  —Window-centered vector in data base coordinates.
- $(WXSIZE, WYSIZE)$  —A diagonal vector from the center of the window to the upper right corner, in data base coordinates.
- $(VXSIZE, VYSIZE)$  —A diagonal vector from the center of the viewport to the upper

right corner, in screen coordinates.

$(VXCTR, VYCTR)$  —The center of the viewport, in screen coordinates.

$(X_s, Y_s)$  —The screen vector in screen coordinates.

The Viewport Map module implements this transformation and also the inverse, in which a screen coordinate vector is input, resulting in a window-centered data base coordinate vector. In both cases, vectors are input from the pipeline and the resulting vector is output through the pipeline to the next module.

Calculations are performed in 16-bit precision. Multiplications are done in fixed point for multipliers of less than one—in floating point for multipliers greater than one. Since, in general, this module operates on fewer vectors than the preceding modules (since clipping has taken place),  $X$  and  $Y$  are produced sequentially and the total time to map a vector is 13 microseconds.

#### Line generator module

This module receives screen coordinate vectors of four types—absolute move, absolute draw, relative move and relative draw. In Display mode, the module is enabled. It takes all "draw" vectors and performs a line algorithm in firmware to turn on bits in the current frame buffer along the path of the line. For gray scale, two bits are written at each pixel position along the line. For other modes, this module is disabled and passes all received vectors through itself to the pipeline.

The line algorithm is essentially the same eight-vector incremental algorithm used in CalComp plotter software and hardware, biased so that a line is drawn identically when drawn from either end. The line generator operates in 12-bit precision so not to limit future display resolution.

#### Video function module

This module has several tasks, all related to display. It manages the frame buffer outputs by receiving commands through the pipeline which direct it to connect the two frame buffer outputs together to the screen through a priority scheme, or to connect only one at a time, as used by the pan/zoom LFM operation. It can optionally synchronize the connection of frame buffer output to the next video frame to avoid flicker during rapid motion.

The Video Function module also manages the actual video outputs, monochrome and gray scale, as well as providing a reverse video capability (black on white). It should be noted that this module is in the pipeline only so that it can receive buffer connection commands from the Display Manager—all other pipeline information is passed through unchanged.

## PIPELINE THROUGHPUT

The pipeline architecture allows the processing of the Display Manager, Matrix Transform, Window/Clip, Viewport Map and Line Generator modules to operate essentially at the speed of the slowest module. For a given number of displayed lines, only the latter two modules have a constant processing time—the others depend on the drawing structure and the current window in use. The design goal called for 5000 visible one-half-inch vectors, with an arbitrary mix of primitive and group structures, to be displayed in 100 milliseconds. In general this has been met for all except pure text, in which the inclusion of an italic transformation at the character level has raised the display time for 1200 visible four-segment characters to approximately 220 milliseconds.

## ACKNOWLEDGMENTS

The architectural definition, design and implementation of the Picture Processor was performed by a small group consisting of the author, Robert Trousdale, Walter Reed and Robert Tingley. Thanks are due to the CalComp management for their unswerving support during the gestation period, to Lefty Miyahara and Vee Fanning for their faultless work in building the first prototype boards and to Jan Wen-

del for her patient typing of 13 revisions of the Picture Processor Interface Manual.

## INTRODUCTION

To have fast response time is often a requirement for a data base system especially in the on-line environment such as inventory control, stock quotation or hotel/airline reservation. This requirement for fast response time can be easily obtained by carefully organizing the file at loading time. Due to subsequent insertions, the file structure designed with fast response time would be damaged because insertions were stored in overflow area. As more insertions are added, the response time will be lengthened since accessing records in overflow area takes more time than in home area. When the response time exceeds the tolerance limit that a user can stand, a reorganization is required. In general, reorganization of a file is a costly and time-consuming job and should be avoided as much as possible. In order to maintain a fast response time and to avoid frequent reorganizations, a technique called "distributed free space"<sup>10</sup> within home area was introduced.

When data description and instances are loaded into a physical storage device by a data base management system (DBMS), the access methods (or file manager), which are a portion of DBMS, allocate one or more storage rooms, each of them includes spaces for both initial records and future insertions. Such a storage room allocated at loading time to accommodate both initial records and insertions is called a "data storage area (DSA)." Figure 1 shows an example of DSA. There will be no problem of future deletion of data because many DBMSs have utility routines to reclaim the vacated space and merge them to the realm of distributed free space for future insertions. So the effect of deletion is not discussed here. Many commercial DBMSs have such facilities. Examples are VSAM in IBM's IMS, CYBER RECORD MANAGER in CDC's DMS-170, CINCOM's TOTAL, MRI's System 2000 and Cullinane's IDMS, etc.

In commercial access methods, there are parameters provided for users to claim an amount of free space at creation. In general, a user may overestimate or underestimate the amount of distributed free space he needs. In order to determine how much distributed free space a user should

claim, Chin<sup>2</sup> presents a mathematical model to estimate the size of free space so that insertions do not cause the fast response to exceed the pre-set limit. The model in Reference 2 is derived based on the worst case, namely all insertions are added into a single DSA. As a result, that model reserves too much free space. In this paper, we present a new model, which reserves less amount of distributed free storage space than Chin's model, without increasing the fast response time.

In the next section the models are discussed. We illustrate the simulation tests in the third section. Finally, characteristics of the models and consequences of the experimental tests are discussed in the fourth section.

## MATHEMATICAL MODEL FOR DISTRIBUTED FREE SPACE

For clearness, let us restate Chin's problem, assumption, and classification on access methods.

- *Problem and Assumptions*—If the number of initial records and the subsequent insertion rate of a file are both known a priori, how much free space should be claimed such that the probability of overflow is less than any pre-specified value?
- *Classification on Access Method*—The various access methods can be classified into two groups by way of data organization; namely, ordered access method (OAM) and non-ordered access method (NAM). The former refers to those access methods which require data in an ordered sequence with respect to some field values such as index sequential access method or binary search. The later refers to those access methods in which data are not required to be in an ordered sequence for storage or retrieval such as hashing function or non-ordered sequential searching. Hereafter, the size of "distributed free space" has been analyzed on the base of these two classes of access methods.

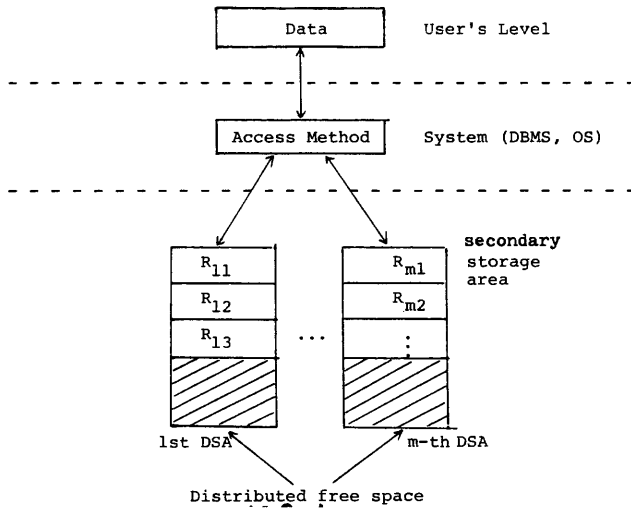

Figure 1—Data storage area (DSA).

**Notations**

- R*: The total number of initial records within a file at load time.
- I*: The number of records inserted into the file in time *t* units subsequent to the load time.
- S<sub>i</sub>*: The number of initial records loaded into the *i*th DSA at load time.
- r<sub>i</sub>*: The number of insertions added to the *i*th DSA.
- E(r<sub>i</sub> | S<sub>i</sub>)*: The number of expected insertions added to the *i*th DSA given *S<sub>i</sub>* initial records within *t* units after load time.
- I<sub>i</sub>*: The amount of free space should be pre-allocated in the *i*th DSA.
- VAR(r<sub>i</sub> | S<sub>i</sub>)*: The variance of random variable *r<sub>i</sub>* with a given *S<sub>i</sub>*.
- m*: The number of DSAs created at loading time.
- B*: The insertion ratio of the file at time *t* units after the load time. It is a given value which is used to estimate the quantity of *I*. *B* = *I* / *R*.

*Ordered access method*

When a file is created by using an OAM such as IBM's VSAM, records in a DSA are stored, maintained and retrieved with respect to a pre-ordered sequence which depends upon the value of a selected attribute. It bases on the mathematical model, called B-tree, which is developed by Bayer and McCreight.<sup>1</sup>

Traditionally, each DSA is initially loaded with the same number of records at file creation time. If *n* fixed-length records are loaded in *m* DSAs at load time, then *S<sub>1</sub>* = *S<sub>2</sub>* = ... = *S<sub>m</sub>* = *n*, and  $\sum_{i=1}^m S_i = R$ . Ideally, one would like to have the probability of inserting records into each DSA

to be the same, which is the case if the number of initial records in each DSA is the same and the ranges of key-values are evenly distributed among all DSAs. However, if DSAs have the same number of initial records, it is impossible to make the range of key-value to be evenly distributed among all DSAs. Different DSA will have different ranges of key values. Hence the probability of inserting records into different DSA is different. Keehn and Lacy<sup>6</sup> show that the probability of adding exactly *x* insertions to a DSA with *n* initial records is as follows:

$$P_{S_i=n}(r_i=x) = P_n(x) = \frac{\binom{I}{x} \binom{R}{n}}{\binom{R+I}{n+x}} \frac{n}{n+x} \quad (1)$$

$$0 \leq x \leq I, 1 \leq n \leq R, \text{ and } \sum_{x=0}^I P_n(x) = 1$$

Curves of *P<sub>5</sub>*(*x*), *P<sub>10</sub>*(*x*) and *P<sub>20</sub>*(*x*) are shown in Figure 2.

The probability *P<sub>n</sub>*(*x*) in (1) is true regardless of the key-value distribution *F<sub>k</sub>* so long as that both the *R* initial records and *I* subsequent insertions are originated from the same *F<sub>k</sub>*.

Using (1), we find that the expected number of records to be added into a DSA with *n* initial records is

$$\mu_i = E(r_i | S_i = n) = \sum_{x=1}^I x P_n(x) = \frac{nI}{R+1}^* \text{ for } 1 \leq i \leq m \quad (2)$$

Its variance is

$$\sigma_i^2 = \text{VAR}(r_i | S_i = n) = \frac{nI}{R+1} \left[ \frac{(n+1)(I-1)}{R+2} + 1 - \frac{nI}{R+1} \right]^* \text{ for } 1 \leq i \leq m \quad (3)$$

Since  $\mu_i$  of (2) is only an "expected estimation," the

Figure 2

\* Derivations are given in Appendix.

probability of overflow could not be known even if  $\mu_i$  records are reserved as free space within the  $i$ th DSA. Intuitively, an "appropriate free space" within a DSA will not only be able to accommodate  $\mu_i$  insertions, but also give an arbitrarily small amount of deviation for  $\mu_i$  insertions. For these reasons, we use the Central Limit Theorem to determine an "appropriate free space,"  $I_i$ , for the  $i$ th DSA as follows:

Step 1—Use (2) and (3) to find the expected value and standard deviation of random variable  $r_i$ .

Step 2—By Central Limit Theorem, the probability density function (pdf) for random variable  $z_i=(r_i-\mu_i)/\sigma_i$  approaches a normal distribution for a large sample. We are interested in the probability that the number of subsequent insertions added to the  $i$ th DSA is less than  $I_i$ , i.e.,  $P(r_i \leq I_i)$ . Hence,

$$\begin{aligned} P(r_i \leq I_i) &= P\left(\frac{r_i - \mu_i}{\sigma_i} \leq \frac{I_i - \mu_i}{\sigma_i}\right) \\ &= P\left(z_i \leq \frac{I_i - \mu_i}{\sigma_i}\right) \\ &= \Phi\left(\frac{I_i - \mu_i}{\sigma_i}\right) = \Phi(z) \end{aligned} \quad (4)$$

Step 3—Choose the probability  $\Phi(z)$  as large as needed so that we can lower the percent of overflow.\* For a value  $z$  from the normal table,<sup>4</sup> we can obtain  $I_i = \mu_i + z\sigma_i$ .

Example 1— $R=1000$ ,  $I=500$ ,  $n=100$ ,  $m=10$   
From (2), (3)  $\mu_i = 100 \cdot 500 / 1001 = 50$   
 $\sigma_i = 8.06$

From these values of  $\mu_i$  and  $\sigma_i$ , we know that the degree of deviation away from a "mean" value of 50 is 8.06. This value of  $\sigma_i$  signals us that we have a non-zero overflow probability of  $\mu_i = 50$  records pre-allocated as free space. In order to avoid the overflow problem,  $I_i$  should be adjusted according to Steps 2 and 3.

From the normal table,<sup>4</sup> we select a value for  $z$  such that this selection makes  $\Phi(z)$  approach one. In our example, selection of  $\Phi(z) = 0.9995$  makes  $z = 3.29$ .

Using  $z = 3.29$  as an adjustable coefficient and by (4),  $I_i$  should be equal to  $50 + \lceil 3.29 \cdot 8.06 \rceil = 77$ . Therefore, the size of DSA should be 177 records. The additional 77 records are allocated for subsequent insertions. Under such arrangement, the probability of overflow will be less than 0.0005.

#### Non-ordered access method

When a file is created by using NAM such as hashing or sequential access method, records within a DSA are stored,

\* When  $\Phi(z)$  approaches one, it really means that the probability of more than  $I_i$  insertions being added to the  $i$ th DSA is very small. That is,  $\Phi(r_i > I_i) \rightarrow \epsilon$ . When  $\Phi(r_i > I_i)$  is small, it means the probability of adding insertions outside of the  $i$ th DSA is small; therefore, the probability of overflow is small whenever  $\Phi(z)$  is large.

retrieved and maintained in a random, non-ordered sequence. For instance, if a file of 1000 records is created by using a hashing function with divisor 11, then the divisor may be represented as 11 DSAs whose sizes are undefined at the moment. Due to the key distribution of original records, each DSA may be initially loaded with different amounts of records. Assume  $S_i$  initial records are loaded into the  $i$ th DSA at load time, and  $r_i$  insertions are added to the  $i$ th DSA within period  $t$ . Then, we cannot use the model derived in the last section since both the key distribution of initial records and the function of an access method play an important role in determining the number of insertions  $r_i$ .

The earlier model of Chin<sup>2</sup> uses the concept that all  $I$  insertions may be added into a single DSA and hence focuses his analysis on one DSA only. It performs well for a file organization with a few DSAs. But when the number of DSAs increases, it will over-allocate free space and thus yield low storage space utilization.

A different approach to this problem can be illustrated by the following example. Suppose the key-values of a given file originate from a "global key space," denoted as  $N$ , and suppose the key-values of  $R$  initial records and  $I$  insertions are members of  $N$ . Now let  $N$  be the nine-digit social security number system, which contains  $10^9$  distinct members. These  $10^9$  members can be partitioned into seven disjoint clusters, say  $N_1, N_2, N_3, \dots, N_7$ , when a division method with divisor 7 is used.

According to a certain NAM,  $N$  can be partitioned into  $m$  disjoint clusters  $N_1, N_2, \dots, N_m$ , which correspond to  $m$  DSAs. Let the  $i$ th cluster contain both  $S_i$  initial records and  $r_i$  subsequent insertions. All those records will eventually be mapped into the corresponding  $i$ th DSA through loading and insertion operations. From the point view of clustering, the probability of having  $x$  records, whether they are stored at loading or subsequent insertion time, added to a DSA is a hypergeometric distribution. Without ambiguity, we will use  $N$  and  $N_j$ , to represent the size of global key space and the size of the  $j$ th cluster, respectively.

Consider a population of  $N$  individuals, of which  $N_1$  are in the cluster 1,  $N_2$  are in the cluster 2,  $\dots$ , and  $N_m$  are in the cluster  $m$ , with  $\sum_{j=1}^m N_j = N$ . Suppose a sample of size  $R$  is chosen from  $N$  individuals without replacement. Then the joint distribution of the random variables,  $S_1, S_2, \dots, S_m$ , which represent the numbers of individuals in clusters  $N_1, N_2, \dots, N_m$  in the sample space  $R$ , is defined as

$$P(S_1, S_2, \dots, S_m) = \prod_{j=1}^m \binom{N_j}{S_j} / \binom{N}{R} \quad (5)$$

with

$$\sum_{j=1}^m S_j = R, \quad 0 \leq S_j \leq \min(N_j, R)$$

for  $j = 1, 2, \dots, m$ .

This is called by Johnson<sup>5</sup> the multi-variate hypergeometric distribution with parameters  $N_1, N_2, \dots, N_m, R$ . Therefore, the probability distribution function of  $S_i$  is hypergeo-

metric with parameters  $R, N, N_i$ :

$$P(S_i|N, N_i, R) = \binom{N_i}{S_i} \binom{N-N_i}{R-S_i} / \binom{N}{R} \quad (6)$$

$$0 \leq S_i \leq \min(N_i, R) \text{ for } 1 \leq i \leq m$$

where  $R, N$ , and  $N_i$  represent the file size, the number of elements in global key space and the number of elements in the  $i$ th cluster, respectively. Since (6) is a hypergeometric distribution, its mean and variance can be written as follows:<sup>5</sup>

$$E(S_i) = R * N_i / N \quad (7)$$

$$\text{VAR}(S_i) = R * (N_i / N) * (1 - (N_i / N) * (N - R)) / (N - 1) \quad (8)$$

Unfortunately,  $N_i$  is unknown and cannot be determined analytically since different hashing functions generate different clusters. However, we can estimate  $N_i$  from the known value  $S_i$ . For any particular set  $S_i, R, N$ , the value of  $N_i$  for which  $P(S_i|N, N_i, R)$  is the largest is denoted by  $\hat{N}_i$ . It is called the maximum likelihood estimator of  $N_i$ .<sup>4</sup> For convenience, let (6) be abbreviated as  $q_{S_i}(N_i)$ . Then

$$q_{S_i}(X) = \binom{X}{S_i} \binom{N-X}{R-S_i} / \binom{N}{R}$$

and

$$q_{S_i}(X+1) = \binom{X+1}{S_i} \binom{N-X-1}{R-S_i} / \binom{N}{R}$$

The ratio  $q_{S_i}(X+1)/q_{S_i}(X)$  equals to  $(X+1)(N-X-R-S_i)/(X+1-S_i)(N-X)$ , simple calculation shows that when this ratio is equal to one,  $q_{S_i}(N_i)$  achieves its maximum. When

$$\frac{q_{S_i}(X+1)}{q_{S_i}(X)} = \frac{(X+1)(N-X-R+S_i)}{(X+1-S_i)(N-X)} = 1,$$

we have  $X = S_i * (N+1) / R$ .

Hence, the maximum likelihood estimators  $\hat{N}_i$  is the greatest integer less than or equal to  $S_i(N+1)/R$ . That is

$$\hat{N}_i = \lfloor S_i(N+1)/R \rfloor. \quad (9)$$

In a similar way, the probability of  $x$  out of  $I$  insertions that are added to the  $i$ th DSA with  $S_i$  initial records is also a hypergeometric distribution:

$$P(r_i = x | N, N_i, R, I, S_i) = \binom{N_i - S_i}{x} \binom{N - R - (N_i - S_i)}{I - x} / \binom{N - R}{I} \quad (10)$$

for  $0 \leq x \leq \min(I, N_i - S_i)$

We use  $N_i - S_i$  instead of  $N_i$  for the reason that  $S_i$  initial records were chosen at load time and there are only  $N_i - S_i$  records left in the  $i$ th cluster. The insertions are originated from these  $N_i - S_i$  records out of a sample of  $N - R$  records.

Now the values of all parameters are known. The expected number of insertions  $r_i$  to be added into the  $i$ th DSA with  $S_i$  initial records is

$$E(r_i | S_i) = I * (N_i - S_i) / (N - R) \quad (11)$$

Its variance is

$$\text{VAR}(r_i | S_i) = I \left[ \frac{N_i - S_i}{N - R} \right] \left[ 1 - \frac{N_i - S_i}{N - R} \right] \left[ \frac{N - R - I}{N - R - 1} \right] \quad (12)$$

Using the same strategy as OAM, the free space to be left in the  $i$ th DSA is  $E(r_i | S_i) + z * \text{VAR}(r_i | S_i)^{1/2}$ , where  $z$  is an adjustable coefficient as noted in OAM.

Example 2—A file created by using a hashing function through a selected three-digit field. Suppose there are five DSAs available for the file and each file is initially loaded with 16, 11, 26, 52 and 295 records, respectively. If 200 insertions ( $I=200$ ) are estimated to enter into the file within the  $t$  time units, then the corresponding size of each DSA is tabulated below:

$$R=400, \quad I=200, \quad N=\{000 \sim 999\}, \quad z=3.29$$

ith DSA	$S_i$	$E(r_i   S_i)$	$\text{VAR}(r_i   S_i)$	Distributed	
				Free Space	Size of DSA
1	16	8	4.9	15	31
2	11	5	3.2	11	22
3	26	13	7.9	22	48
4	52	26	14.9	38	90
5	295	147	25.9	164	459
				400	650

Using  $S_4=52$  as an illustration, we know  $N=10^3$ ,  $R=400$ , and  $I=200$ .

From Equation 9,

$$\hat{N}_4 = N_4 = \frac{52}{400} (10^3 + 1) = 129.$$

From Equation 11,

$$E(r_4 | S_4) = 200(129 - 52) / (1000 - 400) = 26$$

From Equation 12,

$$\text{VAR}(r_4 | S_4) = 14.9$$

$$I_4 = E(r_4 | S_4) + 3.29 * \text{VAR}^{1/2}(r_4 | S_4) = 38.$$

Therefore, the size of the 4th DSA is equal to 90 records.

## SIMULATION AND DISCUSSION

### Methods of simulation

Since data can be stored, retrieved and maintained differently by different access methods, experiments are done separately for each method. In OAM, the total number of

records in a DSA are dominated by the following two factors—(i) the number of initially loaded records in each DSA and (ii) the key distribution of these initial records and the subsequent insertions. As both data must be chosen from a specific global key space with a distribution  $F_k$ ,<sup>6</sup> we generated 10 sets of key-value each with 1000-5000 distinct elements from a selected distribution. Five of them are sorted and used as initial records, the second five testing data sets are used as subsequent insertions. Therefore a test consists of a set of 25 repetitions. Experiments are divided into two parts, one with changing number of DSAs and the other with different insertion ratio. The results are given in Table I and Table II.

In NAM, the dominative factors include those in OAM as well as which hashing functions are used. Here we did many different experiments. The procedure of generating test files was the same as that used in OAM. At first, we tested whether the DSA size has an effect on the model by changing the number of DSAs available for the file. Next we changed the insertion ratio. The results are given in Tables III and IV. Since the hashing function is a dominant factor, we also did our experiments on various hashing functions such as division transformation, radix transformation, random transformation, etc. The results are given in Table V. In addition, comparisons between our model and Chin's model are made in terms of total distributed free space, average overflows,

average additional accesses, total storage utilization and free space utilization. Results are given in Table VI.

As for the file organization, we use a conventional indexed sequential method for OAM, and a division transformation for NAM. We use both of them as main access methods because of their popularity. If overflow occurs, we use chaining as an overflow handling technique.

The values in the fourth column of the Tables is calculated as follows: Each record located in its home area is required one access. If an overflowed chain has length  $L$ , then a given overflow record took  $L+1$  accesses. If  $I_i$  was the amount of free space reserved in the  $i$ th DSA, and  $x$  insertions were added to that DSA, then overflow occurred for  $x > I_i$ . The number of accesses to fetch all these records which are sequentially chained together is  $0+1+2+\dots+(x-I_i)=n_{ai}$ . Then the average additional access per record is equal to  $\sum_{i=1}^m n_{ai} / (R+I)$ .

Discussion of results

Based on the results obtained from both OAM and NAM, we see that there are almost no overflows whenever  $F$  records are reserved, where  $F$  equals  $\sum_{i=1}^m I_i$ . But if more than  $F$  insertions were added, the number of overflows would increase rapidly. It means that the distributed free space reserved by the model is sufficient to maintain the short response time and yet not much storage space is wasted.

When the number of DSAs increases, more free space will be allocated. The collection of free space of all DSAs

reduces the storage utilization as indicated in Figures 3a and 4a. As shown in Figures 3b and 4b, when more DSAs are claimed at loading time, more distributed free space is allocated.

In Figure 5, as insertion ratio increases, the free space utilization will increase also. The reason is as follows: A high insertion ratio means a larger amount of insertions will be added into a file. Therefore, the amount of pre-allocated free space is more effectively utilized than that of a small insertion ratio. On the contrary, total space utilization decreases as insertion ratio increases. The reason is that a high insertion ratio pre-allocates a larger portion of free space than that of small insertion ratio.

From the Column 4 of Table V, the free space reserved for each hashing function is nearly the same but the addi-

tional accesses have a slight difference. The average additional accesses of division method, random method and radix method are 0, 0.00002 and 0.00008, respectively. The result is the same as in Reference 9; namely, division method often outperforms other methods.

Figure 6 shows the comparison of storage space between our method and Chin's. As shown by this figure, the new model (NEW in Figure 6) is superior than the old model (OLD in Figure 6), especially when a large number of DSAs are allocated to the file.

Figure 7 shows the comparison between response time of the new model and the old model. As indicated in Figures 6 and 7, the fast response times are nearly the same for both models, but the new model reserves less amount of free storage space than the old model does.

Figure 6a—NAM.  $R=1000, z=3.29, \text{METHOD}=\text{DIVISION}$ .

Figure 6b—NAM.  $R=1000, z=3.29, \text{METHOD}=\text{DIVISION}$ .

A set of tests was done to verify the correctness of the mathematical models. For free space ranged from  $u_i$  to  $u_i + z\sigma_i$  the probability of overflow calculated from testing data is nearly equal to the corresponding probability calculated from the models.

CONCLUSION

In this paper we have developed a new mathematical model to determine a sufficient "distributed free space" within a DSA in terms of the number of records. In either OAM or NAM, we assume initial records and subsequent insertions are selected from the same distribution. But in NAM, we further assume that the size of global key space  $N$  can be calculated from the length of key field. In practice this may not be true. However, in general,  $N$  is much larger than the file size so that this assumption causes no serious problem.

Although the experiments have shown that there is almost no overflow when  $F$  records are reserved as free space for subsequent insertions, it is not easy to know mathematically that how long the fast response time can be kept. The reason

Figure 7—Response time comparison for NAM.

is that various applications have different rates and period of insertions.

From the testing results, we know the storage space utilization is economical for a larger DSA. How to partition a large DSA into a number of small blocks has been discussed in Reference 2.

If the storage cost does not exceed reorganization cost, it is economical to distribute free space within home area even if distributed free space has poor storage utilization. If storage cost exceeds reorganization cost, it is very costly to leave large amount of free space. In this case, optimal reorganization point should be considered and the associated topics have been studied in References 11-13.

# Forecasting computer resource utilization using key volume indicators

by DAVID E. Y. SARNA

Price Waterhouse & Co.  
New York, New York

## INTRODUCTION

The purpose of capacity planning is to determine how much computer power we have overall, how much we are using and, most importantly, how much is left and how much is required. There is some justification for the current interest in capacity planning. We have recently improved our ability to predict the quality of service, i.e. the turnaround time that can be expected from a given configuration when a known workload is imposed. This is a basic activity in capacity planning.

If we use the right tools, and obtain the right measurements, we can determine the service requirements of existing workloads. Capacity planning tools, usually based on queueing theory, enable us to predict with remarkable accuracy the effect on utilization, thruput, turnaround and response times to be expected for a given change in computer workload or configuration. The challenge then comes not in predicting how much raw capacity remains unused on the existing computer, but rather in predicting the expected workload. The specific equipment required can be determined straightforwardly once the expected workload has been established.

## CURRENT FORECASTING TECHNIQUES

Forecasting growth in computer utilization is the key to successful capacity planning. There are three basic techniques that have been used up to now, with varying degrees of success, to forecast computer utilization:

1. Divide up the total current usage by department. Ask each department to estimate next year's requirements in terms of CPU-seconds and EXCPs.
2. Take this year's job accounting figures and adjust them for expected change over the next year.
3. Apply a trend analysis to this year's job accounting tapes to obtain an (overall) forecast for next year.

What are the disadvantages of these techniques?

1. *Ask the user*—Try forecasting your monthly requirements for dishwashing liquid! To most users, CPU-

seconds or EXCPs are quantities even more obscure and difficult to estimate.

2. *Estimate based on last year's results*—This is the classic seat-of-the-pants approach. Some are better at it than others.
3. *Watch the trend*—This is a step in the right direction. Use of this technique presupposes that next year's usage pattern will mirror this year's. If sufficient data are used and the trending techniques are sufficiently sophisticated, good results can often be obtained. However, there is no assurance that the current trend will continue. For example, an installation may experience flat growth this year, but may then experience a large workload increase when the applications currently under development go on-line. Simple trend analysis is not going to predict that type of growth. In a decentralized environment, such as is found in many RJE-oriented shops, this problem is particularly acute.

## KEY VOLUME INDICATORS

We have been using a concept called key volume indicators (KVI) to overcome deficiencies in forecasting using existing methods. The tools required are a job accounting analysis program and a regression program found in statistical software packages and available on many pocket calculators. The underlying principle behind this technique is that the end user, given sufficient information, understands his business best. He should be responsible for predicting his own needs. He cannot be expected to predict computer usage, but he probably can predict business-related growth with a fair degree of success. The key volume indicator is a way of relating an application's inputs and outputs to computer utilization. Appropriate key volume indicators (KVI) must be chosen in order to prepare reliable forecasts. The key volume indicators must relate to computer usage and at the same time be business- and application-related in order to be forecastable by the users. Procedures have been developed to assist in selecting statistically valid indicators based on the accumulated volume and computer usage data relating to an application. A useful by-product of the process will be the availability of unit costs for many applications,

permitting comparisons among user constituencies and better cost estimates for planned applications.

Once the indicators have been identified, the user will prepare a forecast in terms of the key volume indicator units, and the computer will translate these units into a forecast of computer resources. EXCPs, CPU-seconds, or any other measure of utilization can be forecast using this technique.

## TYPES OF WORKLOADS

Growth in corporate computer use will come primarily from three sources: (a) Increased workloads for existing applications, (b) shifts from batch to on-line processing and (c) new applications. Other factors influencing use are related to changes in processing time caused by program modifications, new techniques such as a conversion from sequential processing to a data base management system, or changes in run frequency.

## DETERMINING KEY VOLUME INDICATORS FOR AN APPLICATION

To determine key volume indicators, potential indicators are selected for their forecastability, relationship to the application and availability of historical data. Then, historical volume and computer utilization data is examined statistically, in order to select the potential volume indicators with the greatest correlation to computer utilization over time.

## MONITORING AND IMPROVING FORECASTING ABILITY

Forecasts will improve because (1) users will be able to do a better job of forecasting key volume indicators than computer-related measures such as CPU seconds or EXCPs, (2) the indicators will be chosen carefully and bear a known relationship to computer utilization and (3) users will prepare forecasts periodically and as they gain experience in actual usage as compared to their forecasts, their forecasts should improve.

## STANDARD COSTS

An additional benefit from the use of key volume indicators is the collection of data relating to the computer resources required per KVI unit of work. This data can be used to develop standard costs for applications, and to compare the standard costs with actual costs to highlight variances for further study and possible management action. Comparisons of the costs of similar applications among the divisions should assist in identifying inefficient programs and in reducing costs.

## DETERMINATION OF THE ADEQUACY OF INSTALLED EQUIPMENT TO MEET PROJECTED REQUIREMENTS

Simulation models based on queueing network theory can be used to predict the effect on response times and CPU utilization of workload changes. For a given computer configuration and workload, the model will predict the average CPU utilization, the average batch job turnaround times and the average terminal response times to be expected due to workload changes. The model also can be used to predict the effect of volumes different from the forecasts.

## NEW APPLICATIONS

Usage data is not available for applications not yet installed. If a similar application is installed at another division, the key volume indicators and coefficients may be borrowed as a first approximation. If such comparable data is not available, the analyst will have to base his estimate on the time required to process the approximate number of CPU instructions and I/O operations per transaction. If a new application will replace an existing application, care must be taken to deduct from the total forecast all resource utilization to be displaced by the new application. After the application is placed in production, and the usage data becomes available, the procedure for existing applications should be followed.

## ON-LINE APPLICATIONS

On-line application usage can be projected using basically the same procedures as for batch systems, using key volume indicators appropriate to the on-line system. However, interactive programming systems pose a special problem. We have found that the number of programmers is an appropriate KVI since in most shops the amount of computer utilization for interactive systems is directly related to the number of programmers doing interactive programming, and this relationship is fairly constant from month to month.

## STEPS IN DEVELOPING THE FORECAST

Forecasts for existing and new applications are prepared in terms of key volume indicator work units. These figures are extended by coefficients produced by the statistical routines to give forecasts of computer resource utilization. A forecast is also prepared for all other computer workloads. The sum of all the individual forecasts gives the total computer utilization forecast, which may be adjusted to take into account additional factors, such as overall improvements to operations as a result of equipment changes, or performance improvement programs. The procedure for forecasting computer utilization will be summarized. More detailed procedures are provided in the appendices.

1. List the potential key volume indicators. For example, potential indicators for an order/billing/accounts receivable system commonly found in computer shops might include: number of invoices, number of orders, number of updates, number of line items, number of parts in the file, and dollar invoice value.
2. Sort and summarize the job accounting records (SMF tapes) by major application system. At least six months' worth of records should be used. Please note that summarization should be by major application. In many shops one or two letters of the job name or other job accounting information is used to identify the major application.
3. Summarize the total monthly resource consumption by CPU-seconds, EXCPs, monthly computer charges, or any other quantity to be forecast. The resource usage data are referred to as dependent variables.
4. If a significant portion of the application is run on a daily basis, divide the figures obtained in Step 3 by the number of workdays per month.
5. Obtain from the appropriate user department actual monthly volume figures for the potential key volume indicators identified in Step 1, for the accounting periods used in Step 2. If the computer usage was divided by the number of workdays per month in Step 4, divide the potential key volume indicators by the same figure. The data for the key volume indicators are referred to as independent variables.
6. Perform stepwise multiple linear regression using the potential indicators as the independent variables and CPU-seconds, or other quantities to be forecast as the dependent variables. The important outputs from the regression program are (a) regression coefficients and (b) a standard error of estimation. The regression coef-

ficients for each computer resource, when extended by a forecast expressed in terms of key volume indicators, predict the expected utilization of the resources by the application being forecast.

Potential key volume indicators are ranked by the regression program in order of correlation. The standard error of estimation tells us how well the coefficients explain or predict the input data. An indication of the "goodness" of fit is given by the coefficient of determination. A high value indicates a good fit and a low value indicates a poor fit.

Generally speaking, we have found that one or two potential key volume indicators will account for most of the utilization and these become the key volume indicators. At one client, we found that the number of invoices could be used to explain almost all utilization within an order-entry/billing/accounts receivable application. (See Figures 1 and 2).

#### FORECASTING PROCEDURE

How are key volume indicators used in practice? Assume that the number of monthly invoices has been found to be an appropriate key volume indicator. The user would then be given a report showing the number of invoices produced each month over the past year. He is asked to prepare a quarterly forecast of invoices—the key volume indicator—to be generated over the next year. His forecast is extended by the regression coefficients to obtain the resource forecast. This process is continued for all major applications. In most shops, Pareto's law applies. Most of the utilization can be accounted for by a relatively few major applications, and only these applications need to be forecast individually. All

	OCT	NOV	DEC	JAN	FEB	MAR	APR
<b>1. Key Volume Indicators</b>							
Numbers of invoices	24,017	21,570	23,411	21,644	23,476	26,311	24,774

Regression: invoice only. $R^2=.78$ , $a=7768.21$ , $b=-.16$	3930.8	4321.7	4027.6	4309.9	4017.2	3564.2	3809.0

Figure 1—Key volume indicators in an accounts receivable application.

The above figure shows the measured resource consumption and the expected utilization predicted by the regression equation using the indicated KVIs. It can be seen that the best correlation was achieved using both invoices and open items as KVIs. However, forecasting using only invoices as the KVI still gives an acceptable correlation. Other potential KVIs, such as volume of vendor master records, did not correlate well.

other utilization is lumped together, and the number of jobs used as the key volume indicator. Regression is performed and the regression coefficients obtained. These coefficients will be extended by the overall growth forecast for the coming year. Note that, where a CPU utilization forecast is being prepared, the sum of the individual forecasts must be multiplied by the ratio of the total CPU time recorded by a hardware or software monitor to the total recorded by job accounting (the "capture ratio") to obtain a forecast for the total CPU consumption. This correction is necessary because most job accounting systems do not allocate all of the CPU time to individual application programs. For example if it is known that only two-thirds of the total CPU time is allocated by a job accounting system, the total result forecast would be multiplied by three over two to obtain a more accurate estimate of the total CPU consumption being forecast.

**FORECASTING ACCURACY**

What unusual conditions may arise when preparing forecasts using key volume indicators? The most obvious possibility is that the standard error reported by the regression program is unacceptably large. This indicates either that the key volume indicators selected are not, in fact, good predictors of computer utilization, or that the data are incomplete or reflect a temporary exceptional condition. This question can be resolved by inspecting the output from the regression program.

Most regression program listings contain the following:

<i>Regression Program Output</i>	<i>Explanation</i>
Independent variables	Key volume indicators
Dependent variables:	Resources utilization being forecast:
<ul style="list-style-type: none"> <li>• Expected values</li> <li>• Actual values</li> <li>• Variance</li> </ul>	<ul style="list-style-type: none"> <li>• Predicted values</li> <li>• Input values</li> <li>• Difference between expected and actual values</li> </ul>

If the variance is large for most months, the potential key volume indicators were not found to correlate well with utilization, and different indicators must be selected. However, if the data generally correlate well, but correlate poorly for a few months, this would also impact the standard error of estimation. If possible, the data should be researched to determine whether there were any unusual conditions relating to processing the application system for those months where the variance is large. The non-representative data should then be disregarded and the regression program run once again, using the remaining data. This will often produce an acceptable result.

Another item of concern in some shops relates to distribution of the workload by shift. The procedure described will calculate a total load for the CPU. Where an installation's workload is distributed unevenly over the day, it may be necessary to calculate the expected load on a per-shift

basis. To do this, the accounting data should be sorted using the shift as the major sort key and the application name as the minor sort key. Regression would then be performed for each shift individually. The assumption here is that the distribution of utilization throughout the day will be the same next year as in the past year. If this assumption is definitely known to be incorrect, the forecast should be appropriately adjusted.

Other adjustments to the forecast may be necessary. For example, a computer performance improvement program may be under way, and an overall reduction of perhaps 20 percent in CPU utilization may be anticipated. The forecast would then be reduced by the amount of expected performance improvement.

**ADVANTAGES OF KVI FORECASTS**

What are some of the major advantages to be expected from using key volume indicators to predict computer utilization? The main advantage is that the forecasts themselves will be prepared by the end-user who will now be forecasting in terms he can understand. Forecast usage is then accurately related to resource consumption. Once use of key volume indicators is instituted, the reliability of the forecast can be monitored. This feedback can be expected, over time, to improve the forecast's accuracy. Moreover, if the user exceeds his forecast utilization, he cannot demand that the computer center handle the unexpected workload with the same ease that it handles scheduled work. On the other hand, users who consistently overforecast their requirements should be penalized by the pricing algorithm employed in the computer center. For example, the rate charged the user should be based on forecast usage. Unforecast usage should be charged at a higher rate. Usage forecast but not used should be charged for, although perhaps at a lower rate than charges for actual usage.

As previously noted, other benefits expected through use of key volume forecasts are the accumulation of standard cost information and the suitability of the data generated for input to a queueing model. This makes it easy to predict not only the total utilization "demand" but also the ability of existing and/or planned configurations to handle the expected workload.

**UTILIZATION FORECASTS AND CAPACITY PLANNING**

One last observation relates to the accuracy of forecast: In our experience with this technique, accuracy was surprisingly good. However, a key point to remember, though, is that computer capacity does not generally come in very small increments. The purpose of preparing a capacity forecast is to determine the need for additions or changes to the computer configuration. The forecasting accuracy is sufficient if it can correctly predict the need for equipment changes. One useful way to test the sensitivity of the capacity prediction to small changes in user forecasts is to

Figure 2—Actual and predicted CPU utilization in an accounts receivable application.

bracket the projected forecasts when preparing the capacity plan. This is especially easy to accomplish where a model is employed. As is well known, up to a point, computers are very tolerant of additional workloads imposed upon them; they respond with only small changes in turnaround time and thruput until a critical point or knee is reached. Loads in excess of the critical values will cause serious deterioration in service. By appropriately bracketing the forecast assumptions, it would be possible to estimate the equipment's ability to handle the probable range of the expected computer workloads.

We have found the use of key volume indicators to be a useful method of improving the accuracy of computer utilization forecasts.

## APPENDIX 1—PROCEDURE FOR DEVELOPING EQUIPMENT UTILIZATION FORECASTS USING KEY VOLUME INDICATORS

1. Select the key volume indicator for each application for which a utilization forecast is to be prepared, by carrying out the appropriate procedure (batch, on-line or new) for determining key volume indicators in Ap-

- pendix 2, 3, or 4. As a result of this step, regression coefficients will also be obtained for each application.
2. Obtain the users' forecasts for each application in terms of the key volume indicators identified in Step 1.
  3. To forecast CPU seconds per month and I/O count per month, extend the volume forecasts by the corresponding regression coefficients obtained in Step 1.
  4. Adjust each forecast to take into account other factors, such as expected
    - Changes in run frequency or additional runs.
    - Equipment and software changes.
    - Changes in resource utilization due to optimization or tuning.
    - Any other factors expected to influence computer use.
  5. Forecast the net additional utilization from all other applications and for system software. To do this, for the most recent month, subtract from the total monthly utilization (CPU seconds and I/O count) that portion of utilization represented by applications forecast individually in Step 3, above. This result represents the net additional utilization from all other applications ("other work"). Determine regression coefficients for the net additional utilization for other work by carrying out the procedure for determining key volume indicators. Use the number of jobs as the potential key volume indicator. As in Step 3, extend the regression coefficients obtained by the net number of jobs forecast for other work to obtain a forecast of CPU seconds per month or I/O count per month.
  6. In order to obtain the forecast of total CPU seconds and I/O counts, add the individual forecasts resulting from Step 4 to the net additional utilization developed in Step 5, giving a forecast of total utilization.
  7. To correct for inaccuracies in recording CPU utilization by job accounting routines, multiply the total CPU utilization obtained in Step 6 by the ratio of total CPU utilization, as measured by a software or hardware monitor to the total CPU utilization recorded by the job accounting programs. Other resource measures, such as I/O counts, are usually accurately recorded by job accounting programs and do not require adjustments.
  8. The ratio of the forecast to current utilization gives the growth percent. This growth percent is used by capacity planning tools such as queueing models to predict the effect of the changed workload on terminal response times and job turnaround times.

#### APPENDIX 2—PROCEDURE FOR SELECTING KEY VOLUME INDICATORS FOR INSTALLED BATCH APPLICATIONS

1. For each application, list all transaction types and the organization (key or sequence) of each major file and report. These are potential key volume indicators. Also identify the job names used to identify the application to the operating system.
2. From this list, identify logical intersections within the application. For example, paychecks/employee and updates/employee are logical intersections within a payroll system, and line-items/order is a logical intersection for an order entry system. These also are potential key volume indicators.
3. List any other potential key volume indicators.
4. Reduce the list to those potential indicators that would be forecastable by the divisions, and for which historical data could be collected. These are called "predictors."
5. Obtain the monthly volume data by application for these predictors, together with the corresponding CPU seconds and total I/O count, which are figures that should be available in the job accounting reports. These are the major measures of equipment utilization most subject to fluctuation and directly related to individual applications and, therefore, these are the statistics that will be forecast.
6. Use a statistical package, such as BMD, developed by the University of California, or SPSS, developed by the National Opinion Research Center of the University of Chicago, to perform stepwise linear regression using the predictors as the independent variables and the CPU seconds and I/O counts as the dependent variables. The regression program should be used for each application to relate CPU seconds to each predictor and also I/O count to each predictor. The advantage of running the regression program separately for CPU seconds and for I/O count is that it is possible that certain predictors will correlate well with CPU seconds and others will correlate well with I/O count. Input to the regression program consists of the monthly volumes for each predictor, and the CPU seconds or I/O counts for that application. In addition, certain regression programs must be provided parameters which limit the number of program iterations to the most likely range of coefficient combinations and weightings. Appropriate values to be specified are 1.0 for the "F-level for inclusion" parameter, 0.5 for the "F-level for deletion" parameter, and a "tolerance level" of .001. These values will minimize the computation required. The regression program calculates the correlation between predictor volume and computer utilization (CPU seconds and I/O count). This correlation is expressed in values called regression coefficients for each predictor. The regression program automatically bypasses predictors that do not correlate well with computer utilization. Output of the program is a rank listing of predictors and regression coefficients in order of best correlation. For each predictor following the first, the program gives the additional correlation that is obtained by using that predictor in addition to the prior, better predictors. Also given by the program is the multiple correlation coefficient called  $R^2$ . This is the precision of the regres-

sion coefficient for the group of best predictors selected by the program.  $R^2$  is calculated by the statistical program based on the variance between the actual utilization data and the utilization predicted by the regression program. The value of  $R^2$  can range from 0.0, for an imperfect fit, to 1.0 for a perfect fit. An  $R^2$  value of 0.7 or more is usually adequate for planning since the objective of a utilization forecast is equipment capacity planning, which usually involves large increments of capacity. A small value for  $R^2$  may indicate either that the predictors are unsatisfactory key volume indicators or that certain historical data associated with the predictors may have been skewed by some additional factor. Therefore remove the one or two months' data (called "cases" in the regression computer output listing) with highest "residual," that is, the largest difference between the predicted and empirical results. Rerun the regression program. If the value of  $R^2$  is satisfactory, proceed to Step 7. If the precision ratio is still unsatisfactory, additional predictors must be chosen.

7. When a satisfactory precision ratio has been achieved, the predictors selected in the final regression step should be used as key volume indicators.

#### APPENDIX 3—PROCEDURE FOR SELECTING KEY VOLUME INDICATORS FOR NEW APPLICATIONS

For new applications, no usage data would be available and a different approach must be used.

1. If forecasts have been prepared for a similar application (perhaps one in use at another division) the regression coefficients obtained for that application may be borrowed and used in developing equipment utilization forecasts.
2. If there are no similar applications, the following "rules of thumb" may be used in place of the resource utilization data normally collected:
  - a. Based on the feasibility studies and system design documentation, estimate the number of I/O operations by multiplying the average number of I/O operations for each transaction type by the expected monthly transaction volume. Use this estimate in place of actual I/O counts.
  - b. Average CPU utilization can be estimated by using the average CPU utilization per key volume unit. In one test on an IBM 370/158 computer, the average CPU utilization for batch portion of the accounts receivable application was 0.6 seconds per invoice and for on-line CICS applications the average CPU time per transaction was found to be 0.3 seconds. These rates appear to be representative. Therefore, to estimate for any other CPU of similar architecture, multiply these figures by the ratio of the relative CPU speeds of the 370/158 and the other CPU.

c. If a more detailed estimate is desired, the following procedures can be used:

- Estimate the number of CPU instructions required for processing each transaction, based on the system design specifications. Multiply the number of I/O operations obtained in Step 2a by the average number of machine instructions per I/O operation to obtain the number of CPU instructions for I/O processing. Add the number of CPU instructions for transaction processing to the number of CPU instructions for input/output processing to obtain an estimate of total CPU instructions per transaction. Multiply by the average machine instruction time to obtain estimated CPU time per transaction. Multiply the CPU time per transaction by the expected monthly transaction volume to obtain expected total monthly CPU utilization for the application.
  - For the IBM 370/158 running under the OS/SVS operating system and using the COBOL/VS compiler, the estimated number of COBOL statements executed can be multiplied by 16 to give the estimated number of machine instructions. About 2,000 instructions are required for each EXCP. The average machine instruction time is 1.24 microseconds.
3. Subtract the computer resources used by any existing programs expected to be displaced by the new application from the estimates obtained in Step 1 or Step 2 to obtain the net increase expected from the planned new application.
  4. Include the estimates developed above when carrying out Step 6 of the procedure for developing the equipment utilization forecasts (Appendix 1).
  5. Once the application is placed into production and meaningful utilization figures become available (probably after a three-month shakedown period), the appropriate procedure for determining key volume indicators should be carried out using actual utilization statistics.

#### APPENDIX 4—PROCEDURE FOR SELECTING KEY VOLUME INDICATORS FOR ON-LINE APPLICATIONS

On-line systems can be projected using basically the same procedures as for batch systems.

1. List the potential key volume indicators. The basic unit of work for an on-line application is the transaction. Most on-line teleprocessing monitors collect statistics about the number of executions of each transaction type, and also the number of transactions per terminal. The major transaction types and the number of terminals are thus potential key volume indicators. For on-

- line programming systems, the number of programmers is frequently an appropriate key volume indicator.
2. Reduce the list to those potential indicators that would be forecastable by the divisions, and for which historical data could be collected. These are called "predictors."
  3. Obtain from the teleprocessing monitor monthly data for those predictors together with the corresponding utilization, i.e., CPU seconds and total I/O count.
  4. Perform Steps 6 and 7 of Appendix 2 (*Procedure for Determining Key Volume Indicators for Batch Applications*).

# Workflow—A technique for analyzing JES systems

by H. PAT ARTIS

Bell Laboratories  
Piscataway, New Jersey

## INTRODUCTION

During the last decade, the mode of operation of many centralized computer installations has been significantly changed by the widespread use of remote job entry (RJE) facilities. The increasing usage of remote work stations presents the analyst a significant problem in sizing remotes to efficiently handle the flow of jobs. Currently, few, if any, tools exist to aid the analyst in this area.

A tool called Workflow Analysis has been developed to assist the analyst in identifying bottlenecks and sizing JES systems. This tool processes the System Management Facility<sup>1</sup> (SMF) log file to produce graphical reports on the queues managed by a JES subsystem.

## BACKGROUND

RJE was initially provided to IBM users by the HASP and ASP<sup>2</sup> spooling packages in the late 1960s. Since then, the number of installations using RJE facilities and the percentage of their system's workloads handled by the remotes have steadily increased. When the MVS operating system was introduced, HASP and ASP evolved from optional spooling packages to subsystems called JES2 and JES3. Today, a typical JES2 or JES3 system serves 20 to 30 remotes with a high percentage of the system's workload being submitted by the remotes.

Coincident with the evolution of the software to support RJE has been the development by IBM and other vendors of a wide range of potential remote devices. They range in size from a 360 or 370 CPU work station supporting multiple readers and printers to small work stations or minicomputers that emulate a remote's protocol. With the variety of available hardware, a user can size a remote from a single 300 to 500 line-per-minute (LPM) printer to a CPU that can handle multiple 2000 LPM printers. The development by many vendors of moderately-sized\* and -priced devices has hastened the proliferation of remotes by allowing more users to request and justify their own workstations.

\* These remote stations typically consist of a 300 card-per-minute (CPM) reader and a 1000 line-per-minute (LPM) printer. These values are rated speeds that are usually degraded by transmission line capacity and other influences.

Experience has shown that only one or two poorly-sized remotes can significantly skew turnaround statistics for an entire JES system. Also, it is generally the users who control the flow of work to and from the remotes by their selection of an input station and specification of an output destination. Hence, a tool was needed not only to assist in the sizing of remotes but to monitor and report on their daily utilization.

## JES MEASURABLES

To identify and comment on the measurable quantities in a JES system it is useful to consider the diagram in Figure 1. As shown in the figure, at the center of the system is one or more processors that process the jobs submitted by the users.\*\* There are three methods for entering a job into the system. They are

- Reading in the job at a local input device.
- Reading in the job at a remote.
- Submitting the job to the system's internal reader. The internal reader is available to TSO users and any job currently executing in the system.

When a job is entered into the system it is queued for execution. The input queues are maintained by job class and JES provides priority queuing within each job class.

Once a job has been processed, its output is queued for spooling. The output queues are maintained by destination,\*\*\* output class and output forms type. Priority queuing is also available for the output queues.

It should also be noted that jobs are free to enter and exit the system at any point specified by the user. The user may also specify that various portions of a job's output be routed to different or multiple destinations.

One of the most convenient methods for studying a JES system is to measure the content of the queues on an interval basis. The following measurements of system activities are

\*\* JES2 systems typically contain a single processor while JES3 systems consist of two or more processors. However, some users employ the shared spool facility of JES2 to control multiple processors.

\*\*\* The term "destination" refers to the location to which a file is to be spooled. A file may be spooled locally or to a remote work station.

# JES SYSTEM

Figure 1

considered to be important for each interval:

*Jobs Read*—The number of jobs read into the system during the interval. This measure allows the analyst to study the load arrival pattern for the entire system. The cumulative value of this measure gives the total number of jobs that have entered the system since the start of the study.

*Jobs Purged*—The number of jobs purged from the system during the interval. The difference of the cumulative values for Total Jobs Read and Total Jobs Purged is number of jobs in the system.

*Input Queue*—The average number of jobs of all classes waiting in the input queues during the interval. This value provides a measure of the total amount of work queued for the processor(s).

*Output Queue*—The average number of jobs waiting in the output queues for all locations during the interval. A comparison between this measurement and the Input Queue measurement provides an indication of how well the system's output facilities are matched to the load arrival pattern.

*Executing*—The average number of jobs currently executing on all processors during the interval. This measure is the sum of the average multiprogramming levels of all of the processors.

*Job Queues*—The average number of jobs of each class queued for execution during the interval. This measurement allows the analyst to study the arrival patterns and the system's capability for serving each job class.

Furthermore, the following measurements of location (i.e.

local or a remote workstation) activities are considered to be important for each interval:

*Jobs Read from Location*—The number of jobs read into the system from a location during the interval. This measurement allows the analyst to study the work patterns of users at different locations.†

*Jobs Backlogged from Location*—The average for the interval of the number of jobs in the system that originated from a location. This measurement allows the analyst to compute the percentage of the system's current backlog that originated at any location.

*Lines Backlogged to Location*—The average for the interval of the number of logical records (print and punch) queued for spooling at a location. This measure allows the analyst to determine how well the hardware at a given location is matched to the load which it is assigned.

*Files Backlogged to Location*—The average for the interval of the number of files (print and punch) queued for spooling at a location. This measure allows the analyst to estimate how many users are waiting for output at the location.

The jobs processed by the system may also be measured. These measures are collected for each job, by job class and for all jobs. The measures are:

*Input Queue Time*—The input queuing delay from the time a job was read into the system until it was selected for execution.

*Output Queue Time*—The output queuing delay from the time the job completed execution until it was purged from the system.

*Total Queuing Time*—The total of the input and output queuing delays. This is the total non-productive time the jobs spent in the system.

*Execution Time*—The duration the job spent in execution.

*Turnaround Time*—The total time the job spent in the system. This measure is the total of the job's execution, input queuing and output queuing times.

## IMPLEMENTATION

The measurements described in the previous section can be implemented using the data available in the JES Job Purge (Type 26) and the JES Output Writer (Type 6) SMF records. The JES Job Purge record contains the following items used by the algorithm:

- JES Job Number
- JES Input Device (location)
- Job Class

† The measure "Jobs Purged by Location" is not suggested since jobs need not be returned to the location at which they entered the system. One of the best examples of this is jobs submitted to the internal reader from TSO users. The output from these jobs is routed to some location convenient to the user for printing.

JOB STATISTICS

JOB CLASS	NUMBER OF JOBS	INPUT QUEUE (MIN)	OUTPUT QUEUE (MIN)	EXECUTION (MIN)	TOTAL QUEUE (MIN)	TURN AROUND TIME (MIN)
A	12,457	2	35	2	37	39
B	4,108	6	35	9	41	50
C	5,555	25	64	5	89	94
E	1,431	4	14	1	18	19
J	997	1	38	2	39	41
M	571	20	21	3	41	44
N	493	2	23	13	25	38
ALL JOBS	25,612	8	40	4	48	52

Figure 2

- Reader Start Time and Date,  $T_1$
- Execution Start Time and Date,  $T_2$
- Execution End Time and Date,  $T_3$
- Job Purge Time and Date,  $T_6$

Since a job may spool multiple output files there may be more than one JES Output Writer record for the job. The record for the  $i$ th output file contains

- JES Job Number
- JES Output Device (location)
- Number of Logical Records Printed
- Writer Start Time and Date,  $T_{(4,i)}$
- Writer End Time and Date,  $T_{(5,i)}$

The Type 26 and all of the Type 6 SMF records for a job may be assembled using the JES job number as a key.

Each of the variables to be measured must be represented by a table whose size is determined by the granularity of the interval size chosen. Currently, the existing implementation uses a granularity of five minutes and requires 288 full words for each table to represent one day.

Figure 3

Figure 4

Using the tables and the data from the SMF Type 6 and Type 26 records, the previously-listed measures can be implemented as follows:

- Jobs Read*—Increment the table at time  $T_1$ .
- Jobs Purged*—Increment the table at time  $T_6$ .
- Input Queue*—Increment the table from time  $T_1$  to time  $T_2$ .
- Output Queue*—Increment the table from time  $T_3$  to time  $T_6$ .
- Executing*—Increment the table from time  $T_2$  to time  $T_3$ .
- Job Queues*—Increment the table for the job class specified in the Type 26 record from time  $T_1$  to time  $T_2$ .
- Jobs Read from Location*—Increment the table for the input location specified in the Type 26 record at time  $T_1$ .
- Jobs Backlogged from Location*—Increment the table for the input location specified in the Type 26 record from time  $T_1$  to time  $T_6$ .
- Lines Backlogged to Location*—For the  $i$ th output file for a job increment the table for the output location specified in the Type 6 record from time  $T_3$  to time  $T_{(4,i)}$  or  $T_{(5,i)}$  by the number of logical records to be spooled.\*
- Files Backlogged to Location*—For the  $i$ th output file for a job increment the table for the output location specified in the Type 6 record from time  $T_3$  to time  $T_{(5,i)}$ .

§ Unfortunately, the Type 6 SMF record does not indicate when an output file was queued. Hence, all files are usually assumed to be queued for output at the termination of the job's execution. Although this is generally true, JES does provide the user the ability to dynamically free a file to the output file during execution. In such cases, the output is assumed to have been queued since  $T_2$ .

\* The analyst may either choose to credit the output as being backlogged until the writer starts or stops. One could also choose to credit the complete output as being backlogged to  $T_{(4,i)}$  and then use a linearly declining value until  $T_{(5,i)}$  when zero lines would remain. The current implementation uses  $T_{(5,i)}$ .

- Input Queue Time*—The difference between  $T_2$  and  $T_1$ .
- Output Queue Time*—The difference between  $T_6$  and  $T_3$ .
- Total Queuing Time*—The difference between  $T_6$  and  $T_1$ , plus the difference between  $T_6$  and  $T_3$ .
- Execution Time*—The difference between  $T_3$  and  $T_2$ .
- Turnaround Time*—The difference between  $T_6$  and  $T_1$ .

CASE STUDY

A study was conducted of a moderately-loaded 370/168 JES2 system that supported TSO users and seven remote

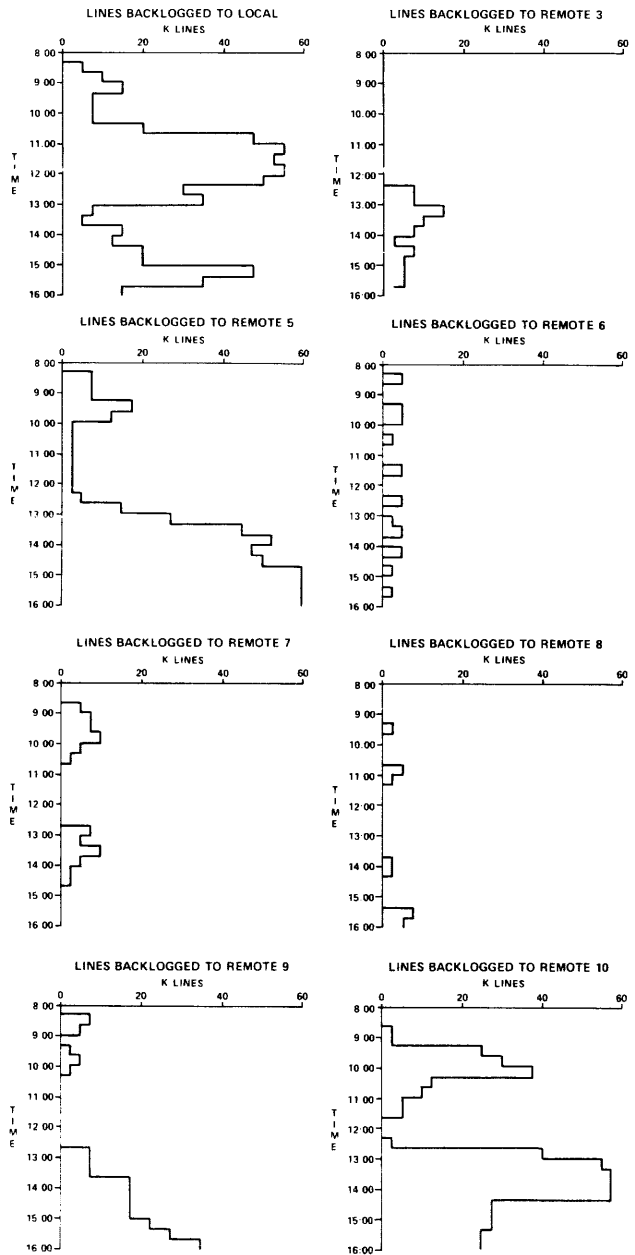

Figure 5

workstations in a testing environment. Although this system only processed about one thousand small jobs per day, the system's service objective of a 30-minute average turnaround time for batch jobs was not being achieved. One month of SMF data was obtained for the system.

The first step of the study was the analysis of the turnaround time statistics for the month. The turnaround time statistics were compiled by job class and summarized for all jobs. As shown in Figure 2, the average turnaround time for all jobs processed by the system was 52 minutes. However, the average input queuing and execution times only represented 12 minutes, 23 percent, of the average turnaround time. The low values of input queuing and execution times corresponded with the observations of moderate load and relatively small jobs. The high average value of output queuing time, 40 minutes, indicated the presence of a bottleneck in the system's output spooling.

The prime shift period, eight AM to four PM, was analyzed for a number of days in the month using the Workflow Analysis tool. In each of the days studied, the same output spooling bottlenecks were evident. A typical day is discussed in the following paragraph.

The arrival pattern of the jobs, Figure 3, is very typical for testing installations. The arrival rate of jobs peaks just before and after lunch and prior to each coffee break. The system's output queue length, Figure 4, follows the arrival pattern of the jobs. However, the output backlog does not decline as rapidly in the afternoon as it does in the morning. This led to an investigation of the Lines Backlogged to

Location reports for the local and remote stations. As shown in Figure 5, Remote Stations 3, 6, 7 and 8 are lightly loaded throughout the entire day. However, remote stations 5 and 10 present significant output bottlenecks in the afternoons with backlogs of 50 to 60 thousand lines. Since the remotes are configured with printers that average only 450 LPM, these backlogs represent more than a two-hour output delay for jobs routed to either of the remotes. It is the output delay of these two remote stations, used by about 20 percent of the jobs, that results in the system's service objective not being met. Although similar output backlogs occur at the local station, it is not a concern since the local station has several high-speed printers with a net effective rate of more than five thousand LPM.

#### REMARKS

The tool presented in this paper is relatively uncomplicated and is very straightforward to implement. However, it provides a great deal of information to the analyst about the flow of jobs thru a JES system that is not currently available from other sources.

# MMPS—A reconfigurable multi-microprocessor simulator system

by DANIEL KLEIN

Carnegie-Mellon Institute of Research  
Pittsburgh, Pennsylvania

## INTRODUCTION

The computing industry is currently undergoing a quiet revolution. Along with the recent advances in LSI design and production, a new trend in computation is forming. Many corporations are realizing that an important part of the future of computers lies in distributed data processing. The emphasis here is not on distributed data, for this field has been extensively (though certainly not completely) researched by computer scientists, but on distributed *processing*.

While there exist a great many design and debugging tools for uni-processor systems, such as simulator systems, as well as off-the-shelf in-circuit emulators for almost any mini- or microprocessor on the market, there exist few real design or debugging tools for multi-processing systems. While it is relatively easy to simulate any uni-process machine on almost any other, there is no easy method of either simulating a multiprocessor or of simulating any algorithm which is designed to run on such a system. And while it is possible to hand code a multi-processor simulator, this is certainly not a desirable method. Any design modifications must be incorporated into the current simulator by reprogramming (possibly large) sections of the code. A network simulator cannot limit itself to the simulation of a specific network, with fixed characteristics and configurations. Rather, what is needed is a software system development tool which is a general purpose network simulation package to provide a simulation environment for the design, checkout and maintenance of multiprocessor computer networks.

What we have set out to do is to construct tools for the network designer. A multi-microprocessor design language and dynamically reconfigurable multi-microprocessor simulator (MMPS), (which can be used in conjunction with a reconfigurable hardware network emulator, the BUCS system,<sup>1</sup> provides an aid to an efficient design methodology, and is described here.

DDP system description and simulation is an important step in the development of computer network systems. It not only tests the correctness of the overall design scheme, but also that of the individual elements, with relation to speed, instruction set, unit MTBF, etc. It should also test for possible run-time hazardous conditions which might arise, such as integrity problems, before the actual construc-

tion of the network, thus enabling the designer to bypass large amounts of testbed development.

The simulator should have the capability to provide both hardware and software level breakpoint tracing, as well as a static method of tracing the overall system performance, for later evaluation and possible redesign. Such a system, coupled with a full complement of production aids such as cross-assemblers, cross-compilers and cross-interpreters, is a highly desirable precursor system to the actual construction of the network system. If this system also has the ability to interface with some high-level hardware descriptive language, so that previously undefined pieces of hardware may be easily included into the library of simulator components already available, then this system becomes a very powerful multi-processing development tool.

Unfortunately, most of the existing computer hardware descriptive languages (CHDLs) such as LOGICSPEC, AHPL, CDL, DDL and CONLAN are designed to specify, or to reduce to, the gate level of operation within the described piece of hardware. While this may suffice for describing small logic elements, such as interface devices, or even small processors, it most certainly is not ideal for describing a large computer, and even less suited for describing a network of computers.

From the system standpoint, a designer of a multi-processing network only needs to know about the interactions between the individual processors, not how each of them performs on the minute scale. Realistically, all that is needed for each element of the network is a knowledge of how fast an element can accept an input, how fast it provides an output, and that the time between input and output is a black-box function of the data provided. The black-box programming, is of course effected by the designer of the individual elements, and "hooks" into the box should be provided, should observations of the gut-level functions of the elements be desired. However, for the most part, all the system designer need know is that the black-box exists, and that it functions as specified. Gate level CHDLs are simply not suited for this purpose. On the one hand, they are exceptionally slow when simulating large systems, and on the other hand, they are not designed to be reconfigurable, as the specifications state.

There exists at least one CHDL that approximates the

desired functions. In its current state, ISPS<sup>2</sup> is semi-interpretive, but it has the capabilities to be a compiled language. In ISPS, it is sufficient to declare a memory subunit of a specific size, and not need to specify (or have automatically specified) the specific gate level functionings of a memory module. The register transfer level that ISPS reduces to is on a much higher level than the gate level reduction of most other CHDLs. Being an instruction set processor, ISPS can provide the black-box simulation desired with a small description of the hardware. A Digital Equipment Corporation PDP-8 can be described in ISPS on a page or two of code, while LOGICSPEC, for example, would require many more pages of description to perform the same operations in a greater amount of time. (An ISPS description of the Manchester Mark-1 computer, the simplest ISPS description available, appears in the Appendix). Although ISPS is better suited for a multiprocessor simulator environment than any of its companion hardware languages, it would still require some modifications to optimally interface it with a reconfigurable network simulator.<sup>3</sup> These modifications are, however, beyond of the scope of this paper, and will be dealt with at some later date.

#### USER LEVEL DESCRIPTION OF MMPS

The MMPS system is currently being designed on the UNIX time-sharing system,<sup>4</sup> produced at Bell Laboratories. This system was chosen for its availability on small main-frame systems, and for the multiprocessing capabilities it provides.

When the user initializes MMPS, he has available to him a number of "build" commands, for declaring and connecting elements of his network together. Once the network is defined, there are a set of "trace" commands for defining breakpoints and for passively monitoring actions within the network. There is also a set of "peek/poke" commands for loading and dumping memory, and setting or reading the values of certain busses. Additionally, on-line help is always available for any command or set of commands.

The main goal in designing the command set of MMPS was to parallel the predicted actions of a hardware designer. Thus through the use of a **DECLARE** command, the user can define any number of duplicate elements of particular (predefined) system elements. Thus, a sample command:

```
DECLARE 8085[2], MEMORY[1](4,8), MEMORY[2](8)
```

would define two 8085s, one memory with four bits of addressing space and eight bits of data, and two memories with eight bits of address and data. Using the standard pinouts of the 8085, the user could then **CONNECT** the various elements together via a generalized backplane by issuing a command of the form:

```
CONNECT 8085[*](12-15), MEMORY[1](0-3) TO  
WIRE(0-3).
```

This command would connect four of the 8085's address lines, and the four address lines of memory module 1 to-

gether on backplane wires zero through three. This effectively makes a common memory unit, shared by both processors. If the user wants to disconnect a wire, all he need do is use the **DISCONNECT** command to do so. Notice, that all of these commands are dynamic, and may be done at any time during the simulation. Thus, if the user wished to test a fault tolerant system, various elements could be **DISCONNECTED** during the run, and faulty elements could be **CONNECTED** in, thus effectively simulating a failing unit.

Special consideration has also been made for non-standard features in a network. The user has the facility with which to clock each processor at a different speed (via the **CLOCK** command), and to specify wired **OR** connections (via the **WIREDOR** command). In this way, potential difficulties may be overcome. There is also a way to specify the default floating value of any particular wire. Through the use of the **FLOAT** command, lines may be declared to float high or low, depending on the application. Special consideration has also been made for the accommodation of bidirectional busses, and tri-state bus features. Depending on the type of simulation, I/O may be simulated in any of a number of modes, including ASCII or binary/octal/hex dump modes.

The "peek/poke" commands are designed to emulate the loading and dumping of memory, but on a much higher level than is currently available to the technician. While it is of course possible to load memory from the simulator, mimicking the insertion of a different PROM, it is also possible to dump memory at any time, examine the signals on any of the wires and, most importantly, assert different signals than are currently on the bus. Since the user has the capability to "freeze" the state of the system at any time, he may dynamically alter the state of the system, and continue its operation. Additionally, through the use of the **SAVE** command, the user may save the current state of a network simulation, to be **RESTORED** at a later time.

However, of all the commands, the "trace" commands give the MMPS simulator its most power. To make a simulator better than the hardware it is emulating, the simulator must provide features that the hardware cannot. The MMPS system does this by providing both breakpoint and passive tracing facilities. MMPS provides passive tracing in the form of an active hardware bus monitor, which records in a file all bus transfers across the backplane. Once the system has been halted, this log file may be examined by a group of people at their leisure. MMPS also has three other levels of selectable tracing. Operations which occur local to a processor (such as a register to register move, or addition of two loaded operands) can be **TRACED** in a log file that is local to the processor. Since all of the log files have their entries keyed by time, multiple log files may be merged and compared to detect possible race or lock conditions. Additionally, operations may be switched to **SIGNAL** the user of their occurrence without freezing the system, or by causing a **BREAK** in operations, and holding the system in a frozen state following an action. The access of certain memory locations (such as the entry point to a subroutine) may be monitored, as well as the values of internal processor registers. Certain classes of information, such as PC overflow and halt instruction execution, are not switchable, but are

considered serious enough to warn the user of their occurrence, regardless. The system *can* be continued after this type of breakpoint error, though.

#### OPERATIONAL LEVEL DESCRIPTION OF MMPS

Since MMPS is not only simulating the parallel processing of a network, but also spawning a series of parallel UNIX processes to do this simulation, special consideration had to be given to the problem of simultaneous actions in the network. The problem of two processes reading or writing the same bus *at the same time* must be dealt with, as these actions can and will happen in the real network. To cope with this problem, MMPS uses an asynchronous queue to schedule the actions of the individual elements. When two elements have simultaneous actions, the scheduler allows both to occur, and then updates the state of the busses in any of a number of user selectable ways. Simultaneous reads present no problem, but simultaneous read/write operations do. The user may select a random order of evaluation, or may elect to have all reads processed before writes, or all writes processed before reads. If the wired OR capability has been selected, simultaneous writes will be dealt with according to the specified logic, and if not, an error is generated (since two processes writing at the same time to a non-wired OR bus will cause that bus to blow).

The best way to describe the mechanism of synchronization of MMPS is to call it a packet-switched network. Whenever a process needs to interact with the "outside world," it sends a packet to the "overlord" indicating which units it wishes to communicate with. Of course, a unit (or process) may interact only with those elements to which it has been **CONNECTed**. Upon receipt of this message, the "overlord" process sends as many copies of this message as are necessary to the other subunits of the network. Thus, a sample interchange between a processor and memory would be as follows:

1. Processor puts address on bus, and sets memory read request line on control bus. (Message is sent from

processor simulator to "overlord," and then to memory simulator.)

2. Memory gets signal on control bus, reads address bus, and gets the appropriate memory location. (Message is received by memory simulator, and the appropriate calculations and simulated delays occur.)
3. Memory places contents of selected address on data bus. (Message is sent from the memory simulator to the "overlord," and then to the processor simulator.)
4. Processor, after appropriate delay, reads data bus, and completes the memory fetch. (Message is received by processor simulator, and cycle is complete.)

Since simulated times may vary considerably from real times, each message also contains the time of its occurrence, so that the actions may be properly synchronized. Notice, also, that the distinction is made between internal and external actions. That is, if a process need not communicate with the "outside" world for a while, and need only update its internal registers, when it again writes a message, the time field will reflect this time spent "inside."

Since it would increase the general simulation time to have a process poll a particular bus (as does the hardware) to implement interrupt lines, a special feature has been built into the "overlord" whereby a process can advise which of its lines an interrupt can be generated on. The process can then go into an idle state (i.e. not polling, but perhaps doing other operations), and be automatically interrupted when the indicated line is asserted by another process. This method takes full advantage of the asynchronous method of coordinating the various subprocesses.

#### EXAMPLE

The following is a sample interchange between the system designer and the MMPS system. In this example, the user will connect two imaginary processors, called MINIs, to a common memory. The MINI is used for simplicity's sake. As in the MMPS simulator, commentary (which is ignored by the command parser) is preceded with a "!", and ends with a carriage return.

---

```

>! First, the user must declare the processors, the memory, and the
>! associated backplane wires.
>
>DECLARE MINI[2],
+>     MEMORY[1] <4:4>,
+>     WIRE[10];
>
>! Notice that the memory is declared to have four bits of addressing,
>! and four bits of data space. The control lines are assumed. The
>! nine backplane wires are for connecting the processors to the
>! memory units, etc.
>
>! Now the clock speeds are set on the processors
>
>CLOCK MINI[1] at .5MHz,
+>     MINI[2] at .75MHz;
```

```

>
>! Now the elements are connected. The address and data lines of
>! both the processors and the memory are connected together, along
>! with the control lines. One I/O line of each processor is
>! connected to the other for handshaking purposes. (This is declared
>! to be wired OR). The remaining I/O line per processor is connected
>! to a wire for monitoring purposes.
>
>CONNECT MINI[*] <0:3>, MEMORY[1] <0:3>
+>          TO WIRE <0:3>;
>
>CONNECT MINI[*] <4:7>, MEMORY[1]<4:7>
+>          TO WIRE <4:7>;
>
>CONNECT MINI[*] <8> TO WIRE <8>;
>
>WIREDOR WIRE <8>;

>
>! Set the traces names.
>
>TRACE MEMORY[1] : MREAD, MWRITE, ADDRESS;
>
>! Print out what is being traced, and also what is being signaled
>! on in the memory.
>
>PRTRACE MEMORY[1];
MREAD MWRITE ADDRESS
>PBREAK MEMORY[1];
      <No break names>
>
>! Load the memory, starting at location 5.
>
>LOAD MEMORY[1] FROM 5 WITH PROG
Locations 5—15 loaded from PROG; Total 11 words.
      <End of memory reached before end of file!>
>
>! Set the default tracing on the MINI's, and go
>
>TRACE MINI[*] : DEFAULT;
>NOBREAK MINI[*];
MINI[1] : Are you sure? Y
MINI[2] : Are you sure? Y
>GO
.
.
.
BREAK on MINI[2] : Halt executed at time 5135ms.
>
>! Now dump memory.

```

```

>
>DUMP MEMORY[1] TO DMPDIL
Locations 0-15 dumped to DMPFIL; Total 16 words.
>QUIT
%
```

The logfiles (called MINI.1, MINI.2, and MEMORY.1) can now be examined. Additionally, BUSREQ is a file that contains all information transferred along the busses, including that information that came out of the I/O lines to wires nine and ten. In case the user wanted to recreate the system above, he could utilize the USE command with the file COMLOG, which contains a running summary of the commands given to MMPS.

## CONCLUSION

MMPS provides a highly flexible tool for the network designer. As such, it can be used by many applications users, including the communications and data base management fields. Since MMPS is a simulator, it of course runs considerably more slowly than the hardware it is simulating. There are plans to interface MMPS with a downloadable hardware emulator, giving the added advantage of being able to look at detail with the simulator, and an overall picture with the emulator. With these tools, network design and implementation speed should be greatly increased.

# A (31,15) Reed-Solomon code for large memory systems

by RAYMOND S. LIM

NASA-Ames Research Center  
Moffett Field, California

## SUMMARY

This paper describes the encoding and the decoding of a (31,15) Reed-Solomon Code for multiple-burst error correction for large memory systems. The decoding procedure consists of four steps—(1) syndrome calculation, (2) error-location polynomial calculation, (3) error-location numbers calculation and (4) error values calculation. The principal features of the design are the use of a hardware shift register for both high-speed encoding and syndrome calculation, and the use of a commercially available (31,15) decoder for decoding Steps 2, 3 and 4.

## INTRODUCTION

With present technology, very large memory systems ( $\geq 10^{12}$  bits) designed for the archival storage of digital data are critically dependent on electronic error correction systems (EECS) for ensuring system viability and integrity.<sup>1-4</sup> In the IBM 3850 Mass Storage System, the EECS used is an Extended Group Coded Recording capable of correcting up to 32 eight-bit bytes of data in a 208-byte data block. In the CDC 38500 Mass Memory System, the EECS used is a modified Group Coded Recording similar to that used in the IBM 2400 Series magnetic tape systems. The use of magnetic tape systems for archival storage of digital data depends even more critically on EECS to make them viable. The EECS, devised by Brown and Seller, and used in the IBM 2400 series magnetic tape system, is not adequate for long-term archival storage of data.<sup>5-7</sup>

At the Institute for Advanced Computation (IAC), archival storage systems such as the UNICON 690, magnetic tape systems, and other mass memory systems are no exceptions. The viability of these systems depends critically on EECS. Instead of designing a different EECS for each particular archival system, it is advantageous to design a single EECS powerful enough to serve all systems within the Institute.

This paper describes a (31,15) eight-error-correcting Reed-Solomon (RS) code and a decoding procedure suitable for implementation using present technology. This code is not a binary code, but a q-ary code with code symbols from  $GF(2^5)$ ; i.e., each code symbol consists of five bits. For the I4-TENEX system—PDP-10, PDP-11, and ILLIAC IV com-

puters—the RS code is planned to have two modes of operation—the 36-bit mode and the 16/8-bit mode. Decoding will be implemented by hardware which consists of four steps—(1) syndrome calculation, (2) error-location polynomial calculation, (3) error-location numbers calculation and (4) error values calculation. The encoding process is performed by a hardware shift register in 31 clock cycles (50 ns per cycle). The syndrome calculation in Step 1 is also performed by the same encoding shift register in 31 clock cycles. Decoding Steps 2, 3 and 4 are performed by a commercially available (31,15)  $GF(2^5)$  decoder<sup>8</sup> in one msec maximum, depending on the number of errors which actually occurred.

## REED-SOLOMON CODES

Reed-Solomon (RS) codes<sup>9-12</sup> are the most powerful of the known classes of block codes capable of correcting random errors and multiple-burst errors. From coding theory, there are codes with code symbols from a  $q$ -symbol alphabet if  $p$  is a prime number and  $q$  is any power of  $p$ . These codes are called q-ary Bose-Chaudhuri-Hocquenghem (BCH) codes. RS codes, with code symbols from a Galois field of  $q$  elements  $GF(q)$ , are a special subclass of BCH codes.

For present engineering applications only binary codes derived from RS codes are of interest. For this reason,  $GF(q)$  will be restricted to  $GF(2^m)$  where  $m$  is a positive integer. The field  $GF(2^m)$  is formed by a primitive polynomial of degree  $m$  with  $\alpha$  as the primitive element of the field. In the algebra of a Galois field,  $\alpha$  is also called the  $n$ th root of unity in  $GF(2^m)$  since  $\alpha^n = 1$  for  $n = 2^m - 1$ . With  $q = 2^m$ , the code symbols of an RS code are  $\alpha^i$ ,  $i = \infty, 0, 1, 2, \dots, 2^m - 2$ , which are the  $2^m$  distinct elements of  $GF(2^m)$ . The notation  $\alpha^\infty = 0$  is used here.

The RS codes have  $\alpha, \alpha^2, \alpha^3, \dots, \alpha^{2t}$  as roots. Since the minimum polynomial with root  $\alpha^j$  is simply  $(x + \alpha^j)$ , the generator polynomial  $g(X)$  of a  $t$ -error-correcting RS code of length  $2^m - 1$  is

$$g(X) = (X + \alpha)(X + \alpha^2), \dots, (X + \alpha^{2t}) \quad (1)$$

The code word polynomials generated by  $g(X)$  consist of the multiples of  $g(X)$  modulo  $X^{2^m - 1} + 1$ , and have  $\alpha, \alpha^2, \alpha^3, \dots, \alpha^{2t}$  as roots. Since  $g(X)$  has degree  $2t$ , and  $\alpha$  is a primitive  $n$ th root of unity in  $GF(2^m)$ , the RS code generated

by  $g(X)$  is a  $t$ -error-correcting cyclic code with the following parameters:

$$\left. \begin{aligned} \text{Code length (symbols)} \quad n &= 2^m - 1 \\ \text{Number of parity check symbols} \quad n - k &= 2t \\ \text{Minimum distance} \quad d &= 2t + 1 \\ \text{Number of information symbols} \quad k &= 2^m - 1 - 2t \end{aligned} \right\} (2)$$

Since a symbol in  $GF(2^m)$  can be expressed as an  $m$ -tuple over  $GF(2)$ , the parameters of an RS code over  $GF(2)$  are simply  $m$  times larger.

**ERROR-CORRECTING CAPABILITY**

RS codes over  $GF(2^m)$  are very effective in correcting random and burst errors. Since each code symbol is an  $m$ -tuple over  $GF(2)$ , a  $t$ -error-correcting RS code is capable of correcting any error pattern that affects  $t$  or fewer  $m$ -bit symbols. For example, since a burst of length  $3m + 1$  cannot affect more than four  $m$ -bit symbols, a four-symbol correcting code can correct any single burst of length  $3m + 1$  or less. It can also simultaneously correct any combination of two bursts of length  $m + 1$  or less because each burst can affect no more than two symbols. At the same time, it can correct any combination of four or less random errors. In general, the RS code with error correcting capability  $t$  can be used to correct any of the following errors:

1. All single bursts of length  $b_1$ , no matter where they start, if  $b_1 \leq m(t-1) + 1$ .
2. Two bursts of length no longer than  $b_2$  each, no matter where each burst starts, if  $b_2 \leq m[(t/2) - 1] + 1$ , or any  $p$  bursts of length no longer than  $b_p$  each, no matter where each burst starts, if  $b_p \leq m[(t/p) - 1] + 1$ .

From the previous discussion, it follows that the RS code can be used to correct random errors, single-burst errors, or multiple-burst errors.

**CODE SELECTION**

RS codes offer the designer a wide range of code parameters as indicated in Equation 2. In coding theory, a block code with parameters  $n$  and  $k$  is denoted as  $(n, k)$ . For the IAC I4-TENEX system that consists of computers with work lengths of 16 bits (PDP-11s), 36 bits (PDP-10s), and 32/64 bits (ILLIAC IV), the best choice for fitting these word lengths is the (31,15) code. The formats for the 36-bit and the 16/8-bit are shown in Figure 1.

**ENCODING**

There are two methods for encoding linear cyclic codes—the serial shift register method and the parallel matrix method. Because of hardware complexity in the parallel method, only the serial method is described in this paper.

Figure 1—Data formats of the (31,15) RS code for 36-bit and 16/8-bit modes. Unused leading bits are always zero.

Let  $M(X)$  be a message polynomial with  $k$  symbols encoded into a code polynomial (code word)  $V(X)$  with  $n$  symbols. In the serial shift register method, encoding in systematic form is accomplished by dividing  $x^{n-k}M(X)$  by  $g(X)$  and appending the remainder  $r(X)$  to  $X^{n-k}M(X)$ ; i.e.,

$$V(X) = r(X) + X^{n-k}M(X) = q(X)g(X) \quad (3)$$

where  $q(x)$  is the quotient. This indicates that  $[r(X) + X^{n-k}M(X)]$  is a multiple of  $g(X)$  and, therefore, is a code polynomial generated by  $g(X)$ . The code word generated is

$$(r_0 r_1 r_2, \dots, r_{n-k-1} m_0 m_1, \dots, m_{k-1})$$

$\left| \leftarrow \text{parity check bits} \rightarrow \right| \left| \leftarrow \text{message bits} \rightarrow \right|$

and the most significant symbol of the message,  $m_{k-1}$ , is sent first.

There are two shift register methods for encoding linear cyclic codes. One method uses an  $(n-k)$ -stage shift register, and the other uses a  $k$ -stage shift register.<sup>9</sup> In practice, the  $(n-k)$ -stage shift register is more commonly used unless  $n-k$  is much greater than  $k$ . For encoding the (31,15) RS code, an  $(n-k)=16$  stages shift register (Figure 2) can be used to implement Equation 3. The feedback multipliers  $g_0, g_1, \dots, g_{15}$  are coefficients of the generator polynomial  $g(X)$ , where  $g(X)$  from Equation 1 is

$$g(X) = (X + \alpha)(X + \alpha^2), \dots, (X + \alpha^{15})(X + \alpha^{16}) \quad (4)$$

Multiplying out Equation 4 and selecting the primitive polynomial  $p(X)$  in  $GF(2^5)$  to be

$$p(X) = X^5 + X^2 + 1 \quad (5)$$

Figure 2—Encoder for (31,15) code.  $g_i$  is a field element from  $GF(2^5)$  and  $R_i$  is a five-tuple shift register stage.

the coefficients are

$$\begin{aligned} g_0 &= \alpha^{12} & g_4 &= \alpha^{14} & g_8 &= \alpha^{25} & g_{12} &= \alpha^8 & g_{16} &= 1 \\ g_1 &= \alpha^{18} & g_5 &= \alpha^{23} & g_9 &= \alpha^{21} & g_{13} &= 1 \\ g_2 &= \alpha^{22} & g_6 &= \alpha^4 & g_{10} &= \alpha & g_{14} &= \alpha^{13} \\ g_3 &= \alpha^{23} & g_7 &= \alpha^7 & g_{11} &= \alpha^3 & g_{15} &= \alpha^{23} \end{aligned}$$

Each  $R_i$  register stage is a five-tuple shift register. The operation of the encoder is as follows. With  $S1$  set for feedback and  $S2$  set to position 2,  $k$  information symbols are shifted into the encoder and simultaneously sent to the channel. Then  $S1$  is turned to disable the feedback and  $S2$  is turned to position 1; the 16 parity-check symbols stored in the encoder now are shifted out to the channel, clearing the shift registers.

## DECODING

Let  $V(X)$  be the transmitted code word,  $E(X)$  be the channel noise-error pattern, and  $R(X)$  be the received code word and represented as follows:

$$\left. \begin{aligned} V(X) &= v_0 + v_1x + v_2x^2 + \dots + v_{n-1}x^{n-1} \\ E(X) &= e_0 + e_1x + e_2x^2 + \dots + e_{n-1}x^{n-1} \\ R(X) &= r_0 + r_1x + r_2x^2 + \dots + r_{n-1}x^{n-1} \end{aligned} \right\} \quad (6)$$

where  $v_i$ ,  $e_i$  and  $r_i$  are elements of  $GF(2^m)$ ,  $i=0, 1, 2, \dots, n-1$ . At the decoder

$$R(X) = V(X) + E(X) \quad (7)$$

The error pattern  $E(X)$  can be described by a list of values and locations of its non-zero components. For the decoding procedure to be described, the error location will be given in terms of an error-location number which is simply  $\alpha^j$  for the  $(n-j)$ th symbol. Let  $x_j$  be the error location number and  $e_j$  be the error value. Then for each non-zero component of  $E(X)$ , a pair of field elements  $(x_j, e_j)$  is required to describe that error. If  $E(X)$  has  $p$  errors, then  $p$  pairs  $(x_j, e_j)$  are required to describe the errors. Any decoding procedure is a procedure for locating these  $p$  pairs of  $(x_j, e_j)$  if  $p \leq t$ .

Assume that  $E(X)$  is an error pattern of  $p$  errors at locations  $j_1, j_2, \dots, j_p$ . Then

$$E(X) = e_{j_1}x^{j_1} + e_{j_2}x^{j_2} + \dots + e_{j_p}x^{j_p} \quad (8)$$

where  $p \leq t$  and  $0 \leq j_1 < j_2 < \dots < j_p \leq n-1$ . The first step in decoding is to check whether  $V(X)$  is a code word by calculating the syndrome. If the syndrome is zero, then either  $V(X)$  actually has no errors or  $V(X)$  has an undetectable error. In either case,  $V(X)$  is accepted as errorless. A non-zero syndrome indicates that an error has been detected; the error may or may not be correctable. For the RS codes, the syndrome is defined as a vector  $S$  with  $2t$  components as follows:<sup>7-10</sup>

$$S_i = R(\alpha^i) = r_0 + r_1\alpha^i + r_2(\alpha^i)^2 + \dots + r_{n-1}(\alpha^i)^{n-1} \quad (9)$$

for  $i=1, 2, 3, \dots, 2t$ . Combining Equations 7 and 9, the

result is

$$S_i = V(\alpha^i) + E(\alpha^i) \quad (10)$$

Since  $V(\alpha^i) = 0$ .

$$S_i = E(\alpha^i) = \sum_{l=1}^p e_{j_l} X_{j_l}^i \quad (11)$$

An effective decoding procedure is described below and a design implementation for the (31,15) RS code is given. This procedure consists of four major steps as follows:<sup>9-12</sup>

1. Calculate the syndrome  $S = (S_1, S_2, \dots, S_{2t})$  from  $R(X)$ .
2. Calculate the error location polynomial  $\sigma(X)$  from  $S$ .
3. Determine the error locations  $X_j$  by finding the roots of  $\sigma(X)$ .
4. Calculate the error value  $e_j$  from  $X_j$  and  $S$ .

Decoding Step 1 is straightforward. Steps 2-4 are difficult and are very time-consuming.<sup>9-12</sup>

### Step 1—Syndrome calculation

For large  $t$  ( $t \geq 4$ ), a good way to calculate the syndrome is to use the  $g(X)$  encoding shift register as shown in Figure 2, except that  $R(X)$  is exclusive-ored with the output from  $g_0$  to form the input to  $R_0$ . This will result in some saving in logic because this shift register is already used for encoding. If  $V(X)$  has no errors, the  $S$  calculated is always zero. However, if  $V(X)$  has an error, the  $S$  calculated by  $g(X)$  is not the same as the  $S$  calculated by  $R(\alpha^i)$  of Equation 9, but they are related. This relationship is described below.

From Equation 9, let

$$S = (S_1, S_2, \dots, S_{2t}) \quad (12)$$

be the syndrome calculated by  $R(\alpha^i)$  with

$$S_i = R(\alpha^i) \quad (13)$$

for  $i=1, 2, \dots, 2t$ . Let

$$S^* = (S_1^*, S_2^*, \dots, S_{2t}^*) \quad (14)$$

be the remainder calculated by dividing  $R(X)$  by  $g(X)$ . The remainder  $S^*$  is another form of the syndrome but  $S^* \neq S$ . Using the Euclidean division algorithm, the result of  $R(X)/g(X)$  is

$$R(X) = Q(X)g(X) + S^*(X) \quad (15)$$

where  $Q(X)$  is the quotient and

$$S^*(X) = S_1^* + S_2^*X + S_3^*X^2 + \dots + S_{2t}^*X^{2t-1} \quad (16)$$

is the remainder. Substituting  $X$  by  $\alpha^i$  in Equation 15 gives the result

$$R(\alpha^i) = Q(\alpha^i)g(\alpha^i) + S^*(\alpha^i) = S^*(\alpha^i) \quad (17)$$

since  $Q(\alpha^i)g(\alpha^i) = 0$ . From Equations 13, 16 and 17, the

relationship between  $S$  and  $S_1^*$  is

$$S_i = S^*(\alpha^i) = S_1^* + S_2^*(\alpha^i) + S_3^*(\alpha^i)^2 + \dots + S_{2t}^*(\alpha^i)^{2t-1} \quad (18)$$

for  $i=1, 2, 3, \dots, 2t$ . In our design, the actual value of  $S$  is not needed because decoding Steps 2-4 will be performed by the GF1<sup>TM</sup> decoder. The GF1<sup>TM</sup> decoder has a built-in capability for calculating  $S$ , albeit at a lower speed.

#### Steps 2-4—Error correction

The implementation of decoding Steps 2-4 in our design will use the GF1<sup>TM</sup> decoder, which is a commercially available device.<sup>8</sup> Viewing the GF1<sup>TM</sup> decoder as an LSI chip, its functional block diagram is shown in Figure 3. The received code word  $R(X)$  has 31 five-bit digits. Assuming the the GF1<sup>TM</sup> has been initialized by pulsing the INIT line and that the DATE-IN ENABLE line is activated,  $R(X)$  is input, one digit at a time, to the DI lines. After the last digit (31st) of  $R(X)$  is input, the GF1<sup>TM</sup> decoder immediately starts the decoding procedure to correct the errors in  $R(X)$ . The decoding time is a variable depending on the actual random errors as well as erasures in  $R(X)$ . The GF1<sup>TM</sup> can correct at a maximum of  $2t+s \leq 16$  errors, where  $t$  is the number of random errors and  $s$  is the number of erasure errors. Input code symbols that have erasure errors are indicated by the ERASURE INDICATOR line. In the worst case, the maximum decoding time is one millisecond.

The corrected output of  $R(X)$  is  $V(X)$  and  $V(X)$  is available on the DATA OUT lines as soon as the OUTPUT READY line is activated by the GF1<sup>TM</sup>. The GF1<sup>TM</sup> output has a total of 19 digits. The first four digits are labels and are used to indicate correctable and uncorrectable status

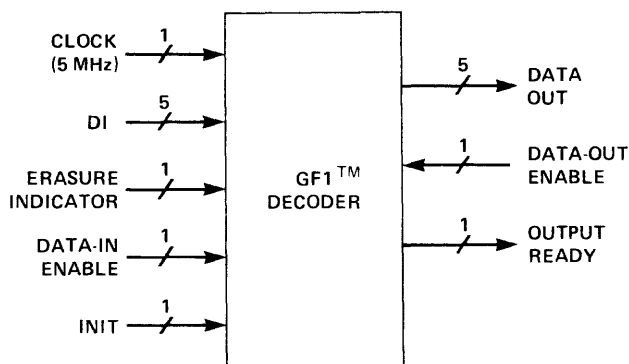

Figure 3—Block diagram of GF1<sup>TM</sup> decoder.

and the actual number of errors which have occurred. The last 15 digits are the information digits of  $V(X)$ .

#### CONCLUSION

A decoding procedure has been described for a (31,15) eight-error-correcting Reed-Solomon (RS) code. The code parameters are chosen for cyclic codes so that encoding and syndrome calculation can be implemented by shift registers, each requiring 31 clock cycles. Using current STTL technology, a clock cycle can be as short as 50 ns so that encoding or syndrome calculation can be accomplished in 1.55  $\mu$ s (about 48 megabits per second). For error correction, decoding Steps 2-4 are implemented by the GF1<sup>TM</sup> decoder,<sup>8</sup> which is a commercial (31,15) RS decoder. This decoder can correct  $2t+s \leq 16$  errors where  $t$  is the number of random errors and  $s$  is the number of erasure errors. The maximum decoding time of the GF1<sup>TM</sup> is one millisecond.

# English dictionary searching with little extra space

by DOUGLAS COMER

Purdue University  
W. Lafayette, Indiana

## INTRODUCTION

When text is typeset using a computer-based system, it can also be checked for spelling errors automatically and efficiently. Several methods of spelling error detection have been proposed. Morris *et al.* [MORR75] study statistical properties of English words, and describe an algorithm to catch possible typos by examining the relative frequency of trigrams (3-letter combinations). Kernighan *et al.* [KERN78] report a more conventional approach which looks up each word in a machine readable spelling dictionary.<sup>1</sup> Knuth [KNUT73] comments on dictionary storage, and suggests an organization intended to reduce space requirements. Another, somewhat unsophisticated technique sorts all words in a document and prints those which occur infrequently. Of course, habitually misspelled words escape unnoticed in a frequency based system.

Both [KERN78] and [KNUT73] mention removing suffixes from the spelling words and storing only the stems. When a word is to be looked up, its suffixes are removed by the same method, and only the stem is checked. This method has the advantage of requiring less space, but the disadvantage of not always catching illegal stem and suffix combinations. For example, the typo "computions" would pass the spelling test because removal of the suffix "ions" leaves the valid stem "comput."

Because there are several hundred thousand words in the English language, a complete spelling dictionary is too large to keep in main memory. Fortunately, a complete spelling dictionary has almost no value for catching typos: misspellings commonly turn out to be obscure or archaic terms which appear in the dictionary. Even a dictionary of 40,000 words may be too large to be useful. For example, the 40,000 word dictionary used by Purdue University's computing center includes terms such as "de," "hod," "ila," "lo," "moo," and "pul," which would probably be typos in technical prose.

While one cannot give an optimum size for an on-line dictionary, it is clear that "the bigger the better" does not apply. Since writers use most words infrequently and a few words very frequently, the best scheme seems to be:

1. Start with a small core of, say, 10,000 commonly used English words.
2. Add new words to the dictionary only as users request them.

This way, an appropriate dictionary evolves without unnecessary or obscure words. A small dictionary, grown by user request, is less likely to accept misspellings, and it can be managed more efficiently as well.

Carrying the evolution strategy further, researchers at Bell Labs derived a spelling dictionary solely from user's documents [KERN78]. The resulting dictionary is one-third the size of their original spelling dictionary. It has proved to be more useful, however, since it contains all the heavily used technical jargon as well as common words. Of course, if the user population spans a wide variety of interests, each group should probably grow its own augmentation dictionary, keeping the core for common English words. Any term appearing in all augmentation dictionaries should be deleted and moved to the common core.

Small spelling dictionaries often fit into main memory and can be searched without accessing secondary storage. The words themselves usually occupy a large portion of the available space, however, leaving only a little extra space for the program and data structures. This paper explores searching techniques in the context of a small spelling dictionary, and presents a technique which exploits a small amount of extra space to lower access costs. The second section reviews conventional search methods; the third section presents the trie-binary search (which uses a modest amount of memory). The fourth section examines an application to a particular spelling dictionary, and the fifth section presents performance statistics for typical input data. The final section suggests extensions and improvements.

## DICTIONARY SEARCHING TECHNIQUES

We view a *spelling dictionary*  $D$  as a static set of keys  $k_i$ ,  $1 \leq i \leq n$ , each key being composed of  $m$  letters. For each word  $w$  in the input text, the search procedure must answer the membership question, "is  $w$  in  $D$ ?" We assume that:

<sup>1</sup> More precisely, a word list; this paper uses the terms interchangeably.

1. The dictionary fits into main memory and occupies a fraction of the available space,  $\alpha$ ,  $0 < \alpha \leq 1$ .
2. The dictionary is not to be compressed (see [MORR75] for compression techniques).
3. The dictionary may be preprocessed (eg. sorted) to decrease search times. In particular, an index may be built to speed retrieval.

The general problem of data storage and retrieval for static sets of keys has received wide attention in the literature. Knuth [KNUT73] provides a summary. When the keys themselves occupy all but a small fraction of the available memory space, only a few candidate strategies emerge:

- sequential search —each probe eliminates 1 key.
- binary search —each probe eliminates half the keys.
- interpolation search —each probe eliminates more than half the keys in a uniform (or nearly uniform) distribution.
- hash table search —each probe eliminates most of the remaining keys (given sufficient memory).
- partial index —a small, auxiliary data structure is searched to eliminate all but a subset of the keys. Then, one of the above methods is used to search the subset.

The first four methods have been analyzed, and expressions for the expected number of comparisons per look-up have been derived under the assumption of a uniform distribution of keys. Sequential searching examines one-half of the dictionary for each look-up, and is obviously inferior to binary searching, which makes an average of

$$C_{Binary} = \log_2 n - 1 \tag{1}$$

comparisons in a dictionary of  $n$  words [KNUT73].

Interpolation search requires only  $C_1 \cdot \log_2(\log_2 n) + C_2$  comparisons on the average for nearly uniform distributions [YAO76]. In practice, however, the constants make interpolation search too expensive, especially with a highly skewed distribution like that of a spelling dictionary [KNUT73].

The performance of hashing depends on the fraction of the space that is occupied,  $\alpha$ , and can be estimated as:

$$C_{Hash} = (1 + 1/(1 - \alpha))/2 \tag{2}$$

comparisons for a successful search, and

$$C'_{Hash} = (1 + 1/(1 - \alpha)^2)/2 \tag{3}$$

comparisons for an unsuccessful search [KNUT73].

Ignoring for the moment partial index methods, one must choose between binary searching and hashing. In the case of an English spelling dictionary which contains less than  $2^{16}$  words, binary searching requires less than 15 probes on the average, and 17 probes in the worst case. From (2) we have that hashing is inferior for  $\alpha > .966$ . For example, when only

2 percent of the space is unused, hashing requires over 25 probes for an average successful search, and 1250 probes for an average unsuccessful search.

### TAKING ADVANTAGE OF A LITTLE EXTRA SPACE

As shown in Figure 1 when only a small fraction of memory is free, binary searching requires fewer comparisons on the average than hashing, even though a binary search uses none of the extra space that is available. This section presents a partial index method that uses only a little extra space; the next section demonstrates that it makes fewer comparisons on the average than a binary search.

Figure 2 illustrates the use of a partial index mechanism. During each look-up, the spelling program searches the index to identify the appropriate subset of the dictionary to search. Presumably, the index identifies the proper subset rapidly. The program then uses a binary search to explore the specified subset.

One particular index method, called a *trie-binary search* keeps the dictionary in sorted form, using a trie index [FRED60] to identify the correct subset to search. As shown in Figure 3, the simplest trie index consists of an array of 26 pointers, one for each letter of the alphabet, which give the starting location of words starting with that letter. Using the first letter of a word to index into the array, one can quickly locate the subset of all words starting with that letter. The array is referred to as a *node* of the trie; many standard English dictionaries provide a 1-node trie in the form of a thumb index to help the user find the appropriate section faster.

A trie index can be extended to more than one level easily by allowing a pointer in the first level to point to another trie node instead of directly into the dictionary. For example, if the level one pointer for "c" pointed to a second node, then the second node would contain the starting locations of the subsets of words beginning with "ca," "cb,"

Figure 1—The relationship between memory size and optimal search strategies. Binary search is superior to hashing when only a little space remains free, even though it does not use the free space.

Figure 2—The idea of an index. A short search in the index data structure identifies some subset of the keys which is then searched for the exact key.

... , "cz." If a third level node were inserted following the pointer in a second level node for "co," then the third level node would give the starting locations of words beginning with "coa," "cob," ... , "coz."

The following terminology will be useful in the sequel. Pointers in the trie which point into the dictionary are called *leaf pointers*; all others are called *trie pointers*. The level one node of a trie is called its *root*, and a node which can be reached by following a pointer from a level *i* node is said to lie at *level i+1*.

Searching in the trie begins by indexing into the root node based on the first character. Decisions at subsequent nodes depend on subsequent letters. In general, an *i*th level node in the trie further restricts the subset of words to be searched by testing the *i*th letter.

Since storage space is limited, care must be taken to build the trie so that each node allocated reduces the average number of comparisons by the maximum amount possible. For example, if space exists for only two nodes, dividing the set of words starting with letter "s" results in fewer comparisons than dividing the set of words starting with "a." The idea of allocating nodes to produce lowest cost searches leads to the following algorithm for trie construction:

**Algorithm A:** (construct minimum cost trie using available storage)  
*construct* a 1-node trie for the dictionary;  
*while* storage is not exhausted *do*

```

begin
  find dictionary pointer p which yields best improvement in search time when its set is divided;
  insert a new node after pointer p
end
end A;
    
```

Algorithm A exhibits a high running time unless one employs an efficient method for finding the optimum dictionary pointer to be replaced. For uniformly distributed sets of keys, dividing a largest set is optimal; for non-uniform distributions the size of the set is not always related to the effect that division of that set would have on the cost. However, assuming that division of the largest remaining subset produces a good, if not optimum, trie leads to an efficient, practical algorithm for index construction:

**Algorithm B:** (construct a low cost trie efficiently)  
*construct* a 1-node trie for the dictionary;  
*select* a maximum set size, *t*;  
*while* a dictionary pointer, *p*, points to a subset of more than *t* keys *do*  
     *insert* a new node after pointer *p*  
*end B;*

Note that the tries constructed by either algorithm do not have fixed depth. Of course, each pointer in a variable depth trie must have an indication of whether it points into the dictionary or to another level of the trie, so an additional bit is required to store the indicator. Furthermore, pointers into the dictionary should include both a starting and ending

Figure 3—The simplest trie-binary search. The index consists of one array of 26 pointers giving the starting locations of words beginning with 'a,' 'b,' ... , 'z.'

location, since finding adjacent pointers in the trie would be time consuming. Even with these additions, the variable depth trie uses far less storage to achieve the same search time as a fixed depth trie.

The choice of the maximum set size,  $t$ , is crucial to fitting the trie into a small amount of memory. If  $t$  is too large, not enough nodes will be generated, and search efficiency will be lost. If  $t$  is too small, the algorithm will run out of space before the trie can be completed, and search performance may be poor. The next section discusses the relationship between storage used and the maximum set size, giving data from a sample dictionary.

## PERFORMANCE OF TRIE-BINARY SEARCH

This section describes the performance of the trie-binary search strategy on a typical spelling dictionary. Usually, such empirical data has limited value because key distributions vary from file to file. In English, the relative distribution of keys remains fairly constant over a large range of dictionary sizes. Thus, the performance study presented here applies directly to other English dictionaries.

The sample dictionary consists of 16,949 words, and was originally formed from computer tapes of newspapers. Gradually, some technical terms have been added, and obscure and nonsense words have been eliminated (although words like "MR", "MRS", "AVE", "ST", and "BLDG" remain).

With space for 26 pointers (1 node), trie-binary, binary, and hash search were implemented, and the actual number of probes<sup>2</sup> necessary to find each word in the dictionary was recorded. Using the collected data, the average and worst case number of probes for a successful search were calculated. Using equations (1), (2) and (3), and assuming that the trie divided the set of words into 26 equal size subsets, predicted average and worst case probes were computed. Table I summarizes the results.

The trie-binary search (using 1 node) requires only 75 percent of the probes needed by a straight binary search, and clearly performs better with only 26 extra storage locations. Two questions arise immediately: how does trie-

TABLE I

		Binary Search	Trie-Binary	Hashing
Observed	avg.	13.05	9.80	—
	worst	15	12	—
Predicted	avg.	13.05	9.35	652
	worst	15	11	16949

The average and worst case search times for 16949 word dictionary, and the predicted values assuming equal size subsets are produced by the trie. The observed values for hashing are omitted because of the excessive computation costs.

<sup>2</sup> Throughout this paper we count each access in the index as one probe. Thus, if two characters are tested in the trie and three comparisons are made in the dictionary, the lookup requires five probes.

binary search perform with more space, and what is the relationship between the maximum set size,  $t$ , and the number of nodes allocated?

The graph shown in Figure 4 answers the first question in the case of the sample dictionary. It is clear from this plot that the best tradeoff space for time occurs with a small amount of space. For example, Table II summarizes the number of nodes necessary to lower the average number of probes in steps of one. Each successive reduction requires more space.

For the dictionary in question, a choice of 100-120 nodes represents a good compromise and brings the average number of probes for a successful search down to about 6.25 (or 48 percent of that used by a binary search). Doubling the space to 200-240 nodes further reduces the average number of probes by only .5, and hardly seems worthwhile.

The relationship between the maximum set size,  $t$ , and the number of nodes allocated,  $p$ , is important because the fast trie building algorithm depends on  $t$ , while the user can most easily estimate  $p$ . Knuth [KNUT73] estimates that

$$p = n / (t \cdot \ln b)$$

for a file of uniformly distributed keys, where  $b$  is the branch factor of each node. Using a branching of 26 for English yields

$$p = n / (3.3 t)$$

For the sample spelling dictionary, the estimate turns out to be close to 50 percent low for some  $t$ . This discrepancy can be explained easily by the non-uniform distribution of keys. It turns out that an average branching factor of around 8 provides a closer estimate of  $p$ :

$$p = n / (2.08 t) \quad (4)$$

Figure 5 shows both the estimated and actual number of nodes needed as a function of the maximum set size,  $t$ . Unfortunately, the number of nodes rises rapidly for small  $t$ , the steep slope making selection of optimum  $t$  difficult. However, the cost of trie construction is small, and the task will be performed once in a preprocessing phase, so version A of the trie building algorithm can be used to find optimum  $t$ , if necessary. As noted earlier, adding a few extra nodes does not lower the average number of probes drastically. Thus, a conservative estimate of  $t$  will not degrade performance severely when version B of the algorithm is used.

TABLE II

total nodes allocated	average probes
1	9.8
9	8.8
24	7.8
77	6.8
236	5.8

The number of nodes necessary to lower average probes in steps of 1. Each successive reduction takes increasingly more space.

Figure 4—The average number of probes needed to find a word as a function of the number of nodes allocated in a trie. This data comes from an actual dictionary of 16,949 words.

## IMPLEMENTATION PERFORMANCE

To see how trie-binary search performs in practice, algorithm B was implemented and compared to binary search. The implementation was done in Pascal, and the programs shared all code not involving the searching. Each program was run and timed ten times on a CDC 6500, using as input a text file of 7841 words arranged on 1359 lines. The maximum set size for the trie-binary search was  $t=125$ , which resulted in a trie with 77 nodes (using approximately 3 percent extra storage). The performance from runs with median search times is given in Table III.

TABLE III

	read dictionary	build trie	search	read text
binary search	991 ms	—	4908 ms	4203 ms
trie-binary search	998 ms	1642 ms	2242 ms	4193 ms

CPU times from a CDC 6500 for processing a text file of 7841 words using binary search and trie-binary search. The column "read text" includes CPU time for scanning and extracting the words as well.

Note that trie-binary search requires only about 46 percent as much CPU time during searching as a binary search on the sample input. Furthermore, binary search requires 20 percent more CPU time than trie-binary search, even if the trie is built "on the fly." When the trie is built and stored, the time required to read it is insignificant compared to the time required to read the dictionary.

## OTHER INDEX STRUCTURES

This section considers several other index structures, and compares them to trie-binary search. The first variation, called a *length-binary* search, works as follows: words in the dictionary as sorted by length, and within each length lexicographically. An index is created which consists of a vector of pointers giving the starting location of each length group. Searching proceeds by indexing the length vector to find the locations of words of the appropriate length. Having located the appropriate subset, the spelling program searches it using a binary search. Length-binary search has the advantage that equal length words are stored contiguously so that memory can be compacted.

For many computer architectures, a combination of length- and trie-binary search leads to the best use of stor-

Figure 5—The relationship between nodes allocated and maximum set size, t, for a spelling dictionary of 16,949 words. The estimate assumes uniform distribution of keys.

age. At the root node of the trie, the length is used as an index; successive nodes rely on character indexing. Because words are stored compactly, a significant amount of memory is available for the trie.

Another variation is related to the work of Coffman and Eve [COFF70] who consider storage of keys in a tree. To improve the tree balance, they suggest hashing the key first, and using the bits of the hashed value to make decisions in the tree. Figure 6 shows how hashing can be applied to trie-binary search. First, one divides the dictionary into subsets by hashing the words into a fixed number of "buckets." Each subset is stored contiguously, in lexicographic order, and its starting position is stored contiguously, in a 1-level trie node. During a search operation, the program hashes the input word to obtain an index into the trie node, from which it obtains a pointer to the appropriate subset. In fact, one can view trie-binary searching as a hashed trie search in which the hash code is given by the character ordinal.

One final variation frequently suggested involves a tree-structured index which guarantees the dictionary will be divided into equal size subsets. Figure 7 shows how the method, which is based on the Indexed Sequential Access

Method [GHOS69] organizes the tree. By selecting  $K_1$  keys at equally-spaced intervals in the dictionary and placing them in the root, the tree divides the file into equal size subsets. Of course, a program to search the multi-level tree makes approximately  $\log_2 K_1$  comparisons at the root before finding the correct pointer to follow (assuming a binary search). If the search continues through  $m$  levels, the method makes an average of:

$$C_t = \log_2 n - 1 - m \tag{5}$$

comparisons and follows  $m$  pointers, where  $n$  is the number of keys in the dictionary. We assume here that the number of keys promoted into the index is insignificant compared to the total number of keys.

For trie-binary search we assumed that the cost of following one pointer was the same as the cost of performing one comparison. Applying the same assumption here implies that an Indexed Sequential tree costs the same to search as a straight binary search when the entire set of keys resides in main memory. Therefore, trie-binary search is far superior.

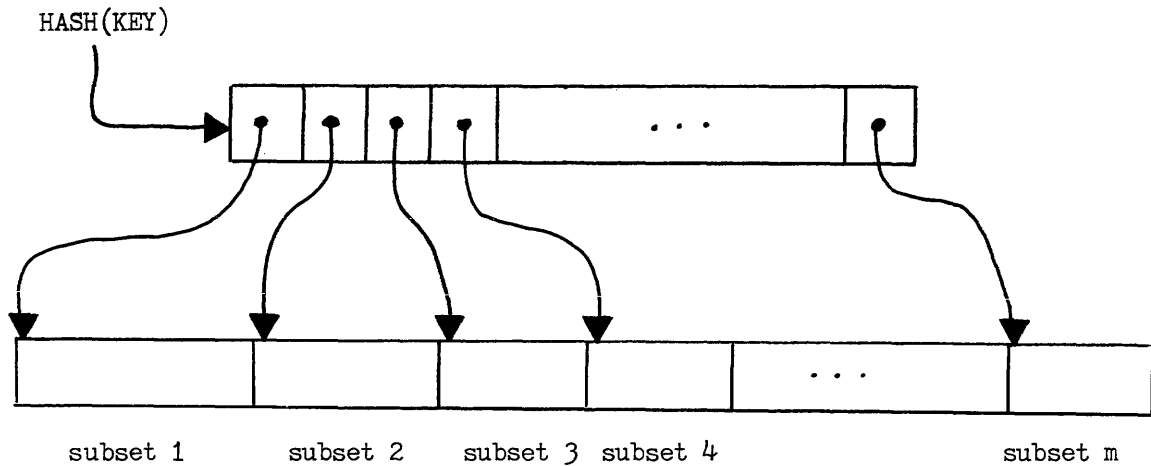

Figure 6—A 1-node trie using hashing. To locate a key, its hashed value is used to index a vector which points to the correct subset. The subset must be searched to locate the exact match. Note that the subsets may differ in size.

CONCLUSIONS

This paper has presented a data structure and algorithm, the trie-binary search for dictionary searching. The method performs well compared to a binary search while using very little extra space beyond that required to store the keys themselves. Trie-binary search has been applied to a typical spelling dictionary, and statistics have been gathered on its performance. For the distribution of words in a typical spell-

ing dictionary, trie-binary search makes 52 percent fewer probes than binary search, while using less than 3 percent extra space. For an input document of roughly 30 pages, trie-binary search required 74 percent as much total CPU time (46 percent as much CPU time during searching) as a binary search.

Several questions remain unanswered. It would be interesting to find out how trie-binary search performs on sets of keys other than spelling dictionaries. One might conjecture

Figure 7—A multi-level tree which requires searching at each node. The structure works well for a file in secondary storage, but is no better than a binary search when keys reside in main memory.

that typical data are no more skewed with respect to a uniform distribution than a spelling dictionary. If this is the case, trie-binary searching should perform well. There is also no reason to test the letters in left-to-right order. Testing in other orders might produce a better distribution for English. Finally, if a hashed method is considered, choice of an appropriate hash function needs to be considered.

# New indices for bibliographic data and their applications

by YAHIKO KAMBAYASHI, SHUZO YAJIMA, OSAMU KONISHI and TAKAKI HAYASHI

Kyoto University  
Kyoto, Japan

## INTRODUCTION

The KWIC Index is a widely-used tool for finding desired paper titles since it is simple yet very powerful. So in a bibliography of some specific area, the KWIC Index of Titles, Author Index and Subject Index are normally used. These indices are, however, not always sufficient for finding mutually-related papers. In this paper new indices for bibliographic data will be presented together with their applications.

The RS Index (Reference Structure Index) handles reference citation structure and is suitable for detecting influential papers, getting research trends and finding mutually-related research fields. A basic algorithm and improved algorithms have been developed, each of which requires memory only proportional to the number of papers to be handled (i.e. minimum). Functions of these algorithms are explained and example outputs are shown (see Figures 1, 2, 9 and 10).

The MULTI-KWIC has a capability of automatic detection of key phrases by finding maximum common subsequences contained in the paper titles. Using these key phrases, the following two kinds of indices are generated: (1) A MULTI-KWIC list (a linear list of titles ordered by one key phrase and one keyword, as in Figure 6), and (2) a year-distribution table (for each key phrase a table which shows identifications of papers classified by year is prepared, as in Figure 8).

These new indices are applied to 1600 papers in relational database and related areas which have been collected by the authors. The result shows their usefulness in bibliographic data-handling. A personal information system based on these indices has been also developed.

## REFERENCE STRUCTURE INDEX

In order to treat a reference citation structure of bibliography, the following problems must be considered:

1. Large amount of input data is required, since for each paper the information on its references must be supplied.
2. Reference citation relationships among papers are usually represented by a directed graph. It is, however, very difficult to print out a directed graph.

3. Usually a large amount of memory space and large software are required to print out a directed graph.
4. It is necessary to print out a directed graph which is human-oriented (i.e., the information contained in the graph is understood easily by looking at the graph).

In our implementation of the RS Index, these problems are solved by the following methods:

1. Reference information is shortened by the use of the identification code (ID for short) representing the paper. The ID is constructed from the names of the authors and the publication date. It can be easily constructed and the maximum length is 10.
2. Usually we need to know a set of papers which have a direct or a transitive citation relationship with a given paper. In such a case, we can use a tree expansion of a directed graph. By this reason, the RS Index only treats tree outputs, which are easy to understand. This output tree is called an RS tree.
3. Even if we restrict the outputs to trees only, usually the required space for output buffer is more than  $O(n)$ , where  $n$  is the number of papers contained in the output tree and  $O(n)$  denotes that the value is proportional to  $n$ . We have developed a procedure which utilizes a push-down stack.  $O(n)$  is the minimum storage space for memorizing the data, and the stack itself normally requires  $O(\log n)$  space.
4. An RS tree is printed from left to right. When the RS tree reaches at the right end of the output paper, successive trees are printed after the main RS tree. So we can print the tree whose maximum level is arbitrary. Since the width of the tree is also arbitrary, essentially the tree of the arbitrary size can be printed (the size of the tree is actually restricted by that of push-down stack).
5. When the number of papers in the RS Index is large, the RS tree spreads widely. In such a case it may be difficult to get useful information from the RS tree. A procedure to produce compact RS trees without changing their structure is developed as well as a procedure with tree trimming and ordering facilities. These facilities are also realized by algorithms based on pushdown stacks, thus we don't need separate procedures for these facilities.

We have developed a PL/I program for the RS Index, which consists of approximately 800 steps.

Identification codes for papers must be simple as well as human oriented. We use a character string  $oooo\Phi\Pi\Pi\Delta\Delta\chi$  of length ten as an ID.

$oooo\Phi$ : (*author field*) It consists of first four characters of the first author's name ( $oooo$ ) and first character of the second author's name ( $\Phi$ ). When the first author's name is shorter than four and there is a second author, - (hyphen) is inserted. If only the first author is shown with *et al.*, \* is used.

$\Pi\Pi\Delta\Delta$ : (*date field*) Year ( $\Pi\Pi$ ) and month ( $\Delta\Delta$ ) of the publication are shown. If not known, ? is used.

$\chi$ : (*extension field*) It is optionally used to distinguish the papers which have the same name and date fields. It is taken from the first letter of the title of the paper except articles. If two distinct papers have the same extension, the next unused character in the alphabetical order is assigned.

There are two kinds of RS Indices; one uses "A refers to B" and the other uses "A is referred to by B". For simplicity, only the "A refers to B" relationship is considered in this paper to explain the algorithm.

#### Basic algorithm for the RS index

This algorithm needs only one-line output buffer and has a simple recursive formulation, which shows why a stack is needed.

Call display ( $P, 0$ ), where  $P$  is the root paper and procedure display is defined as follows:

```

procedure display ( $p$ : Paper,  $i$ : Integer);
  begin  $L \leftarrow$  list of papers referred to by  $p$ ;
  for  $x$  in  $L$  do;
    begin display ( $x, i+1$ );
    if  $x$  not last in  $L$  then newline;
    end;
  print  $p$  at level  $i$ ;
end

```

In an actual program, in order to add many additional facilities easily the iterative procedure is adopted using a push-down stack.<sup>1</sup> The above algorithm is simple since it does not need to store the output position of each ID. The lines to indicate reference relationships among papers can be drawn by providing a bit for each level of the tree. In actual program, if there exists a paper appearing more than once, after first appearance only "TO  $i**j$ " is printed if the paper is first printed at the  $j$ -th position of the  $i$ -th level. This algorithm needs constant output buffer, and the required size for the stack is  $O(n)$ , which is in the worst case, where  $n$  is the number of nodes in the tree. If each paper has more than one reference (it is normally satisfied), the size is  $O(\log n)$ .

In order to use the RS Index practically the following two problems must be solved.

1. If there exist two papers  $A$  and  $B$  such that  $A$  and  $B$  refer to (or transitively refer to)  $B$  and  $A$ , respectively, then the basic algorithm fails.
2. When the number of references increases, it may be difficult to see the whole figure produced by the basic algorithm, because it spreads widely (see Reference 1 for the output of the basic algorithm). Figure 1 is an example generated by an improved algorithm.

In order to handle Problem 2 some useful facilities are prepared such as ordering facilities and filtering facilities.

1. Elementary facilities
  - a. Output of keywords, comments for each paper.
  - b. Output of information about connection between papers. These are printed on edges.
  - c. Designation of the width of the print-out by restricting maximum level of the RS tree.
  - d. Process of pattern matching for IDs. In the case of specifying a paper, we may not know when the paper was published even though we know who wrote it. For this reason, if we specify "COD-D\*\*\*\*\*," for example, the RS trees can be produced whose root paper's first author is Codd.
2. Ordering of references

We have adopted the following orderings from the practical viewpoint:

- a. To arrange IDs in alphabetical order by author's name.
  - b. To arrange IDs in order of published date.
  - c. To arrange IDs in order of labels of edges, which means the relationship or connection strength between a pair of papers.
  - d. To arrange IDs in order of the path length from the root. In an RS tree, in order not to print out redundant subtrees, if there exists a paper appearing in the tree more than once, "TO  $i**j$ " is printed after the first appearance. This means that the maximum path from the root is not always expressed explicitly. We can position papers in the RS tree more clearly if the maximum path is output explicitly.
3. Tree-trimming facilities
    - a. To eliminate IDs expressed such as "TO  $i**j$ ." This is available when looking over what papers are printed.
    - b. To print out the papers which are cited more than  $N$  times, where  $N$  is a threshold value.
    - c. To delete the transitively connected edges from the RS Index.
    - d. To print out IDs whose authors and publishing date are specific.
    - e. To eliminate IDs by the label of edges.

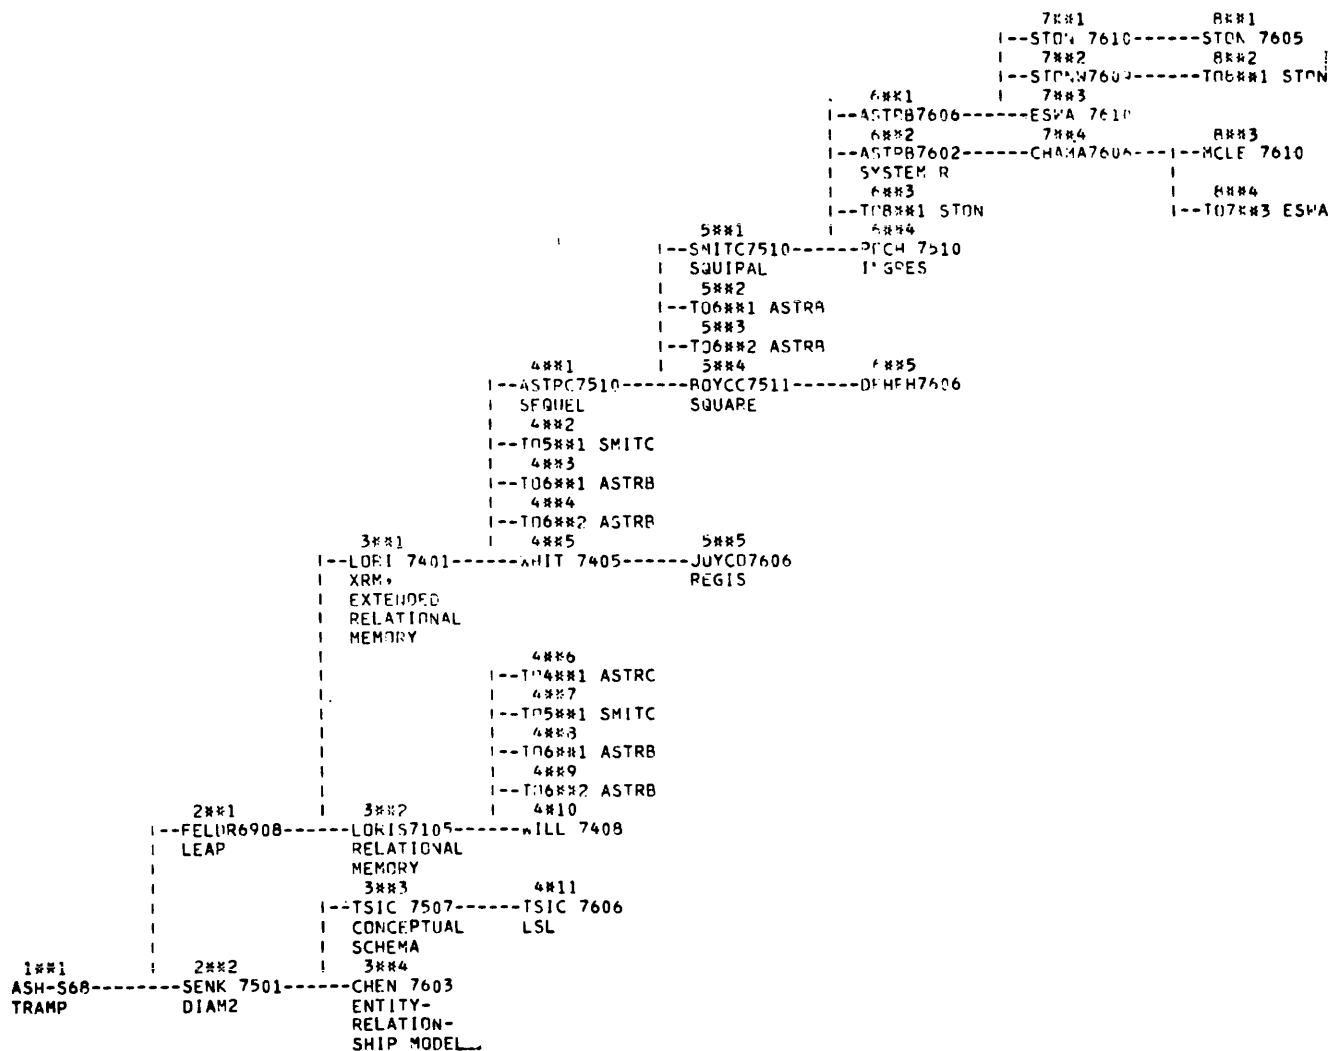

Figure 1—An example of the RS Index.

Figure 1 is an example which expresses the maximum path explicitly. Figure 2 shows the RS Index obtained by deleting transitively connected edges from Figure 1. More complicated examples are shown in Figures 9 and 10.

The algorithms of the aforementioned facilities are given in Reference 2.

### MULTI-KWIC INDEX

The MULTI-KWIC Index offers the following facilities:

1. *KWIC list with an improved ordering*—Paper titles are ordered by a keyword and words before and after the keyword.
2. *Key phrase extraction*—Key phrases are extracted by finding maximum common subsequences contained in the given set of paper titles.
3. *MULTI-KWIC list*—Titles with one common key

phrase and one common keyword are adjacently printed in a MULTI-KWIC list.

4. *Year-distribution table*—For each extracted key phrase, a table is prepared in which IDs are grouped by their publication years.

For the purpose of simplifying the algorithm, the MULTI-KWIC Index uses no dictionary. The program is written in PL/I and the total number of steps is about 1000. A utility for sorting is combined with the program.

Figure 3 shows a KWIC list produced by our program in which paper titles are ordered by a keyword and words before and after the keyword. There are two known versions of the KWIC. A primitive version produces a KWIC list by considering only a keyword. Figure 4 shows an example of such a KWIC list. In this example two titles with the common phrase "RELATIONAL DATA BASE MANAGEMENT SYSTEM" are not adjacently printed since words other than the keyword are not used to determine the order

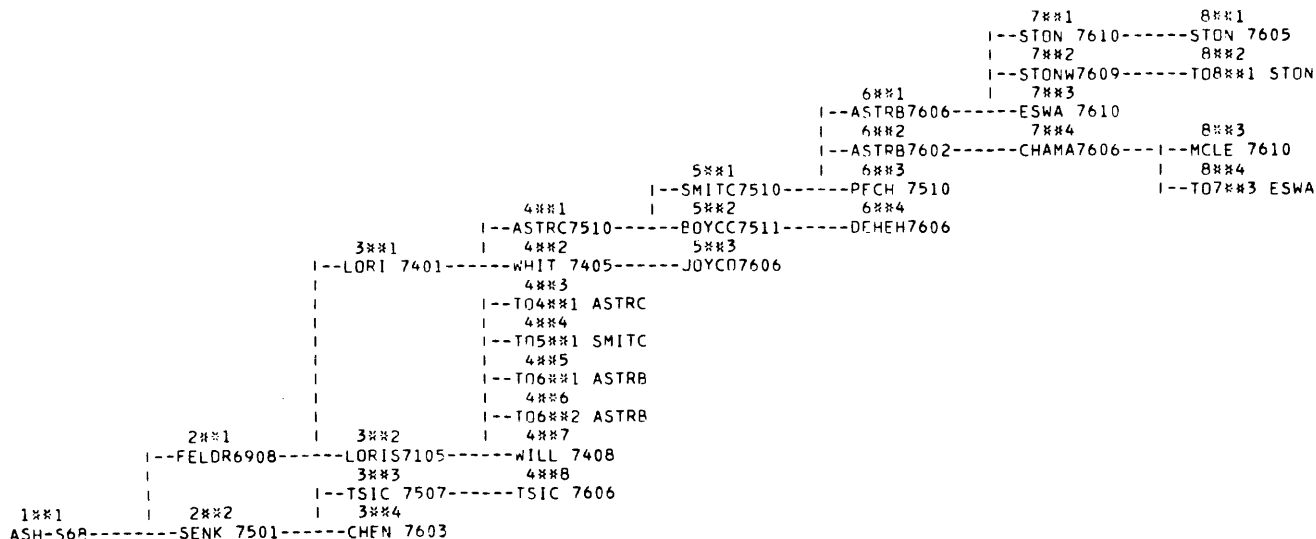

Figure 2—The RS Index obtained by deleting transitively connected edges from Figure 1.

Figure 3—An improved KWIC list.

Figure 4—Conventional KWIC list.

of the titles. In another version a KWIC list is produced by considering the keyword and words after the keyword. The total length of the subsentence (the keyword and the words after the keyword) is fixed and thus a sorting facility can be used to produce the output. This version, however, still has

the following problems:

1. Since titles are not ordered by the words before the keyword, there are still cases when two titles with a common key phrase are not printed adjacently.
2. Because of the inflections of words, similar key phrases may be printed separately.

Figure 5—Rearrangement by the consecutive retrieval property.

In our version of KWIC the following methods are used to solve these problems:

1. For each word only the first six characters are used for the ordering information.
2. Words before the keyword are considered as well as the keyword itself and words after the keyword.

Figure 6—Multi-KWIC list.

Approach 1 is employed since a dictionary is not required. By our experience in using 750 titles there are only three cases when different key phrases are regarded as the same ones. For the purpose of handling this kind of error, an editing facility is prepared in the program. In order to handle the problem of ordering by words before and after the keyword the following approach is used:

1. First, a primitive version of a KWIC list is prepared.
2. Let  $f_6(w)$  be the operation of extracting first six characters from  $w$  (when the length of  $w$  is less than six, blank characters are added and the length is adjusted to six;  $w$  can be a null string—a string of length 0) and let  $W$  be the keyword in the list prepared in Step 1. For each subsentence  $w_4w_5W w_1w_2w_3$  of the title, calculate  $f_6(W)$ ,  $f_6(w_1)$ ,  $f_6(w_2)$ ,  $f_6(w_3)$ ,  $f_6(w_4)$  and  $f_6(w_5)$ . Here  $w_1, w_2, w_3$  are words after the keyword and  $w_4, w_5$  are words before the keyword.
3. Sort the titles by  $f_6(W) \circ f_6(w_1) \circ f_6(w_2) \circ f_6(w_3) \circ f_6(w_4) \circ f_6(w_5)$ , where  $\circ$  denotes the concatenation of the words.

The output of the above procedure gives an improved KWIC list. For further improvement the consecutive retrieval property is used. The consecutive retrieval property is introduced by Ghosh<sup>4</sup> for organizing an efficient file. (For further information see the list of papers prepared by Lipski, currently of the Coordinate Science Laboratory, University of Illinois<sup>5</sup>). For example, consider the titles containing key phrases  $AB, CA, CAB$  where  $A$  is the keyword. The ordering shown in Figure 5(a) is appropriate. By this method the list shown in Figure 5(b) is rearranged and the list in Figure 5(c) is obtained.

Using this result key phrases consisting of less than seven words can be extracted from a set of titles. The program has a facility to extract key phrases contained in  $M(\cong N)$  for a given threshold value  $N(\cong 2)$ . By this method key phrases of the form of " $w_1$  of  $w_2$ " or " $w_1$  and  $w_2$ " can be extracted. Extraction of such key phrases is not possible by the commonly used extraction method whereby phrases are selected from words between conjunctions and prepositions.

By this method sometimes improper key phrases are extracted. Editing facility for eliminating such key phrases is also prepared. Since key phrases contained in many titles are not useful for characterizing the paper, key phrases contained in  $M(N_1 \cong M \cong N_2)$  titles can be used for paper characterization, where  $N_1$  and  $N_2$  are the user-determined threshold values. There will be, however, papers without

any characterizing key phrases and thus thesauri may be required for full automatic classification of papers.

The extracted key phrases are used to generate a MULTI-KWIC list. In the list titles with one common key phrase and one common keyword are adjacently printed. A

Figure 8—Year-distribution table.

Double-KWIC list<sup>3</sup> is also known as a list with two keys. The major differences are (1) a MULTI-KWIC list has a capability of automatic key phrase extraction and (2) the output format of MULTI-KWIC is similar to conventional KWIC so the both outputs can be combined.

An example of the MULTI-KWIC list is shown in Figure 6, where the titles containing "access" and "data" are listed. The procedure used for the MULTI-KWIC list is explained in Figure 7. Assume that we have a set of titles having key phrases and keywords shown in Figure 7(a) (here, the first line shows that the identification number is 1 and the title contains one key phrase *ABC* and two keywords *E* and *F*). The priority of sorting is determined as (1) the keyword part of the key phrase, (2) the keyword and (3), the remaining part of the key phrase. The result is shown in Figure 7(b).

Figure 8 shows a year-distribution table which will be prepared for each extracted key phrase (here, 'relations' and 'conceptual schema'). If a paper contains two key phrases  $W_1$  and  $W_2$ , where  $W_2$  is a proper substring of  $W_1$ , then the paper is classified to key phrase  $W_1$  category. By this table activity transition of some specific area will be observed.

## APPLICATIONS

Figures 9 and 10 show RS Indices taken from the result of application to papers of relational database and related areas, which are collected by the authors (it is an extension of Codd's bibliography<sup>9</sup>). Figure 9 shows the RS tree for the referred-to-by relationship whose root is Abrial's paper which discusses data semantics. This RS tree presents many papers concerned with some kinds of data models and conceptual schema. For example, there are the DIAM II model by Senko (SENK7601, SENK7501), conceptual schema by Tsichritzis (TSIC7507, TSIC7606), DBMS architecture of

the next generation by Nijssen (NIJS7601), criterion of conceptual schema by Kent shown in KENT7609, entity-relationship model by Chen (CHEN7603), and so on. Figure 10 is a descendant tree whose root is the paper of Armstrong. This paper is concerned with axiomatization for functional dependency in relational databases. Some of the descendants of this paper are one of Bernstein, which discusses a synthetic design of relational databases, and one of Fadous, which introduces the algorithm for finding candidate keys efficiently. The papers written by Zaniolo, Fagin and Beeri are also printed, which discuss multi-valued dependency or generalizations of functional dependency.

Another application of indices introduced in this paper is a personal information system. The system has been developed under the LABOLINK network<sup>7</sup> using the model M-190 computer of Fujitsu at the Data Processing Center, Kyoto University. Papers are accessed by a combination of keywords, authors and years. The system has the following specific features:

1. For selecting appropriate keywords, a key phrase KWIC table is shown (see Figure 11). It is a KWIC list of key phrases which are automatically detected by the MULTI-KWIC.
2. For each specified key phrase a year-distribution table (Figure 8) can be displayed.
3. For each paper an RS Index for the paper can be generated.

The system is examined by JICST (Japan Information Center of Science and Technology) bibliographic data tapes as well as the papers of relational database areas collected by us (about 1,600 papers) and the effectiveness of the system is proved. These facilities are to be merged with the relational-model-based research information system currently under development.<sup>8</sup>

# Visual inspection of metal surfaces

by J. L. MUNDY

General Electric Company  
Schenectady, New York

## INTRODUCTION

The majority of applications of automatic visual inspection have been the case in which a high contrast image can be obtained. This will result from object silhouettes<sup>1</sup> and high contrast reflectivity changes as in printed text. In these cases, the image can usually be successfully segmented by a threshold operation<sup>2,3</sup> leading to a two-level or binary image.

The cases that lead to difficulty at present involve the use of reflected light. Here one is faced with shadows and highly variable reflected intensity. This is the case for metal surfaces where the reflected intensity is a strong function of illumination and viewing direction. On the other hand, the inspection of metal surfaces represents an important domain of applications. Of particular interest is the detection of small surface defects such as nicks and scratches.

In order to implement automatic computer inspection of metal surfaces, optical and illumination means must be provided that provide high contrast images of surface defects. In addition, there must be a relationship between image intensity and surface profile. This paper will discuss a number of theoretical aspects of the scattering of light from metal surfaces. This provides a basis for computer modeling of the metal surface. The theory is based on earlier work by Beckmann<sup>4</sup> and Horn.<sup>5</sup> The method has been tested experimentally and several examples will be demonstrated.

## SCATTERING THEORY

Several phenomena play a role in the distribution of light scattered from a metallic surface. The most important effects are 1) the variations of the surface normal and 2) shadowing. The variation of surface normal generally occurs on two scales. A fine scale variation is present that represents the basic surface roughness. In the case of surface defects, there exists a more gradual variation corresponding to the surface deformation associated with the defect. The combined variation is illustrated in Figure 1. In the case of shadowing, portions of the surface are occluded by variation in the surface due to defects. This condition is shown in Figure 2 for a crater or pit type defect.

The theoretical situation is best developed for the case of surface normal variations in the presence of random fine

scale surface height variations. Beckmann and Spizzichino<sup>6</sup> have explored this case extensively for various scales of surface roughness. In this paper we will only consider the case where the surface is rough compared to the wavelength of light. The reflection coefficient for scattered power in this case is given as

$$\langle \rho \rho \rangle^* = \frac{\pi R^2}{4kA^2 \cos^2 \theta_1} \frac{V^4}{V_z^4} \left( \frac{T}{\sigma} \right)^2 \exp \left\{ \frac{-V_{xy}^2}{4V_x^2} (T/\sigma)^2 \right\}$$

where

R=Reflection coefficient of an equivalent smooth surface.

k=2π/λ (λ—wavelength of illumination)

A=Area of illuminated surface

$\vec{V} = \vec{k}_1 \vec{k}_2$

V<sub>x</sub>=Component of V along the surface normal

V<sub>xy</sub>=Component of V perpendicular to surface normal

$\vec{k}_1$ =Incident wave vector

$\vec{k}_2$ =Reflected wave vector

T=Correlation distance of surface roughness

σ=Surface height variance.

The coordinate system and scattering vectors are defined in Figure 3.

It will prove useful to transform this notation to that introduced by Horn. This notation is defined in Figure 4. It follows that

$$-\vec{k}_1 \cdot \vec{k}_2 = k^2 \cos g$$

$$\begin{aligned} V^2 &= \vec{k}_1^2 + \vec{k}_2^2 - 2\vec{k}_1 \cdot \vec{k}_2 \\ &= 2k^2(1 + \cos g) \end{aligned}$$

also

$$V_z = k(\cos i + \cos e).$$

Horn defines the I, E, G as the cosines of the angles i, e, g respectively. From the consideration above,

$$V^2 = 2k^2(1 + G)$$

$$V_z^2 = k^2(1 + E)$$

\* This appears as Equation 59, p. 88 of Reference 4.

Figure 1—The variation in surface height for a rough surface in the vicinity of a surface defect.

Noting that

$$V_{xy}^2 = V^2 - V_z^2$$

we finally obtain

$$\langle \rho \rho^* \rangle E_0^2 = \alpha \left( \frac{(1+G)^2}{(1+E)^4} \right) e^{-\beta[2(1-G)/(1+E)^2 - 1]} \quad (2)$$

$$\alpha = \frac{R^2 A}{\pi r_0^2} \beta$$

$$\beta = \frac{T^2}{4\sigma^2}$$

Here  $E_0^2$  is proportional to the power scattered by a smooth plane of area  $A$ . This is given by

$$E_0^2 = \frac{k^2 A^2 I^2}{4\pi^2 r_0^2}$$

where  $r_0$  is the distance from the observer to the plane. Thus the result in (2) would be proportional to the scattered power from the rough surface. This form is suitable for interpretation and comparison with experiment.

CASE I—SOURCE AT OBSERVER

If the illumination source is colimated (unidirectional) and located on the axis of the observation, then  $I=E$  inde-

Figure 2—The shadowing of the surface due to a defect.

Figure 3—The scattering geometry according to Beckmann.

pendent of the direction of the surface normal. In this case we find

$$P = \langle \rho \rho^* \rangle E_0^2 = \frac{\alpha}{4 I^4} e^{-\beta[(1/I^2)-1]} \quad (3)$$

This is a particularly simple form which can be easily interpreted. The first observation is that  $\beta$  depends only on surface roughness. As the surface becomes rougher  $\beta$  decreases. The exponential term in (3) dominates the behavior of  $P$  and, for large  $\beta$ , will lead to a rapid fall off in intensity for  $I \neq 1$ .  $P$  is maximum for  $I=1$  which corresponds to the specular reflection condition. Note also that surface reflectivity only affects  $\alpha$  and thus not the angular distribution. Also the peak power is proportional to  $\beta$ , which is to be expected, since smoother surfaces concentrate more power into the specular direction.

This expression was tested for a number of surface roughnesses found from a selection of metal industrial parts. The

Figure 4—The scattering geometry according to Horn.

Figure 5—The experimental and theoretical variation of reflected power with surface normal inclination. The theory in Expression 3 is shown as a solid line.

surface was rotated relative to the optical viewing axis and the reflected power on axis is given in Figure 5 for two surfaces. In the same figure a best fit of Expression 3 is shown as solid lines. The agreement is quite satisfactory.

CASE II—GRAZING AND NORMAL ILLUMINATION

From the previous development, it can be seen that the slope of metal surfaces can be deduced from reflectivity

measurements. This assumes that both reflectivity and surface roughness are known. The former condition is not easily obtained in practice. Industrial parts are usually dirty and reflectivity can vary rapidly over the surface.

In order to obtain more information it is necessary to provide an additional direction of illumination. The arrangement shown in Figure 6 provides two nearly orthogonal directions. To see the relationship between the power due to each illumination direction consider (2) for each case. It is assumed that the direction of view is along the normal illumination direction.

Figure 6—An optical configuration for obtaining two directions of illumination.

a)

b)

Figure 7—(a) A photomicrograph of a surface nick and (b) the resulting S array shown in perspective. The signal variations near the top of the array are due to an unilluminated region.

## a) Normal illumination

This is just the previous case, i.e.

$$I_n = E_n$$

$$G_n = I$$

$$P_n = \frac{\alpha}{4} \frac{1}{I_n^4} e^{-\beta(1/I_n^2)^{-1}}$$

## b) Grazing illumination

$$G_n \approx 0$$

$$I_g = \sqrt{1 - E_g^2}$$

$$E_g = E_n = I_n$$

So in terms of  $I_n$

$$P_g = \alpha \frac{1}{(\sqrt{1 - I_n^2} + I_n)^4} e^{-e(1/I_n + (1 - I_n^2)^{-1})}$$

If we assume that the surface normal does not vary greatly from the direction of normal illumination,

$$I_n \sim 1.$$

Thus

$$P_g \approx \frac{\alpha}{(I_n)^4} e^{-\beta(1/I_n^2)^{-1}}$$

Now taking the ratio of power due to grazing illumination and normal illumination we have,

$$\frac{P_g}{P_n} = 4e^{-\beta(1/I_n^2)^{-1}}$$

Taking the logarithm of this ratio and dropping subscripts we have

$$S = \ln \left( \frac{P_g}{P_n} \right) = \ln 4 - \beta/I_n^2 \quad (4)$$

Figure 8a—A photomicrograph of a series of .005-inch-wide scratches. Note the large relative surface roughness.

Figure 8b—The perspective of the corresponding S array.

Note that this quantity depends only on surface roughness and slope and not surface reflectivity. It is a reasonable assumption that roughness is constant over a region larger than the size of defects that are to be detected.

A number of surface defects on metal surfaces were imaged using the illumination scheme in Figure 6. Two images were obtained for each case, one for normal illumination, one with grazing light. The quantity  $S$  in Expression 4 was obtained by digitizing the images and performing the indicated calculations.

The first case consists of the nick shown in Figure 7a. The resulting  $S$  array is shown in perspective in Figure 7b. The nick appears near the center of the array with good contrast. The mountainous peaks near the top of the array were due to random sensor noise since that region was not illuminated.

A more striking example is the series of scratches ( $\sim .005''$  wide) shown in Figure 8a. The  $S$  array is shown in Figure

Figure 8c—A binary image of the S array produced by thresholding.

a)

b)

Figure 9—(a) A photomicrograph of a small pit. (b) The resulting S array as a grey-level image to illustrate the contrast.

8b. The signal has enough contrast to allow a reasonable segmentation of the scratches by thresholding the S array as shown in Figure 8c.

As a final example consider the pit ( $\sim .010''$ ) shown in Figure 9a. The resulting S array is shown as a grey-level image in Figure 9b. The main contribution to S in this case is the occlusion of the grazing illumination. There is good contrast between the pit and surrounding metal even though the surface roughness is on a scale comparable to the defect.

## CONCLUSIONS

By considering the theory of scattering from rough surfaces, it has been possible to derive an illumination scheme and method of image analysis that results in good contrast and detectability of surface defects.

It is also noted that the scattering ratio, S, is sensitive to surface occlusions and shadowing. Thus we have a result that provides good contrast for most surface defects. The main drawback to the approach is the necessity to provide two directions of illumination.

## ACKNOWLEDGMENTS

I am indebted to P. Beaudet for suggesting the relationship of Beckmann's result to Horn's notation. Also to T. Cipolla for his assistance in obtaining some of the experimental results.

# Monitoring the earth's resources from space— Can you really identify crops by satellite?

by DAVID LANDGREBE

*Purdue University*  
West Lafayette, Indiana

## INTRODUCTION

Of the most important questions facing society today, those near the top of the list include the status and future of the world's food supply, its environmental quality and its sources of energy. These questions have increasingly been before the general public in recent years and have for an even longer period of time, been of concern to the world's thinkers, planners and policymakers. It had long been recognized that after all, our earth and its resources are finite and that as society continues to grow we must find better ways to manage these finite resources.

A primary need for good management is up-to-date and accurate information on the status of the resources to be managed. Thus it was that early in the last decade the possibility of using aerospace technology for accumulating better information about the current conditions of agriculture, the earth's resources and man's environment began to be examined. It seemed clear that to monitor resources directly associated with the land, the best vantage point would be above the land looking down upon it.

The need to be higher simply resulted from the need to see more. In practical terms this immediately implies the gathering of larger and larger quantities of data, and the computer was immediately suggested therefore, as somehow an important tool. But how? There now exists a first generation answer to this question. The program of systematic and step-by-step research which led to it, will first be briefly outlined. After description of some typical examples of its use, we will examine the directions being taken to devise an even more effective second generation solution.

## THE FIRST LAYER OF TECHNOLOGY

Figure 1 shows a view of a small portion of the earth's surface as seen from space. This image was made from data from the Landsat-2 multi-spectral scanner. It is a simulated, color-infrared image of a region in north central Indiana, 100 nautical miles on a side. Such an image could only be imagined in the early 1960s as no one had seen it at that time. But even then the immensity of the problem was readily apparent. To place a sensor capable of producing such an

image appeared challenging but possible, but scenes such as this would present a real challenge to analyze by computer. The human interpreter can immediately recognize a major river generally flowing in a southwesterly direction across the scene and with a little additional information can identify forest lands in the river bottoms as compared to lands which have been prepared for crops in a great portion of the rest of the image. The more obvious features of a major city, Indianapolis, Indiana are apparent in the southeastern portion of the image; however, a number of smaller cities are barely even identifiable. To see how by computer analysis one would be able to answer such questions as "How many acres of wheat are there in this scene and what will their yield be?" or "Where are there serious problems of soil erosion, resulting not only in stream pollution but also loss of valuable agricultural land?" or "What is the extent and condition of various classes of urban land use and how are they changing?" surely represented a great challenge.

In addition, thinking of this scene in terms of the data volume to produce it and therefore the processing capability which would be needed to analyze it also revealed another challenge. This image consists of about 7.5 million digital pixels in each of four spectral bands. Each of these pixels may have any of 64 shades of gray. This amounts to 180 million bits for only one look at a 185×185 km (100×100 n. miles) area. Landsat collects such images at a rate of more than two a minute.

Such a situation seemed made to measure for the emerging field of pattern recognition to tackle. Figure 2 shows the now classical view of the organization of a pattern recognition device. A series of measurements are taken of the scene by the receptor, which in this case corresponds to the spaceborne sensor system, and these measurements are turned over to a classification algorithm. Realizing the great complexity of the scene it was recognized as especially important to devise a receptor which was very efficient in representing the needed scene characteristics in a manageable number of features.

For it to become possible to measure crop acreages in data such as shown in Figure 1 it was decided to rely for these features upon the spectral characteristics of individual pixels.<sup>1</sup> Figure 3 shows in conceptual form the spectral characteristics of three types of land cover. The features to be

Figure 1—A scene of north central Indiana from the multispectral scanner of Landsat-2. (Original in color.)

measured would be the relative spectral response in each of the several wave bands. These responses would then be represented in a multivariate form as implied by the two-dimensional plot in Figure 3. The pattern classifier is trained by segmenting this multivariate space into an exhaustive list of nonoverlapping regions, each region corresponding to one informational class.

The choice of this spectral approach puts primary emphasis on the spectral characteristic of the measurement as compared to the image characteristics. For this reason a multispectral scanner, as opposed to a camera, was needed for the sensor so that the precision of the wave band energy measurement could be high and regions of the spectrum in

addition to the visible and the near infrared would be accessible.

The results of the first test of this concept are shown in Figure 4.<sup>2,3</sup> On the left is an air photo of an agricultural area with the crop type present in each field indicated by a letter symbol. On the right is the result of using a maximum likelihood classifier on four bands of data in a pixel by pixel fashion. Based on this and similar early results obtained in 1966 there followed a period of two or three years of intensive research to define methods for data collection, pre-processing, classifier design, training procedures and the like.

By 1969 with the launch of the Apollo 9 spacecraft the

technology was ready for its first test on space data. The Landsat-1 spacecraft then referred to as ERTS-A, was already in the planning and design stages. Apollo IX carried aboard it an experiment known as S065. This experiment consisted of a bank of 4 boresited cameras with film and filter combinations to simulate the expected Landsat data. After exposure and developing of the film each of the 4 images from the different parts of the spectrum of the same scene were scanned then precisely registered to one another. This was accomplished by computer implemented precision image registration algorithms which had also been devised during the previous research period. Since these algorithms were capable of registration to subpixel accuracy, data simulating multispectral scanner data was available. Promising results were obtained from pattern recognition results in applications associated with agricultural crops, general land use and geologic recognizance mapping among others.<sup>4</sup>

A second major test of this emerging technology occurred in 1971 as a result of a major episodic event in the corn belt. Southern corn leaf blight emerged during the 1970 growing season, and though it arrived late enough in the season that devastating damage did not occur, it appeared that a catastrophe could occur during the 1971 season before new strains of seed corn which would be resistant to the blight could be produced. Thus during the winter of 1970-71 a major effort to monitor the corn crop during the 1971 season was planned. The effort involved overflight of some 220 1×10 mile segments located over the seven states of the corn belt on a bi-weekly basis. All segments were overflown by a high altitude aircraft carrying photographic cameras; 30 of the segments in western Indiana were also overflown by a low altitude aircraft carrying a multispectral scanner. The results showed that not only could crop species be distinguished accurately but that the condition of a single crop (corn) could be successfully subdivided into subcategories based on the degree of blight infestation.<sup>5</sup> This proved to be true using both the more well established manual image interpretation methods and the newer computer implemented mul-

tispectral techniques. In the latter case however, the results were demonstrably more precise and objective.

Thus by the time of the launch of Landsat-1 in July 1972 a new technology had been well researched and tested and was ready for exposure to the potential user community. This exposure began with the studies of some more than 400 principal investigators in the U.S. and around the world who for the first few years of Landsat-1's life tested out both image-oriented and computer-implemented algorithms for extracting information from earth-orbital views of the earth.<sup>6-8</sup> Since that time Landsat-2 and Landsat-3, launched in January 1975 and March 1978 respectively with nearly identical sensor systems to that of Landsat-1, have been used. Landsat is now an essentially operational system in that data is routinely collected and placed in the public domain. It is routinely available to anyone from any nation. Table I gives the location of Landsat ground stations in addition to the three operated by the U.S.

The technology represented by this satellite series and computer-aided processing techniques associated with it is indeed now quite broad touching essentially all application fields which deal with land resources.<sup>9-11</sup> Machine-implemented techniques for processing the data for improvement of its geometric properties to high cartographic standards are now not uncommon. The registration of two frames of data of the same scene collected at different times is now also being accomplished at a number of locations and to pixel and in some cases subpixel accuracies. A large number of pattern recognition algorithms implemented on both special purpose and general purpose hardware are being used routinely and are commercially available.

#### EXAMPLE APPLICATIONS

The precise definition of operational is an elusive one, however clearly routine use of these methods is now beginning to occur in the fields of agricultural crops and soils

mapping, forest cover and condition assessment, geology and mineral prospecting, rangeland assessment, general land cover mapping especially associated with the mapping of the urban and near urban regions. We will discuss only a few examples to illustrate this technology, especially that portion with it associated with computer processing.

*Land Cover Mapping Examples.* One of the earlier large scale applications of Landsat data came about as a result of the need to remedy problems of pollution of the Great Lakes. The International Joint Commission of the U.S. and Canada set about to determine the precise causes of the problem. It established several reference groups associated with sources of the pollution, one of which was the reference group on land use. This reference group was concerned with the introduction of undesirable materials into the Great Lakes which enter them through the various streams of the

Figure 4—An early result of crop species classification from multispectral data. (Original in color.)

watershed and which result from the manner in which the land of the Great Lakes watershed is being utilized. To begin this work it was necessary to study the relationship of the land use to the possible pollutants which might be carried by these streams. It was immediately found that no up-to-date land use maps of the region existed. Thus the first step would be the construction of such maps. More specifically land use maps of each of the 192 counties were needed on a county-by-county basis. It was desired to know the type of land use in each four- to five-acre plot of counties. Furthermore, while the requirements on map classification accuracy were modest, the time available was short being less than one year. Such maps were produced in 1973 at a cost of approximately \$1,000 per county. The processing required involved selection of the proper Landsat frame, geometric correction of the data to reasonable cartographic precision, and delineation in the data of the county boundaries. This was followed by derivation of appropriate classifier training statistics and classification of the county using a maximum

likelihood Gaussian classifier. Maps were then produced in a color coded form showing the various land cover classes. Place names and boundaries were later overlaid onto the maps using conventional (non-computer) techniques and the intention was to interpret the required land use knowledge from these land cover maps by conventional means. Tables giving the aerial proportion of each county in each land cover class were also produced.

Work has continued since that time to further refine the techniques and adapt them to the needs of user agencies. In 1978 the U.S. Geologic Survey produced and published a land use map of the Washington, D.C. urban area using essentially these same techniques.<sup>12</sup> This map which is for sale by the U.S. Geologic Survey at Reston, Virginia (map I-858-E) is to a scale of 1:100,000; it contains a color coding showing the classes given in Table II. Supplied along with this map are quantitative tabulations of land use classes in each 5×5 km UTM grid cell.

An even more detailed land use map has been prepared and published as a demonstration product by the U.S. Department of Interior, the Pacific Northwest Regional Commission and the National Aeronautics and Space Administration.<sup>13</sup> This map of the land cover type of the Puget Sound Region in the state of Washington is at a scale of 1:250,000 and shows 21 land cover types as listed in Table III.

*An Example in Forestry.* The field of forest lands management is another important application area; to illustrate the use of earth observational data in this field we will consider briefly the management of commercial forest lands. In this case the need is for (1) complete, accurate, and current data as a basis for both immediate and long range management planning, (2) information within the time span required for the management decisions, and (3) augmentation of the difficult task of data collection by increasing the efficiency of ground sampling procedures while maintaining the scope and precision of the data collected.

Active forest management practices were begun in the United States at the turn of the century but have become greatly intensified in the post World War II years. They have in this period become increasingly quantitative in nature and quite sophisticated. The problem is one of choosing the correct management actions to take on forest lands which may total millions of acres but which may require different management decisions on tracks as small as a few tens or hundreds of acres. Management decisions required are both of a technical nature (plantation and fertilization schemes, harvesting schedules, etc.) and an administrative

nature (decisions on buying, selling or leasing of lands, contracting for timber, etc.). Time intervals between decisions and results may be as long as 30 to 40 years and as short as a few days or weeks.

Variables to be monitored include (1) quantitative timber values in terms of commercial units of value (cubic feet, board feet, tons, etc.), (2) stand structure and condition including stand composition by species, cover type, timber size and condition, age classes, density, topographic position, competing vegetation, past cultural activity, etc. and (3) the dynamic response of the stand in time, both to natural and cultural factors. A manager must know not only the conditions at the present time but how well and in what fashion a stand has responded to past management practices and natural environmental conditions.

Traditionally, data for forest management has been acquired by manual ground observations. This can, of course, be a very expensive (and disagreeable) process to carry out. Sites must be suitably located over the land to be managed according to a suitably designed statistically sampling plan. These sites have to be visited by ground sampling teams periodically. The work may be slow and difficult to carry out because of terrain difficulties. It was natural in this case for the field to turn to remote sensing techniques, first from aircraft and now spacecraft, as a means to increase the efficiency of data collection, to increase its objectivity, and to realize its availability on a more timely basis.

Even if it were not possible from remote observations to increase the accuracy of data collection, one would anticipate that it should be possible to improve the timeliness and especially the efficiency of ground data collection. For example, the number of ground sites needed in a sampling scheme depends on how well they are located relative to the stratification of parameters to be measured. The synoptic view from space provides a very effective vantage point for sensing this scene stratification and therefore can lead to improved efficiency in dispatching ground teams.

The techniques of machine processing of Landsat MSS data have been shown over the last few years to very clearly be capable of providing the needed stratification and identification capabilities in an objective and timely manner. Even in the rugged terrain of the U.S. Rocky Mountain region where the high degree of terrain relief causes variations in illumination due to shadowing and slope angle effects, it has been possible to convincingly demonstrate the ability to distinguish between deciduous and coniferous stands and to some extent to distinguish between species or species groupings.<sup>14-16</sup> These capabilities are precisely the

ones needed to more efficiently assign ground observations teams and to provide accurate aerial determinations for use in multistage statistical sampling procedures. These techniques have been and are being adapted very rapidly to the specific requirements of forest information systems operated over both public and private land holdings. The St. Regis paper company, Southern Timberlands Division, for example has a very active program at the present time to incorporate such Landsat techniques for managing its 1.7 million acres of land owned or controlled in the states of Florida, Georgia, Alabama, Mississippi, and Louisiana. St. Regis had some time ago seen the need for objective management schemes and had devised a number of computer implemented management models. The development of these models gave the corporation the ability to rapidly make large numbers of decisions of a forest lands management nature. This, in turn, very greatly increased the need for input data on quantitative timber values, stand structure and condition and dynamic temporal response, the very variables which the Landsat technology can readily produce. This situation is not atypical of that which the manager of both commercial and public lands finds himself in today.

*A Food Commodity Production Forecast Example.* As a third example of the application of computer technology in remote sensing we will cite an experiment known as LACIE, the Large Area Crop Inventory Experiment.<sup>17</sup> LACIE was a proof of concept experiment conducted between 1974 and 1978 by NASA, USDA, and NOAA in which the major wheat production areas of the world were monitored by Landsat in order to obtain continual estimates of the acreage, yield, and production of wheat. The goal of the program so far as accuracy is concerned was that the at-harvest estimates were to be within 10 percent of the true estimate at the national level nine years out of ten. This goal, if achieved in an operational system, would be a significant improvement in the current ability to be able to estimate at-harvest production. An important feature of LACIE for the application of existing remote sensing technology was a self-imposed constraint against the use of observations from the ground to identify wheat. This restriction was imposed on all geographic areas, both the U.S. and foreign, to insure the development of a technology applicable to regions inaccessible to observations from the ground.

The procedure used involved a statistical sampling scheme in which 5×6 mile segments located in each subregion were used to estimate the wheat acreage in that subregion. Weather station reports of the subregion were used with a yield regression model to estimate the subregion yield. The total wheat production for each subregion is then obtained as the product of the available wheat hectareage times the yield for that subregion. The production forecasts for all subregions are then summed to obtain the national level forecast.

During the course of the LACIE program about 15,000 such 5×6 mile data sets from more than 2600 sample segments in five major global crop regions and meteorological data from more than 1500 reporting stations were used. During at least one growing season of the program, monthly reports on area, yield, and production estimates on wheat

were generated for the U.S. Great Plains, Canada, and the U.S.S.R. Exploratory analysis was carried out for segments in five other countries; Argentina, Australia, Brazil, India, The Peoples Republic of China.<sup>17</sup>

Based upon a very extensive effort to measure, evaluate, and report the results of LACIE, it is clear that the ability to monitor wheat production by multispectral means has been demonstrated. Figure 5 shows an example LACIE result for the U.S.S.R.<sup>17</sup> The solid curve of this figure shows the monthly estimate reported by the project. These production forecasts were generated and released to USDA in Washington, D.C. the day prior to the corresponding public release by the USDA Foreign Agricultural Service (FAS).

The FAS forecasts are also shown for comparison. The third variable graphed in the figure are LACIE recomputed estimates. The recomputed estimates are the seasonal forecasts obtained from the LACIE system after correction of two Landsat data problems encountered during that year of operation; these problems were of a type typical of first time system operation and would not be expected to occur in an operational system. Also indicated in this figure is the 1977 production figure of 92 million metric tons officially released by the U.S.S.R. in January 1978. The ability of this system to produce an accurate estimate but also to produce an estimate of this accuracy so early in the season is indeed impressive.

Figure 5—LACIE Phase III USSR total wheat production results for 1977 compared to FAS and official USSR estimates.<sup>17</sup>

The need for such data grows stronger as the degree of international interdependence increases. Though this interdependence has always been growing the growth has accelerated greatly in the last few years. For example in 1950-52 the U.S. Balance of Trade in the agricultural area was at approximately minus one billion dollars. By 1960-62 the figure was approximately plus one billion dollars. By 1970 the figure had increased to approximately 1.5 billion and by 1975 the same figure exceeded 12½ billion. Clearly these figures show the increasing importance to the U.S. of early and accurate estimates not only of the projected U.S. production but that of its trading partners around the world as well.

These three examples were selected not only to sample the spectrum of different uses as related to different disciplines but also to illustrate the differing types of information needs which the technology is now able to supply. In the case of the land cover mapping example the need was for highly accurate categorization of land cover type displayed in a map format of high cartographic quality; ground observations were readily obtainable. In the second example the information required was not in map but statistical form. In addition in this case the remote observations were to be used to reduce the amount of ground observations which had been previously necessary. In the third case again statistical information rather than map output was required and no ground observations were possible at all. In all three cases an improvement in an existing data source was the objective rather than the production of a wholly new type of data.

#### RESEARCH DIRECTIONS FOR A SECOND LAYER OF TECHNOLOGY

These techniques are flowing rapidly into routine use in a series of application areas which is so large and diversified as to defy listing. Given the continued availability of data of the type now being returned to the earth, the technology seems destined to mature to a position of considerable importance. However, in addition to this maturing of the current technology significant new advances are in the offing. A new series of Landsat satellites is now under construction. The first will be launched in 1981. In addition to the current type multispectral scanner (MSS) it will carry a more advanced scanner known as thematic mapper (TM). Table IV provides a comparison of the specifications of thematic mapper as compared to MSS. It is seen that thematic mapper will have a larger number of bands of greater spectral resolution covering not only the visible and near IR but the middle IR and thermal region as well. Note also the significant improvement in spatial resolution and the signal-to-noise ratio of the data as reflected by the 8 bit data providing 256 shades of gray per band as compared to the 6 bit data of MSS providing 64 shades of gray. The data thus provided will make possible deeper penetration into the hierarchy of classes of earth cover. For example, as compared to the identification of wheat using MSS in the LACIE experiment the thematic mapper should make possible crop species

TABLE IV.—A Comparison of some Parameters of MSS, the Multispectral Scanner Aboard the Early Landsat Satellites with Thematic Mapper (TM) to Be Aboard Landsat D in 1981

Scanner Parameter	MSS	TM
Spectral Bands	4: .50- .60 $\mu\text{m}$	7: .45- .52 $\mu\text{m}$

	.70- .80 $\mu\text{m}$	.63- .69 $\mu\text{m}$
	.80-1.1 $\mu\text{m}$	.76- .90 $\mu\text{m}$
		1.55-1.75 $\mu\text{m}$
		2.08-2.35 $\mu\text{m}$
		10.4 -12.5 $\mu\text{m}$
Instantaneous Spatial Field of View	80 m	30 m
Data System Precision	6 bit	8 bit

identification and condition estimation approaching that achieved with the airborne scanner used in the 1971 corn blight watch experiment. In this latter case, corn, soybeans, and other crops typical of the U.S. Corn Belt were identified with high accuracy throughout the growing season.

A second area of progress in the research laboratory which is leading to an advancement in applications capability is in the use of various types of ancillary data geographically associated with Landsat data. Data bases constructed by registering Landsat observations at different times through the season together with such variables as elevation, slope, aspect, radar return, political boundaries, land ownership data, soil type, etc. will significantly widen the number of applications by greatly increasing the number of land cover classes to which the data can be divided into.

On the other hand, the construction of such new data sets will greatly increase the amount of stored data which must be accessible and will place increased demands upon analysis procedures of higher and higher sophistication. It is in these areas techniques associated with the construction, storage, and accessing of more complex data sets and the creation of more sophisticated analysis procedures capable of achieving the full advantage which such data sets provide that an enhanced research effort is needed at the present time.

Though it is usually the case that advancements are first made in data collection, in this field it is most important that a balance be achieved in the development of the state-of-the-science of data collection and information extraction. These in turn require a continued effort to increase our understanding of the scene and just which attributes in the scene are information bearing and also in the problems of the user community and which techniques are needed to interface the information extraction techniques of this emerging technology with bonafide user needs.

# Digital image shape detection

by R. MICHAEL HORD

*Institute for Advanced Computation  
Alexandria, Virginia*

## INTRODUCTION

Determining algorithmically the presence of specified objects in test imagery is desirable in many circumstances. Typically, a reference image containing an example of the object of interest is compared with a test image. The four primary characteristics of the object used for this compari-

son are:

- Translation—location of the object's centroid in the format.
- Orientation—rotation of the object's principal axes with respect to the format axes.
- Size—scale of the object with respect to the sample spacing.

Figure 1

Figure 2

- Shape—the distribution of gray level values of the object.

Often, only the shape is relevant, i.e., a match is sought between the test image and the reference image even if they differ in translation, orientation and scale. It is desirable in these cases to transform the image pair in ways that are independent of these irrelevant geometric features.

Shape detection has been a topic of interest to the digital image pattern recognition community for many years,<sup>8</sup> and it remains a prominent topic of discussion in the current literature.<sup>1,2,5</sup> Two recent survey articles<sup>3,4</sup> document the popularity of the topic.

The Power Spectrum of an image is well known to be independent of translation. The Mellin Transform has been shown<sup>9</sup> to be scale-independent. The Polar-Cartesian (POLCAR) Transform<sup>10</sup> described in the following, converts rotation into translation. The Power Spectrum of the POLCAR Transform is then independent of rotation. Hence, a combination of these performed successively will allow shape to

be matched to shape, independent of translation, rotation and scale. Mention of this approach is found in the literature;<sup>6,7</sup> this paper explores this approach in more detail. Listings of the FORTRAN programs used in this study are available from the author on request.

POLCAR TRANSFORM (32x32)

In a NXN image, let I be the row index and J be the column index with (I, J)=(1, 1) in the upper left hand corner. Let

$$S=(N/2)+1.01 \tag{1}$$

$$X=J-S \tag{2}$$

$$Y=-I+S \tag{3}$$

$$R=\text{SQRT}(X \times X + Y \times Y) + .1 \tag{4}$$

$$T=\text{arctan}(Y/X) + 3.14159 \tag{5}$$

Then for  $N=32$ , the X axis is originated at 17.01 and is positive to the right while the Y axis is originated at 17.01 and is positive upward in the I, J system. R ranges, for integer I, J, between 0.11 and 22.74 while T ranges between 0 and 6.2832. Let

$$IR = \text{INT}(\text{LOG}(R) * 13.155 + 14.2) \quad (6)$$

$$ITH = \text{INT}(T * 5. + 1.) \quad (7)$$

then IR is an index ranging between 1 and 32 and ITH is an index ranging between 1 and 32. Let IR be a row index and ITH be a column index with  $(IR, ITH) \doteq (1, 1)$  in the upper left corner of a  $32 \times 32$  array. This array is termed the POLCAR transform of the input array:  $G(IR, ITH) = G(I, J)$ .

An input array of horizontal lines is shown in Figure 1; the geometric features of the POLCAR Transform of Figure 1 is shown in Figure 2. Figure 3 shows the isolines of Figure 2. Figure 4 shows the full POLCAR Transform of Figure 1, including gray level amplification as a function of R squared.

Asterisks indicate format overflow for values greater than 99.

A set of vertical lines are shown in Figure 5; the geometric features of the POLCAR Transform of Figure 5 are shown in Figure 6 with the isolines drawn in in Figure 7. Note that Figure 7 resembles Figure 3, shifted eight spaces to the right corresponding to a 90-degree rotation of the input array.

Figure 8 shows the array of IR values as a function of I, J; Figure 9 shows the isolines of Figure 8. The array of ITH values as a function of I, J is shown in Figure 10. The isolines of Figure 10 are shown in Figure 11.

The FORTRAN subroutine implementing the POLCAR Transform is given in Table I. It is intended that the input array, *IMAG*, is the Power Spectrum of a  $32 \times 32$  image, rearranged to emulate an optical power spectrum so that the zero frequency component is position at (17, 17). Setting, the origin at (17.01, 17.01) assures that R is strictly positive.

The form of IR is

$$IR = H \log R + K.$$

Figure 3

Figure 4

H and K are chosen so that the minimum value of IR is 1 and the maximum value of IR is 32. The log is employed to provide the scale insensitivity of the Mellin Transform.

The gray-level values are amplified by a factor of R squared since in the frequency domain this is comparable to taking a second derivative of the spatial domain input image.

SHAPE DETECTION ALGORITHM

A block diagram of a shape detection algorithm incorporating the POLCAR Transform is shown in Table II. Two images, I1 and I2, are input. Their Power Spectra are obtained using a Fast Fourier Transform subroutine (FFT). The output of FFT has the zero frequency component at (1, 1); by analogy with optical power spectra, a rearrangement of the frequency components with the zero frequency component at (17, 17) is desired. The output, aside from various intermediate displays, is a value of QMAX(I1, I2). This is used to obtain M(I1, I2).

DISCUSSION

Sixteen binary 32x32 arrays containing simple objects were studied. There are essentially six types of objects categorized by shape in the set of test images:

- A. Solid rectangles, 2.6:1 aspect ratio; I1, I2, I5, I6
- B. Solid right isosceles triangles; I3, I4, I10
- C. Solid rectangles, 3.0:1 aspect ratio; I7, I8, I9
- D. Solid circles; I11, I12
- E. Hollow right isosceles triangles; I13, I14
- F. Hollow rectangles, 3.0:1 aspect ratio; I15, I16

The values of M obtained by comparing various image pairs using the SHAPE program are shown in Table III. High values indicate a good match, low values, a poor match.

I6 is simply I2 with gray values multiplied by 4; the M values in Table III for I6 as expected are virtually identical

Figure 5

to those for I2. Hence, I6 need not be analyzed as a distinct object for these purposes. For the 15 distinct objects, 105 cross comparisons are possible. It is expected that objects with shapes of the same type should have high M values. Naturally, all objects have somewhat the same shape as all other objects. Hence, M can take on a continuous set of values from zero to one. For discrimination purposes a threshold T can be specified; here T=0.080 is chosen, that is, M is considered high if M is greater than or equal to T.

Tables IV through IX exhibit subsets of Table III for the six object types. Of the 12 comparisons shown, 11 detections succeed, but one falls below the threshold T, that for I1 vs. I5. This comparison involves a scale factor of 2, together with a 90 degree rotation and a translated centroid.

There are, other than these expected high M values, 36 cross object high M values. Most of these are not too disturbing. Twenty are rectangles matched to rectangles but solid vs. hollow or of differing aspect ratio. Five are triangles matched to triangles, solid vs. hollow.

Seven spurious high M values match triangles with circles; of these seven, 5 are solid triangles, 2 are hollow triangles. Discrimination is shown to be unreliable in these 32x32 format cases.

I12	0.066	0.231	0.154	0.232	0.150	1.000

TABLE XII—Object B

	I1	I2	I9	I11
I1	1.000			
I2	0.229	1.000		
I9	0.205	0.217	1.000	
I11	0.806	0.162	0.216	1.000

For the distinct objects, 120 cross comparisons are possible. It is noted that in contrast to the 32x32 study, the average M value is lower by half. The mean of the 105 entry M32 table is 0.122; the mean of the 120 entry M64 table is 0.061. Accordingly, a lower threshold for discrimination purposes can be selected; here T=0.056 is selected, where T=0.080 was used in the 32x32 case.

Tables XI through XIV exhibit subsets of Table X for four of the five object types. No table is needed for object type E since, as expected, none of the other objects produce a high M value when compared with I16, random noise.

Figure 11

Of the 25 comparisons shown, 22 succeed, but three fall below the threshold T. The three failures are all for I5. I5 is a vertical rectangle and matches are found for the other vertical rectangles, I7 and I12, but matches are not found for the horizontal rectangles I3 and I4, nor is a match found for the 45 degree rectangles, I10. The other vertical rectangles do find matches with the horizontal rectangles and the 45 degree rectangle.

There are, other than the 25 expected high M values, 11 cross object high M comparisons. Of these 11 false alarms, seven are for object type D. I13 is mistaken for vertical rectangles three times and once for a triangle; I14 is confused

twice for horizontal rectangles and once for the 45-degree rectangle. Clearly this algorithm is not suited for discriminating unequal arm crosses from other simple objects. The other four false alarms are triangle/rectangle mismatches.

It is satisfying to note that the circle/triangle discrimination problem encountered in the 32x32 case has in the 64x64 case gone away. All circles are detected, no circles are false alarmed. The other 84 M values of Table X are all less than T.

No attempt at minimizing execution time was made in programming. Execution time for the 32x32 SHAPE Program on a PDP-10 computer operating under the TENEX

operating system is approximately 17 seconds; the 64×64 SHAPE Program executes in approximately 23 seconds.

#### CONCLUSION

The performance of the SHAPE algorithm on these simple objects continues to be encouraging; additional investigation is intended.

#### ACKNOWLEDGMENT

Gratitude is expressed to Charles Sheffield who suggested the POLAR-Cartesian Transform for research.

# PM<sup>4</sup>—A reconfigurable multiprocessor system for pattern recognition and image processing\*

by FAYÉ A. BRIGGS, KING-SUN FU, KAI HWANG and JANAK H. PATEL

Purdue University  
West Lafayette, Indiana

## MOTIVATION AND OBJECTIVES

Pictorial information is often described by digitized arrays, syntactic (and semantic) strings and high-dimensional trees or graphs. The analysis and extraction of meaningful information for pictorial patterns by digital computers is called *pictorial pattern analysis*. Pattern analysis tasks require a wide variety of processing techniques and mathematical tools. In most machine intelligence systems, large computers are employed to process pictorial information. Because most image processing tasks require only repetitive Boolean operations or simple arithmetic operations defined over extremely large arrays of picture elements (pixels),<sup>1</sup> the use of large computers with rigidly structured sequential or parallel processors may result in intolerable waste of resources.<sup>2</sup> For example, the array-structured ILLIAC IV<sup>3</sup> and STARAN<sup>4</sup> are efficient for processing fixed-length vectors, but are very inefficient for mixed scalar and vector operations, due to the fact that multiple instruction streams do not exist simultaneously in these supercomputers.

In the application domain, explosive amounts of pictorial information need to be processed. For example, a single frame of LANDSAT imagery contains 30 million bytes of information and it takes 13 such images to cover the state of Alabama. What is even more demanding is that an entirely new set of imageries is produced for the entire earth surface every nine days. The conventional parallel computers are not tailored for such large-scale image processing. A computer system is demanded to maximize the utilization of parallelism embedded in repetitive image operations. A simple example may help to quantitatively justify such a need. Suppose that we are interested in performing the texture analysis of an image with size  $500 \times 500$  pixels. A  $10 \times 10$  pixel window size is selected. Assume that, on the average, ten assembly instructions are required to perform one texture analysis (neighborhood) operation. It then requires  $500 \times 500 \times 10 \times 10 \times 10 = 2.5 \times 10^8$  instructions to analyze the whole image. For a computer system with one MIPS, it will take  $2.5 \times 10^8 / 10^6 = 250$  sec. = 4.17 min. to perform each texture analysis operation on the whole image. An increase of

machine speed to 100 MIPS will reduce the time required to perform one texture analysis operation to 2.5 seconds. Similar examples can be easily found in cluster analysis and statistical classification of high-dimensional pattern recognition problems.

To meet the needs of the 80s or beyond, a versatile computer system must be able to execute more than 100 MIPS with a memory bandwidth of 256 megabytes or greater. With the rapidly growing IC technology, it is now possible to consider the use of a large number of microprocessors as the processing elements of a computer system for pattern recognition. This system will derive its high performance by the multiplicity of processing elements and the high level of concurrency of processing.

In this paper, we report a powerful computer system that is currently under development at the Advanced Automation Research Laboratory (AARL) of Purdue University. The system consists of hundreds of LSI bit-slice microprocessors with a large number of shared memory modules and flexible interconnection networks for efficient image processing and pattern recognition applications. The system is designed to be able to reconfigure its resources under system control to assume four different operation modes—SIMD, MIMD,<sup>2</sup> multiple SIMD and distributed mixed modes. Fast interactive I/O and large image data base are incorporated into the system. Cost effective system architecture and wide range of applications are the main development concerns.

An overview of various existing special computer architectures for pattern information processing can be found in Fu.<sup>5</sup> The system presented here offers a relatively new architectural configuration with high application flexibility and high system throughput at only a moderate system cost.

## THE PM<sup>4</sup> SYSTEM ARCHITECTURE

The architecture of the Purdue Multi-mode Multimicroprocessor (PM<sup>4</sup>) system grew from a consideration of existing system organizations like the C.mmp<sup>6</sup> ILLIAC IV and Cm\*.<sup>7</sup> We wanted a system that would reconfigure itself to execute MIMD or SIMD processes. In fact, the flexibility was extended so that the system can be partitioned into groups of processors which may be assigned to different

\* This work is partially supported by the National Science Foundation Grant ENG 78-16970.

SIMD processes. Hence, multiple SIMD (MSIMD) and MIMD processes can be in execution concurrently. Moreover, since we wanted dynamic system reconfiguration of resources and high level of concurrency of processes, each processor would be designed to handle such system requirements. The reconfiguration is mostly software controlled. This architecture differs from the restructurable computer system proposed in Reference 8 or the partitionable multiprocessor system discussed in Reference 9 in many aspects, as will be seen shortly. The architecture of the PM<sup>4</sup> was configured by considering some of the major problems involving multiprocessor systems as discussed in Reference 10.

The basic components of the PM<sup>4</sup> consist of  $N$  identical Processor-Memory Units (PMU),  $K$  identical Vector Control Units (VCU), a three-level hierarchical memory connected by a set of interconnection networks and memory management units. Figure 1 shows a block diagram of the PM<sup>4</sup>. We

will give a brief description of each of the individual components and their interrelationship in the system.

The *Vector Control Units* (VCU) are used in the SIMD mode of operation. Each of these units has a microprocessor, a local memory (LM) which is managed by its own *Local Memory Management Unit* (LMMU) as shown in Figure 2a. The vector control instructions and program of an SIMD process are loaded into the VCU local memory prior to execution. When the SIMD process is ready-to-run, the VCU broadcasts instruction to all of the *Processor-Memory Units* (PMU) that are assigned to the SIMD process. The VCU may also send permutation function commands to the *Interprocessor Communication Network* (IPCIN) to permute the data in a group of PMUs. Furthermore, the VCU has the ability to *mask* or disable PMUs so that only the active or unmasked PMUs execute the broadcasted instructions.

Each of the PMUs consists of three functional units,

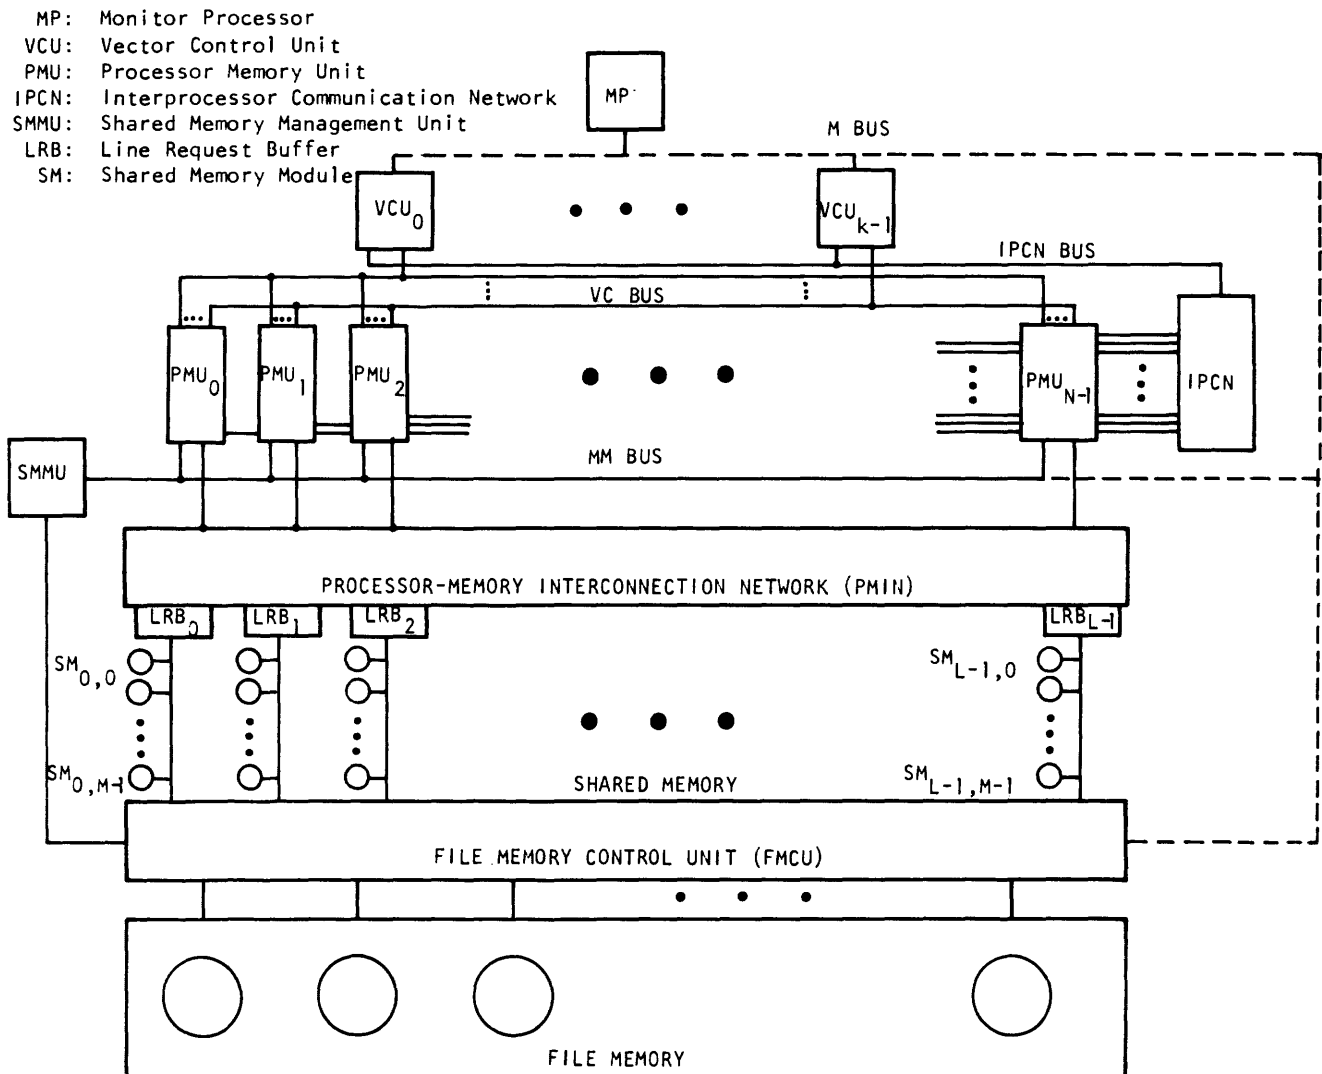

Figure 1—The PM<sup>4</sup> architecture.

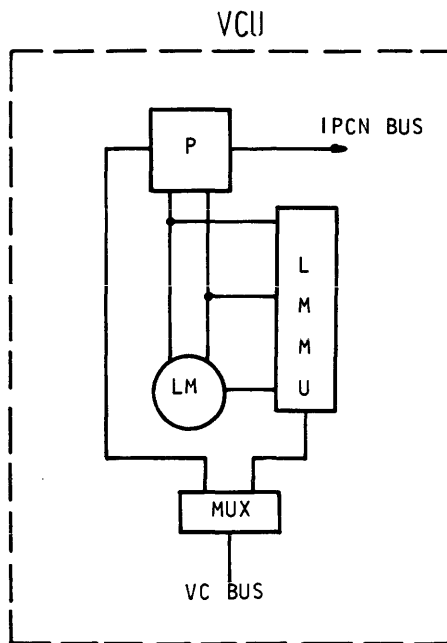

Figure 2a—Details of Vector Control Unit (VCU).

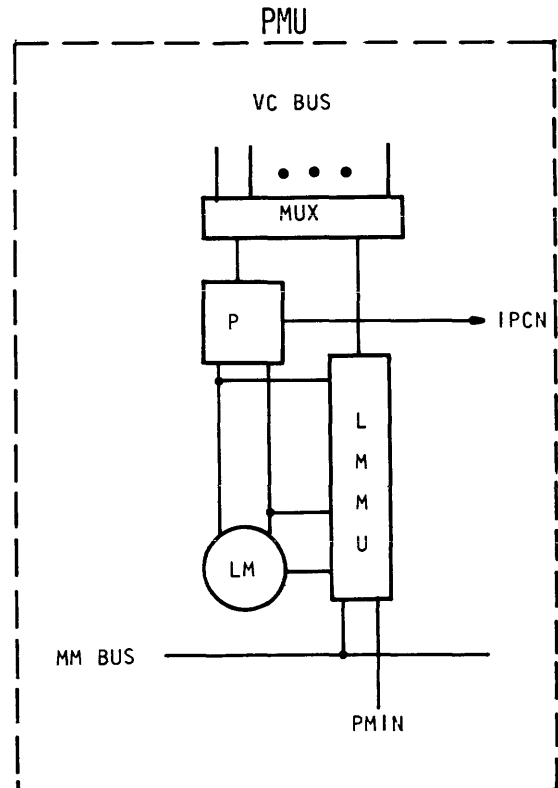

Figure 2b—Details of Processor Memory Unit (PMU).

namely, a microprocessor (P), a local memory (LM) and a local memory management unit (LMMU) as shown in Figure 2b. The LMMU in the PMU is similar to that in the VCU. Each local memory, which acts as a cache memory to its associated processor, is interleaved to allow it to meet the speed requirements of the high speed LMMU.

Both VCU and PMU operate under a virtual memory system and hence have hardware facilities to map virtual addresses to physical addresses. We have decided to implement each processor so that it can directly address all of shared memory.

The LMMU of the PMU is also used to load and unload the local memory of a PMU. Furthermore, it can also act as a channel to transfer a block of shared memory to any VCU memory that is associated with that PMU. Each LMMU in a PMU or VCU handles the page replacement policy for its local memory. In both cases, the transfer may be initiated by a command from the processor of the PMU to its LMMU. A multiplexer has been conveniently located between each PMU and the Vector Control busses to switch the signal path from any VCU to either the processor (P) or the LMMU of the PMU. Hence, the program for an SIMD process may be transferred from shared memory to the VCU's local memory through the LMMU of an assigned PMU. Moreover, during the execution of the SIMD process, the multiplexer can route the broadcasted instruction from a VCU to the PMU.

The Interprocessor Communications Network (IPCN), is used to implement permutation functions needed during execution of SIMD processes. This network permits concurrent permutation of data from multiple SIMD processes which are assigned to distinct subsets of PMUs to be performed simultaneously. The IPCN is controlled by the

VCUs over a time-shared bus and contains its own internal conflict resolution logic.

The *Shared Memory Management Unit* (SMMU) is connected to each LMMU of a PCU via the Memory Management (MM) Bus. The SMMU acts to control the use of the shared memory by communicating with each LMMU or the *File Management Control Unit* (FMCU) and effecting appropriate page replacement policy in the shared memory.

The *Processor Memory Interconnection Network* (PMIN) is used to transfer information between the shared memory and the LMMUs. Transfers are made in a *burst-mode* on this network. Hence, once a path through the network has been established, it is held (for the most part) until the transaction is completed. Further discussion on the PMIN is given in a later section.

The file memory control unit (FMCU) controls the transfer of information between the shared memory and the file memory. We defer the discussion of the shared memory to a later section.

For performance measurement purposes, we have incorporated a monitor processor (MP) to monitor the activities of the various modules of the system as shown in Figure 1. The information collected will be used to determine the operating characteristics of the system.

We have incorporated fault-tolerance capabilities into the architecture of the PM<sup>4</sup> by modularizing the system structure. This, for example, may permit a PMU or VCU to be logically isolated from the rest of the system once a fault is

detected in the unit. The logical isolation of a unit will permit its diagnosis to be carried out without appreciably affecting system performance.

### CHARACTERISTICS OF THE MICROPROCESSORS

The processors used in the multiprocessor system must have certain desirable characteristics in order to handle the multi-modal requirements of the PM<sup>4</sup> system architecture. We have investigated the characteristics of existing LSI microprocessors such as the LSI 11, Intel 8086, Z8000 and Motorola 68000 only to find that they do not meet either our operating system requirements or they fall a bit short on our speed requirements. We will discuss some of the processor characteristics we find desirable in our system configuration. We feel that such processor requirements can be attained by using bit-slice microprocessors.

For swift reconfiguration of system resources, a processor must be capable of holding more than one active process state. Hence, the VCU and PMU are multiprogrammed. The degree of multiprogramming in the PMU is tentatively chosen to be four. Hence, the processor of a PMU should consist of four register arrays. Each register array may be used to hold the state of an active process. For example, one array may be assigned to the kernel of an operating system while the other three are assigned to user MIMD and SIMD processes. A register array which is designated for an SIMD process when the PMU is allocated to a VCU will retain the state of the SIMD process until the PMU is deallocated. The coexistence of SIMD and MIMD processes in a PMU will permit the switching of a current SIMD process to an active MIMD process, and vice versa, efficiently. Further studies will be needed to determine the degree of multiprogramming in the VCU which will be required to maintain a high level of concurrency efficiently.

Each processor of a VCU or PMU has a Status Output Register (SOR), the contents of which can be read by any other processor. Traps and interrupts are also needed to handle fault and communication problems. For example, a page fault from either VCU or PMU should cause a page fault trap which will abort the execution of the current instruction. The instruction may be re-executed when the page fault condition is resolved. In the case when the trap condition occurs in a PMU which is assigned to a VCU for an SIMD process, the VCU is signalled to suspend its instruction broadcasting. Furthermore, all PMUs in that group will be interrupted to suspend the current SIMD process and switch to a ready-to-run MIMD process until the SIMD process is awakened. The context switching of processes can be performed, in this case, simply by modifying a *Current Process Pointer* (CPP) register in the PMU to point to a ready-to-run MIMD process whose process state is resident in a register set of the PMU.

Note that when an SIMD process is suspended due to, say, a page fault, the PMU group is still allocated to the suspended SIMD process. When the VCU is ready to resume its suspended process, it may do this by broadcasting an instruction to the allocated PMU group. If the PMU is

within an instruction cycle of a current MIMD process when the vector instruction is broadcasted, it sets an internal VIP (Vector Instruction Present) flip-flop. Hence the broadcasted instruction may be asynchronous with respect to a group of PMUs. The VIP flipflop is checked at the end of the instruction cycle if the PMU is allocated to an SIMD process. If the VIP is set, the CPP register may be modified to point to the state vector of the resumed SIMD process which is resident in the processor of the PMUs. Further, it puts the processor in the instruction fetch state in order to receive the broadcasted instruction.

When a processor of a PMU is executing broadcasted instructions in the SIMD mode, an instruction completion signal is sent to the associated VCU at the end of each instruction cycle. This will permit the VCU to broadcast the next instruction to the PMUs. In general, instruction fetch and execution may be overlapped in both the VCU and PMU by prefetching the instructions in both SIMD and MIMD modes. We are currently investigating some other characteristics of the processors.

### MEMORY HIERARCHY

The memory hierarchy consists of three levels of memory. The highest level of memory are the local memories in the Vector Control Unit (VCU) and the Processor-Memory Unit (PMU). The next level is the shared memory that is shared by all the processors in the system. The lowest level is the file memory which is essential for the data base. Generally, the higher the level of the memory, the faster is its speed, the higher is its cost per byte and the smaller is its capacity. Transfer of information between adjacent levels of memory in the hierarchy is entirely controlled by activities in the first level. The first level in this case consists of the set of VCUs and the set of PMUs. However, this does not imply that the memory access times for the local memory in the VCU is identical to that in the PMU.

One of the advantages of the hierarchical memory organization is that the working set<sup>11</sup> of a process accumulates rapidly in the fastest level. Hence, accesses to memory words in a process are completed at nearly the speed of the local memories, but the total cost of the storage system approaches that of the lowest level. Another advantage is that the mechanism which effects the transfer of pages between adjacent levels of memory can be readily implemented with very little intervention by the operating system.

The local memory of a PMU or VCU acts as a "cache" memory to its local processor. The wide usage of cache memories has shown that a process' memory references tend to cluster in a small portion of its address space in a space-time window.<sup>12,13</sup> Each local memory is logically partitioned into several pages which is large enough to hold the working sets of the several active processes. The local memory also has the appropriate hardware to keep track of the usage of each page. This information may be collected by the Local Memory Management Unit (LMMU) and used to implement the page replacement policy.

The shared memory uses a buffered version of the L-M

memory organization studied by Briggs and Davidson.<sup>14</sup> This memory consists of  $l$  memory lines and  $m$  memory modules on each line. A line refers to a bus within the shared memory. Each memory module has an address and data latch so that the address cycle (hold-time),  $a$ , is much shorter than the memory cycle time,  $c$ . Hence, if  $a=1$  and  $c=4$ , four memory requests can be in different stages of the service concurrently on the same line, thereby increasing the memory bandwidth without increasing the cost of the PMIN. Multiple-access conflicts which occur when simultaneous (parallel) requests reference the same line are resolved in the PMIN as discussed in the next section.

In our studies, we assume that the number of lines,  $l$ , is equal to the number of parallel PMUs,  $N$ , so that the cost of the processor memory interconnection network (PMIN) will be kept to a minimum with respect to  $l$ .

Each line has a Line Request Buffer (LRB) which buffers and resolves the conflicts of the memory requests made to modules on the same line. The LRB may subsequently issue the request to a referenced memory module which is idle, and initiate a return path through the PMIN for the referenced data. A memory request for a page can be made to the LRB which will eventually generate the series of sequential accesses required to retrieve or store the requested block. Furthermore, the LRB may be interrupted by the File Memory Control Unit (FMCU) when it performs DMA (direct memory access) transfers between shared memory and file memory.

The performance of the L-M organization was discussed in Reference 15 for the nonbuffered requests with random address references. The analysis of the buffered requests is currently being investigated, but intuitively the implementation of block transfers on such an organization would result in a higher memory bandwidth than discussed in Reference 15.

The file memory is a very large data base and backup for the programs and data in the system.

INTERCONNECTION NETWORKS

Several communication paths exist between different components of the PM<sup>4</sup> system. A glance at the block diagram of Figure 1 shows the explicit connections between vector control units (VCUs) and the processors. Other principal connections shown simply as black boxes are inter-processor communication network (IPCN), processor-memory interconnection network (PMIN), and the implied connection in the file-memory control unit (FMCU). Of these three networks the connection in the FMCU is the simplest and the least demanding of all. For these reasons, a single high-speed time-shared bus is chosen as the communication path between the shared memory and the file memory due to the slow transfer rates of the file memory. The other two networks, namely, PMIN and IPCN, are quite complex and if their design is not properly chosen these networks can either become the bottleneck of the system or they can become the most expensive parts of the whole system.

For processor-memory interconnection (PMIN) we have

Figure 3—An 8x8 delta network.

investigated the delta networks.<sup>16</sup> These networks are easy to design and control. The networks use 2x2 crossbars as the basic building blocks. The logic for arbitration between conflicting requests is distributed throughout the network. A connection between a processor, LMMU, and a shared-memory module is established at the request of the processor which sends the address of the requested module on the control lines. This address acts as the pathfinder through the network and the path is established locally at each 2x2 crossbar module. Each module requires a single bit from the address to establish a path, thus the control is completely distributed. An example of an 8x8 delta network is shown in Figure 3. The 2x2 modules used are sketched in Figure 4. The complexity of a  $N \times N$  delta network grows as  $N \log_2 N$

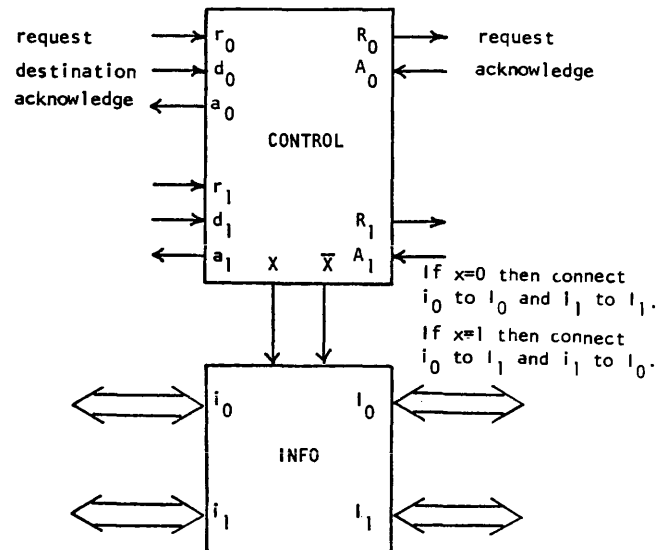

Figure 4—Details of 2x2 modules for delta networks.

as opposed to  $N^2$  for a full crossbar. However, the bandwidth of the delta network, assuming completely random requests, is not substantially less than that of crossbars. For example, for a delta network of size  $256 \times 256$ , the expected bandwidth is 77 requests per memory cycle; for a full crossbar of the same size the bandwidth is 162; however, the crossbar costs about 20 times as much as delta. Once a path between a processor and a memory module is established, the words can be transferred at a continuous rate without any conflict. Thus, every subsequent word transfer does not suffer the initial delay to establish a path, and, therefore, the effectiveness of a delta network is higher in the block transfer mode than in single word transfer mode. We will study the use of delta networks to do block transfers between the processor memory and the shared memory, where a block may consist of 64, 128, 256 or 512 bytes.

The interprocessor communication network (IPCN) is still under investigation. When it is finally designed, it will have the following characteristics.

The network will be of low cost, recirculating type. The design will be such that the permutations most frequently used in an SIMD environment can be generated in a single pass through the network. Other less frequently used permutations may require several passes. Furthermore, the network will be partitionable in fixed-size blocks so that several small size independent SIMD operations may be executed in parallel. For example, a network of size  $64 \times 64$  can be partitioned into four networks of size  $16 \times 16$ , and each of these networks will be partitionable into two networks of size  $8 \times 8$ . To reduce the cost and delay, arbitrary partitions will not be implemented. Again for cost reasons, the network will not necessarily be of the same dimension as that of  $PM^4$  system. For example, if we build the system with 256 processors, we may have an IPCN of size  $64 \times 64$ . The design and cost performance trade-offs of the IPCN will be reported at a later date.

## PARALLEL PROGRAMMING LANGUAGES

In order to have an operational  $PM^4$  system, a multiple mode operating system must be developed for the multiprocessor system. The resident UNIX system in PDP 11/45 is currently under extensive revision at Purdue to handle the following four operation modes of  $PM^4$ . Special high-level programming languages for parallel processing need to be developed, most probably by extension of the C-programming language or the concurrent PASCAL<sup>17</sup> or APL. The parallel programming language will provide the user the power to exploit the full capacity of the system. This will include vector operations (SIMD mode), and two or more distinct vector operations in parallel (Multiple SIMD mode). MIMD mode will permit concurrent execution of several scalar processes and distributed mixed mode allows part of the  $PM^4$  system to operate as an SIMD computer and part as an MIMD computer. The user will not be burdened with the layout of the vectors in the memory, or the allocation, deallocation and synchronization of processors.

The four fundamental operation modes of  $PM^4$  and the

corresponding user programming requirements are briefly described as follows:

1. *SIMD Mode*—Vector instructions with *Single Instruction Stream and Multiple Data Streams* (SIMD) must be explicitly declared by user's programs. The compiler is responsible for the layout of vectors and the VCU is responsible for broadcasting the instructions. The VCU executes control or non-vectorized instructions without passing them to the PMUs. In this mode, each SIMD vector statement is executed in parallel, but subsequent vector statements are executed sequentially. In other words, no multiple SIMD statements can be simultaneously executed as demonstrated.

**Example 1:** Consider the use of a 32-processor  $PM^4$  system for SIMD operations.

```
Begin
Integer Vector A, B, C [0:31];
Real Vector X, Y, Z [0:31];
Integer I, J;
:
A ← I*B + C;
X ← Y + (Z/2);
:
End
```

2. *Multiple SIMD Mode*—In this mode, multiple number of SIMD operations are executed in parallel. With a 64-processor system, typical Multiple SIMD instructions may assume the following form. In this example, A, B, and C can be considered to be arrays of 128 vectors each, where a vector has 16 elements. Similarly X, Y and Z are arrays of vectors with 32 elements in each vector. The notation  $X[I,*]$  signifies a vector:  $X[I,0], X[I,1], \dots, X[I,31]$ .

**Example 2:**

```
Begin
Integer Vector A, B, C [0:127, 0:15];
Real Vector X, Y, Z [0:127, 0:31];
:
Parbegin
For I=0 until 127 do
A[I,*] ← B[I,*] + C[I,*],
For J=0 until 127 do
X[J,*] ← Y[J,*] + Z[J,*],
:
Parend
End
```

The two vector processes between the *parbegin* (parallel begin) and *parend* (parallel end) may be executed simultaneously by two VCUs in this mode.

3. *MIMD Mode*—*Multiple Instruction streams and Multiple Data streams* (MIMD) operations are the most generalized parallel programs. Each individual instruction stream must have a sequence of scalar operations. These parallel processes may be interdependent. System deadlock would be a major problem to be solved for MIMD operations. Vector instructions may not ap-

pear in strict MIMD mode, but may appear in the mixed mode to be described in 4.

**Example 3:**

```
Parbegin
  Subprocess 1,
  Subprocess 2,
  :
  Subprocess n,
Parend
```

4. *Distributive Mixed Mode*—In this mode, SIMD vector instructions and parallel MIMD processes are simultaneously executed as declared by the following statements.

**Example 4:**

```
Parbegin
  A ← B + C,
  X ← Y * Z,
  Subprocess 1,
  :
  Subprocess n,
Parend
```

} SIMD mode

} MIMD mode

The above operation modes are only the fundamental ones to be implemented. There are many combinations of the above modes. Only after we implement the basic modes can we challenge the implementation of more sophisticated operation modes to upgrade the system throughput and enhance its flexibility.

Special system control instructions must be developed to make the above operations possible. Listed below are several typical system command instructions that may be implemented in the system.

1. INITIALIZE—Set the program counters of allocated processors to specific values.
2. SYNCHRONIZE—Put the allocated PMUs in the WAIT or FETCH state.
3. Vector issue, mask, routing, etc.
4. Memory management, interrupts and I/O commands, etc.

For special parallel-processing applications, such as multiple-frame image processing or pattern classification, special programming or query languages must be developed to handle the very large scale data bases. There always exists a trade-off between the complexity of user programming language and the operating system capabilities.

## OPERATING SYSTEM REQUIREMENTS

The operating strategy for the PM<sup>4</sup> system has to be decided from the following choices:

1. *Multiprogramming* versus *uniprogramming* on vector control and processor-memory units.
2. *Distributed* versus *dedicated* processor operating system.

Based on the architectural features of PM<sup>4</sup>, a *Distributed Multiprogramming Operating System* (DMOS) is under development for the PM<sup>4</sup> machine. The DMOS system will be developed based on operating system design trade-offs of existing MIMD machines such as the C.mmp Hydra,<sup>18</sup> the CM\* operating system.<sup>19</sup> We will also consider the incorporation of some of the operating system aspects of multiple SIMD machines proposed by Nutt for the MAP system<sup>20</sup> and the DIMO for the DAMP system discussed in Hwang and Ni.<sup>21</sup>

The DMOS is to handle all the four operation modes described in the preceding section with emphasis on multiple SIMD and MIMD modes. We have considered the case in which the operating system is distributed over all PMUs. Each PMU contains a local kernel operating system which resides partly in its local memory and partly in shared memory. This kernel will be used for scheduling of MIMD and SIMD processes as well as supervising the execution of MIMD and component vector processes.

In the DMOS system, the processes are scheduled to processors on the basis of processor availability and its workload. In addition, the availability of other system resources demanded by the processes will influence the process scheduling algorithm. However, we have investigated a vector or SIMD process scheduling procedure that is flexible. In this case a PMU, which is a temporary *master* scheduler, schedules the vector process to an available VCU. In the following illustration we assume that the VCUs are uniprogrammed systems and the PMUs are preemptible. Hence a vector process always has a higher priority over a user's MIMD process in being assigned to a PMU.

Let us assume that a vector process which was allocated to a (VCU<sub>*i*</sub>, S<sub>*j,k*</sub>) pair has just been completed. S<sub>*j,k*</sub> is a set of 2<sup>*k*</sup> consecutively numbered PMUs starting at PMU<sub>*p*</sub>, where *p* = *j* · 2<sup>*k*</sup>, for *j* = 0, 1, 2, . . . and *k* is a nonnegative integer. For example, S<sub>4,3</sub> = {PMU<sub>32</sub>, PMU<sub>33</sub>, . . . , PMU<sub>40</sub>}. Furthermore, assume that there exists a PMU<sub>*m*</sub> ∈ S<sub>*j,k*</sub> which is a master for the S<sub>*j,k*</sub> group of PMUs. The completion of the old vector process causes PMU<sub>*m*</sub> to search the vector process queues (VPQ<sub>*i*</sub>s) (which may reside in SMMU) for a *schedulable process*. A vector process of vector size, *V*, is schedulable if it is independent or if all the dependencies for that process have been satisfied. The schedulable process is scheduled by the PMU<sub>*m*</sub> to VCU<sub>*i*</sub> if there exists a set, S<sub>α,β</sub> of PMUs which is not currently allocated to an SIMD process and consists of 2<sup>*β*</sup> PMUs such that β = ⌈log<sub>2</sub> *V*⌉. If the vector process is scheduled to VCU<sub>*i*</sub>, PMU<sub>*m*</sub> requests allocation of processors in S<sub>α,β</sub> for the new SIMD process by transmitting the request signal to the processor via the MM bus as shown in Figure 2. Of course, such a scheduling process would be implemented as a *critical section*.<sup>22</sup>

The PMU<sub>*m*</sub> also gives the processor in S<sub>α,β</sub> the necessary information to load-in the multiple data streams required for the SIMD process into their respective local memories. While these PMUs are being loaded with their data, the PMU<sub>*m*</sub> may also initiate the loading of the program segment of the SIMD process through its LMMU to the VCU<sub>*i*</sub>'s local memory. After the loading of VCU<sub>*i*</sub> is complete, the PMU<sub>*m*</sub>

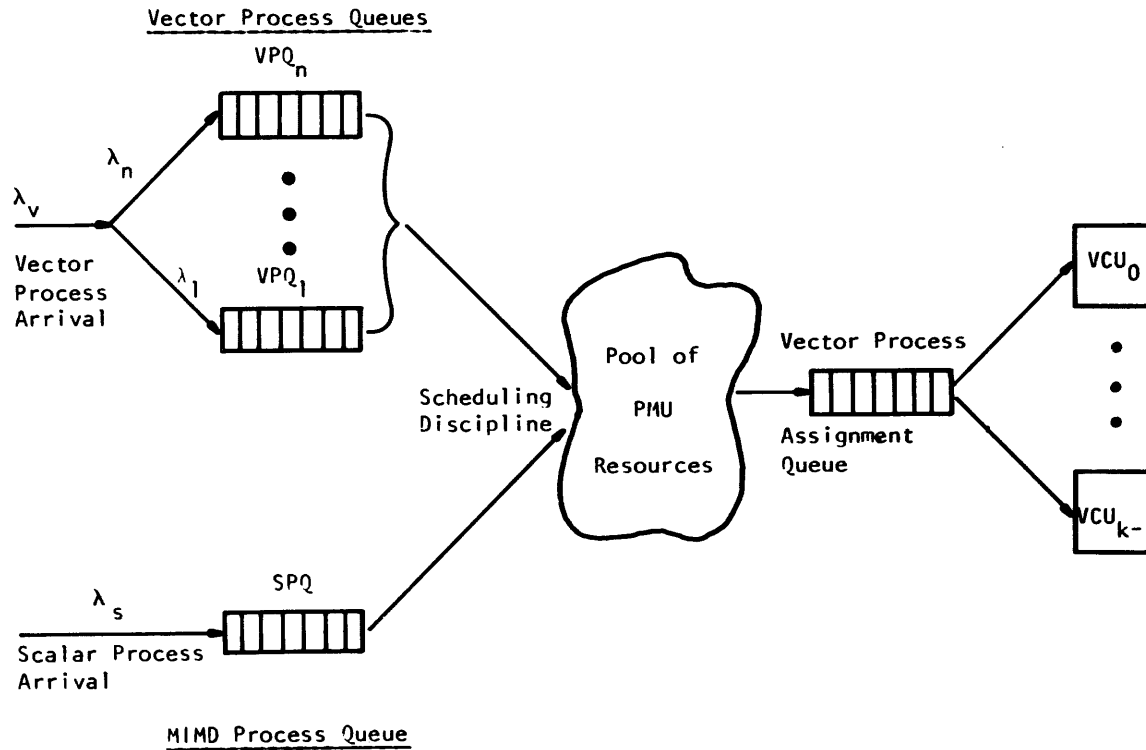

Figure 5—Queuing model for performance evaluation of scheduling disciplines.

may assign any  $PMU_n$  in  $\mathcal{S}_{\alpha,\beta}$  as the new master of  $\mathcal{S}_{\alpha,\beta}$ . Henceforth, the current master,  $PMU_n$ , will coordinate and monitor the activities of  $VCU_i$  and handle page fault traps from  $VCU_i$ . Notice that the loading of multiple data streams in  $\mathcal{S}_{\alpha,\beta}$  may be overlapped with MIMD process execution in these processors. Now the new pair  $(VCU_i, \mathcal{S}_{\alpha,\beta})$  is allocated to execute the new SIMD process.

In case a vector process is not scheduled because of the unavailability of an appropriate sized  $\mathcal{S}$  group of PMUs, the master of the next set of PMUs released may check the vector process queue for the schedulability of a vector process. However, if the VP queues are empty, any PMU not currently assigned to an SIMD process may periodically check the VP queues for a process. Alternately, if an empty VP queue becomes non-empty it may signal PMUs not assigned to an SIMD process for service.

Figure 5 shows a typical queuing model which may be used to study the performance of various scheduling disciplines for SIMD and MIMD processes in the PM<sup>4</sup>. In this diagram,  $VPQ_i$  is a queue which buffers vector processes that require a set of  $2^i$  PMUs for their execution.  $SPQ$  is a queue which buffers MIMD processes. Each process may have tags that will indicate the dependency of the process on another.

Control and scalar instructions in an SIMD process are executed directly by the VCU with no need to broadcast them to the PMU. However, some information may be broadcasted to the PMU during such executions to inform the PMU of current activities in the VCU. During the execution of a sequence of vector instructions, the VCU may

issue a MASKing instruction to select the necessary subset of PMUs among the PMU group allocated to the VCU. Only the masked (enabled) PMUs will execute the broadcasted instructions while the remaining allocated PMUs can continue executing their resident MIMD processes. A DEALLOCATE or RELEASE instruction is needed to release part or all of the allocated PMUs when the SIMD process or subprocess is completed.

Figure 6 illustrates a simplified state transition diagram for each PMU assuming the VCU is operated in uniprogramming mode. States  $\phi$ ,  $K$ ,  $V$  and correspond to the PMU being idle, executing a kernel process, vector process or an

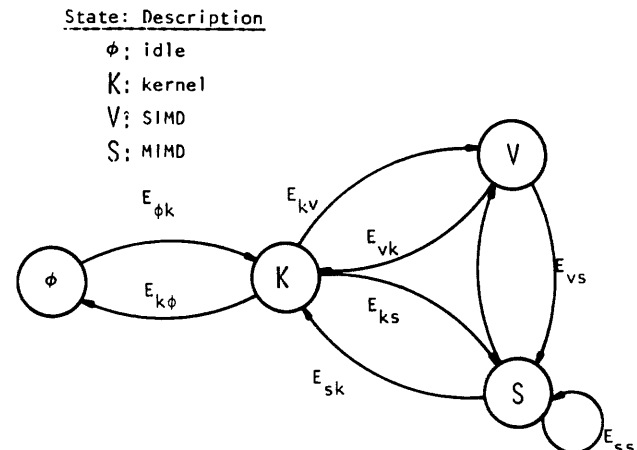

Figure 6—State transitions in PMU for SIMD and MIMD modes.

MIMD or Scalar process respectively. The events which trigger the state transitions are listed below.

- $E_{\phi_K}$ —Arrival of a new process
- $E_{K\phi}$ —Departure of a last process in PMU
- $E_{KV}$ —Vector process initiation on allocated PMU
- $E_{VK}$ —Trap condition in SIMD process
- $E_{KS}$ —MIMD process scheduled
- $E_{SK}$ —Trap condition in MIMD process
- $E_{VS}$ —Suspended SIMD process causes process switch to MIMD
- $E_{SV}$ —Process switch to ready-to-run SIMD process
- $E_{SS}$ —Process switch from one MIMD process to another

It is expected that the utilization factors of the PMUs will

be high if we assume that deadlock problems are eliminated in this multi-mode multiprogrammed operating system.

APPLICATION AREAS AND COMPUTATIONAL TASKS

The PM<sup>4</sup> system was designed for the following applications. Both statistical and syntactic methods<sup>23,24</sup> are to be used in image enhancement, feature extraction, picture segmentation, pattern recognition and scene analysis.

1. Industrial automation (automatic assembly and inspection)
2. Medical diagnosis of X-ray pictures and cytology analysis

TABLE I.—Computational Tasks Required for Various Application Problems in Intelligent Systems

Image Processing & Pattern Classification Problems	Typical Computational Tasks											
	Image Registration	Image Restoration	Image Enhancement	Image Coding	Image Segmentation	Feature Extraction	Pattern Classification (statistical)	Clustering Techniques	Parsing of string or Tree Languages	Error Correcting Parsing	Graph Matching	Computer Graphics
Solving Linear System of Equations	X	X					X	X				X
Solving Nonlinear System of Equations		X					X					
Matrix Multiplication and Inversion	X		X		X		X				X	X
Polynomial Evaluation		X		X	X		X	X				
Nonlinear Mapping		X	X									
Interpolation Methods	X	X										
Iterative Relaxation Methods		X			X			X				
Transformation & Convolution Methods	X	X	X	X		X						
Linear and Non-linear Programming		X					X					
Searching & Sorting			X		X	X		X	X	X	X	
Counting, Backtracking & Estimating						X		X	X	X	X	
Graph Operations					X			X	X		X	X

3. Remote sensing of LANDSAT pictures
4. Automated cartography and stereo compilation
5. Target identification and change detection
6. Computer vision and three-dimensional scene analysis
7. Recognition of human faces, fingerprints and hand-written characters
8. Speech recognition and understanding
9. Pollution control, archaeology and socio-economics

Typical computational tasks associated with above application problems are summarized in Table I. Both numerical and combinatorial (syntactic) algorithms need to be efficiently implemented. An illustrative example is given here to show the advantages of using parallel processing in syntactic pattern recognition and image analysis.

It has been demonstrated that tree languages are efficient in describing and analyzing two-dimensional pictorial patterns.<sup>25</sup> Application examples include classification of bubble chamber events,<sup>26</sup> fingerprint identification,<sup>27</sup> texture analysis<sup>28</sup> and recognition of objects of LANDSAT images.<sup>29,30</sup> In order to effectively analyze noisy and distorted images, the use of error-correcting tree automata has been suggested.<sup>30,31</sup> The price to pay for the error-correcting capability in image analysis is the increase of computation time. However, with a parallel processing computer system, such an increase of computation time can be easily reduced. An SIMD parallel parsing algorithm for tree languages has been recently proposed.<sup>32</sup> Computer simulations based on the analysis of five tree languages  $L(G_1)$ ,  $L(G_{22})$ ,  $L(G_{34})$ ,  $L(G_{38})$ ,  $L(G_{68})$  (one for highway recognition is a LANDSAT image and four for texture analysis, with a window size of  $9 \times 9$  pixels) have produced the interesting results shown in Figure 7. Furthermore, since all the windows in an image are independent in this problem, they can certainly be proc-

Figure 7—Speed-up for a  $9 \times 9$  window.

Figure 8—Speed-up for 100 windows.

essed in parallel to improve the processing speed. With 100 window patterns processed in parallel, the speed-up of highway recognition ( $L(G_1)$ ) result is shown in Figure 8. It is noticed from Figures 7 and 8 that either the parallel parsing of tree languages or the parallel processing of image windows would result in significant speed-up of computation time in image analysis and recognition.

#### ACKNOWLEDGMENT

We would like to extend our appreciation to Richard W. Bishop for his direct contributions to the PM<sup>4</sup> architecture.

# Transportable image-processing software\*

by R. G. HAMLET and A. ROSENFELD

*University of Maryland*  
College Park, Maryland

## INTRODUCTION

The computations of image processing, like those of many technical disciplines, require substantial programs to perform. These programs are often organized into "packages" with the intent of making them easy for the (computer) novice to use. Access to a package of programs is an important resource, since its creation is beyond the capabilities of all but a few research groups. Unfortunately, while packages are invaluable, they could often be improved in the following ways:

1. They could be easier to use. The intellectual task of communication with the package is too difficult, the commands too peculiar and errors too easy to make. When things go wrong, very little help is available.
2. They could make more efficient use of the underlying machine and its operating system. A package may use very sophisticated algorithms for its discipline-oriented operations, while at the same time using the most cumbersome mechanisms for controlling the resources of the machine. Its authors are seldom systems programming experts.
3. They could be easier to move from machine to machine. In the process of getting the package to work at all, many peculiarities of the programming language (in its local implementation) and the local system become entwined in the code and getting it to run elsewhere may be difficult or impossible.
4. They could be easier to understand, modify and extend. To add a new routine or alter the behavior of an existing one may not be too difficult for the program's author, but for others it may be impossible. If many changes are made independently, combining them without conflict is difficult.

Improvements in package programs must resolve the conflict between quality (Items 1, 2 and 4) and transportability (Item 3). Here, "transportability" is to mean more than the ability to export software from a development site to many others. We have in mind a software system moving freely

among research groups using a variety of machines, in which modifications arise simultaneously in several places. In this situation the structure of the programming package is all-important—it must be rigid enough to support changes that conform to the style of the original; yet, changes must be easy to make. In the research environment no single group can long afford to maintain and support a large, changing system, so the system must be so constructed as to take care of itself.

Although the scheme presented here applies to many kinds of packages, it is designed to support image processing. From a systems point of view, this means that the computations of the package are characterized by a short interchange of control information with a human user, which determines the amount of resources needed (and these vary greatly), followed by operations that are either input-output limited, or in which there is little overlap between input-output and computation. This rough characterization is used to decide the compromise between quality and transportability.

In the sections to follow, we assume that transportability is a requirement, then attempt to find a way to attain it with the smallest loss of quality. The second section considers the programming language to be used; the third section deals with the operating system and program organization is the subject of the fourth section.

## PROGRAMMING LANGUAGE

Even a cursory survey of existing computers shows that FORTRAN is the only programming language with a standard, widespread implementation. FORTRAN is widely implemented partly because it is already so popular, but also because it was designed to fit the von Neumann architecture, still in widespread use. Most FORTRAN implementations "extend" the ANSI standard of 1966<sup>1</sup> in some (nonstandard) way; of course, these extensions are not transportable.

The deficiencies of FORTRAN are widely recognized, but they are largely the other side of the transportability coin—the language allows no control of computer resources; except for the ability to write arithmetic formulas, it is not very high-level and the facilities for separating, protecting and centralizing information are minimal. If a modern language designed with software engineering in mind were

\* This work was partially supported by National Science Foundation Grant MCS 77-18719.

widely available, its programs could be moved more easily than FORTRAN programs can be. For example, a language like Alphard<sup>2</sup> produces programs that are easy to move. The kicker is that Alphard compilers (when there are some) can be expected to be very difficult to implement on a variety of machines, since the compiler (and its run-time support) must make up the gap between the machines and the transportable programs.

The history of digital computers certainly shows that it is foolish to await the rapid spread of good ideas—somehow the bad ideas wind up cheaper—so there seems little danger in making FORTRAN work properly rather than waiting for (say) Pascal.<sup>3</sup> Furthermore, an ambitious language may never spread to the range of machines on which FORTRAN already exists. Major vendors will have to deal with better languages; many mini- and micro-processor systems may never support them. We thus consider how FORTRAN can be tamed and transported.

RATFOR<sup>4</sup> is the most popular version of structured FORTRAN. It has the virtues of a published definition and a partial inverse processor.<sup>5</sup> Perhaps it should have been designed with one less iteration construct and one more conditional construct, but its wide acceptance more than compensates for such matters of taste. If we specify RATFOR as the implementation language for a transportable package, we must consider the transportability of RATFOR itself. Although the preprocessor exists for many machines, that is not sufficient. Minor variations result from conflicts between the definition<sup>4</sup> and its presentation in a text<sup>6</sup> and from an unfortunate choice of delimiting characters unavailable on many machines. The solution is evidently to transport RATFOR along with the package, and the techniques for doing so are well developed.<sup>7</sup> RATFOR is written in RATFOR, and once any preprocessor exists, a pure FORTRAN version is available, for use on any machine. (It is tempting to use this mechanism to extend RATFOR, for example, to include a fancy macroprocessor;<sup>8</sup> we judge that the departure from the published standard is not worth the power gained.)

Even with a universal RATFOR available, there may be difficulties in transporting programs and difficulties in writing them, because RATFOR is a "permissive" translator—most of a source is never examined, but simply passed along to FORTRAN. There are three difficulties:

1. Errors in the source are first detected by the FORTRAN compiler, and difficult to relate back to RATFOR.
2. Nothing prevents the FORTRAN imbedded in the RATFOR structure from being machine-dependent, so that although it gets through compilation on a machine, it will not run properly.
3. RATFOR makes no attempt to eliminate a number of legal but error-prone constructs in FORTRAN, notably involving undeclared variable names and inconsistencies in usage. These usually result in strange run-time behavior.

Difficulty (1) is more annoying than fundamental; the oth-

ers can be eliminated without compromising transportability, by a mechanism similar to preprocessing—the RATFOR source can be checked for problems before being translated, compiled and run. The PFORT verifier<sup>9</sup> is a tool of this kind that attacks Problem 2—it checks that the FORTRAN does not go outside the 1966 ANSI subset and that certain machine-dependent tricks are not used.

There is one transportability problem of any word-oriented language that PFORT makes no attempt to solve, that of numeric precision in the presence of different word sizes and arithmetic algorithms. Techniques have been devised to attack this difficulty,<sup>10</sup> but for the purposes of many packages, it is sufficient to trust the mathematical subroutine library of the target computer.

Problem 3 remains. For all that programmers try to keep usage consistent, mistakes are easy to make. In FORTRAN, a well-meaning programmer cannot see if his intentions were carried out. Since most of the errors that we want to detect occur across the boundaries of separate compilations, checks must operate on the complete package of subprograms as a single source. It is convenient to distribute a package as a single file on magnetic tape, so the preprocessor that goes with it should divide the routines for separate compilation and checking can then be done on the composite source. The following seems a minimal set of operations, and its implementation is no more difficult than building an identifier scanner coupled with a symbol table of usages:

- a. Check for declaration of all variables and observance of conventions in variable names. (The latter is necessary to avoid conflict in libraries.)
- b. Check for consistency across subprograms—argument counts and types, COMMON sizes and types, etc. More restrictive conventions can be enforced here; for example, one can forbid potential side effects.
- c. Prepare a cross-reference table for all symbols of the composite program, listing usage and location in the source. (This can be helpful in decoding FORTRAN-generated error messages.)

Writing in RATFOR according to a set of conventions, then checking for those conventions before preprocessing and compilation, is almost as pleasant as programming in a modern language. On many systems it is more cumbersome, since several programs are involved in a sequence, but the payoff in debugging time saved is excellent.

## OPERATING SYSTEM INTERFACE

FORTRAN's deficiencies as a low-level language—its inability to get at this or that machine feature—have always been supplied by a "few little assembler routines." As operating systems have grown and excluded regular programs from direct manipulation of shared resources, the most valuable machine instructions have become the system service calls. Since shared resources are scarce, a program that makes intelligent use of operating system service calls can

run more efficiently than one that does not. Two obvious examples are

1. A program that calculates an optimal memory allocation will give better response at less cost than one which runs with the largest space it might ever need.
2. A program that knows its pattern of record requests on a file can seek these records more efficiently than can any standard access method.

Proper support services are available in almost every system, but in varied form. For transportability we need a standard FORTRAN-callable interface to system functions. This interface must be kept so small that its implementation on a new machine is easy. At the same time, there is a need to make operating system services easy to use, and to tailor them to the application. These conflicting needs can be resolved by separating the interface into two parts—a “kernel” and a “surround.”

In the kernel we seek the bare minimum of code, which we expect to be machine-dependent. The kernel is to be a collection of entry points that transmit essential system functions outward without regard for convenience of use. This kernel is always too large to best serve transportability, partly because there are many needed features. Part of its size results from seeking a set of features common to all systems—the smallest set may not be implementable in some cases. This factor also works against the quality of the kernel—it tends to mimic the worst system on which it must be implemented rather than the best.

Outside the kernel we disguise its awkward properties with another level of interface, the “surround.” The surround contains only machine-independent FORTRAN code. It is therefore appropriate to make its routines easy to use and not worry about their extent. The surround has the special property that although its calling sequences are fixed, and it is viewed as a part of the operating system interface, its code may be juggled in package conversion. In contrast, the kernel routines *require* modification to implement their standard calling sequences; in the package code outside of the surround the code is movable, and the calling sequences themselves are subject to alteration. It can happen that on some particular system one of the surround routines is easy to rewrite as a direct system call, with important advantages in efficiency. So long as the entry sequence is not changed this is encouraged, but no package user *needs* to make the change and it has no effect should the package be retransported.

#### *Functions supported by the kernel*

A detailed description of the interface kernel, with FORTRAN calling sequences and implementation hints for many machines, is presented in Reference 11; here we only indicate the necessary functions.

Random-access file operations form the heart of the kernel. It must be possible to create mass storage files, manipulate their names and protections and read or write them in

arbitrary-sized blocks in a true random-access fashion. The input-output operations themselves, and the file formats, should be at the lowest level the operating system provides, to minimize memory and processing overhead. Thus it is important that the operations move data directly to/from FORTRAN arrays without invisible buffering; where possible, the operations should be started and the calling FORTRAN routine permitted to continue, waiting for completion only when necessary. It is common to provide routines of this kind for FORTRAN use and the implementation is straightforward.

FORTRAN provides no memory control facilities. In image processing it is often desirable to calculate memory space required for a given picture (particularly for input-output buffers). The usual implementation of this scheme in FORTRAN uses “get” and “put” routines to move blocks of words out of and into dynamically allocated space. This is unsatisfactory because the overhead is high whenever the elements are addressed in small groups. It is much better to provide a single array whose addressing is efficient and which can grow and shrink as needed; in almost every system it is possible to place such an array in memory so that it can indeed change its real size.

Process control is needed in the kernel to support the open-ended programming techniques suggested in the sixth section. The minimum facility required is the ability for an executing program to “call down” another as its replacement, without the overhead of more than an input operation. In some systems implementation is difficult, but a variety of tricks exist.

The final portion of the kernel is concerned with user communication, in the form of cosmetic features and error control. Most systems can provide information such as the date and time. Of more importance are parameters such as the best record sizes to use for disk operations and the precision/storage capacities of machine words. Run-time information should include resource usage and limitations, particularly for memory. The more a package can find out about what is really happening in the underlying system, the better it can communicate with its human users about problems encountered in execution and the more efficient it can be. Error control is also important. Most errors are unexpected in the sense that they appear as failures at a very low level, and are then communicated up to be processed by the package code. The kernel must see to it that *all* errors are in fact handled in this way, and in some systems that can be very difficult, since the error appears first as an asynchronous interrupt. Something similar to PL/1's ON unit can usually be arranged, leading to cumbersome but complete control.

#### *Functions supported by the surround*

Serial file operations can be easily built on the random-access ones of the kernel and there is seldom any reason to rewrite these outside the machine-independent FORTRAN versions, since these can be better adapted to a package's needs than the usual serial routines of either FORTRAN or

most systems. For example, it is easy to specify a buffered scan through a file in which (say) every tenth record is actually read; or, a file can be reblocked to take advantage of the availability of large buffers.

The surround can also be used to eliminate functions from the kernel that cannot be accomplished on all machines. For example, if immediate-return input-output operations are impossible, placing the entries in the surround allows implementation of the starting operation as "start and wait" and waiting as "no operation."

Most interactive communication with package users can employ the FORTRAN formatted input-output package. The memory overhead of the format-scanner routines is high, however, so formatted i-o can be eliminated by including some functions in the surround.

### *Experience with two systems*

An operating-system interface has been implemented on two very different systems. The first is Univac 1100 Exec 8, an "old" system. The second is PDP-11 UNIX, which is about as "new" as operating systems come. The design philosophies of these two are also almost opposite—the Univac is very low-level, compensating for its deficiencies with large library packages; UNIX is designed to support high-level programs.

A technique designed to reduce the implementation effort was used for the kernel. On each machine a routine was written in assembler to provide FORTRAN access to the necessary system calls. For example, on Exec 8, one such call is for programmatic execution of a control statement; under UNIX one is for direct execution of another program. Neither system has the other's service; their different services are needed for a "change to new program" function of the kernel. Once these basic services are available, the interface routine to employ them is written in FORTRAN. The code is peculiar to one machine, but it is often easy to adapt to another. In the example, 30 lines of FORTRAN are common to both systems, the Univac routine has 20 extra lines setting up its peculiar system call, while for UNIX this takes only one line.

In another example, the input-output part of the kernel keeps a table of open files and their characteristics. The

format is different for the two systems, but the code that uses the table is exactly the same.

Code characteristics of the complete kernel are summarized in Table I.

Because the interface routines are largely independent of each other, they can be tested individually. An interesting point is that the test driver is machine-independent, so it can be distributed with a package to help the systems programmer who must convert the kernel. Debugging is further aided by the existence of the package itself. It may contain bugs, but when one of its working features goes wrong, it tends to point to an error in the kernel.

### OPEN-ENDED SOFTWARE

The package software that is to be built in FORTRAN on the operating system interface can be expected to undergo almost constant modification, to fit the changing needs of a community of research users. Under this stress it is easy to imagine a "good" package turning into many disparate "bad" packages as the code is modified by many unskilled hands. Insult is added to injury when even the most slipshod changes are hard to make, requiring extensive study of the existing code, then extensive debugging. The internal structure of the package must protect against such changes.

Careful adherence to programming and documentation standards are often offered as solutions to the problems of program modification. But it is observed that not everyone will follow standards and not everyone who tries, succeeds. The bad easily drives out the good. The only structure that will preserve itself is one that is easier to work within than to violate.

The primary technique for structuring software to encourage change is that of centralization and information hiding.<sup>12</sup> Operations should be confined to a single place in the code and encapsulated with access to just the information needed to perform properly. For example, in a package program, the user interface is a candidate for this treatment. If all interactive communication is confined to a collection of routines, rigidly bounded by a well defined interface across which the information passes to other parts of the software, several advantages are gained:

1. It is easy to learn to employ the communication routines, because only the stable interface need be mastered.
2. Collecting the code in one place makes it easier to study, and if it is modified, the modification applies uniformly to all parts of the system.
3. When the centralized code is not in use, it may be possible to get rid of it, reducing the memory overhead.

There are two common methods of circumscribing operations in software. The operation may be implemented as a separate, stand-alone program, linked to other programs only by files. Or, the operation may be implemented as a collection of sub-routines and data structures within a program, communicating with the rest of the program through parameters and global data. In the first mechanism separa-

TABLE I

<i>Property</i>	<i>Exec 8</i>	<i>UNIX</i>
Systems programmer experience (excluding learning assembler)	5 years	5 hours
Assembler "service caller"		
Number of system calls	50	15
Code instructions (excluding dispatch tables)	80	100
Hours to design, code	15	10
FORTRAN Routines		
Number of interface entries	11	11
Support function routines	20	14
Total RATFOR statements	700	530
Hours to initially design, code	30	—
Hours to convert	—	10

tion is easy to enforce, but it is less easy to provide support functions for the independent programs; in the second mechanism support routines are readily available and the problem is to preserve the separation of the parts. Both mechanisms are valuable in an image-processing package.

### *Communicating independent programs*

Of course, any two programs can "cooperate" by interchanging information in files. The user interface of a package is a good example. One program is the collection of routines that interact with the human user, and another is devoted to actually processing the information so obtained. Communication between the programs is through a file of commands/results. The separation is perfect in the sense that the processing program does not interact with the user, and the user routines do not process the information they receive. Furthermore, memory overhead is handled perfectly by this organization—the scanner, command tables, etc. are entirely gone once processing starts, leaving only a standardized command, already checked so that little error recovery code need be part of the processing. The payment for this ideal separation comes when one of the independent programs is changed—how can the changes be taken into account by the other programs without modifying them also? In the example, suppose the behavior of one processing program is changed. How can this be automatically reflected in the user dialogue? Similarly, how can the communications program really check input commands when it does not know exactly what the processing program intends to do with them?

These problems can be solved by arranging another level of communication between the independent programs. Each can notify the others of its capabilities in an initialization run, resulting in the creation of a kind of "configuration" file. This file records what programs exist, what operations they perform and describes the commands for those operations. When a change takes place it is only necessary to repeat the initialization run to have its effect felt throughout the collection of programs. This organization suggests another independent program function, that of explaining the system's capabilities and operation. A "help" program would make use of the configuration file to explain difficulties and provide on-line documentation, with this high-overhead operation entirely divorced from all "working" programs, yet necessarily up-to-date.

The two essentials for cooperation of independent programs are the ability of one to invoke another (and itself be reinvoked to inspect the results), and the definition of processing tasks in a format that can be concisely described in a configuration file. The operating system interface provides the former and the latter is a natural consequence of any command language that can be formally described.

### *Linked sub-routine organization*

The primary reason for encapsulating package operations as complete, independent programs rather than as loadable

overlays is that overlaying is done very differently on different machines, and is usually a high-overhead process. Nevertheless, connecting groups of sub-routines by conventional linking is often a better organization than that of separate programs. In particular, this organization is essential for cascaded processing such as neighborhood operations on an image. In this situation the separate-program organization would lead to as many passes through the image file as there are operations, while subroutines called in sequence would require only one pass. The question for linked sub-routines is how we can centralize support functions and make it easy to add sub-routines and integrate them with existing ones.

There is no difficulty in passing information about sub-routine capabilities across program boundaries—the description in the configuration file can be broken down by routine within program. Rather, the problem is that existing routines interact in an intricate pattern, and a new or altered routine must be allowed to participate without its author mastering very much of the complex code environment. We illustrate how this can be done for the composition of neighborhood operations.

Neighborhood operations in cascade can be performed on a very restricted portion of an image. There is always a "window" that, moving serially through a file, contains all the pixels needed to perform one step of the composite operation. Some operations in the cascade make use of the results of others as well as data from this window, but it is straightforward to arrange row buffers so that all of the necessary data is present at once. Control flow is more complex, since one operation (or sequence of operations) may have to be repeated before the next can proceed. An open-ended package requires that the routines which participate in the sequence be written as unit operations, transforming a fixed number of rows of input into a similar output.

To add a routine requires no understanding of the complex driver mechanism that adjusts buffer pointers and sequences the operations, but only the understanding of the parameter conventions for receiving unit input and delivering unit output. The existing routines are selected and called through tables, which must be updated to reflect changes. This organization is as flexible and easy to extend as might be imaged. The routine-name table is the basis for building the configuration file, so an independent program interacting with users knows which neighborhood operations are available, and what parameters each requires. Any sequence of these operations can be passed to the program in which the unit-operation routines are driven by the same table. The user-communication program can even determine memory requirements, and break the sequence up with intermediate files if not enough core is available for the necessary window.

## PRESENT AND FUTURE PLANS

Our immediate goal is the production of an image-processing package design that is both transportable in the wide sense described in the first section, and of high quality. As

a practical demonstration of this design we imagine the following pieces of software:

1. Operating system interface kernels for several machines, along with documentation describing the implementation on a new machine. Operating system interface surround.
2. Preprocessors for RATFOR and for extended syntax checking of transportable code, themselves transportable.
3. An independent user-interface module capable of checking commands for and invoking any number of processing routines, their operations described and driven by tables. This module will include "help" information driven by the same tables.
4. A sample processing module implementing neighborhood operations with almost arbitrary cascade and parallel capabilities.

Once this design has proved itself, it will be appropriate to extend it to a full-blown image processing package by the addition of other processing modules. This task will be less difficult than the complete creation of a package, but it is not easy. The major advantage is that once the effort has been expended, nothing like it should ever be needed again—the package should be adaptable to new situations at very low cost.

# A data-handling mechanics of on-line text editing system with efficient secondary storage access

by SAKTI PRAMANIK

Indiana University-Purdue University  
Indianapolis, Indiana

and

EDGAR T. IRONS

Yale University  
New Haven, Connecticut

## INTRODUCTION

The data-handling algorithm in many current editors<sup>2</sup> uses a text which is a continuous string of characters. In this technique the characters are moved directly from their input source to the text string by expanding it in the core buffer. The disadvantage of such existing systems is due to the core buffer constraint. The buffer can be extended to the auxiliary storage but will result in less efficient auxiliary storage accessing.

The data-handling algorithm presented here uses a text which consists of several substrings. Initially the text consists of only one substring which is the original version of the text. This text resides in the consecutive blocks of the scroll area of the tape; the characters carry smoothly across the blocks boundaries, producing a continuous string. No writing is permitted on this scroll area during the editing process. The characters which are inserted into the text for editorial changes are moved directly into a core buffer, producing new substrings. The substrings are logically interconnected in a linear fashion through a map. The map, in fact, contains pointers to all the substrings in the text.

## DESCRIPTION OF THE EDITING PROCESS

The editing process starts with the original version of the text residing on the tape unit. Initially the map will contain pointers to this text string. An entry consists of the location of the string in the storage and its length, i.e., the number of characters in it. Figure 1 below, for example, shows that the pointer which corresponds to the string of characters "ABCDEF," consists of two integers,  $L_A$ , the address of the string starting with the character A, and the length 6. The string A through F is assumed to reside on the tape unit.

Suppose an input string "xyz" is to be inserted between the character positions D and E of the string as shown in

Figure 2. Instead of physically splicing in this string between D and E, it is moved into a buffer located in main storage. The entire string now consists of characters in the following sequence:

1. Characters ABCD      on tape
2. Characters XYZ      in core buffer storage
3. Characters EF      on tape

We have given the name "substring" to each of these smaller strings (e.g., "ABCD") and the map of Figure 1 is updated to contain three pointers to identify each of the above three substrings. The first entry in the map (Figure 2) consists of the location of the first character A of the substring "ABCD" and its length, 4. The second entry contains the location of the first character x of the substring "xyz" and its length 3. The third entry consists of the location of the character E of the string "EF" and its length 2. The location of "E" is  $L_A+4$  because it is four character positions to the right of the character A in the string "ABCDEF." A delete command simply updates the map. If the character "Z," for example, is deleted the length field of the second entry in Figure 2 is changed from value 3 to 2.

When the input buffer is full an overflow area is needed to save the characters currently being input. Instead of this overflow area the buffer can also be emptied onto a disk storage. In the latter case, however, the most recently input characters will no longer remain in the main storage; two input buffers can be used to eliminate this problem. One difficulty of transferring substrings onto the disk is that the substring locations in the map have to be updated. To avoid this update logical addresses are used for the substrings. Several of these substrings are stored in fixed size page. A substring location is now given by the page number and the offset of the substring in the page. To handle all characters uniformly, the initial text on the tape is assumed to be split into fixed length substrings each fitting into separate pages.

Address	Length
L <sub>A</sub>	6

Figure 1—Map for the character string "ABCDEF"

Paging scheme is simple here because the content of a page is not directly updated when they are on the tape or on disk; this is done logically through the map.

The direction of data flow between the storage mediums is shown in Figure 3 below. The flow of data from disk and tape into core is required to regenerate any part of the text.

Figure 3—Data flow between storage devices

GROWTH OF THE MAP

The growth in the number of pointers in a map is due to the splitting of the substrings by the edit operations into more substrings of smaller sizes. The number of substrings created for each edit operation depends on the type of edit function (i.e., insert, delete and replace) and the editorial point. Figure 4 below shows the number of new entries created by each edit function. Some of the factors that influence the growth rate of the map are the type of editing task the user is performing, the familiarity of the user with the editor, and the type of edit functions available on the editor. Figure 5 below shows the growth rate of the maps on an experimental editor described in Appendix 1.

BOUND ON THE MAP SIZE

The size of a map depends on the growth rate of the pointers in the map and the time a user spends in editing the file. Let Y<sub>i</sub> be the growth rate of the pointers in the i<sup>th</sup> map buffer. Then at anytime the total number of pointers in the buffer is less than or equal to t. Y<sub>i</sub>, where, t is the total time spend in editing. The total number of pointers for editing N files is given by

$$t \cdot \sum_{i=1}^N y_i \quad (\text{for pooled buffer})$$

A B C D E F  
          ↑  
          x y z

Address	Length
L <sub>A</sub>	4
L <sub>x</sub>	3
L <sub>A+4</sub>	2

Figure 2—Updated map

The probability of overflow for a buffer size of N.α is as follows:

$$\Pr \left( \sum_{i=1}^N y_i \geq \frac{N \cdot \alpha}{t} \right)$$

where α is a constant.

Let {y<sub>i</sub>} be a set of statistically independent, identically distributed random variables. Then by Markov inequality the bound is given by the relation

$$\Pr \left( \sum_{i=1}^N y_i \geq \frac{N \cdot \alpha}{t} \right) \leq \frac{t \cdot E_y}{\alpha}$$

where E<sub>y</sub> is the expected value of the random variable y. In direct editing system the bound on the size of the buffer is computed as follows:

Let F<sub>i</sub> be the size of the i<sup>th</sup> file. Then the storage requirement for N files is given by

$$\sum_{i=1}^N F_i$$

So the probability of buffer overflow for an in-core buffer

Note: A: characters on auxiliary storage  
I: characters in the input buffer  
a,b,c,d,e, and f denotes the editorial point.  
Insertions are made preceding the character

Editorial Point	Insert	Delete	Replace
a	2	0	1
b	1	0	0
c	2	1*	0
d	2	0	0
e	1	0	1
f	2	1*	2

\*Delete function does not produce any new substring if it is the end character of the substring to be deleted

Figure 4—Number of pointers created for each edit function

Figure 5—Probability density function of the growth rate of the pointers in the map

Figure 7—Probability density function of the growth rate of new data

size of  $N \cdot \alpha$  is bounded by

$$\Pr \left( \sum_{i=1}^N F_i \geq N \cdot \alpha \right) \leq \frac{E_F}{\alpha}$$

where  $E_F$  is the expected value of the variable  $F$ . From Figures 5 and 6 one can compute the value of  $t \cdot E_y$  and  $E_F$  to be 310 and 1140 DEC-10 words respectively. A session time of two hours is assumed. Thus  $E_F \gg t \cdot E_y$  which implies that the map requires much less core storage than the direct editing system.

GROWTH RATE OF INPUT CHARACTERS

Figure 7 shows the growth rate of input characters per user in the experimental editing system. A typical editing session of two hours has been assumed. The bound on the growth rate, of course, is determined by the typing speed of the user. Each user in the experiment was using CRT terminals to debug and run the scientific programs. The actual

growth rate is much smaller than the speed at which a user can type. In fact, users working at display terminals appear to spend much of their time displaying different parts of the text and only occasionally making an editorial correction. Figure 8 below shows the overflow rate for different input buffer sizes. This is computed on the basis of the growth rate of input characters in Figure 7.

PERFORMANCE COMPARISON OF MAP EDITING WITH A DIRECT-EDITING SYSTEM

One commonly used data structure for a direct-editing system is a continuous string of characters stored in the logically contiguous blocks of the tape unit.<sup>2</sup> Here, a block is simply the transfer unit between the tape and the main storage. Locating any part of the string on the tape unit, however, takes longer time because the blocks are accessed sequentially. This problem is eliminated by storing the entire text in random access core storage. But the typical constraint in the size of core storage often allows only a part of

Figure 6—Probability density function of file size

Figure 8—Overflow rate of the new data buffer

the text to remain in it while the rest is resident on the tape unit. Whenever the data to be edited or displayed is not in the core, the new data is read in from the tape unit by scrolling through the text. Many times this process requires the re-writing of data from the core to the same tape unit. These write operations slow down the scrolling process because the sequence of read and write operations involves reversing the tape motion. This reversal occurs more frequently when core buffer sizes are small. Writing is completely eliminated in map editing, thus considerably improving the access speed of the tape drive.

In a direct-editing system the insert or delete operation causes the character strings to expand or contract within the core buffer. This character movement can be reduced to some extent by inserting sparingly null characters in the text string<sup>1</sup>. But the reduction of character movements by this method will depend on the nature of the programmer's editing pattern. In map editing these character movements in core is completely eliminated. In many tape systems writing in place is not permitted because positioning the tape at a precise location is not possible; here direct-editing is impossible. Usually, tapes are completely rewritten for making any update changes.

## CONCLUSION

The increased processing time in this editing system is due to a considerable amount of fragmentation of the text. The substrings need to be remapped, sometimes, into one continuous string for improved editor performance. This remapping is done by copying the substrings into a scratch file on the disk.

## APPENDIX 1

### *Experimental Editor*

This is a CRT-oriented text-editor implemented on a PDP-10 time-sharing system at Yale University. When the user is editing a file, his CRT screen appears to be a window on the target file. This window can be moved up or down to display any part of the file on the screen. A cursor on the screen is used to point to the place where the editor is to perform an editing function such as inserting and deleting text. In most non-CRT editors this is accomplished by typing a line number or the surrounding text (context), neither of which is as convenient or natural as being able to directly use the cursor. This editor works in the user mode under the standard PDP-10 operating system and uses its file structure.

The general format of the edit commands is as follows:

(Enter) Parameter (Edit-function)

The angular bracket indicates a key on the terminal keyboard. (Enter), for example, is a key on the terminal which when pushed echos a `^` character on the terminal to indicate

that the system is in parameter mode. Any text now typed in goes into a parameter buffer without affecting the file. Parameter mode is terminated when any other function key is typed in and the parameters typed in are associated with that function. The command to delete next seven lines, for example, will be as follows:

(Enter) 7 (delete-lines)

The following commands are available on this editor:

### File functions

These functions specify the target file to be edited.

(Enter) File-name (Make-File) Creates a new file whose name is file-name and gets it ready for inputting text.  
 (Enter) File-name (Set-file) Gets an already existing file ready for editing

### Screen movement functions

These functions move the window represented by the CRT screen with respect to the file.

(Enter) N (+Lines) Moves the window N lines forward in the file  
 (Enter) N (-Lines) Moves the window N lines backward in the file  
 (Enter) N (+Pages) Moves the window N pages forward in the file (a page is defined as 20 lines—the size of the screen)  
 (Enter) N (-Pages) Moves N pages backward

### Cursor positioning functions

These functions move the cursor around within the window without moving the window with respect to the file. Up, down, left and right cursor keys are grouped together on the keyboard and have a built-in auto-repeat which makes it convenient to position the cursor rapidly at any desired place on the screen. Echo to the CRT terminal is generated at monitor level by the teletype service routine. This ensures instantaneous response and the editor may not process the functions till somewhat later. These four function keys do not need any parameter.

### Editing functions

These functions are used to update the text on the screen.

(Enter) N (Insert-space) Opens N spaces by expanding the text

---

<Enter> N <Delete-space> Deletes N characters from the text

<Enter> N <Insert-line> Inserts N blank lines in the text

<Enter> N <Delete-line> Deletes N lines from the text

<Enter> N <Pick> Picks N lines from the text and saves it in the pick-buffer

<PUT> Does not require any parameter. It puts the content of the pick-buffer into the text.

In all of the previous cases the editorial point is indicated by the location of the cursor.

# How do we best control the flow of electronic information across sovereign borders?

by PETER SAFIRSTEIN

*Data Processing Management Association*  
Arlington, Virginia

When all is said and done, the United States must answer one basic question: How do we best control the flow of electronic information across sovereign borders?

Essentially the question is one of power politics. Information is an entity which must be viewed as a form of power. When one considers that 50-60 percent of European domestic records are processed by American companies,<sup>1</sup> it becomes rather apparent that the United States subsequently exerts a great deal of power *vis-a-vis* Europe. Our "power," or ability to influence, does not end in Europe though, but extends rather significantly into the Third and Fourth Worlds as well, thus making our basic question a global one.

Electronic technology, by providing the means to accumulate, store, change and transmit information on an unprecedented scale,<sup>2</sup> has recently emerged as an issue of great importance as well as controversy. The complex myriad of issues involves personal data, economic data, financial data, statistical data, etc. and affects our daily lives through television, telephones, satellites, etc. More specifically, electronic technology's uses can be seen today in the airlines reservations network (SITA), the international banking network (SWIFT), creditworthiness evaluation data bases usually situated in the United States, global satellites providing remote sensing, corporation electronic information systems used in management controls for production, marketing, personnel, capital expenses and investment.<sup>3</sup> These examples represent just a few of the controversial issues which governments are beginning to realize that they must confront.

Confrontation has emerged as a necessity for one overriding reason directly related to the recent emergence of electronic technology. That one concern is economic power. Europe has recognized that the uncontrolled flow of data creates hardships for its economy. European political pundits are frightened by the prospect of being cut off from vital data that is stored in foreign data bases. Hence, advisers warn of the dangers of dependence and advocate the creation of domestic data bases. Europeans are quickly developing their own data processing capabilities, yet they remain still far behind the Americans for primarily economic rea-

sons. It should come as no surprise then, that European governments feel an incentive to make their data processing industry competitive with that of the United States. In order to make a domestic data base network more competitive with the United States alternative, Europeans are implementing non-tariff barriers that take on the very appealing appearance of privacy legislation designed ostensibly for the protection of the principles of individual rights and national sovereignty.

It has been stated repeatedly that the principle questions involved in the transborder data flow controversy revolve around the issues of privacy and sovereignty. To view the controversy in terms of these areas is to beg the question. The essence of the dispute is, as stated above, *economics*. What we are dealing with is a question of economic domination which dwarfs the privacy and sovereignty questions to a status deemed secondary at best.

Privacy and sovereignty are relative objectives within the framework of international affairs. It may be well and good to espouse a policy that fosters absolute privacy and total sovereignty; however, a realistic appraisal must encounter the notion that in a world of interdependence and tradeoffs, there can exist only limited privacy as well as limited sovereignty. The days have passed when we could have viewed both individuals and nations as islands unto themselves.

Policies of privacy and sovereignty gain importance, though as convenient diplomatic tools to facilitate economic gains. That is precisely how Europe is using them.

Sweden, France, and West Germany have already implemented restrictive privacy laws and five other Western European nations are considering similar action. These restrictive laws are said to be the basis for the confrontation. Of course both sides want to have the economic edge and it is clear that the United States' business community is considerably opposed to any non-tariff barriers that might effectively exclude or hinder the opportunities within the European community. On the other hand, France, for example, does not want to be dependent upon the United States for raw data. France considers its present situation to be troublesome. William Fishman of the National Telecommunications and Information Administration noted France's pre-

dicament in a speech before the 4th International Conference on Computer and Communications in Japan: "at a recent OECD Symposium in Vienna . . . an official of the French government noted with alarm that France relies for a good deal of its macroeconomic planning on economic models, data bases and associated expertise located in the United States."<sup>4</sup> The dispute is a clear one, with both sides defending vital national interests.

Yet, it is the author's opinion that Europe should not be the dominant area of concern for U.S. policymakers and businessmen. The teachings of history indicate that the United States and Europe have been in competitive situations before the postwar era and that reasonable statesmen have followed prudent guidelines of diplomacy toward resolution of the differences. Because of the interdependent status of the Western developed nations and the complex nature of the entire array of policy linkages, a compromise is inevitable.

The main domain of concern should be the Third World, yet the literature on the transborder data flow controversy focuses primarily on Europe. This is an unfortunate situation, for unlike the European case, we cannot depend upon reasonable men and prudent statecraft to win the day for us in the Third World.

The Third World is an area of significance to the United States (as is the Fourth World) because U.S. based multinationals have expanded into this area in large numbers over the past years so that they may take advantage of the wealth of natural resources and the plethora of cheap labor that exists in those regions. This considerable investment, though always at a risk, is now further threatened by the clamorings of the Third and Fourth World for a new economic order. In regard to information specifically, the major conflicts revolve around the precept of equity. Ali Shumo, of the Sudanese government, was referring to the upcoming World Administrative Radio Conference (WARC) where nations will reevaluate the allocation of the radio spectrum, when he stated to representatives of industrial nations, "You have 90 percent of the spectrum and 10 percent of the population. We have 90 percent of the population and 10 percent of the spectrum. We want your share."<sup>5</sup>

At the recent Spin Conference (Intergovernmental Conference on Strategies and Policies for Informatics) held in Torremolinas, Spain, Benin and Tunisia submitted a recommendation calling for aid in assisting developing countries to obtain "access to information located in national and international data banks in the more advanced countries." The impetus behind the motion is obviously a strive for equity. At that same conference, Bolivia, Morocco and Tunisia submitted a resolution recommending that "countries which have developed substantial data base capabilities should provide in their programs for the use of scientific and technological information resources by all interested countries."<sup>6</sup> It is rather apparent that these nations have realized the "power" that information holds.

What makes negotiations with Third and Fourth World nations so difficult is their perception of capitalism and colonialism (with all its distasteful connotations) as synonymous. Hence, leaders of the nations can achieve great do-

mestic popularity and support by challenging the developed nations.

Historically, consider the example of Nasser of Egypt. It was said that his power and influence rest on his ability to symbolize Arab nationalism as an idea and as a political force. As he walks on the world stage, millions of Arabs see him playing the role they would like to play and doing the things they would like to do. . . . When he challenges the great powers and takes daring risks in the name of Arab rights and dignity, and gets away with it, the Arab masses feel an emotional lift and a satisfaction that no Arab leader has given them within memory.<sup>7</sup>

Stated simply, Nasser achieved immediate political consensus by maintaining an obstreperous foreign policy. His death was heavily mourned by the masses despite the fact that his failure to provide substantive leadership left the Egyptian economy and standard of living in shambles. It is quite conceivable for Third and Fourth World nations to neglect their nations' standard of living status for immediate political support. This becomes much clearer when one takes note of a major paradox of our times: there is a political disincentive for widespread economic improvements. This is so for two reasons: 1) When Third World nations increasingly move toward modernity, their population inevitably succumbs to discontent due to the principle of rising expectations. Citizens of a nation are told that political and economic subservience to technologically superior nations is necessary and should be tolerated, despite its distaste, for economic gains. When these economic gains are not immediately forthcoming to the populace due to a lack of an industrial base, there is political upheaval and popular support will sway to the leader that promises to throw the "exploiters" out. 2) The second economic reality is also unpleasant. Industrialized nations will insist that underdeveloped nations use the former's technology to industrialize, yet the situation will quickly emerge into one where everyone realizes that the more they, the indigent population, work and increase their production, the more prices in the marketplace will fall resulting in economic displacement.

Having stated these principles; how is this Third and Fourth World discourse relevant to the information community? It is relevant on a number of levels: 1) Industry will be faced with difficulties at times in exporting hardware and software to these areas, 2) these nations could conceivably pass laws making it difficult for multinationals to transmit vital data into and out of the country and 3) these nations could unite and sabotage multilateral conferences such as WARC.

In the final analysis, Europe and the United States will achieve agreement that is satisfactory because the economics of the situation mandate it. As was pointed out, the Third and Fourth Worlds are not easily impressed with compromises that will strengthen them economically. This makes dealing with the Third and Fourth World more difficult. It has become clear that economic assistance does not provide the United States with the leverage that it did with regard to different regions in different times.

These political and economic realities affect everyone, but the information community is right at the core of the dispute.

for the information community carries great weight in political and economic planning. Inevitably, the solution must be comprehensive and this is the major criticism that the author has of the present attempts to deal with the transborder data flow problems. Our present approach is a fragmented one that carries with it devastating consequences. Few people are looking at this problem *in toto*; rather they maintain specialists who are keyed into certain areas of controversy.

While it is true that the United States lacks a unified and coherent national information policy which would give legitimacy to a definition of information; it cannot be denied that recent major conferences have scheduled information policy questions on their agendas. It is in that regard that they are all somewhat similar. The conferences, however, take on a fragmented appearance:

- A UNESCO meeting in Paris in October, 1978, where a topic for discussion revolved around a government's right to control news generated and reported within its own borders.
- A World Administrative Radio Conference next September where Third and Fourth World nations will seek a far larger share of radio frequencies now used by the United States and other developed nations.
- A United Nations Committee meeting next spring and summer where many countries will push a resolution requiring TV broadcasters of one nation to get advance clearance from another nation before sending programs there directly via broadcast satellites.<sup>8</sup>
- The United Nations Conference on Science and Technology for Development meeting will take place next year where developed and developing nations will discuss the linkages involved between science and technology applications and the world economic order.
- The United Nations Conference on the Peaceful Uses of Outer Space will meet to discuss the implications of remote sensing. That is, one nation's surveillance of another nation's vital resources.
- OECD will meet to discuss the transborder data flow problem.

Further adding to the disparate attempts to come to grips with the problem:

- The President has ordered a review of the recommendations of the Privacy Protection Study Commission which contains transborder data flow considerations.
- The State Department Advisory Committee on Transnational Enterprises has set up a sub-group on data flows.<sup>9</sup>

This listing of the conferences dealing with information policy questions is not complete. When one considers how disjointed our approach to the transborder data flow problem is, one realizes that our method is dangerous as well as impractical. Undoubtedly, the United States will be pressed for concessions at each of these conferences. Should the United States concede certain holdings at each of these

discussions, as is expected, it will be confronted with a cumulative effect of astronomical proportions. The United States must negotiate from a position of strength which will not be facilitated in a framework in which the United States is pitted against hostile entities negotiating on a piecemeal basis.

What is desperately needed is a joining of public and private sector forces in a comprehensive, international conference where all the relevant issues will be discussed by all interested nations. This conference should be held in lieu of the list of conferences mentioned before. The United States should seek internationally acceptable parameters as to what information entails. Furthermore, the United States should seek, similar to the U.N. Law of the Sea Conference, a weighted vote so that bloc voting by the developing nations will lose some of its effectiveness.

For the United States to achieve its aims, three factors loom important:

1. Confronted by a demanding Third and Fourth World, the United States and Europe need to unite on the common ground that they have. While their interests, as explained previously, are presently not compatible, a quick resolution of their differences will strengthen their position in such a conference. Despite their problems, Europe and the United States should realize that they are closer to each other than they are to the LDC's and that a united position can only serve to strengthen their hand.
2. The United States and Europe need to take advantage of changes within the Third and Fourth Worlds. Some of the leaders of the developing nations have established such a firm political foundation in their lands that they can afford to be friendly toward the developed nations and the multinational corporations. The dichotomy between a Sadat of Egypt and a Qaddafi of Libya serves an analytically useful purpose. Both these lands are designated as developing states, yet no reasonable man can lump these two states together and call them identical. Sadat reflects a slow but changing nature toward prudent judgment within the Third and Fourth Worlds whereas Qaddafi represents the uncompromising element that is just as much a reality today as well. The key for the United States and Europe deals with their ability to put the developing nations at odds with each other. A weighted industrial nation vote linked with a divided Third and Fourth Worlds vote does make the prospects for success of American objectives seem encouraging.
3. Within the context of a comprehensive conference, the developed nations are afforded the luxury of tradeoffs and compromises that go into the formation of a unified and coherent international information policy. The comprehensive nature of the conference will tactically provide negotiators with linkages that are not subjects for discussion within a more limited framework. This will serve to guard against sacrificing elements on all issues which would only serve to weaken the United States' position in the world.

This comprehensive conference is a realistic solution. The position of the United States should be that it will negotiate on its own terms at a conference of its choosing. This it can do now, because it is U.S. possessions that the others want. A United States refusal to attend WARC with a comprehensive conference offered as an alternative would serve to signal to those Third and Fourth World nations that the United States is ready to take a firm stand.

A more limited comprehensive conference was given the support of Representative Goldwater in his Joint Resolution 1141 offered in the 95th Congress. Unfortunately, Mr. Goldwater's resolution is internally inconsistent. He claims:

Whereas communications and information transactions and associated activities are of major and growing economic importance to industrialized societies and developing societies which require rapid and reliable information transmission and processing systems to effectively advance commerce and governmental responsibilities; and whereas a growing divergence in national laws, regulations, and practices which impose special conditions, preferential rates, tariffs and technical standards, taxation policies and licensing, reporting, and disclosure practices, may threaten fair commercial competition and may jeopardize the widest sharing and utilization of information and knowledge made possible by electronic technologies; and whereas such a divergence threatens international cooperation and harmony: Now therefore be it resolved that the President of the United States shall 1) convene an international conference on Communication and Information not later than January 1, 1980, to which governments of the PRINCIPAL INDUSTRIALIZED NATIONS (emphasis added) will be invited to designate official delegations to attend. . .<sup>10</sup>

Mr. Goldwater explicitly states that developing societies are integral to communications and information transac-

tions, but then he calls for a conference that would not contain even all industrialized states, but only the *principal* industrialized nations.

That is an unacceptable solution. The conference that should be held must invite all interested parties. While the position that the United States takes should be strong, there still is a need to settle the dispute with all interested actors. Failure to do so would simply further the animosity that is felt between the developed and developing nations.

How do we best control the flow of electronic information across sovereign borders? Only when all sovereign states are involved in a major conference that supersedes the present fragmented approach.

## INTRODUCTION

Transnational data processing systems are international value-added, public, special-interest community, or private computer-communications networks that operate computers in several countries and provide computing services to users in these and other countries. Examples of such systems are the North American-based Telenet, Infonet, Mark III, Tymnet, and Datapac, and the European developmental Euronet and the Nordic Data Network. Among computer networks operated by international communities are SITA, an airlines reservation system, and SWIFT, a worldwide interbank financial telecommunications network. In development is the European Informatics Network (EIN) which will provide information services and data base access to users in the countries of the European Economic Community (EEC). Finally, private computer-communications systems are operated over international data carrier networks by multinational corporations in many countries.

To date, transnational data flows in the various types of computer communications networks have proceeded relatively freely among most of the industrialized countries in the world, subject only to economic and technical considerations, but these flows have not been balanced. Most of the international data processing services are offered by vendors that are located in a single country—the United States. Multinational corporations, likewise, tend to be headquartered in only a few countries. As a result, data are flowing to these countries for processing and storage from the countries that subscribe to the services of international data processing systems or that contain subsidiaries of multinational corporations. Thus, organizations in public and private sectors in many “computer-poor” countries depend heavily on vendors of data processing services, data processing industry, and computer communications networks located in and operated from abroad. It is not surprising, therefore, that a number of concerns over this situation have surfaced in countries from where such trans-

national data flows originate:

1. The possible erosion of the sovereignty of a country when large amounts of data about its economy, citizens, or government operations are transmitted abroad for processing or storage in data bases. Increased vulnerability to disruption of access to these data, and the lack of control over data processed and stored abroad can put a country in a position of significant dependency on foreign data processing services.<sup>1</sup>
2. The increased complexity and technical and procedural difficulties in ensuring data security and maintaining accountability when data are transmitted in networks that may span several countries, may involve several transmission link technologies, and may be operated by several organizations that may be headquartered in different countries. As discussed later, international conventions regarding communications further complicate the situation.
3. The possible erosion of privacy rights provided to individuals in their home country when identifiable personal information about them is transmitted to be processed and/or stored in countries where privacy protection requirements are weaker. Thus, the possibility of “data havens” arises, where personal data about individuals may be maintained and used in ways that are violating the privacy protection requirements that exist in their home countries.
4. Potentially adverse effects on the development or continued existence of native data processing expertise and industry in countries that utilize foreign data processing services. The principal reasons for using foreign data processing services are economy, as compared to services available in the home country, and unavailability of the desired data processing resources or capabilities in the home country.<sup>2</sup>

These problems and the possibility that restrictive meas-

ures may be taken by data-exporting countries to alleviate them, are causing concern among vendors of transnational data processing services, multinational corporations and users of international computer communication systems that (1) free data flows (i.e., subject only to economic considerations and not hindered by the so-called "non-tariff" barriers) may be constrained by national laws, (2) international business, commerce and information exchanges may be severely discouraged when the necessary transnational data flows are continuously at risk of being curtailed by the countries involved, and (3) protectionist policies regarding international data processing systems and services will be instituted by data-exporting countries.

Extending privacy rights of individuals to countries where personal data about them may be processed and stored, and providing security to all data in transnational computer communication networks are two of the important questions that are currently in the focus of attention of national policy-making bodies and international organizations. The purpose of this paper is to examine the technical and procedural considerations that arise.

## PRIVACY PROTECTION REQUIREMENTS

In the context of automated personal data record-keeping systems, the term "privacy" is used to refer to certain rights of individuals *vis-à-vis* collection, processing, storage, dissemination and use in decision-making of personal data about them. In Europe, the term "data protection" is used in the same sense, but the difference in terminology is causing some confusion. Privacy protection is achieved when these rights are granted, corresponding requirements are placed on record-keeping organizations, and compliance is enforced. Privacy protection takes on a transnational scope when individuals can exercise their privacy rights in other countries where personal data about them are handled or maintained.

### *National privacy protection laws*

Privacy protection legislation has been enacted in several countries. In the United States, the Privacy Act of 1974 places privacy protection requirements on record-keeping agencies of the Federal Government.<sup>3</sup> In the private sector, legislation has been enacted to provide privacy protection in the areas of credit reporting, education, bank records and in emerging EFT systems. Several states have enacted their own privacy protection and information practices laws.<sup>4</sup> In Canada, privacy protection requirements are placed on agencies of the federal government by the Canadian Human Rights Act of 1977.<sup>5</sup> In Europe, several countries have enacted privacy protection legislation, starting with Sweden in 1973 and followed by the Federal Republic of Germany, France, Norway, Austria and Denmark in 1977 and 1978.<sup>6,7</sup>

The important dimensions of a privacy protection law include the following: (1) The scope of coverage (e.g.,

public sector, private sector, both, or various subsections of them); (2) data subjects covered (physical persons, associations of physical persons, legal persons); (3) types of record-keeping systems covered (automated, manual); (4) privacy rights granted to individuals; (5) privacy protection requirements placed on record-keepers; (6) mechanisms and authorities for enforcement (licensing, self-regulation, national commissions); and (7) systems of penalties. There are strong similarities between, but also considerable differences in, these dimensions between the laws enacted in the United States and in Canada, on one hand, and those enacted or pending in Europe, on the other hand. These differences can lead to problems in attempts to implement privacy protection requirements on an international scale.

To date, privacy protection legislation in North America has followed an area-by-area approach in the scope of coverage—laws have been enacted to regulate record-keeping by federal governments, other laws have been enacted by state or province legislatures, and additional laws provide for privacy protection in selected parts of the private sector. In Europe, however, privacy protection laws tend to be based on an omnibus approach—the same law and the same requirements apply to record-keeping organizations in both the government and the private sector. There are differences also in other dimensions, as depicted in Table I.

### *Privacy rights and requirements*

Despite some of the differences previously described, privacy rights granted to individuals by the national privacy protection laws tend to be remarkably similar, and so are the corresponding requirements placed on record-keeping organizations. This is due to the use of essentially the same principles of privacy protection—the Code of Fair Information Practices as first stated in a U.S. government committee report in 1973<sup>8</sup> and augmented by the Privacy Protection Study Commission in 1977,<sup>9</sup> and the Council of Europe's resolutions on individual rights of privacy.<sup>10,11</sup> Collectively, these principles can be stated as follows:

1. *Openness.* There must be no personal data record-keeping systems whose very existence is secret, and there must be a policy of openness about any organization's record-keeping policies, practices and systems.
2. *Individual access.* There must be a way for individuals to find out what personal data about them are on record and how they are used, and to see and make copies of those data.
3. *Individual participation.* There must be a way for individuals to correct or amend personal data about themselves.
4. *Collection limitation.* There must exist limits on types of personal data organizations may collect about individuals, and restrictions on the manner in which they collect these data.
5. *Use limitation.* There must be a way for individuals to

TABLE I—Features of National Privacy Protection Laws

Country	Scope	Covered data subjects	Enforcement mechanism	Explicit trans-national data flow requirements
United States	Federal gov. Some states Parts of private sector	Citizens Certain aliens*	Self-enforcement	No
Sweden	Both public and private sectors	All residents	Data Inspection Board	Yes
Federal Republic of Germany	Both sectors	All residents	Data Protection Commissioner	No
France	Both sectors	All residents	National Commission on Informatics and Liberties	Yes
Norway	Both sectors	All residents Associations	Data Surveillance System	Yes
Denmark	Both sectors (separate laws)	All residents	Register Board	Yes
Austria	Both sectors	All residents Legal persons	Data Inspection Board	Yes
Canada	Federal gov. Some provinces Some parts of private sector	Citizens Certain aliens*	Privacy Commissioner	No

\* Aliens admitted for legal residence

prevent the personal data collected about themselves for one purpose being used for other purposes without their prior knowledge or consent.

6. *Disclosure limitation.* There must exist limits on external disclosures of personal data about individuals that record-keeping organizations may make, and there must exist legally enforceable confidentiality obligations of record-keeping organizations with respect to the use and disclosure of identifiable personal data.
7. *Accountability.* Record-keeping organizations must be accountable for their personal data record-keeping policies, practices and systems.

In privacy protection laws these principles are stated as rights that individuals have *vis-à-vis* record-keeping organizations, and requirements that the latter must comply with. As is to be expected, the national privacy protection legislation in each country tends to state the requirements and provide for compliance in a manner that is consistent with its existing legal system, traditional approach to establishing regulatory mechanisms and cultural setting. For example, some countries require licensing of record-keeping systems prior to permitting operation (e.g., Sweden), while other countries (e.g., the United States) rely on a corrective approach—those record-keeping organizations that fail to comply can be subject to court proceedings and penalties.

In general, national laws require that record-keeping organizations implement the following types of procedures and safeguards:

1. Inform individuals and the public in general about the existence and details of all record-keeping systems.

2. Notify individuals about existence of personal data records about them.
3. Establish procedures and facilities where individuals can inspect their own records; make records available in comprehensible form; establish procedures for reviewing challenges to data quality; provide means for correction and inclusion of rebuttal statements; and establish mechanisms for notifying prior recipients of disputed records of any corrections or additions.
4. Refrain from using data for new purposes unless explicitly permitted by law or by individuals concerned; establish procedures for requesting permission.
5. Keep accountings of all disclosures to external organizations such that the data could be traced (e.g., for sending corrections).
6. Establish procedures and means to ensure that personal data are collected by lawful means, and that they are appropriate and relevant to the purposes for which they are collected, and that they are maintained accurately, completely, and are up-to-date.
7. Maintain confidentiality of personal data by permitting access by only those personnel who need them to carry out their job functions.
8. Conform with security standards that afford reasonable protection to the installation, programs and data against accidental or willful loss or destruction, and against unauthorized access, alteration, or transfer.

A guiding principle in implementing privacy protection requirements by record-keeping organizations should be "easy access" by individuals to personal data about them—by mail or at locations close to their residences, at convenient times, without need to justify why they would like to

inspect their records, with the least amount of red tape in identifying themselves, and with the record-keeper, rather than the individual, charged with the burden of proof that the challenged data are actually correct or relevant.

#### *International aspects*

Any extension of one country's privacy rights to some other country to follow exported personal data involves the possibility that privacy rights in the "host" country are weaker, totally absent, or incompatible in some manner. For example, compared to some of the European countries, privacy protection in the United States at present is weaker, since only a small part of the private sector is covered, only citizens or aliens admitted for permanent residence are covered, and compliance is on a self-enforcement basis. Consequently, non-tariff barriers to international data flows and transnational data processing can arise when countries with strong privacy protection laws restrict data exports to those with weaker laws. While privacy protection should relate only to personal information about individuals, its scope can be extended to data that are indirectly related to individuals. Laws that also cover legal persons (e.g., corporations) have, of course, a much wider scope and can be used to restrict export of nearly all data.

The potential legal obstacles and conflicts in providing privacy protection on a transnational scale have prompted several international bodies to study the problem and develop solutions.<sup>12</sup> Since 1977 the Council of Europe is developing an International Data Protection Convention to establish a minimum set of privacy protection principles for all people in countries that ratify the convention (possibly the 21 countries in Europe, but others are also encouraged to join) without regard to their nationality, but permitting each signatory country to choose its own method of implementation.<sup>13</sup> Several procedural considerations in the Convention are still unresolved, such as the question of which country has jurisdiction, and what international mechanism is best for enforcement.

Another activity toward harmonization of national privacy protection laws is taking place in the Organization for Economic Cooperation and Development (OECD) in France. OECD membership includes a larger community of countries (European countries, U.S., Canada, Japan, Australia, New Zealand) and, thus, could achieve harmonization on a larger scale. At the present time OECD is drafting a set of guidelines for establishing the basic rules governing transborder data flow and protection of individual privacy in transnational data processing systems.<sup>14</sup> Finally, also concerned with privacy protection on an international scale and the associated concerns in transnational data flows are the European Economic Community (EEC) and the Intergovernmental Bureau for Informatics (IBI).<sup>15,16</sup> The latter represents many of the so-called "third world" countries which, as data exporters, have many serious concerns regarding their position *vis-à-vis* the developed countries.

The recent conference on Strategy and Policies for Informatics (SPIN) brought out many of these concerns.<sup>16,17</sup>

#### IMPLEMENTATION IN TRANSNATIONAL SYSTEMS

Implementation of privacy protection requirements in transnational data flow situations can be discussed with the help of a set of simple models. The following basic elements will be used in these models:

*X*—An organization in a "home country," *A*, that collects, maintains and uses personal data on individuals residing in *A*, subject to privacy protection laws and regulations that may be in force in *A*.

*Y*—An organization in a foreign "host country," *B*, that collects, receives, processes, stores, and/or uses, as the case may be, personal data about residents of *A*, subject to applicable privacy protection laws and regulations of *B*.

In each of the following data-flow situations, the basic goals from the point of view of privacy protection authorities in the home country *A* are to ensure that (1) individuals involved be able to continue exercising their privacy rights granted in *A*, (2) data quality and integrity continues to be maintained, (3) misuses of the data, as defined in *A*, are prevented, and (4) confidentiality and security of the data are maintained.

#### *Transnational service bureaus*

A common situation in transnational data flows is the case where *Y* is an international vendor of data processing services with computers and data bases in country *B*, as well as in several other countries, that services subscribers in several countries. *Y* may provide processing services only, or provide both processing and long-term storage of the subscribers' programs and data. A record-keeping organization *X* in its home country *A* may contract for *Y*'s services because of competitive economic advantage or because *Y* may offer resources or capabilities not otherwise obtainable.

The responsibility for complying with any privacy protection requirements in its home country, *A*, naturally belongs to *X*, independently of where the data themselves are processed and stored. Thus, in the public notices about its record-keeping operations, *X* must reveal information on any uses of foreign data processing services, and satisfy other requirements regarding the rights of its data subjects to inspect, correct and amend their records. *X* must also assure data quality (relevance, correctness, completeness and currency) prior to transmitting these data abroad. In this regard, it would be preposterous to require data subjects in country *A* to deal directly with the vendor *Y* in country *B* when they want to exercise their privacy rights, or to require that *Y* establish the data quality (e.g., to

assure completeness when engaging in data collection activities in country *A*), in the first place.

In contracting with *Y* for data processing or storage services, *X* must be assured that data accuracy is not diminished while in *Y*'s system, and that confidentiality and security are maintained so as to prevent any unauthorized disclosures or uses while in *Y*'s custody. For this purpose *Y* must implement appropriate procedural and technical safeguards in its computer systems and data communication networks. In general, it is not likely that *Y* would clandestinely copy and retain its customer's programs and data—it would not stay in business very long. Even then, confidentiality and security requirements, and prohibitions about retaining data or programs should be explicitly stated in the contract between *X* and *Y*. Any violations could then be handled in ways commonly used in the case of international contracts.

A more difficult situation arises when *X* deliberately attempts to evade privacy protection requirements in its home country, *A*, by maintaining illicit data abroad. For example, *X* may be a credit reporting bureau that collects personal information items not permitted in *A*. Here it is unreasonable to require *Y* to police the data processing requests of its subscribers and to make determinations whether or not they violate laws in the subscriber's home countries. To protect itself against unknowingly being an accomplice to activities illicit in *A*, *Y* may require that *X* certify in the contract with *Y* that its data processing activities are not illicit. In general, *Y* should not be held responsible for the uses of the data it processes or stores, but it should be obliged to inform privacy protection authorities of suspected violations.

#### *Shared data banks*

In a different situation, *Y*, the data processing organization abroad, may operate a data bank of personal information and make information available to an international community of subscribers who also contribute personal data on individuals in their respective countries. An example would be an international credit reporting bureau. *X* could be an international chain of department stores that gives credit to purchasers in many countries that, as a part of its contract with *Y*, sends credit status information on its customers in country *A* and in other countries. The individual records in *Y* are likely to contain personal information from multiple sources.

In the case of a similar system within a given country, privacy protection laws in that country give rights to individuals to examine their records, request correction, etc. directly at the record-keeping organization (e.g., the credit reporting bureau). In the transnational case the situation is more complicated. Again, it is not reasonable to require individuals to interact directly with the organization *Y* abroad. Enforcement of privacy rights afforded to individuals in *A* whose personal data are in *Y*'s records can also be done only in indirect ways. This is a good example of a

case in which international harmonization and cooperation between privacy protection authorities would pay off—each country would provide at least an agreed-upon level of privacy protection to everyone whose personal data are processed or stored in the country and, thus, all record-keeping organizations would be made to comply to essentially similar laws. In that case, any organization *X* in *A* that subscribes to *Y*'s services could be required to act as an interface between individuals in *A* and *Y*, and *Y* would be required by privacy laws and authorities in its own country to make their records available at *X*'s facilities and treat their requests with the same attention as it would treat those by individuals in its own country.

Maintenance of data confidentiality and security, and taking steps to assure that the existing data quality does not diminish in *Y*'s systems would be the procedural and technical responsibility of *Y*, but the quality of the data provided by subscribers *X* would be the latter's responsibility. Implementation and enforcement of this could be based on affixing unforgeable digital signatures to all data items to indicate their origins.<sup>18</sup> Techniques for generating such signatures through cryptographic methods have recently been developed.<sup>19</sup>

#### *Multinational corporations*

For the case in which *X* is a subsidiary or an operating unit in country *A* of a multinational corporation *Y* that is headquartered in country *B*, *X* is likely to send to *Y* personal data on at least some of its employees who are also residents (citizens) of *A*. Unlike in the previous two models, these data are likely to be used abroad to make decisions about the individuals involved, not just merely to be processed and stored there. *X* must necessarily comply with any privacy protection requirements that are in force in *A*, and, thus, its employees would have access to their employment records to the extent specified by those laws. They would also have to be informed about personal data files maintained on them at the headquarters, *Y*, in country *B*. Again, *X* may have to serve as the interface between these individuals and the corporate headquarters (which it would do anyway as an element of corporate hierarchy) and be responsible for compliance with privacy protection laws in *A*. However, in this case it would not be unreasonable for the employees concerned to interact directly with *Y*, too.

To arrange for access to personal data about them at *Y* in accordance with their privacy rights in *A* when such rights are not available in the headquarter's country *B*, the privacy protection authorities in *A* may have to make special arrangements with *Y*. In the limit, they may prohibit transmission of personal data from *X* to *Y*, or recommend other regulatory restrictions on the operation of the multinational in country *A*. Of course, any such actions would involve analyses of tradeoffs of benefits to *A* of the multinational's operations in *A* as against possible limitations of

the privacy rights of its residents employed by the multinational.

#### *Data collection abroad*

There are at least two cases where data about residents of *A* are acquired by an organization in *B* directly without the role of some organization *X* in *A*: (1) in *B*, personal data on visiting residents of *A* are collected by some organization *Y* (e.g., the customs office or the police), and (2) in country *A*, employees of an organization *Y* located in country *B* are collecting personal data on residents of *A* (e.g., salesmen of a business firm). In both cases it is necessary to find out that such activities are taking place and, if legitimate, attempt to arrange privacy protection available in *A* to include personal data on residents of *A* maintained by these organizations.

In the first case, privacy protection to residents of *A* depends entirely on privacy protection laws that may be in force in *B*, or on bi- or multilateral agreements that may have been made between *A*, *B*, and other countries in this regard. Under such agreements, participating countries could compile lists of organizations in their countries that collect personal data about visitors from abroad, make these lists public on a reciprocal basis with other countries, and permit the basic privacy rights of access and request for correction to be exercised. Thus a certain balance could be established whereby international travelers would be assured that data are not collected about them for purposes of harassment or other actions against them when they are abroad or upon their return home.

Not much can be done in the second case when data collection in *A* in behalf of some organization *Y* in *B* is done clandestinely. When such collection is in the open, however, the privacy protection authority in *A* can insist that this be permitted to continue only if privacy rights in country *A* be extended to cover these data when maintained by the organization *Y* in country *B*. In some cases such collection may be prohibited entirely, as in the so-called *Reader's Digest* case in Sweden where the Swedish Data Inspection Board objected to the establishment of a data base in England on nearly all households in Sweden.

#### TECHNOLOGICAL CONSIDERATIONS

Technical concerns in implementing privacy protection requirements in both national and transnational data systems arise mainly in the areas of data security, maintenance of data quality, design and maintenance of data bases of personal information, auditing, and enforcement of compliance. In each of these areas there exist considerable technical capabilities, but also certain shortcomings of the state of the art. These must be kept in mind when privacy protection requirements are specified. Any problems that may arise in implementing national privacy protection requirements are likely to be amplified in transnational data systems where, unless perfect harmonization of privacy

protection laws is achieved, different countries are likely to have different requirements for data quality, confidentiality, etc., which may have to be reflected in the system design and operation.

#### *Data security*

Privacy protection principles and associated requirements that limit the use and disclosure of personal data, and that establish data quality and accountability responsibilities imply the use of data security techniques and safeguards. In general, data security encompasses the procedural and technical means for reducing the risk of unauthorized data disclosure, distribution, modification, or use, and of any physical damage to the computer communication system. Case histories of computer crime, attacks against computers by terrorists, and uses of computers to defraud their owners or the public at large underscore the reality of these risks. Indeed, concerns of the users of transnational data processing services over continuing availability and integrity of these services are not entirely unfounded.

After a decade of concern over data security and research and development of technological safeguards, there is now available a variety of techniques for implementing physical security, access controls within software and communications security:

1. Except for international standards, physical security techniques are well in hand for protecting computer installations against natural disasters, preventing unauthorized access, providing safe data storage, and setting up backup data bases, processing facilities, and communications links.<sup>20</sup>
2. Software security techniques deal with protecting programs and data, and especially the operating system software against unauthorized access or modification due to hardware malfunctions of deliberate attempts. While software security cannot yet be guaranteed, the "security kernel" approach is promising and is being pursued actively.<sup>21</sup>
3. Techniques for unique, unforgeable identification and authentication of users have made considerable progress; the development of new approaches to digital signatures are particularly relevant in the context of transnational data systems.
4. New developments in cryptographic techniques, such as the Data Encryption Standard<sup>22</sup> and the proposed public-key cryptosystems<sup>23,24</sup> are making communications security easier and less costly to implement.

The use of encryption in transnational data communications is subject to more than just technological and economic considerations that complicate options for achieving effective communications security:

1. While international standards for technical aspects of data communication are being developed, no stan-

dards are available for data security in communications systems.

2. Existing international agreements, such as the International Telecommunications Convention of Malaga-Torremolinos, recognize the "sovereign right of each country to regulate its telecommunications," and reserve the right to monitor any communications and their contents. Thus the use of encryption in transnational data systems depends on whether or not governments involved insist on access to the keys or prohibit the use of encryption entirely in their communications systems. The use of satellite communications can reduce some of the severity of this problem, however.
3. On the international scale, there is no uniformity of legal prohibition against interception or diversion by private parties of data transmitted in telecommunications systems.
4. There is a wide variation in the technical characteristics and quality of the telecommunications links in various countries that may be involved in transnational data flows and, correspondingly, there are wide variations in their vulnerabilities from the data security point of view.

Among the state-of-the-art shortcomings that must be taken into account when formulating privacy protection requirements that depend on implementing data security techniques in various subsystems of a data network are the following:<sup>25</sup>

1. Absolute security is not yet achievable in any automated, multi-user, resource-sharing data processing system or computer network, since it is not yet feasible to prove correctness of its operating system's design and implementation, nor can the hardware be guaranteed to be free of design flaws.
2. Physical security of a computer communication network, even though all techniques are well known, cannot be guaranteed against sophisticated penetration or overpowering attacks.
3. Personnel trustworthiness cannot be reliably predicted, assured, or maintained.
4. Currently-proposed encryption techniques appear to offer high levels of resistance against attempts to "break" them, but this has not been proven against massive analytical or trial-and-error attacks based on advanced computer technology.
5. The "confinement problem," leakage of sensitive data from a protected system using some externally observable system variable (e.g., the execution time of a program), has not been adequately solved and, thus, represents another security vulnerability.

Even a reasonable amount of security may be difficult to achieve in a provable manner in large and complex systems. Risk analysis methodology and techniques have not yet been developed to levels where they can be used with confidence since adequate guidelines on how to satisfy a

specified security requirement are yet to be developed,<sup>26</sup> and threat detection and monitoring techniques are not adequate for detection of covert penetration attempts while they are in progress. These shortcomings are multiplied in complex, transnational telecommunication systems. In statistical data bases that contain personal data in aggregate form, it is still possible to compromise such data by associating the summary data with identifiable individuals on the basis of other data that may be available and the context of particular situations.<sup>27</sup>

Finally, a system of security safeguards is effective only when it is correctly designed and implemented, operates correctly, and is constantly monitored for lapses in performance. In a transnational computer communication system this implies standards, access to equipment that may be located in other countries, ability to audit the system's operation and, if parts of the system are under the control of third parties, cooperation from them when corrective actions must be taken. While many of the necessary procedures can be established within a contractual framework between the parties involved, certain aspects of enforcing these contracts may require effective international agreements and support.

#### *Data base systems*

The design of personal information data bases is strongly affected by privacy protection requirements regarding data quality, confidentiality and security, auditing and accounting. In general, it will be quite difficult and costly to restructure existing data bases to incorporate the additional data fields and data traceability capabilities that are implied. The design of new data base systems that incorporate these requirements is a much simpler matter.

Maintenance of data quality is an important privacy protection requirement in any personal data record-keeping system since these data are the principal and sometimes the only representation of the individual for decision-making purposes. Thus, these data must be (1) appropriate and relevant for the purposes for which they are used, (2) accurate, complete, and up-to-date, and (3) obtained by fair and lawful means. Determination of the relevance and appropriateness of personal data items to be collected is an important policy matter. Inclusion of certain data items and exclusion of others, and the time periods of retention can significantly affect the fairness of decisions. Some of the national privacy protection laws (including the Privacy Act of 1974) contain restrictions on the types of data items that may be collected, and the Council of Europe's draft Convention has proposed others, but more work needs to be done in this area, especially from the point of view of transnational data flows.

Achieving and maintaining accuracy, timeliness and completeness in personal data items that have been determined to be relevant is mainly a procedural and technical matter. It may be necessary to include in records additional data fields to indicate the age of various data items, to provide for appending any rebuttal statements and to provide for

tracking data disseminations such that corrections can be propagated to recipients as well as into backup files. Access limitation requirements imply establishing a selective access capability in the data base system. Special programs, possibly in several languages, may have to be written for translating data codes into natural language statements comprehensible to individuals who may wish to inspect their records. Associated with the above are various accounting requirements to (1) permit furnishing to individuals records of all uses made of their personal data, (2) permit propagation of corrections and rebuttal statements to prior recipients and (3) provide information for audits and compliance verification. While these data base additions are relatively simple to include in newly-designed data bases, retrofitting them into existing data bases is a much more difficult and costlier task.

#### *Auditing and compliance verification*

Auditing of a transnational data processing system for compliance with privacy protection requirements, and verifying that no one involved is taking actions to circumvent required safeguards, is a difficult technical problem. Indeed, there are several reasons why assuring total compliance may be technologically infeasible, especially in transnational data systems:

1. Auditing of the system software and its operation cannot be done with high confidence due to the complexity of tracing system's transactions, and the difficulty of understanding the software. Proving software correctness by formal means is infeasible for all but very small systems, although advances have been made in proving correctness of software design relative to specifications.<sup>28</sup>
2. It is not possible to prove that the system's hardware, software or applications programs have not been specified and designed to covertly circumvent privacy protection requirements, or to mislead the auditors. Clever techniques could be used to hide deception, such as the use of "shadow systems" where auditors may find complete compliance, while illicit data are maintained in other parts of the system inaccessible to the auditors.

Thus, in general, it is not possible at the present time to verify positively without full cooperation of the record-keeping organization being audited that its automated record-keeping systems are in full compliance with privacy protection requirements. That is, it is not possible to prove that an organization does not maintain secret record-keeping systems or illicit data, that it permits individuals to inspect all data about them, that it is not engaged in clandestine data exchanges with other organizations, or that it is not using personal data in its system for purposes that have not been publicly announced.

Technical solutions to the auditing and compliance verification problems are now being developed<sup>29</sup> but they are

likely to be complex and costly. For example, it may be necessary to design and install tamper-proof accounting systems similar to the flight recorders now used in commercial aircraft. In the interim, it may be necessary to depend on the expectation that technically-motivated employees of record-keeping systems, especially those of transnational data processing systems, will inform privacy protection agencies or the media of suspected violations.

#### CONCLUDING REMARKS

Implementation of privacy protection and data security requirements in transnational data systems involves numerous unanswered questions about policies, procedures and technical means. From a brief examination of different types of transnational data processing situations it appears that individual privacy rights are easiest to exercise when organizations that send personal data abroad are made responsible for interfacing with the individuals involved. Organizations abroad that perform only the processing and data storage functions have to be responsible for maintaining data quality at the original level, and assuring data confidentiality and security.

Techniques now exist for satisfying most of the data security requirements, but shortcomings still exist, and their effective use in transnational computer communication systems may be constrained by the lack of international standards and by the policies of the countries involved. No technical problems appear to arise in designing new data base systems that include provisions for meeting privacy protection requirements, but retrofitting old ones may range from excessively costly to downright technically infeasible. No technological means are available to assure total compliance with privacy protection requirements.

Computer technology is advancing rapidly and new capabilities for record-keeping in national and transnational systems are certain to emerge. Some of these may enhance avoidance or circumvention of privacy protection requirements. Hence it is important that technological advances in record-keeping be monitored continually and the adequacy of existing privacy protection requirements be periodically reevaluated.

# A modular approach to computer security risk management

by ROBERT P. CAMPBELL and GERALD A. SANDS

*Headquarters, Department of the Army  
Washington, D.C.*

## INTRODUCTION

Risk management is concerned with the identification, measurement, control and minimization of impact of uncertain events upon organizations that depend upon automated operations.<sup>11</sup> It is an analytical process with a large number of variables, many of which are unique to the environment under consideration. For this reason, there has not yet been developed within general state-of-the-art a single methodology broadly applicable to all risk management environments.<sup>1,10</sup>

The proposed risk management model is designed to provide a framework responsive to the needs of most environments. To derive this model, many risk assessment schemes were reviewed and analyzed for their ability to satisfy a broad range of needs.<sup>3-7,9</sup> While none were found which could meet these criteria, their different philosophies and schemes provided excellent background for development of the present model. Additionally, experts from industry were consulted and many security surveys, tests, evaluations and audits were analyzed for useful methods and procedures.

It is generally accepted within industry and the federal government that, given today's state-of-the-art in data processing and security, there does not now exist the capability to completely assure the security of sensitive automated operations. It is also agreed that the best method of controlling risk and achieving optimum security is through the use of some type of risk analysis or assessment process which provides decision-makers sufficient information to enable them to make informed judgments regarding the relative risks to these sensitive automated operations.<sup>2</sup>

Risk management is a management responsibility, involving all levels of management dependent upon sensitive automated operations.<sup>1</sup> These managers need to play an active role in the risk management process, making decisions regarding impact of risks upon support vital to operations of their organizations. Data processing has traditionally been a support function. However, it has become so indispensable and so much a part of overall business operations as to be virtually inseparable. As part of the risk management process, senior management must accurately ascertain its degree of reliance upon the data processing function.

Current risk management schemes are based almost exclusively on assessing the impact of uncertain events upon the data processing function alone, when in fact, losses

suffered through compromise of sensitive information, unauthorized exposure of personal information, or misappropriation of resources handled by automated systems are not borne by the data processing function. These losses are sustained by the owners of the data, the functional proponents and users of the system who, through senior management at various levels, must be represented in and dominate the decision-making process. Given the risk management responsibility, the data processing function (since it does not absorb the true loss) can reasonably be expected to accept the risk rather than divert resources from the data processing budget to counter security weaknesses.

Similarly, senior managers should carefully assess the impact upon the data processing function of attempting to implement necessary security improvements within existing data processing resource levels. In most instances, because of previous inattention to data processing security needs, considerable resource investment will be needed initially to bring operations up to minimum security standards. Past experience has shown that failure to supplement data processing resource levels for basic security needs has resulted in (a) minimal implementation of security improvements, or (b) considerable degradation of operational programs due to significant diversion of data processing resources. Managers should review these potential impacts and consider an initial supplement of data processing resource levels so as to eliminate undesirable contention for resources.

The specific features desired in a risk management model include the following:

1. It should be modularly structured so that discrete activities and tasks can be described and independently conducted, where appropriate. Some 40 separate modules have thus been identified in the accompanying model as a result of decomposition of basic activities.
2. It should be hierarchical, so that it can be applied in varying depths and degrees based upon the sensitivity and size of the data processing environment being assessed.
3. It should be iterative, logically allowing the entire process or a part of the process to be reinitiated or repeated as necessary.
4. It should prescribe, for each major step or activity, the participants, their responsibilities and decision-making authorities, with particular emphasis upon the involve-

ment of system users, proponents and senior management.

5. It should *not* require all factors to be reduced to quantitative terms. State-of-the-art is such that all factors cannot be reduced to discrete dollars and probabilities. Experience has shown that, except in highly specific situations, attempts to fully quantify all factors usually produce misleading results. Instead, managers and decision-makers must be involved in making qualitative judgments.

**THE RISK MANAGEMENT MODEL (RMM)**

The model described herein decomposes into sufficient detail to allow depth of analysis to vary with the specific nature of the problem. The less sensitive operation will require lesser analysis, while the more sensitive will require considerably more extensive analysis. The RMM (Figure 1) is composed of eight basic steps—Value Analysis, Threat Identification/Analysis, Vulnerability Analysis, Risk Analysis, Risk Assessment, Management Decision, Control Implementation and Effectiveness Review.

*Value analysis (1.0)*

The purpose is to determine the relative value of a facility or operation and its components for the purpose of evaluating its susceptibility to exploitation. The objective is to use value analysis to achieve an understanding of the likelihood that a particular facility, the information handled by that facility, and/or the function performed by that facility would be singled out for exploitation.

The value analysis process is based upon the following analytical procedures as illustrated in Figure 2:

1. Determine sensitivity of information handled (1.1).
2. Determine mission impact of loss or denial of support (1.2).
3. Estimate the asset value of automated resources providing support (1.3).

*Determine sensitivity of information handled (1.1)*

The basic analysis of sensitivity should begin at the application level. The objective is to relate each application (including data base manipulated) to a sensitivity level based upon the most sensitive type of data processed (e.g., privacy, asset/resource, proprietary). This analysis provides the framework for subsequent analysis (Task 1.2), so its detail and accuracy are important.

Information collected at the application level should be aggregated at the subsystem, system and finally at the data processing activity level in order to accurately assess the types of sensitive information being handled and the nature of processing performed on that information. The cumulative value of this analysis lies in the factual data compiled about application software and the data bases being manipulated. This should reveal the sensitivities of the data bases and the products derived therefrom. The bulk of this information should be collected from within the data processing functional area of assessment by system proponents and user organizations.

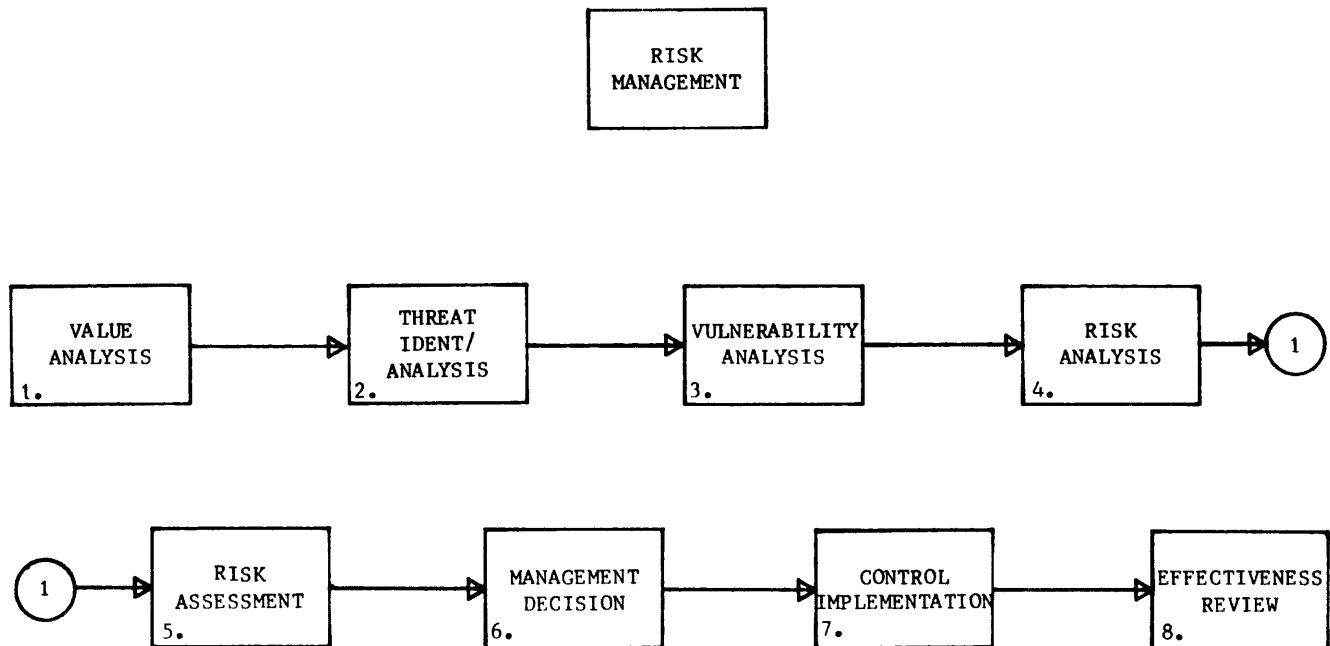

Figure 1—The risk management model.

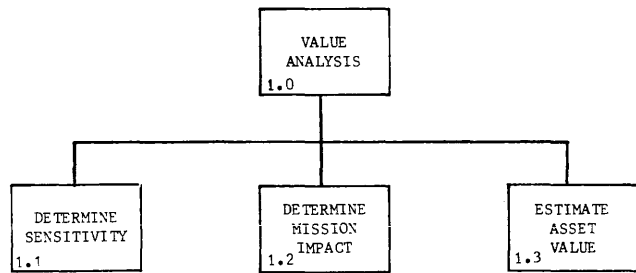

Figure 2—The value analysis process.

*Determine mission impact of loss or denial of support (1.2)*

Analysis should be performed of the general impact upon the mission of the organizations supported in case automation support capability is partially or totally lost for varying periods of time. This includes determination in as much depth as necessary (i.e., application, subsystem, or system level) the impact of any loss of automated support. Impact could be categorized as "Negate," "Major Impact," "Moderate Impact," "Some Impact", and "Little or None." If useful, period of time of loss can be quantitatively estimated for each degree of impact (i.e., one-day loss of support would be of "some impact," whereas loss of support for seven days can have "major impact").

Judgment as to the impact should be made by management officials that use the product of the application. If the users are not the sponsoring organization, the judgment of the sponsoring organization should also be solicited. Judgments on impact of loss should be rendered by higher-level management officials as applications are aggregated into subsystem, subsystems into systems and impact upon entirety of supported organizations is adjudged. Final review and judgments of impact should be made by the heads of organizations supported.

For purposes of value analysis, it is not intended that in-depth study and analysis be conducted into the specific losses and into quantification of losses. Such analyses will be conducted during later tasks. At this juncture, all that is required are subjective statements by management-level officials about the importance of automated operations to the mission of supported organizations.

*Estimate the asset value of automated resources providing support (1.3)*

While the risk assessment process should be oriented primarily toward the impact of loss upon supported organizations, the asset value of automation support resources is often so high as to merit consideration in this process. Consequently, fixed assets such as physical facilities, equipment, furnishings and other ADP-related assets (add equipment, supplies, software and documentation) should also be valued at either cost or replacement value, whichever is more realistic. The following should be determined in terms

of the dollar value of:

**Physical Facility**

- Building/Rooms
  - Office equipment and furnishings
  - Special equipment (fire extinguishers, degaussers, microfiche viewer)
  - Utilities (electricity, air conditioning, heat)
- Subtotal \_\_\_\_\_

**ADP Equipment and Supplies**

- CPU and memory units
  - Peripheral storage devices
  - Input/Output equipment
  - Specialized devices (off line plotters, COM)
  - Communication devices (controllers, modems)
  - Storage media (mag tapes, disk packs)
  - Remote I/O devices
- Subtotal \_\_\_\_\_

**Software** (cost or lease—use estimated purchase price. Do not include applications software unless purchased or leased)

- Systems software
  - Utility software
  - Other software (programming aids)
- Subtotal \_\_\_\_\_  
Total \_\_\_\_\_

**Nature of Supporting ADP Operations**

- Estimated hours of processing (annually)
- Number of applications
- Size of data base manipulated

*Threat identification/analysis (2.0)*

The purpose is to identify threat agents as they relate to the particular facility or operation, and the manner by which they may be manifested. A threat is manifested by a threat agent using a specific technique, methodology, or spontaneous occurrence to produce an undesired effect upon a facility, operation, or system. Threats may be *actual*, in which case there is documented evidence of a threat or class of threats, or they may be *postulated*, based upon an assumed capability for which there is no hard evidence. Research and investigation of threats should be conducted jointly by facility personnel, security personnel, local fire department officials, and others able to contribute to this analysis. Figure 3 illustrates this process.

*Identify threat agents (2.1)*

Threat agents are considered to be environmental factors (tornado, hurricane, earthquake, flood, fire, rain, etc.), au-

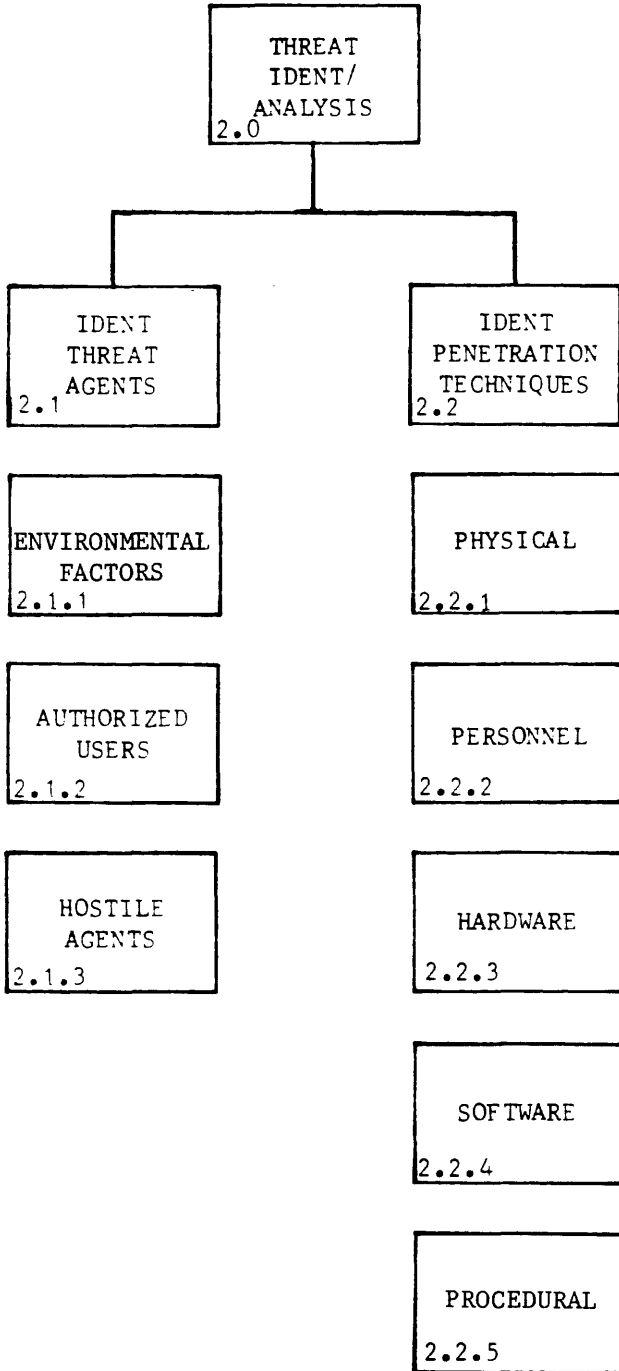

Figure 3—Threat analysis process.

thorized users (programmers, operators, customer) and "hostile" agents (anyone not an authorized user). The purpose of this step is to identify those threat agents likely to affect this specific facility or operation by reviewing generic threat agents, documenting evidence of those agents pertinent to the specific situation and/or drawing inference as to the seriousness of the threat they pose to the facility or operation.

**Environmental factors (2.1.1)**

Some areas of the country are more prone to certain environmental influences than others. Managers should be aware, for example, of the types of natural disasters likely to occur in their area. Some types of disasters, such as fire, are not geographically dependent, while others, such as tornadoes and floods, can be anticipated on a more regular basis in specific areas.

Chapter Two, Federal Information Processing Standards Publication 31 (FIPS Pub 31), June 1974, a U.S. Department of Commerce, National Bureau of Standards publication on Computer Security in ADP Operations, deals with the subject, "Anticipating Natural Disasters." Areas of the country particularly susceptible to the various types of disasters are clearly identified, and methods of preparing for these disasters are discussed.

In addition to natural disasters, appropriate concern should be directed towards the threat of mechanical and electrical equipment failure and curtailment of electrical power. They can easily disrupt operations as effectively as other more hostile types of threats.

**Authorized users (2.1.2)**

Authorized users and ADP personnel engaged in support operations can be considered as potential threats when they exceed their privileges and authorities and thus affect the ability of the system to perform its mission. Personnel granted access to systems or occupying positions of special trust and having the capability or opportunity to abuse their access authorities, privileges, or trusts will have to be considered as potential threats during this evaluation.

**Hostile agents (2.1.3)**

"Hostile" agents could be anyone, not an authorized user of the system, who by design, attempts to interrupt the productivity of the system or operation either overtly or covertly. Overt methods could include outright acts of sabotage affecting hardware and associated equipment, or more subtle efforts of destruction which could be accomplished through the manipulation of software, both systems and application.

**Identify penetration techniques (2.2)**

A threat agent mounts an attack against a facility or operation using a single or a group of specific techniques, methods, or spontaneous occurrences. A useful means of categorizing these techniques is according to the five sub-disciplines of automation security—physical, personnel, hardware, software and procedural security. For example, a threat agent mounting an attack against a facility by trying to subvert access controls would be using a physical penetration technique.

**Physical (2.2.1)**

Physical penetration implies use of a physical means to gain entry into the restricted areas housing the ADP system or any of its components. It could be a building, compound, room, or any other area designated as part of the ADP site.

**Personnel (2.2.2)**

Penetration techniques and methods generally deal with the subverting of personnel authorized some degree of access and privilege regarding a system, either as users or "operators." (As used here, "operators" are considered to be anyone involved in the operation of the system—analysts, programmers, operators, tape librarians, input/output schedulers, maintenance, custodial personnel, or the like.) They can be recruited by a threat agent and used to penetrate the system, operation or facility, or can themselves become disaffected or motivated to mount an attack. Highly technical functions performed with minimum effective supervision or control represent the types of circumstances under which an attack may be launched. For example, the vendor's hardware maintenance personnel are equipped with detailed technical knowledge and sophisticated diagnostic tools that can be used to penetrate the system. Generally, no one in the user organization has the technical knowledge base (a vulnerability) to effectively review and affirm the actions of the customer engineer.

**Hardware (2.2.3)**

Attacks can be mounted against the hardware for the purpose of using the hardware as a means of subverting or denying use of the system. A physical attack against the equipment, a "bug" implanted within the hardware or an attack against the supporting utilities are means of subverting the system by using the characteristics of the hardware. Hardware, as used in this category, generally includes any piece of equipment which is part of, or comprises the system, i.e., the mainframe, peripherals, communications controllers, or modems. It also includes indirect system support equipment, such as power supplies, air conditioning systems, backup power, water supplies and the like.

**Software (2.2.4)**

Software penetration techniques can be directed against systems software, applications programs, or utility routines. Software attacks can range from discrete alterations, subtly imposed for purposes of compromising the system, to less discrete changes, intended to produce catastrophic results such as destruction of data or important systems features.

**Procedural (2.2.5)**

Authorized users or "hostile" agents can effect procedural penetration due to lack or inadequacy of controls, or

failure to adhere to existing controls. Examples of penetrations include former employees retaining and using valid passwords, unauthorized personnel picking up output, users "browsing" without being detected due to failure to diligently check audit trails, and personnel removing material from the computer room when not authorized.

**Vulnerability analysis (3.0)**

The purpose is to identify possible weaknesses existing in the defenses of a facility, system, or operation. Through analysis of identified weaknesses and weighting each on the basis of exploitability, an appreciation of the likelihood that a threat agent will mount an attack to exploit a specific weakness or series of weaknesses will be achieved. Vulnerabilities are weaknesses in our defensive mechanisms, exposing that which we are trying to protect. Vulnerabilities, like threats, are also causative factors. Vulnerabilities are generally under our control and can thus be modified to limit the effectiveness of an attack. Figure 4 illustrates the vulnerability analysis process.

**Identification of vulnerabilities (3.1)**

Weaknesses or flaws in the design, implementation, or operation of the security controls of a facility, system, or operation must be identified, whether through analysis of the security controls alone, or as causal factors directly related to a previously identified threat. Vulnerabilities can be classified and their relationships to threats more easily identified using the same basic categorizations used for threats.

**Weighting of vulnerabilities (3.2)**

Vulnerabilities just identified should be considered in relation to one another and arrayed according to adjudged seriousness and potential degree of exploitability. These

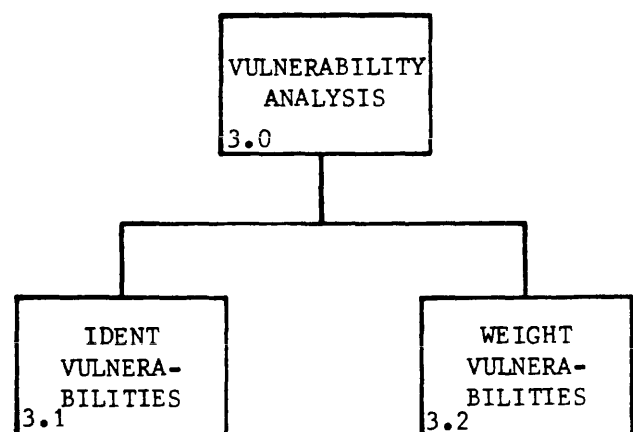

Figure 4—Vulnerability analysis.

judgments are made without consideration of the threat (threat relationship will be evaluated later) and based upon the experience of the appropriate management-level official. Not all vulnerabilities need to be weighted; general categorizations can be used (e.g., extremely serious, serious, minor). Weighting, at this point, should be pursued only to the depth and degree necessary to inform data processing management of the vulnerabilities and elicit management opinion as to their relative exploitability. It is not necessary that discrete values be assigned to each vulnerability or that probabilities and potential dollar losses be computed during this step. Informed judgments by data processing or other knowledgeable management-level official are desired and adequate.

*Risk analysis (4.0)*

The purpose is to identify specific undesirable events through analysis of the possible impacts of previously identified threats and vulnerabilities. The primary objective of this step is to determine the effects upon the system, facility, or operation caused by the interaction of threats and vulnerabilities. This is the "effect" portion of the "cause-effect" relationship. Identification of these relationships is extremely important to future analysis and documentation of impact, identification of countermeasures and cost/benefit analysis. Undesirable events are generally categorized as unauthorized disclosure of information, unauthorized manipulation of information, unauthorized use and denial of service, as depicted in Figure 5.

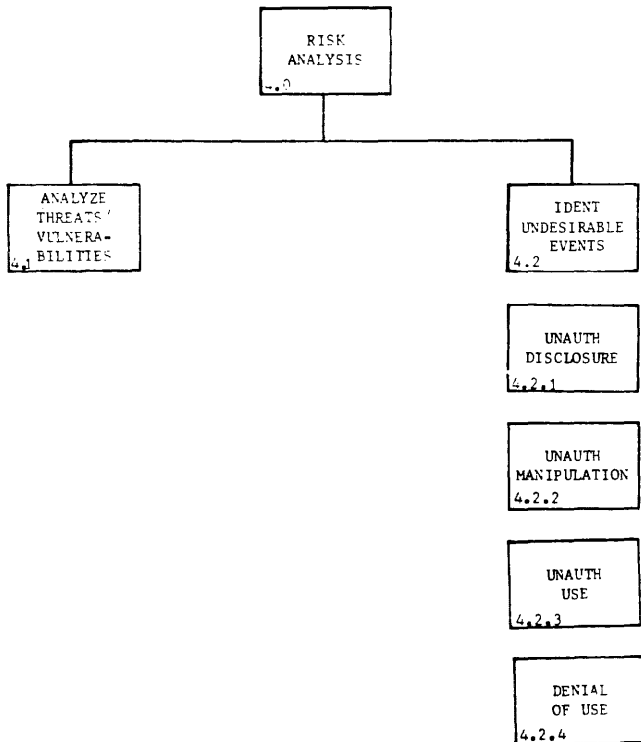

Figure 5—Risk analysis.

*Analyze threats/vulnerabilities (4.1)*

In this step, the formal relationships between threats and vulnerabilities are documented. The threat agent, the specific techniques or methods available to mount an attack and the vulnerabilities to be exploited (as previously identified), are now formally related and their relationship documented. The following two examples illustrate such relationships:

a. *Case 1*

**Threat Agent**—Authorized User.

**Attack Methodology/Technique**—Mounts an attack on the systems software by scavenging through memory workspace searching for passwords or other sensitive data.

**Vulnerability Exploited**—Residual data in memory working space is not erased, thus allowing sensitive information to be accessed by subsequent users not authorized such access; or

b. *Case 2*

**Threat Agent**—Hostile Agent.

**Attack Methodology/Techniques**—(a) Accesses remote terminal by bypassing physical security features; (b) Uses an authorized password, found on printout discarded in trash and unsecured User's Manual to access system.

**Vulnerabilities Exploited**—(a) Inadequate physical security of remote terminal area (area unguarded; simple key lock on door; no alarms or motion detectors); (b) Terminal software not disabled during non-duty periods when use is not authorized; (c) User's Manual left unsecured, revealing detailed sign-on procedures; (d) System software fails to suppress or block out password during sign-on/validation routine; (e) Sensitive trash left unsecured/unattended after duty hours.

As noted in Case 1, the relationship between threats and vulnerabilities may be linear or, as in Case 2, the relationships may be more complex.

*Identification of undesirable events (4.2)*

An undesirable event is considered to be a potential occurrence resulting from the activity of a threat agent exploiting a vulnerability. Whereas threats and vulnerabilities are causative factors, the undesirable events identified herein are the effects of these factors. Undesirable events are generally categorized according to effect upon the system, facility or operation:

- a. Unauthorized disclosure of information.
- b. Unauthorized manipulation of information.
- c. Unauthorized use.
- d. Denial of service or use.

In Step 4.1, the Case 1 situation describing the authorized user as the threat agent scavenging through working memory

covered only the causative threat/vulnerability factors. In this step, the effects must now be described. Continuing with the Case 1 scenario, the effect could be compromise of passwords and thus possible compromise of sensitive data accessed through use of those passwords.

#### Unauthorized disclosure of information (4.2.1)

Unauthorized disclosure includes access, either deliberate or inadvertent, to any type of sensitive information for which the individual has not been authorized access or does not have a need-to-know. In this context, sensitive information includes not only national defense, privacy, asset/resource, or proprietary information, but also critical system or operational information (passwords, system software, sensitive control processes) which should not be disclosed.

#### Unauthorized manipulation of information (4.2.2)

This category implies not only accessing information, but also manipulating and/or modifying it to destroy the integrity of the original information. Generally, a much more serious effect than unauthorized access, unauthorized manipulation is extremely difficult to detect and can insidiously deceive users or processors and contaminate other information. Unauthorized manipulation can also be a vehicle in fraud, and may take the form of creating unauthorized accounts and/or records.

#### Unauthorized use of information (4.2.3)

This category involves an authorized user using information for other than its intended purpose. Examples include using contractual or proprietary information for personal gain or using privacy information, such as home addresses and phone numbers, to solicit business.

#### Denial of service or use (4.2.4)

This category encompasses a wide variety of effects intended to partially or completely prevent use of the system

or its features caused by technologies ranging from blowing up the computer, destroying its source of power, causing the system to crash, or overloading the computer with tasks so as to make it sluggish and unresponsive. The primary variable in denial of service or use is the consistency of the effect lasting from micro-seconds to days or weeks. Denial of service or use may be either deliberate or inadvertent.

#### Risk assessment (5.0)

The purpose is to evaluate identified risks to determine their relative impacts upon the facility, the information handled, the processing performed, the support being provided and the mission accomplishment of the organizations being supported. The primary objective is to assess the severity of the identified risks and weigh the likelihood of occurrence so that they may be ranked according to degree of acceptability or unacceptability. This risk assessment task is the single most important activity in the Risk Management Model since it summarizes all previous risk analysis activities and presents these findings to appropriate levels of management for their review and evaluation. It is during this step that the senior management officials of the supported organizations are able to qualitatively confirm their reliance upon automated support for accomplishment of their mission. It is at this point also that the appropriateness of the assigned sensitivity designation should be reviewed and action initiated to change it, if necessary. The Risk Assessment Process (Figure 6) includes the sub-tasks of Assignment of Event Weights, Determination of Relative Impacts, Estimation of Likelihood and Ranking According to Acceptability/Unacceptability.

#### Assignments of event weights (5.1)

This task relates to the assignment of individual event weights indicating the severity of the effects of the undesirable events identified in the risk analysis process. This step is common to all risk analysis schemes and usually involves

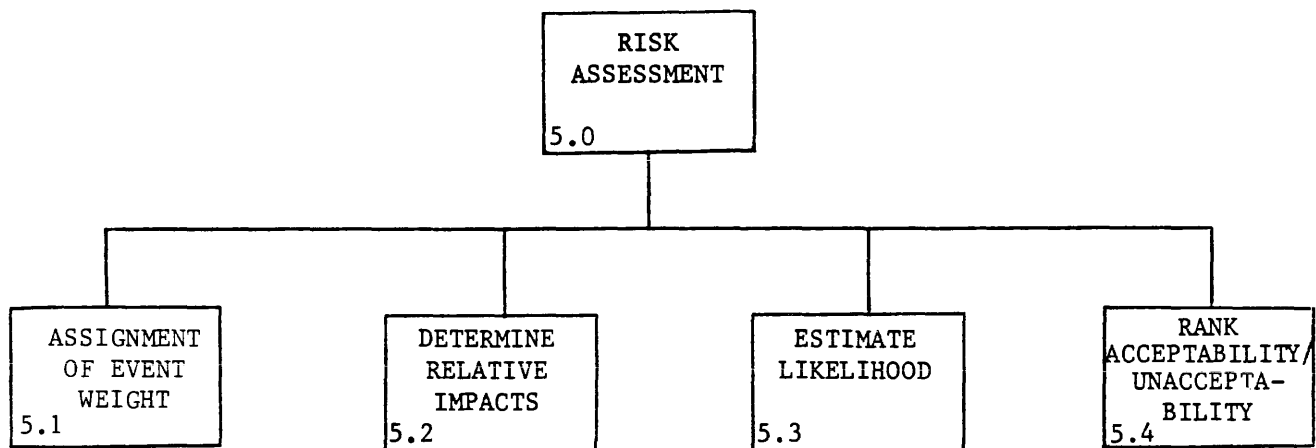

Figure 6—Risk assessment process.

some metric based upon probability of occurrence and estimated annualized dollar loss. As stated previously, use of quantitative probability and dollar-based metrics are generally not appropriate for the total measurement of impact upon the information being handled, the processing being performed, or the mission accomplishment of the supported organizations. Such metrics may have some utility in determining impact upon the physical facility. It is recommended that individual event severities be adjudged qualitatively by management-level officials using descriptive adjectives or a "fuzzy metric" and, at the most, a simple 0-10 or 0-100 rating scale. The success of this activity is dependent upon the quality of judgments made by management officials after they have had the benefit of all previous analysis. It is appropriate for replacement costs of physical facilities, equipment, supplies, data, or software to be estimated and entered into the decision-making process during this step.

#### *Determine relative impacts (5.2)*

This task formally assesses, for the first time, the relative impacts of all identified risks. The objective is to evaluate each in relation to all others to develop an appreciation for their relative severities. All quantitative and qualitative data collected thus far is evaluated and events scaled according to severity of impact. Again, qualitative descriptions such as "severe," "moderate," "light," possibly supported by a simple 0-10 or 0-100 rating scale, applied by the appropriate evaluators and/or managers, are the key inputs to this process. The end product is a table of undesirable events with qualitative descriptors of severity assigned.

#### *Estimate likelihood (5.3)*

This task requires analysis of individual undesirable events, and their interrelationship with other such events, to derive an estimate of the likelihood that each event will occur. Again, the application of qualitative descriptors, of "fuzzy metrics," such as "high," "moderate," or "low," to describe the possibility of occurrence is required. Previous weights and estimates assigned to threats and vulner-

abilities must be considered in arriving at these determinations. The end product is a table of undesirable events with qualitative descriptors of likelihood assigned.

#### *Rank according to acceptability/unacceptability (5.4)*

This task considers all previous analysis in arriving at an assessment of the relative degree of acceptability/unacceptability of each undesirable event. Qualitative descriptors, such as "unacceptable," "marginally acceptable," "acceptable," possibly supported by a simple 0-10 or 0-100 rating scale, and based upon the informed judgments of management officials, are the key inputs to this process. These officials must, for each undesirable event, consider the impact (Step 5.2) and the likelihood (Step 5.3) in order to adjudge the degree of acceptability/unacceptability. The end product of this step is a listing of undesirable events ranked according to acceptability/unacceptability, which will then form the basis of action in identifying and implementing countermeasures. It is in this step that senior management officials will be called upon to make informal judgments as to the effect of undesirable events upon performance of mission and thus assess their dependency upon this automated support.

#### *Management decision (6.0)*

The purpose is to evaluate identified risks according to degree of acceptability/unacceptability and, in consideration of the nature of the threats and vulnerabilities as they relate to risks, to identify and select countermeasures to effectively reduce the risk. The Management Decision Process (Figure 7) requires the use of management techniques such as cost/benefit analysis to determine those countermeasures which appear most effective and offer the best return on resource investment. Top management involvement is required to judge which countermeasures should be implemented and the priority for implementation. The Management Decision Process includes the sub-tasks of Risk Review, Identification of Countermeasures, Evaluation of Countermeasures and Selection of Countermeasures.

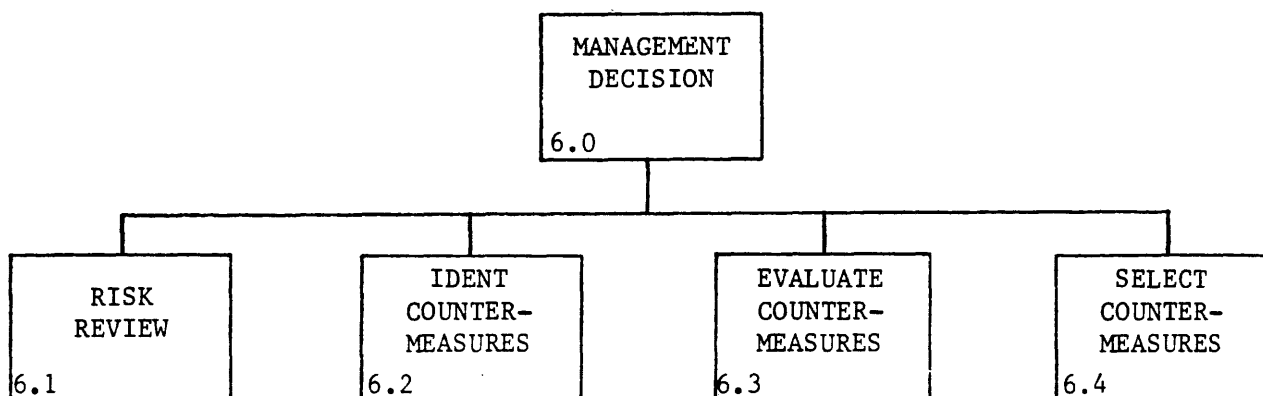

Figure 7—Management decision process.

### *Risk review (6.1)*

This task requires the critical review of previously identified risks and related threats and vulnerabilities. It is a review and revalidation of the cause-effect relationships, previously identified in Steps 2, 3, and 4 of this Risk Management Model, for the purpose of determining which of the cause-effect factors would be most favorably influenced by counteraction. In attempting to alter the cause-effect relationship, countermeasures may be applied to either threats or vulnerabilities. However, countermeasures are usually applied against vulnerabilities since they are most directly under our control and are the easiest and most cost-effective to influence. Such traditional responses as the use of security guards, card-entry access control devices, or sophisticated password systems are directed toward correcting a weakness or vulnerability. In some very limited situations, the threat may also be reduced by taking counteraction; for example, denying the authorization to use the system to a person who fails to follow approved procedures or who abuses the system. The results of this task will be an initial indication of where to apply emphasis in development of countermeasures.

### *Identification of countermeasures (6.2)*

In this task, the threats and vulnerabilities associated with a specific risk are analyzed to determine the best means of countering them. Specific actions are recommended which will lessen or minimize their impact. As pointed out previously, threats rarely can be cost-effectively countered but this course of action should not be discounted without some consideration. In this analysis, countermeasures should also be evaluated for effect upon other causal factors and these effects entered into the considerations. It is rare for a single countermeasure not to impact upon multiple events, so these relationships must be carefully explored so as to fully define their effect. Analysts must be careful that a countermeasure does not create a more serious vulnerability than that which it is intended to correct. The classic example of this situation is the implementation of software security measures requiring multiple, lengthy, passwords which end up being written down in wallets or displayed on walls and provide an easily accessible key to the system and data bases. Whenever possible, this task should present alternative measures for evaluation in the next step. To provide continuity with threat agent attack methodologies/penetration techniques (Step 2.2) and identification of vulnerabilities (Step 3.1), countermeasures should be identified and similarly categorized (e.g., physical, personnel, hardware, software, and procedural security).

### *Evaluation of countermeasures (6.3)*

This step focuses upon alternative countermeasures, evaluating the relative costs and benefits of each in relation to the tangible and intangible losses which each is trying to

prevent. Using such techniques as cost/benefit analysis to display cost offset or detail cost avoidances attributable to a specific countermeasure, this step is intended to provide the informational base for subsequent decision-making by management-level officials. Full life-cycle costs and offset savings should be documented for consideration in the decision-making process. It should be noted that formal cost/benefit analysis techniques are inadequate for detailing intangible losses and benefits of avoidance of a loss, and therefore should be used only as a guide for decision-makers. No countermeasure should be dismissed by analysts based upon cost/benefit analysis alone, but rather should be presented to management-level officials for consideration in light of intangible benefits. Analysts will identify these intangible benefits as part of the evaluation process.

### *Selection of countermeasures (6.4)*

This task is concerned with the gathering of pertinent information regarding proposed countermeasures in order that management may determine those that appear to be most effective and offer the best return on resource investment. Management will decide which should be implemented and the priority for implementation. While all efforts thus far have been directed towards minimization of risk, or "risk avoidance," it is here that management can decide to establish full or partial alternate or back-up capability (e.g., continuity of operations plans) or, if the risk potential is large enough, to no longer entrust the storage and handling of that information to automated processing.

### *Control implementation (7.0)*

The purpose is to develop and execute a plan to implement those countermeasures required to improve the security and provide an acceptable degree of risk to senior management. This process requires the development of a comprehensive plan, the acquiring of management-level approvals necessary to commence implementation of the plan, the actual implementation of the selected countermeasures and testing of the effectiveness of selected countermeasures once implemented. The Control Implementation process (Figure 8) includes the sub-tasks of Development of a Plan, Approval of Plan, Implementation of Countermeasures and Test and Evaluation of Countermeasures.

### *Development of a plan (7.1)*

To develop a plan to implement required countermeasures it will be necessary to establish priorities for their implementation. Generally, countermeasures should be implemented according to the severity of the undesirable effect being countered, as determined during preceding analysis. Using this as the basic criterion, other influences can be brought into consideration (e.g., ease of implementation, fiscal restrictions, personnel constraints, timing limitations).

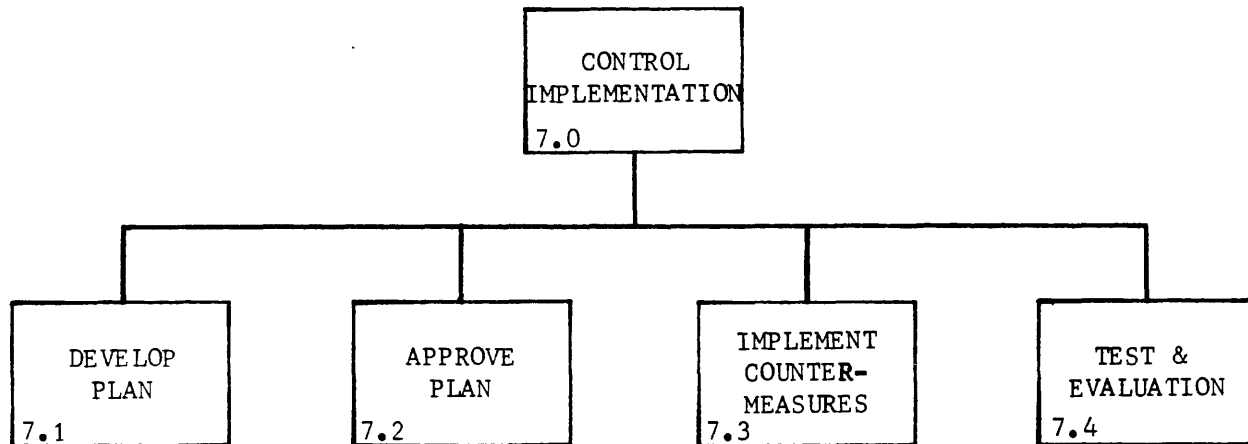

Figure 8—Control implementation.

Each countermeasure must be examined, both individually and collectively, to preclude duplication. The plan should identify specific resource requirements and the timeframe in which these resources will be required so that it may be used as the basis for input to planning, budgeting and other resource justification documents.

#### *Approval of plan (7.2)*

Once developed, the plan must be reviewed and approved by senior management. In this step, senior management must be given the opportunity to validate or change the priority of implementation based upon previous assessment of the risk. The level of management which controls the approval or allocation of resources must exercise decision authority on the plan so that it reflects their priorities and has their support. Senior management will be given the opportunity to assess the full resource impacts and make judgements as to how to best respond to resource requirements. It is important to give these resource requirements separate visibility rather than to attempt to bury them in normal data processing operating budgets. The decision can be made by management whether to handle the plan as a separate major program; to assign an allocated, "charge-back" type cost to users; or to include them in the data processing budget. Once these decisions have been made, formal justification can be made in budget and other resource management documents.

#### *Implementation of countermeasures (7.3)*

Once the planning documents have been completed action can commence on implementation of countermeasures. Some will be procedural or of such small dollar impact that they can and should be implemented immediately, while others have already been implemented during the risk assessment because of the severity of the security deficiency. Others will involve long-term, multi-year projects, such as the construction of an entirely new faculty. During imple-

mentation, it is imperative that the integrity of the plan be preserved and no significant deviations allowed without conscious management decision. The analytical risk assessment process should have resulted in the selection of countermeasures to support interlocking and mutually supportive defensive barriers for the operation. Arbitrary alteration of planned improvements will inevitably disrupt the cohesiveness of security features and lead to less than optimum results.

#### *Test and evaluation of countermeasures (7.4)*

Sensitive systems with stringent security requirements should have formal test and evaluation of significant countermeasures immediately prior to or during initial implementation. The purpose of test and evaluation is to ascertain, with reasonable assurance, that the proposed countermeasure will produce the desired effect and will not result in undesirable side effects. Testing can be supplemented by a formal review and evaluation period during the initial implementation phase during which the effect of the countermeasure is carefully monitored. In some cases, such as the implementation of a security front-end or a secure telecommunications monitor, it would be appropriate to constitute a formal test team, develop a test scenario and conduct a formal documented test of the effect of the countermeasure.

#### *Effectiveness review (8.0)*

The purpose is to periodically review the effectiveness of security controls and to assess the impact of those planned and currently being implemented in order to determine that they do what they were intended to do and have not created additional vulnerabilities. A formal audit of effectiveness should be conducted at a frequency determined by the sensitivity of the facility and its operations. As a result of the audit, management can make the determination whether or not to reinitiate the entire risk management process. Figure 9 illustrates this activity.

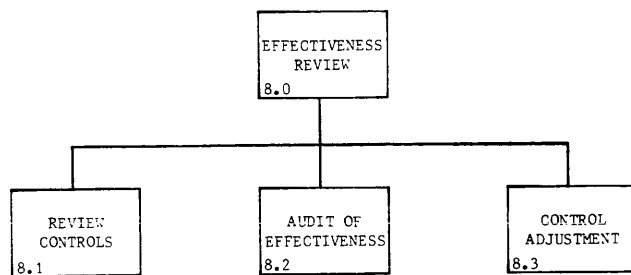

Figure 9—Effectiveness review.

### Review controls (8.1)

Management is responsible for designing and implementing security controls. At this stage in the process, management must review all previously implemented controls to assure proper placement and operation. Particular attention should be paid to new controls and their integration into the overall security system.

### Audit of effectiveness (8.2)

If deemed appropriate, full and formal review by outside experts should be conducted to determine the overall effectiveness of security controls. This can be accomplished by formal security survey teams and internal auditors. Audit is an important part of the risk management process, providing independent review and analysis for senior management.

### Control adjustment (8.3)

This step in the process deals with the "fine-tuning" of the overall security system to address deficiencies and gaps found in the review and audit steps. Based upon the outcome of the effectiveness review, this step may lead to reinitiation of the total risk management process.

## CONCLUSIONS

Most risk analysis/assessment schemes fall prey to the challenge of precise quantification of impact in terms of probabilities and dollar losses, preferring to be "exactly wrong rather than approximately right." To their detriment, these schemes focus primarily upon impact upon the data processing function (e.g., loss of or damage to equipment, cost to regenerate a data base, or accomplish a missed processing) rather than the effect upon the total business system, the real loser and bearer of risk. Perhaps the greatest weakness of these schemes is that they keep the risk analysis/assessment process a strictly data processing problem, inevitably victimized by the "conflict of interest" between security and productivity goals, whether real or merely perceived. This model attempts to address these problems and many of those raised by Turn, Gaines and Glaseman<sup>10</sup> while providing the foundation for further work in this area.

# The design and operation of public-key cryptosystems

by ERIC H. MICHELMAN

Intel Corporation  
Santa Clara, California

## INTRODUCTION

Recently, there has been a major advance in the area of communications security—that of a practical way to implement public-key cryptosystems (PKCS).

Public-key cryptosystems make use of a method for encryption and decryption in which the encryption key is different from the decryption key. Not only are the keys different, but revealing *one* doesn't provide any useful help in determining the *other*. A particular value for one key does of course "set" the value for the other, but for practical purposes, the other key is impossible to determine without additional information.

One major implication of this scheme is that encryption keys can be public; literally anyone can have access to them without threatening the security of encrypted communications. The decryption key is kept private; there is never any need for anyone to communicate his decryption key to anyone else. This eliminates the need for a secret transferral of keys, as is the case with conventional encryption methods. In systems using conventional methods, before two parties can communicate, they must agree on a key to be used for both the encryption and decryption. This key must be kept secret, as well, or someone who intercepts a message will be able to read and/or modify it. This agreement on a key is generally either very expensive and time-consuming or relatively insecure.

PKCS largely eliminate this problem. There is still a need for reliable transferral of the public keys, to be discussed, but it is minimal and, not requiring secrecy, may be done inexpensively.

The second major implication of PKCS is that it is possible to "sign" messages in a way that is unforgeable but easily verifiable. In other words, John can send Mary a "signed" message which she can prove came from him, even though the content and the encryption key may be public knowledge. This can be accomplished because the keys can be used in either order; encrypting with the private key and then decrypting with the public key produces the original message. To sign a message, John first encrypts the message with his private key (yes, his decryption key), then encrypts the result with Mary's public key (her encryption key). Mary now has a doubly-encrypted message which she first decrypts using her private decryption key, then decrypts again

using John's public key (his encryption key) to arrive at the English message. Since only John knows his private key, only John can create an encoded message which produces English when his public key is applied to it.

The idea of PKCS was first publicized in an article by Diffie and Hellman of Stanford.<sup>1</sup> In this article, they discussed the advantages that could be obtained from an algorithm which allowed the implementation of PKCS. They did not, however, suggest a specific algorithm. Such an algorithm was first published in April 1977 by Profs. Ronald Rivest, Adi Shamir and Len Adleman of MIT. This algorithm (the RSA algorithm) is based on the computational difficulty of factoring large numbers. This paper focuses on the use of that algorithm in particular.

## THE RSA ALGORITHM

As described in the paper by Rivest, Shamir, and Adleman,<sup>6</sup> the encryption and decryption operations are quite straightforward.

### *The encryption and decryption algorithms*

Both the encryption key and the decryption key are composed of a pair of numbers,  $(e, n)$  and  $(d, n)$  respectively. To encrypt a message, the message must first be represented as an integer between zero and  $n-1$ . This can be done in any way that is convenient, such as stringing together the characters' ASCII representations. Long messages can be broken up into a series of blocks of this size, with each block treated as an individual message. The purpose of this is to put the message into numeric form as required by the encryption procedure.

The encryption is performed by simply raising the message to the  $e$ -th power modulo  $n$ . That is, the encrypted message  $C$  (for ciphertext) is obtained by raising the message  $M$  to the power  $e$ , and then taking as  $C$  the remainder obtained by dividing  $M^e$  by  $n$ . Decryption is similar to encryption. The  $d$  key is used where the  $e$  key is used for encryption.

Stated as formulas, the encryption and decryption algorithms are:

Encryption:  $C = M^e \pmod n$  for a message  $M$   
 Decryption:  $M = C^d \pmod n$  for a ciphertext  $C$

The encryption key, then, is the pair of integers  $(e, n)$  and the decryption key is the pair of integers  $(d, n)$ .

#### Choosing the encryption and decryption keys

The first step is to generate two very large primes,  $p$  and  $q$ . To compute  $n$ , simply multiply  $p$  and  $q$ :

$$n = p \times q$$

The  $d$  key is a large random number which is prime relative to  $(p-1) \times (q-1)$ . This implies that

$$\text{gcd}(d, (p-1)(q-1)) = 1$$

where  $\text{gcd}$  means greatest common divisor.

Finally, the  $e$  key is computed from  $p$ ,  $q$ , and  $d$  to be the "multiplicative inverse" of  $d \pmod{(p-1)(q-1)}$ :

$$e \cdot d = 1 \pmod{(p-1)(q-1)}$$

Although  $n$  will be revealed publicly, it will be virtually impossible for others to determine  $p$  and  $q$  by factoring  $n$ . This is due to the tremendous computational difficulty involved in factoring very large numbers. The size of the keys involved are typically, but not necessarily, about 50 to 200 decimal digits for  $p$  and  $q$  and about 100-200 decimal digits for  $n$ . Procedures for generating  $p, q, n, e$ , and  $d$  are presented in the Rivest paper.

#### Theoretical security of the RSA algorithm

In terms of theoretical security, using the fastest factoring algorithm known to the authors of the Rivest paper, the amount of time necessary to break the encryption scheme by factoring the  $n$  parameter is given in Table I. Rivest makes the claim that any method of breaking the scheme by mathematical analysis must be at least as difficult as factoring  $n$  as it would provide the factors of  $n$ . This table, taken directly from that paper, shows the time needed to factor  $n$  on a computer which performs one operation per microsecond.

There does exist the possibility that a faster factoring algorithm will be discovered. In that case, the time needed to crack the system with a given key length will decrease accordingly. However, it is likely that any improvement in the factoring algorithm will produce a marginal rather than a dramatic improvement, although that would be relative to

TABLE I

Digits in $n$	Number of Operations	Time
50	$1.4 \times 10^{10}$	3.9 hours
75	$9.0 \times 10^{12}$	104 days
100	$2.3 \times 10^{15}$	74 years
200	$1.2 \times 10^{28}$	$3.8 \times 10^8$ years
300	$1.5 \times 10^{29}$	$4.9 \times 10^{15}$ years
500	$1.3 \times 10^{39}$	$4.2 \times 10^{25}$ years

the key length in use. An improvement of a factor of ten, for example, would be a matter of concern with a key length of 50, but not with a key length of 200. It should be noted, however, that this has not been proved to be a difficult problem. It has been worked on extensively by mathematicians, though, and it is generally believed that there is no easy solution possible.

#### KEY MANAGEMENT AND ADMINISTRATIVE SECURITY

With respect to key management and administrative security, PKCS compare very favorably to conventional systems. In systems where the encryption key is the same as the decryption key, two parties must agree on a key prior to sending messages. This secure transmittal of keys is generally an expensive and time-consuming process.

In establishing a common key in conventional systems, there is always a tradeoff between security and expense—the easier and cheaper ways to transfer the keys, such as by telephone or mail, are relatively insecure. The more secure methods, such as a trusted carrier, are expensive, especially over long distances. Often these systems are not as secure as they should be because of the expense involved and the tradeoff present between expense and security. The risk exposure may be greater than the cost of the desired security; however as is often the case in computer security, the risk of possible security failures in the future is preferable to the manager in charge than the immediate outflow of dollars necessary to provide the desired level of security.

In fact, relying only on the competence and trustworthiness of others in a security system introduces a great deal of risk. This is a primary problem with conventional encryption systems—even using a courier to transmit keys is only as secure as the courier, unless special precautions are taken such as using tamper-proof, locked containers to transport the keys.

With PKCS one still needs to be careful, particularly concerning the authenticity of encryption keys that are transmitted over the communication lines. *It is important to note that there is little security in a system in which people happily broadcast their encryption keys for the other users as often and whenever they like.* With such a system there is nothing to prevent an intruder from tapping into the communications lines and substituting his own encryption key for the legitimate keys sent by users. Other users receiving these encryption keys will then unwittingly send messages encrypted with the intruder's key. The intruder can then read the messages (having tapped into the communication lines), retransmit them with the intended user's real encryption key (which the intruder had intercepted), and even alter the message and then retransmit it. None of this would be detectable by the users.

The suggested remedy for this problem is to have a trusted "system controller" keep track of all the users' encryption keys. With an encryption/decryption key pair of its own, the system controller can send users signed messages indicating what the encryption keys of other users are. As an impostor could not forge the system controller's signature, the users

can be assured of the authenticity of encryption keys received in this manner.

Implementing this scheme requires that each user be able to transmit his encryption key to the system controller in a reliable manner so that the system controller can then relay it to other users. It also requires that each user be sure of the system controller's encryption key so that he can verify the system controller's signature. These keys cannot simply be transmitted over the communications lines for the reason just discussed.

If both keys (the system controller's and the user's) had to be transmitted externally to the system, the requirements would be similar to those with conventional encryption methods. That is, a secure external transferral of keys would be necessary, although with PKCS secrecy would not be required (we are, after all, dealing with just the public keys).

Fortunately, this can be avoided if two conditions can be met. First, the system controller's key needs to be made public knowledge. This shouldn't be very difficult as there is just one for the entire system. Second, there must be an appropriate action available to users if they discover a security problem. This also seems likely; however, if only the first condition is filled, then one can run into the problem of being guaranteed detection of security problems but not being able to do anything about them. These conditions will be further discussed later. Assuming they are filled, users can send their encryption keys to the system controller over the insecure communications lines in the following manner.

To establish a new encryption key, a user first sends it to the system controller. The system controller then signs it and sends it back to that user. As the user knows what the system controller's encryption key is, he can verify the signature on the returned message and thus be sure that the system controller has accurately received the key. If the returned key isn't accurate, then the user knows that there is an active security threat and can take appropriate action.

To prevent an impostor from sending a new key to the system controller purporting to be from someone else, the following restrictions are necessary. First, key changes take effect at prespecified times, perhaps the same time every day, week or month. At a given time before the key changes are scheduled to go into effect, the system controller stops accepting key change messages. It then sends a signed message to each user indicating what it thinks the user's key is for the next period. If there is a discrepancy—either a key was incorrect or the message wasn't received—the user takes appropriate action. All confirmation messages that are sent by the system controller should be date- and time-stamped to prevent an intruder from recording one and playing it back at a later time.

In a physically-insecure communications system, it is not possible to prevent the recording and/or modification of message traffic (presumably in its encrypted form), or even denial of service (perhaps by being as crude as just cutting the line). It is possible, though, to meet the following goals:<sup>2</sup>

1. Prevention of release of message contents.
2. Detection of message modification.
3. Detection of denial of service.

The procedures just described for use in a PKCS meet these three goals without requiring any secure external key transferrals, either between the users themselves or between users and the system controller (with the exception of the one public encryption key for the system controller).

It might seem that an undeservedly large amount of effort is devoted to changing keys with these procedures. Traditionally, key changes have been very important, though. They limit the potential exposure in case of a compromised key to the time until the next key change. The time that a cryptanalyst has to crack a key while it is still active is limited. Also, often after having given someone else a key, a user wants to revoke access by changing the key (e.g. after an employee goes to work for a competitor). In applications where the information transmitted is sensitive for only a short time, one also has the option of using more frequent key changes in conjunction with shorter keys to decrease the cost of encryption and decryption. While the shorter keys would be easier to break, there would be less time to break them while they are still in use.

The system controller referred to here is expected to be contained in either the central computer or the communications links, as appropriate. Little functionality is required other than maintaining a list of user encryption keys and communicating these to users in a signed form. It is necessary, though, that the integrity of this list be ensured although it need not be kept secret. The system controller's decryption key does need to be kept secret, of course.

The two critical assumptions in this scheme are that the system controller's encryption key can be made public knowledge and that appropriate corrective action would in fact exist if a user found that his line was compromised. As the system controller will presumably have only one key for the entire system, it shouldn't be very expensive to make that key public knowledge with respect to the system's users. This can be accomplished in many ways—via company newspapers, the *Federal Register*, public newspaper ads, etc. The success of this phase will be easily and immediately apparent to the system operators and if there is a problem there will be actions that can be taken, ranging from not changing the system controller's key to shutting down the system, depending on how serious the situation is thought to be.

The problem of being sure that a user will be able to take appropriate action in case of a security problem is a bit stickier. If the user finds that his new key confirmation message hasn't come or showed an incorrect key, he may assume that an impostor has substituted a new key. This means that the user must contact the system controller or (human) operators before the new keys are to go into effect or the other users will start using the impostor's key to send encrypted messages to that user. The seriousness of this situation depends on the time constraints and the physical situation. In some cases it is clear that this wouldn't be a concern at all. Such a case would be a communications system that connects sales offices in American cities with the company's main office and in which keys are changed once a month with a two-week clearing period before key changes go into effect. On the other hand, if an operative in

a hostile country had five minutes to contact his home office, he shouldn't be optimistic. We assume physical force isn't an issue, since by that method an intruder could also gain access to everything via the user's own terminal.

It seems likely that this wouldn't be an either-or constraint in most applications, but more of a limitation on how often the keys can be changed. Two weeks to take corrective action should be long enough to guarantee success in almost all applications, while five minutes would be cutting it close in most applications. Where one can safely draw the line depends on the application. It might very well be that keys can be changed once a day (with a few-hour clearing period for the new keys) in the vast majority of applications, especially if the protocols are largely automated.

#### *Obtaining other users' keys*

To communicate with another user, a user obtains the appropriate encryption key from the system controller. This can be done in a number of ways, all relying on the integrity of the system controller's signature to prevent an impostor from posing as the system controller and sending one system user a false encryption key for another user.

One arrangement would be for the system controller to issue signed messages indicating what the encryption key is for any given user. These "certificates"<sup>4</sup> may be traded about among users with the authenticity guaranteed by the system controller's signature. The major disadvantage to this scheme is the problem of outdated certificates when a key is changed.

An alternative similar to certificates is for the system controller to periodically issue a list of the system users' encryption keys. Keys could then easily be changed on new lists, but only when a new list is issued. This sort of arrangement would likely be largely automated within the communication system, with the lists being transmitted as messages signed by the system controller.

Another alternative, but certainly not the last, is for users to request the appropriate key from the system controller prior to communication with other users. This could be a useful adjunct to abbreviated lists, with each user being supplied a list of the most likely communicants and requesting the keys of the others as the need comes up.

## SIGNATURES

### *Uses*

There are two primary uses for signatures in communications systems—future verification and immediate identification. Future verification is potentially very important in commercial systems in which users may want to effect a contract over the system. In this sense the signature is just like a written signature: its purpose is to prove at a later date that the sender did in fact author the message. This is valuable and particularly important among mutually suspi-

cious parties, such as two banks executing a contract over communications lines.

Immediate identification is important for a more technical reason. In an electronic communications system, if someone taps into the communications line he can originate a message purporting to be from someone else. However, with the use of PKCS signatures, a receiver of a message can verify the sender's identity. This is important for both mutually suspicious parties and those who are not. In communications between two trusted parties, one still wants to ensure that he cannot be impersonated.

### *Added cost*

As always, nothing is free. There is a potentially-substantial added cost to using the signature capability, depending on how it is implemented. With a hardware implementation, the added cost is either an extra encryption/decryption device on each terminal and communications link or extra time consumed by cycling messages through one encryption device twice. This applies to both sending and receiving messages.

With a software implementation, if the encrypted message is signed as it is, it will require twice the time to encrypt and decrypt a signed message as an unsigned message. There is, however, a way to save time in this operation—that is to sign a compressed version of the message and send the signed compressed version along with the unsigned version. A reduction procedure for this would have to be such that it wouldn't be possible in practice for someone to change part of the message without changing the compressed version.

### *The need for impartial recording of encryption keys*

Unfortunately, there is another operation requirement in terms of future verification: One must also be able to prove what the encryption key was when the message was sent before a disputed signature can be considered proven. A good example of the issue here would be a money transfer system connecting two banks.

It sounds very easy for two banks to send signed messages back and forth, secure in the knowledge that if there is a dispute each can produce the signed messages from the other as proof of contract. However, assuming that the keys change periodically, they must also be able to prove what the other's encryption key was at the time any given message was received. Otherwise a situation could arise in which one bank fabricates a message purporting to be from the other, generates a decryption key to sign the fake message with, and claims that the message was actually received from the other, and, at the time it was received, the corresponding encryption key was the public key in effect for the other bank.

An analogy can easily be drawn between this problem and conventional paper-and-ink signatures. That paper signatures can be used as proof is partly based on the fact that

someone's signature doesn't change over time. In a court of law, then, the signature on a document can be compared to the person's signature at that or any other time. If people changed their signatures frequently, or at all, it would be much harder to prove that someone did in fact sign a document. Similarly, if the keys didn't change in a PKCS this problem wouldn't exist. However, from a security point of view it is desirable to change keys.

The implication of this is that for signatures to be useful for future verification between two mutually suspicious parties, an impartial referee must record the public keys with the time that they are in effect. This would be very easy for the system controller to do, as it needs to have an accurate list of encryption keys at each point in time so it can transmit key information to users. The only extra effort necessary is the retention of the lists.

#### *The question of automatic signatures*

It seems that one would like two modes of operation, one in which all messages are signed when requested to by the system controller, and one in which messages are signed only when the user indicates.

Whether or not the signature operation should be user-controlled depends on the system and the purpose of the system. If its purpose is to ensure the identity of the sender, then it is probably more convenient to have the signature operation under system control. An example of this might be water-level sensors in a large dam's floodgate control system. There is an instance in which someone proved able to dial into the control computer in a large dam and have it release all of the floodgates. Similarly, if the water-level sensors indicated that the floodgates should be opened, the computer might well ask for a signature to make sure that a disgruntled employee didn't tap into the line and send the message.

On the other hand, in an electronic bill-paying system, one would probably want the user to retain very explicit control over what gets signed.

The major difference between these two examples seems to be that in the first, the signature is used to ensure proper identification. In the second, it is used in the conventional sense as well—for future verification. Through the signature, the user is presumably committing himself to a contract. Another way of looking at it is that the first case concerns itself with ensuring system integrity and therefore should be under system control. The second case concerns itself with user intent, clearly the domain of the user.

## HARDWARE VS. SOFTWARE IMPLEMENTATIONS

The encryption/decryption and key generation functions can be implemented in either hardware or software. A combination is also quite possible, if not often desirable. Presently, hardware implementations are not available, although at least one hardware implementation project is under way

and various companies have given consideration to an IC chip version.

The software programs needed are rather simple and straightforward. With multiple precision routines to work with, they can be on the order of a few dozen lines of code. The multiple precision arithmetic routines are more complicated than the rest of the code, but algorithms and example programs are provided in Knuth's volume on semi-numerical algorithms.<sup>3</sup> Complete functional specifications and design instructions for encryption/decryption and key generation procedures are provided in Rivest's paper.<sup>6</sup> The problem with software implementations is that they seemed to be slow. The speed of software implementations will be explored in depth in the next section.

Until a PKCS chip becomes available (we don't know of any that are planned), the alternative for hardware implementations is the use of microprocessors and discrete ICs. The one hardware implementation project currently known is using ICs. The component cost is expected to come to between \$1900 and \$2000 for one and about \$1200 in quantities of 1000s. For commercial products of this sort, the component cost is usually multiplied by from three to seven to arrive at the selling price for a finished product. This particular implementation is designed to be fast—about 6000 baud—and uses high-quality components. Alternative designs could be done at lower cost. In comparison, a DES (the National Bureau of Standards' Data Encryption Standard) device is available for \$2500 in small quantities and less than \$2000 in large quantities. This particular DES device is faster as well—up to 19.2 Kbaud, depending on mode of operation. DES boards are sold for \$850 in small quantities and less than \$500 in large quantities (these boards operate at 6.7 to 56 Kbaud, depending on mode of operation.)

Microprocessors are now too slow to be used for PKCS applications. This is true for several reasons: the actual instruction speed is slow compared to larger machines, the word size is generally eight bits (necessitating more operations), and they do not have cache memories. On the other hand, microprocessors are continually getting faster, 16-bit microprocessors are becoming commonplace (the Intel 8086 and TI's TMS9900), and cache memories on the chip are expected within a couple of years. So while microprocessors are not presently an adequate vehicle for implementing PKCS, they may well be in a few years. Another interesting possibility is that since message blocks can be processed independently, microprocessor arrays may become a viable alternative. In this case the speed of encrypting one block would be the effective speed for encrypting an entire message.

#### *Software speed analysis*

One of the primary considerations in determining the usefulness of PKCS is the cost of using them. In terms of a software implementation, this refers primarily to the time required to encrypt and decrypt messages. This is dependent on the number and types of instructions necessary to carry

out these operations, as well as the speed of the individual computer.

As software implementations do not offer the option of a speed/cost tradeoff, we present here estimates of the time requirements for software encryption and decryption.

The procedure considered for encryption and decryption, which is recommended in Rivest's paper, is called "exponentiation by repeated squaring and multiplication:"

```
FOR I=LOG2(e) TO 1 BY -1
    C=REM ((C*C),n)
    IF ei=1 THEN C=REM ((C*M),n)
END
```

where  $e_i$  is the  $i^{\text{th}}$  bit, starting with the most significant, in the binary representation of  $e$ .  $C$  is then the encrypted form of the message.

From this procedure, it is clear that the bottleneck in a software implementation will be the multiple precision multiplication and division routines. The multiplication and division routines analyzed here are basically from Knuth.<sup>3</sup> A combination is used, in that each operand is assumed to be split into eighths and the basic "high school" algorithm is used in multiplying the individual eighth sections. They are split into eighths to utilize the following technique:

$$A = A_0 + (2^n) * A_1 \text{ Example: } 110010 = 010 + (2^3) * 110$$

$$B = B_0 + (2^n) * B_1$$

$$A * B = A_1 B_1 * (2^{2n} + 2^n) + 2^n (A_1 - A_0) (B_0 - B_1) + (2^n + 1) A_0 B_0$$

Note that only three multiplications were required, whereas in the basic algorithm, if  $A$  and  $B$  were each more than one computer word long, four multiplications would have been necessary (multiplying by a power of two in a computer is only a shift operation and can be done very quickly; with multiple precision numbers, only keeping track of the decimal point is involved.) Since splitting the operands in half yields only three-fourths the number of multiplications that would be needed otherwise, splitting them into eighths yields  $(\frac{3}{4})^3 = \frac{27}{64}$  multiplications. The actual number of sections the operands can be split into depends on the size of the operands. We chose three splits as a representative illustration.

Adding time for overhead to the  $\frac{27}{64}$  figure, we will estimate that multiplications are done in half the time estimated by Knuth's basic algorithm (he also describes more advanced algorithms, including the one just discussed, but he only provides detailed time estimates for the basic one.) It should be noted that these time estimates are based on simple, straightforward techniques. We are not suggesting that this is the best that can be done. Optimization techniques and coding tricks would provide a time reduction. On the other hand, these figures do not take into account any system overhead. With the assumptions described just below, it is expected that the system overhead would be small, but there would be some.

Since the encryption/decryption routines are small programs running in tight loops, we assume in these calculations that if a cache memory is available, the instructions will be

found in the cache. Further, since the number of operands, parameters, and counters is also small, we assume that operands are found in the general registers. While both of these assumptions will not always be true, they will be true the great majority of the time. One last assumption is that of the total number of cycles required to perform some function, half will be for executing the instructions and half will be for obtaining operands. Encryption/decryption times are shown for four machines: The PDP 11/45, PDP 11/70, IBM 370/168, and CDC 6400. The times are shown for both an  $n$  of 100 and 200 decimal digits, and key sizes of  $n$ ,  $\log_2 n$ , and three.

The key size of three refers to actually using three as a key; it is the smallest key that can work. Using a key of less than  $\log_2 n$  risks the encrypted message coming out the same as the clear text; that is, no encryption will take place. However, if a message block is filled out through all  $\log_2 n$  places, using a key of three will work. Message formatting schemes can be easily devised to ensure that all messages will be encoded; however, there is corresponding overhead.

Note that encryption and decryption of a given message require the use of two different keys, at least one of which will be on the order of size  $n$ . This implies that while a small key may be used on one end, providing very fast operation, a large key must be used on the other end, with its correspondingly-higher overhead. Presumably the decryption key will be about size  $n$  as it mustn't be guessable. To find the total time involved in encoding and then decoding a message, add the time required to encode with whatever size key is to be used to the time required to decode with the decryption key.

Table II summarizes the execution times (in microseconds) for encrypting a 1000-byte message. Table III provides the number of bits per second that can be encrypted using the different key sizes and machine word sizes: The detailed derivation of these timing figures can be found in Reference 5. In comparison, DES software routines have been claimed for the 370/168 which perform encryption/decryption at rates of 600 Kbits/second.

TABLE II—1000-byte Encryption Times in  $\mu\text{secs}$

	KEY SIZE		
	3	$\log_2 n$	$n$
16-BIT MACHINE SIZE (the PDP11)			
200-DECIMAL-DIGIT $n$ SIZE			
without cache store (11/45)	1,826,877	8,563,485	606,821,235
with cache store (11/70)	811,945	3,805,993	269,698,326
100-DECIMAL-DIGIT $n$ SIZE			
without cache store	1,040,185	4,356,207	170,229,626
with cache store	462,304	1,936,092	75,657,611
32-BIT MACHINE SIZE (the 370/168, which has a cache)

### PKCS/DES HYBRID COMMUNICATIONS SYSTEM

A promising technique for utilizing the respective advantages of both PKCS and DES is a two-level key system using PKCS for the primary key system and DES for the secondary key system.

In a two-level key system, each user has a primary key and a secondary key. The primary key is used solely to encrypt secondary key changes that are communicated between the user and system controller over the communications lines. The secondary key is used to encrypt messages. By using the primary key for encrypting the secondary key, the secondary key can be sent over insecure lines and thus be changed frequently at little cost. With traditional systems, the primary key must be transmitted externally to the communications system. This is the expensive and awkward key agreement problem discussed previously.

A promising technique for utilizing the respective benefits

of both DES and PKCS is implementing a hybrid two-level system. Messages would be encrypted and decrypted using DES. The DES keys would be transmitted over the communications lines encrypted with the PKCS system. This would in effect be a two-level system with PKCS constituting the primary key system and DES constituting the secondary key system.

The advantage of such a system would be that the speed of a DES implementation would be available with the key management cost and security of a PKCS implementation. Note that the primary keys would be changed infrequently, leaving plenty of leeway for the key management technique suggested above. Generating and transmitting a new secondary key would only involve encrypting a 64-bit message. This would require little time in a software implementation. At the same time, DES encryption hardware or software routines would be used for the messages, yielding the encryption/decryption cost of a straight DES system.

# Safeguarding cryptographic keys

by G. R. BLAKLEY

Texas A&M University  
College Station, Texas

## INTRODUCTION

Certain cryptographic keys, such as a number which makes it possible to compute the secret decoding exponent in an RSA public key cryptosystem,<sup>1,5</sup> or the system master key and certain other keys in a DES cryptosystem,<sup>3</sup> are so important that they present a dilemma. If too many copies are distributed one might go astray. If too few copies are made they might all be destroyed.

A typical cryptosystem will have several volatile copies of an important key in protected memory locations where they will very probably evaporate if any tampering or probing occurs. Since an opponent may be content to disrupt the system by forcing the evaporation of all these copies it is useful to entrust one or more other nonvolatile copies to reliable individuals or secure locations. What must the nonvolatile copies of the keys, or nonvolatile pieces of information from which the keys are reconstructed, be guarded against? The answer is that there are at least three types of incidents:

- An *abnegation incident* is an event after which a nonvolatile piece of information is no longer completely reclaimable by the organization which entrusted it to a guard. There are three main types of abnegation incidents:
  - Destruction* of the nonvolatile piece of information. For example, a person carrying a copy of a number can meet with an unexpected accident, during which the copy is destroyed.
  - Degradation* of the nonvolatile piece of information. For example, a person may lose his copy of the number and, in embarrassment and confusion, produce some other number when asked.
  - Defection* with the nonvolatile information. For example, the person with the copy of the number may divulge it to the opposition and refuse to tell it to the organization which entrusted it to him.
- A *betrayal incident* is an event after which a nonvolatile piece of information is completely known to an opponent of the organization which entrusted it to a guard. Defection, which we have already encountered among abnegation incidents, is one kind of betrayal incident. The other main kind of betrayal incident is
  - Dereliction* with the nonvolatile piece of information,

an act which reveals it to the opposition so as not to be discovered by the organization which entrusted it to the guard, either before or after he has been requested to return it. For example, the person who has the copy of the number can show it to an opponent but still play the part of a faithful guard, and even report the number back correctly when requested.

- A *combination incident* is an abnegation incident which is also a betrayal incident. The main kind of combination incident is defection. The three types of incident are, thus, A, B and C. And the commonest kinds of A, B or C incidents are the four Ds. Note that none of the four Ds need imply malfeasance, misfeasance or even nonfeasance on the part of the guard. But it would be wise to consider such possibilities whenever an incident of any of the three types is detected.

Why was simple loss of the nonvolatile piece of information not included above? The answer is that some types of loss amount essentially to destruction of the nonvolatile piece of information, in the sense that neither the organization that entrusted it to a guard nor any of its opponents is likely to get the piece of information before the encrypted information becomes valueless. For example, the person with the copy of the number was on a Mars flyby which lost contact forever with Earth as it went behind Mars. But if a loss cannot be confidently regarded as a destruction, the proverbial "prudent man," in charge of evaluating this incident for the organization which entrusted the nonvolatile piece of information to a guard, must regard it as a defection. For example, if the person who memorized the number disappeared after a family quarrel the prudent man evaluating the incident must assume that an opponent knows the piece of information in question.

## COUNTING AND DISCOUNTING INCIDENTS

There are two principles for counting incidents. The first is Boole's law of inclusion and exclusion. Suppose that an organization issues nonvolatile pieces of information to guards and waits a modest period of time during which incidents occasionally occur. Let  $a$  stand for the number of abnegation incidents,  $b$  for the number of betrayal incidents and  $c$  for the number of combination incidents. The total

number  $d$  of incidents is  $d=a+b-c$  because a combination incident gets counted twice, once by  $a$  and once by  $b$ .

The second principle is that incidents are so rare, that the possibility of two separate incidents occurring with the same nonvolatile piece of information is usually dismissed on probabilistic grounds as absurd. A defection is a single incident with two aspects, abnegation and betrayal, so it is not dismissed as too improbable. But the idea that the person who has a copy of the number dies in a plane crash one month after confiding it to an opponent is dismissed as too improbable. Too slavish an adherence to this "second-order improbability" prejudice can lead to ludicrously inappropriate actions, such as that of the statistician who always carries his own bomb on airplanes because it is so improbable that there will be two bombs on the same flight. But it is a good rule of thumb if used properly.

This latter principle implies, among other things, that none of the four numbers  $a$ ,  $b$ ,  $c$  or  $a+b-c$  exceeds the number  $g$  of nonvolatile pieces of information entrusted to the  $g$  guards.

Suppose an organization chooses in advance the number  $a$  of abnegation incidents and the number  $b$  of betrayal incidents it feels it must be protected against when entrusting several nonvolatile pieces of key reconstruction information to a set of guards. Each guard gets a different piece of information. The lifetime of this scheme must not be very many months if separate incidents involving the same piece of information are to be ruled out. We know that  $c \leq \text{MIN}\{a, b\}$  since a combination incident is both an abnegation incident and a betrayal incident. From the two counting principles above it then follows that

$$a+b-\text{MIN}\{a, b\} \leq d \leq a+b$$

and that  $d \leq g$ , where  $g$  is the number of guards to which the organization entrusts the  $g$  nonvolatile pieces of information.

The prudent man, when designing a system of safeguarding key information which is secure from  $a$  abnegation incidents as well as  $b$  betrayal incidents, must assume that the number  $c$  of combination incidents is zero. This means that the maximum number of incidents must be anticipated, since

$$d = a + b - c = a + b - 0$$

in this case. Such a key information safeguarding system must have the property that  $a+b+1$  different nonvolatile pieces of key reconstruction information are generated, and given to distinct guards. The key must be reconstructible from any  $b+1$  of these pieces (this assumes  $a$  abnegation incidents) but there must be no information whatever about the key which can be inferred from knowledge of only  $b$  of these pieces (this is protection against  $b$  betrayal incidents). This last requirement is unusual. For example, a polynomial of degree  $b$  can be reconstructed from its values at  $b+1$  points. But already its values at any  $b$  points tell a lot about it. It can also be reconstructed from the values of its 0th through  $b$ th Taylor coefficients at a point. But already the values of any  $b$  of these  $b+1$  numbers tell a lot about it. What we are asking for, then, is somewhat counter-intui-

tive. Let us coin a metaphor to describe it. We want to give every one of  $a+b+1$  guards a shadow of a different profile of the key, so that the key can be reconstituted in its entirety from any  $b+1$  of these shadows. However, somebody who has seen only  $b$  such shadows should be completely in the dark, in the very strong sense that any key on the keyring could cast these  $b$  shadows when illuminated from  $b$  appropriately chosen directions.

Let us look at what happens if  $a=b=4$ . Then any five of the nine guards have the wherewithal to reconstruct the key. Thus, there is considerable protection against defection and dereliction, since even four of the nine pieces of information are not enough to reveal anything at all about the key to an opponent. There is also protection against destruction. If the four pieces of information belonging to any four guards are destroyed the other five can still be used to reconstruct the key. As to degradation, suppose that six guards give correct reports of the shadows they carry, to return to the metaphor. Then there are six different sets of five guards whose pieces of information can reconstitute the same key. If the other three misreport their shadows then any one of the 120 sets of five guards containing at least one of the misreporting three guards will give a description of the key, but probably all these descriptions will differ among themselves and will also differ from the true value of the key. Thus, the six reports of different sets of five guards which agree are singled out as correct. Of course, if it is possible to tell whether a proffered key is the right one, then it is possible to reconstruct the key when only five guards report correctly. So protection against degradation need not be synonymous with protection against destruction, but they are largely concomitant with each other. In the approach to be discussed it will be assumed that the right key can be recognized when proffered. This assumption is reasonable since lists of plaintext to cryptext pairs can be publicized for testing as a backstop to the simpler test, which is that stored ciphertext messages will probably yield nonsensical diecipherments under a false key.

The rest of the paper describes one way to cast the  $a+b+1$  shadows of a key in such a fashion that it can be reconstructed from any  $b+1$  of them, but that no  $b$  of them tell anything about it whatever. The way this is done is to set up a many-to-many correspondence between keys and one-dimensional vector subspaces of (i.e. lines through the origin of) a finite vector space,  $F$ . One key determines a vast collection of lines but one line determines a tiny collection of keys. When an organization has a key to apportion among  $a+b+1$  guards, it picks at random one of the lines corresponding to that key. Let us call this line  $L$ . Then it picks at random  $a+b+1$  vector subspaces of  $F$ —the shadows of the key—such that any  $b$  or fewer of them intersect in a large vector subspace of  $F$  whose various one dimensional vector subspaces lead back to all possible keys with approximately equal probability, but such that any  $b+1$  of them intersect in  $L$ . Once  $L$  has been found there are only a few possible keys which could have given rise to it. Each one is tried against a stored list of plaintext to cryptext pairs and the correct one identified. This is not the first application of projective geometric ideas to problems involving codes.<sup>2</sup>

## SOME PRELIMINARY RESULTS

$a \uparrow b$  is the  $b$ th power of  $a$ , and  $a * b$  is the product of  $a$  and  $b$ .

- **Lemma 1**—Let  $a$  and  $b$  be positive integers. Let  $R$  be a set with at least  $a+b+2$  members. Then there are more than  $a+b+2$  subsets of  $R$  which consist of  $b+1$  objects. There are more than  $a+b+1$  subsets of  $R$  which consist of  $b$  objects. If  $f$  and  $g$  are two members of  $R$  there are more than  $a+b$  subsets of  $R \setminus \{f\}$  which consist of  $b$  objects, and there are at least  $a+b$  subsets of  $R \setminus \{f, g\}$  which consist of  $b$  objects.
- **Lemma 2**—Suppose that  $a$  and  $b$  are positive integers smaller than  $z$ . Let  $M$  be a matrix with at most  $a+b+2$  rows and at most  $b+2$  columns. Then  $M$  has at most  $(z+1)(2z)$  entries and at most  $(z+1) \binom{2z}{z} b+1$  by  $b+1$  submatrices. Thus  $M$  has fewer than  $3z \uparrow 2$  entries and fewer than  $4 \uparrow z$  submatrices of size  $b+1 = by = b+1$ .
- **Lemma 3**—Suppose that  $0 < 2Ex < 2Q < 2 < E$ . Then  $2|(1-x) \uparrow E - (1-Ex)| < Q \uparrow 2$ .
- **Lemma 4**—If  $4 \leq A < B$  then  $\prod (1-j/B) < \prod (1-2/B)$ , where the products are over positive integers  $j < A$ .
- **Lemma 5**—Suppose that  $A$  and  $B$  are integers and that

$$0 < 2(A-1) \uparrow 2 < 2BQ < 2B < (A-1)B.$$

Then  $1-2Q < B! / ([ (B-A)! ] * [ B \uparrow A ]) < 1$ , and  $1-2Q < ((B-2)/B) \uparrow A < ((B-1)/B) \uparrow A < 1$ .

- **Lemma 6**—Suppose that  $A$  and  $B$  are integers and that

$$0 < 2(A-1) \uparrow 2 < 2BQ < 2B < (A-1)B$$

Suppose that a sample of  $A$  points (with replacement) is taken from a population of  $B$  points. Then the probability  $U$  that all sample points are distinct exceeds  $1-2Q$ . If two distinguished points of the population are specified in advance the probability  $V$  that no sample point is equal to either of them exceeds  $1-2Q$ . Therefore it follows *a fortiori* that if one or two distinguished population points are specified in advance, then the probability  $W$  that none of the points of the sample is equal to any of the distinguished points or to any other point of the sample exceeds  $1-4Q$ .

• **Lemma 7**—Let  $p$  be an odd prime. Let  $d$  be a positive integer. Let  $S(d, p)$  be the collection of all  $d$  by  $d$  matrices with entries taken from the field  $F$  of integers modulo  $p$ . Let  $v$  and  $w$  be two non-zero members of  $F$ . Then there are as many members of  $S(d, p)$  with determinant equal to  $v$  as there are with determinant equal to  $w$ .

• **Lemma 8**—Let  $p$  be an odd prime. Let  $k$  and  $n$  be positive integers. Let  $f(p, n, k)$  be the number of  $k$  by  $n$  matrices over the field  $F$  of residue classes modulo  $p$  whose rank is less than  $k$ . Then  $f(p, n, 1) = 1$  and, whenever  $2 \leq k \leq n$ ,

$$f(p, n, k) = p \uparrow [(k-1)(n+1)] + (p \uparrow n - p \uparrow (k-1)) f(p, n, k-1).$$

Consequently,

$$p \uparrow [(k-1)(n+1)] < f(p, n, k) < p \uparrow [(k-1)(n+2)] + (p \uparrow n) f(p, n, k-1)$$

for every integer  $k$  such that  $2 \leq k \leq n$ .

• **Lemma 9**—Let  $p$  be an odd prime. Let  $f(p, n, k)$  be as in Lemma 8. Then  $p \uparrow (n \uparrow 2 - 1) < f(p, n, n) < 2p \uparrow (n \uparrow 2 - 1)$ .

- **Theorem 1**—Let  $p$  be a prime larger than 6. Let  $d$  be a positive integer. Let  $S(d, p)$  be the collection of all  $d$  by  $d$  matrices with entries taken from the field  $F$  of integers modulo  $p$ . If  $v \in F$  let  $n(v, d, p)$  be the number of members of  $S(d, p)$  whose determinant is equal to  $v$ . Suppose that  $h$  and  $g$  are members of  $F$ . Then

$$n(h, d, p) < 3n(g, d, p)$$

$$\text{and } [p \uparrow (n \uparrow 2 - 1)] / 2 < f(p, n, n) < 2p \uparrow (n \uparrow 2 - 1).$$

Thus, all determinants occur approximately equally often. In fact every non-zero field element occurs equally often as the value of the determinant of a member of  $S(d, p)$  but zero occurs more often, though not thrice as often.

- **Theorem 2**—Let  $a$ ,  $b$  and  $p$  be positive integers. Let  $M$  be a matrix with  $a+b+2$  rows and  $b+2$  columns. Suppose that

$$0 < 2[(a+b+2)(b+1)-1] \uparrow 2 < 2pQ < 2p < [(a+b+2)(b+1)-1]p.$$

Suppose that one position in each row of  $M$  is chosen at random, and that that entry is set equal to 1. Suppose that the remaining  $(a+b+2)(b+1)$  entries of  $M$  are chosen at random (with replacement) from the population of all  $p$  residue classes modulo  $p$ . Then each of the two events

1. Two entries of  $M$ , neither of which is one of the  $a+b+2$  entries which were set equal to 1 at the outset, are congruent to each other modulo  $p$
2. An entry of  $M$ , other than one of the  $a+b+2$  entries which were set equal to 1 at the outset, is congruent to either 0 or 1 modulo  $p$

have probability smaller than  $2Q$ . Consequently, the probability that neither Event 1 nor Event 2 occurs exceeds  $1-4Q$ .

It is easy to verify that if  $Q = 1/10 \uparrow 7$ , and  $a$  and  $b$  are both smaller than 10, then it suffices to choose any  $p > 10 \uparrow 12$  in order to satisfy the hypotheses of Theorem 2. This is the order in which users of the keyguard system will usually proceed. The tiny positive number  $Q$  is a measure of the departure from complete randomness of the concealing procedure. The modest-sized positive integer  $a$  (resp.  $b$ ) is the number of abnegation (resp. betrayal) incidents to be guarded against. After deciding on these three safety levels a user must then accept a value of  $p$  as large as dictated by the hypotheses of Theorem 2 in order to achieve them. The keyspace will then be chosen to contain at least  $p$  keys.

Consider, now, the probabilistic interpretation of Theorem 1. If you choose a member  $x$  of the field  $F$  of integers modulo  $p$ , and choose some  $d$  by  $d$  matrix  $M$  over  $F$  at random (by choosing its successive entries at random with replacement from  $f$ ) then the probability  $W$  that  $\det(M) = x$  satisfies the inequality  $1/2p < W < 2/p$ .

We will assume that the manner in which the matrix in

Theorem 2 is chosen (salting each row with a 1 entry) does not do much violence to this conclusion. In other words, we will make the following (unproven but plausible) assumption.

- *Hypothesis 1*—Let  $p$  be an odd prime. Let  $a$  and  $b$  be positive integers. Let  $M$  be a matrix with  $a+b+2$  rows and  $b+2$  columns. Suppose that a position in each row is chosen at random and that that entry is set equal to 1. Suppose that, thereafter, each of the remaining  $(a+b+2)(b+1)$  entries is chosen at random from the field  $F$  of residue classes modulo  $p$ . Suppose that, then, a collection of  $b+1$  row indices is chosen at random from the set of all  $b+1$  member subsets of the set of all  $a+b+2$  row indices. Suppose, finally, that a collection of  $b+1$  column indices is chosen at random from the set of all  $b+1$  member subsets of the set of all  $b+2$  column indices. Let  $x$  be a member of  $F$ . Let  $W$  be the probability that the value of the determinant of the  $b+1$  by  $b+1$  submatrix  $S$  of  $M$  corresponding to these row and column indices is equal to  $x$ . Then  $W$  satisfies the inequality

$$1/2p < W < 2/p.$$

To put matters in a nutshell, a judicious salting of an otherwise randomly chosen matrix with a few entries equal to 1 should not cause the determinants of its large square submatrices to depart from the quite uniform distribution that determinants of completely randomly selected matrices exhibit.

## GUARDING KEYS

A key  $k$  is a positive integer. A keyset  $K$  is a finite set of keys. Let  $B$  be the largest member of the keyset  $K$ . A reasonably small positive integer  $z$  is chosen. On practical grounds  $z$  should probably be smaller than 100. Two positive integers  $a$  and  $b$  smaller than  $z$  are chosen. A prime  $p$  only slightly smaller than  $B$  is found. It would not, in fact, be too expensive to find the largest *pseudoprime* smaller than  $B$  and let it be  $p$ . A pseudoprime is a large positive integer which satisfies a considerable number of Rabin's (hopefully) stochastically independent necessary<sup>4</sup> conditions for primality, and can therefore be assumed to be prime with a probability in excess of 0.99999 99999 99999 99999, or even more, if desired. Though  $p$  might be composite we shall regard it as prime in the development below. Let  $F$  be the field of integers modulo  $p$ . Let  $V$  be the  $b+2$  dimensional vector space over  $F$  which consists of all lists (written in the form of rows) of  $b+2$  members of  $F$ . For every member  $g$  of the set  $G$  of  $a+b+1$  guards we will define a corresponding  $b+1$  dimensional vector subspace  $V(g)$  of the  $b+2$  dimensional vector space  $V$ . To each key  $k$  there will correspond many lines, through the origin of  $V$ , representing  $k$ . The organization wishing to entrust  $k$  to a set of guards will choose one of these lines at random and call it  $L(k)$ . When  $b$  guards intersect their subspaces the intersection must be at least two-dimensional. Moreover, it will be such that its various one-dimensional vector subspaces represent all members of

$F$  with approximately equal likelihood. But when  $b+1$  guards intersect their subspaces the intersection is the line  $L(k)$ , which does not depend on which  $b+1$  guards were chosen. To  $L(k)$  there will correspond only  $b+2$  possible keys. The candidates can be checked and the key reclaimed. The rest of this section fleshes out this outline.

To begin we pick  $z$  and choose positive integers  $a$  and  $b$  smaller than  $z$ . Then we choose a small  $Q$ , and thereafter a suitably large  $p$  to satisfy the inequalities in the hypotheses of Theorem 2. We construct a matrix  $M$  with  $a+b+2$  rows and  $b+2$  columns as follows. For each row of  $M$  we pick an entry at random and set it equal to 1. Next we pick an entry at random in the first row of  $M$  and choose its value  $k$  at random from  $F$ . Then we choose the remaining  $(a+b+2)(b+2)-1$  entries of  $M$  at random (with replacement) from  $F$ . Now we test  $M$  for acceptance or rejection. In order to pass the first test  $M$  must have only one 1 in each row, it must have no zero entry and no two of its entries can be equal unless they are both equal to 1. Since  $a$  and  $b$  are non-negative integers smaller than  $z$  it follows from Lemma 2 that there are fewer than  $3z \uparrow 2$  entries of  $M$ . Since  $p$  and  $Q$  satisfy the inequalities in the hypotheses of Theorem 2, it then follows from Lemma 4 that such a random process will produce a matrix which passes the first test with probability in excess of  $1-2Q$ . In order to pass the second test  $M$  must have no  $b+1$  by  $b+1$  submatrix whose determinant, calculated in  $F$ , is zero, and must have no two  $b+1$  by  $b+1$  submatrices whose determinants, calculated in  $F$ , are equal. There are fewer than  $4 \uparrow z$  such submatrices, according to Lemma 2. The foregoing suggests that the random process which produced  $M$  will cause it to pass the second test with probability in excess of  $1-2Q$ . Therefore, it should pass both tests with probability in excess of  $1-4Q$ . In other words, the process used almost always produces a usable matrix  $M$  the first time it is employed. Once a matrix  $M$  passes the tests we know from Lemma 1 that we can form more than  $a+b+1$  sets of  $b+1$  rows of  $M$  which contain the first row of  $M$ . So we pick  $a+b+1$  different sets of  $b+1$  rows of  $M$ , each of which contains the first row of  $M$ . Each such set is linearly independent since every  $b+1$  by  $b+1$  submatrix of  $M$  is non-singular. Let  $N(j)$  be the  $b+1$  by  $b+2$  submatrix of  $M$  formed in the obvious way from the  $j$ th of these  $a+b+1$  sets of rows. Its first row consists of the first of  $M$ 's rows which occurs in the set. Its second row is  $M$ 's second. And so on. Now for each  $x \in V$  it is possible to form the  $b+2$  by  $b+2$  matrix  $Y(j,x)$  from  $N(j)$  by appending a last (i.e.  $(b+2)$ nd) row

$$\begin{aligned} x &= (x(1), x(2), \dots, x(b+1), x(b+2)) \\ &= (Y(j,x)[b+2,1], Y(j,x)[b+2,2], \dots, \\ &\quad Y(j,x)[b+2,b+1], Y(j,x)[b+2,b+2]) \end{aligned}$$

The  $b+1$  dimensional vector subspace of the vector space of rows with  $b+2$  entries taken from  $F$  determined by  $N(j)$  is the set

$$U(j) = \{x \mid \det(Y(j,x)) = 0\}$$

Evidently the first row  $f$  of  $M$  belongs to  $U(j)$  for every  $j$  since  $Y(j,f)$  has first and last row equal to  $f$  for every  $j$ .

So when  $b+1$  of these  $b+1$  dimensional vector subspaces of the  $b+2$  dimensional vector space of rows of  $b+2$  entries taken from  $F$  are intersected their intersection is the line through the origin which also contains the vector  $f$  which is the first row of  $M$ . The equation  $\det(Y(j,x))=0$  is, of course, a linear equation of the form

$$c(j,1)x(1)+c(j,2)x(2) \dots +c(j,b+1)x(b+1)+c(j,b+2)x(b+2)=0$$

where  $c(j,t)$  is a determinant of some  $b+1$  by  $b+1$  submatrix of  $M$ . These are non-zero, and pair-wise unequal by the way  $M$  was produced. And, because of the foregoing, they probably appear to be approximately randomly selected from  $F$ .

But now look at what happens when only  $b$  of these subspaces is intersected to form a two-dimensional vector subspace. This means choosing integers

$$1 \leq j(1) \leq j(2) < \dots < j(b) \leq a+b+1$$

and solving the simultaneous equations

$$\begin{aligned} \det(Y(j(1),x)) &= 0 \\ \det(Y(j(2),x)) &= 0 \\ &\vdots \\ \det(Y(j(b),x)) &= 0 \end{aligned}$$

for  $x$ , by using Gauss elimination, then choosing a basis of two vectors for this space of all such  $x$ . The two-dimensional vector space in question contains the first row of  $M$ . But the randomness of the choices of the members of  $M$  should mean the following:

- *Hypothesis 2*—Consider the collection of all vectors in this two dimensional subspace which have exactly one entry equal to 1 and which have pairwise distinct entries none of which is zero. Any two members of  $F \setminus \{0,1\}$  will be represented approximately equally often in the count of multiplicities of occurrence of members of  $F \setminus \{0,1\}$  as entries in the vectors of this collection.

If this is correct then isolation of this two-dimensional subspace sheds no light whatever on how to recover the

key. The recovery system, when you have  $b+1$  subspaces  $U(j)$  is to solve the system

$$\begin{aligned} \det(Y(j(1),x)) &= 0 \\ &\vdots \\ \det(Y(j(b+1),x)) &= 0 \end{aligned}$$

as above. The solution is a line through the origin. A basis for it is a single vector  $g=(g(1),g(2), \dots, g(b+1),g(b+2))$  which is some non-zero multiple of  $f$ , the first row of  $M$ , which contains the key as one of its entries. You know  $g$ , not  $f$ . But for each entry  $g(i)$  of  $g$  it is easy to find the  $h(i) \in F$  such that  $g(i)h(i) \equiv 1 \pmod{p}$ . The  $b+2$  vectors

$$\begin{aligned} h(1)g \\ h(2)g \\ \vdots \\ h(b+2)g \end{aligned}$$

are the only multiples of  $g$  which have 1 as an entry. Therefore  $f$  is among them, and the key  $k$  is among the entries of  $f$ . So one of the  $(b+2) \uparrow 2$  entries on the list of vectors above is the key. And the key is not equal to 1, which occurs once among the entries of each vector. So there are

$$(b+1)(b+2) \leq z(z+1)$$

candidates to be tested. One of them will pass the test.

# Applications for multilevel secure operating systems

by JOHN P. L. WOODWARD

The MITRE Corporation  
Bedford, Massachusetts

## INTRODUCTION

The need for secure computer systems has been identified in many areas of DoD operations, but in the past these systems have not been built in a secure manner because a secure operating system on which to run has not existed. Now that verifiably secure minicomputer operating systems are becoming a reality, applications for secure systems are becoming more clearly thought-out, designed and implemented. This paper surveys some proposed DoD and non-DoD secure computer applications.

We will discuss the applications presented in this paper in the context of their implementation on a secure operating system. This paper will survey four applications:

- a. The "guard" application;
- b. Secure database management systems;
- c. Secure message processing systems; and
- d. Secure front-ends.

We will discuss the first two of these applications in more detail, and the other applications are discussed in Reference 1.

Before the discussion of secure computer applications, the following section describes the past and present work that is leading to the completion of a mathematically verified Kernelized Secure Operating System (KSOS), and briefly discusses the organization of kernel-based secure systems. This organization provides a framework for our survey of major applications for secure computer systems in the next sections. The conclusions highlight some of the major points of the paper.

## SECURE COMPUTER SYSTEMS

### *Background*

The need to process multiple levels of data in a single computer system has been recognized within DoD for a long time. This need led the Air Force Electronic Systems division in 1972 to study how one could verify that a system meets DoD security requirements.<sup>2</sup> This need for verification led to the development of a mathematical model that

describes DoD security policy in terms of a "reference monitor"—an abstract mechanism that controls the flow of information within a computer system by mediating all accesses by subjects (processes, users) to objects (files, I/O devices).<sup>3</sup>

Given the concept of a reference monitor and a mathematical model that embodies a specific security policy, one can formulate an inductive proof in terms of secure system states, proving that security is preserved in moving from state to state. Several models that embody DoD security rules have been developed<sup>4,5</sup> and each of these models has two basic rules: the simple security condition and the \*-property (read "star-property").<sup>6</sup>

The simple security condition mandates that a subject cannot read an object unless the security level (in DoD terms, a classification and a set of categories) of the subject is greater than or equal to that of the object. This rule is a precise statement of the basic premise behind DoD security, and is analogous to controls in the people-paper world.

The \*-property dictates that a subject cannot write an object unless the subject's security level is less than or equal to that of the object. The \*-property is motivated by the need to prevent a program operating on behalf of a user from reading information that the subject (user) is cleared to read and writing this information into a container of a lower classification level, thus allowing access to the information by subjects at lower levels.

The hardware and software mechanism that implements a reference monitor and enforces the rules of the model is called a kernel (or security kernel). To adequately provide security, an implementation of a kernel must have three properties: 1) It must mediate every access of every subject to every object; 2) it must be isolated from other code in the system so it cannot be modified or tampered with; and 3) it must be mathematically verifiable, i.e., it must perform its functions correctly. The kernel satisfies the first property by creating and controlling an environment in which all non-kernel software must run. The second requirement is generally satisfied by relying on hardware domain mechanisms. The third property is satisfied by developing the kernel with a formal methodology that allows proof that the kernel enforces the desired policy correctly. This methodology<sup>7</sup> uses a formal specification technique to describe the kernel interface, and allows the correctness proof to be carried out

in (at least) two steps: a proof that the top-level (kernel interface) specification obeys the rules of the model,<sup>8</sup> and a proof that the kernel code correctly implements this interface.<sup>9</sup>

Some of the earliest kernel work was done under Air Force sponsorship by The MITRE Corporation. MITRE developed a simple kernel for the PDP-11/45 computer.<sup>10</sup> This kernel, designed with no particular operating system in mind, was successfully implemented and verified. The top-level specification was verified with respect to the model and example lower-level proofs carried out.

A logical extension of the early MITRE PDP-11 kernel work led to a MITRE/Honeywell project to design a kernel for the MULTICS operating system,<sup>11</sup> also under Air Force sponsorship. MITRE specified a MULTICS kernel and verified it with respect to the model.<sup>12</sup>

Other major kernel developments have produced prototype kernels for the UNIX<sup>®</sup> operating system, running on PDP-11 computers. Prototype Secure UNIX systems have been developed by UCLA<sup>13</sup> (under DARPA sponsorship) and MITRE<sup>14</sup> (under Air Force and DARPA sponsorship). Experience with these prototypes has contributed to the current development of a production-quality Kernelized Secure Operating System (KSOS)<sup>15,16</sup> by Ford Aerospace and Communications Corporation (FACC), under the sponsorship of DARPA and other government agencies.

The KSOS project has two phases, a design phase and an implementation phase. The design phase was carried out by two contractors, TRW<sup>17</sup> and FACC.<sup>18</sup> Both contractors produced designs for a somewhat machine independent design for a secure operating system that emulated the UNIX operating system. FACC was chosen to implement their design on a PDP 11/70 computer.

### *The organization of secure computer systems*

The organization of KSOS is similar to previous secure system designs. Secure systems are most often divided into three portions: the kernel, the trusted (or privileged) processes, and the Emulator. We will discuss each in turn.

#### **The security kernel**

The kernel, the concrete implementation of the software portion of a reference monitor, encapsulates the security-related functions of a conventional operating system and provides an external interface which allows multiple processes to access data files and I/O devices. Kernels typically operate on the basis of the following assumptions:

- a. The kernel provides a process-structured environment.
- b. Each process (supported by the kernel) has available to it a set of objects that can be created, deleted and accessed only by using defined (kernel provided or mediated) operations.

- c. Each process is confined with respect to the defined protection policy.
- d. Each process can execute whatever programs it pleases; because it is confined it cannot, by construction, violate security.

It is important to note that for any security kernel of some sophistication, the security kernel not only controls access to objects, it must define the objects and construct operations to access these defined objects.

Most kernels also support the notion of a privileged process—a process that is allowed (privileged) to violate some or all of the rules of the security model being enforced. Since a privileged process can potentially violate security, it must be constructed and verified with the same rigor applied to the kernel itself. Privileged processes are often referred to as “trusted processes,” because they are trusted (because of their verification) either not to violate security or to violate the security rules in a known and controlled manner.

#### **Trusted processes**

Trusted processes augment the capabilities of the kernel itself, and provide security-related functions more properly performed above the kernel interface. Examples of trusted processes are: a process to downgrade files; a process to handle logins at terminals (reading user names and passwords), etc. In the UCLA prototype secure UNIX system,<sup>13</sup> trusted processes are used to set scheduling policy, protection policy, and create a primitive, flat, file system.

#### **The emulator**

The emulator portion of a secure operating system runs on top of the kernel and creates an operating system interface out of the interface provided by the kernel and the trusted processes. Because the emulator runs in a kernel-provided process, and typically does not need any privileges, it does not need to be trusted or verified. Most secure minicomputer operating system developments to date have emulated the UNIX operating system.

### **A SURVEY OF MAJOR TYPES OF SECURE APPLICATIONS**

There are two major types of applications for secure operating systems, unilevel and multilevel. We will discuss each in turn.

#### *Unilevel applications*

Unilevel applications involve the use of a secure operating system as a whole to allow many users, each operating at a single level, to use the same computer at the same time. Such operation of a non-secure operating system would be

<sup>®</sup> UNIX is a trade/service mark of the Bell System.

in violation of DoD security rules because you cannot demonstrably prevent a low-level user from accessing higher-level data.

There are many instances within DoD where periods processing and multiple computers are used to perform unilevel operations at several levels. Periods processing refers to a mode of computer operation whereby the system is used to process data of different classifications at different periods of the day, because the multiple levels of data cannot be simultaneously processed without overclassification. Use of secure operating systems in environments such as those running unilevel applications can greatly increase machine utilization and decrease hardware costs due to security.

Unilevel applications rely on the secure computer system to provide complete isolation between users of different security levels. Very frequently, the real driving requirement is for controlled *sharing* among users of different classifications. The applications that permit this are called multilevel.

### *Multilevel applications*

Very often a computer system user needs to process several levels of information at the same time. This need is addressed in some installations by operating in a mode known as "system high:" each user of the system is cleared to the level of most sensitive data being processed, and can operate on any data up to and including that level (within the constraints of the "need-to-know" policy enforced at the installation). The problem with this type of operation is that data tends to become overclassified: all data leaving the system must be considered highly classified until a manual review process allows the data to be properly classified. Although the "system high" mode of operation allows the processing of several levels of data, it is not properly termed multilevel, because it does not preserve the different classification levels of the data it processes.

Whereas the unilevel applications we have previously discussed, if run on a secure operating system, would typically run on the emulator portion, multilevel applications generally run on either the emulator or kernel portions. The basic premise behind kernel-based operating systems is that any unprivileged code running on the kernel, no matter how malicious it is, cannot violate any security rules. Thus, the emulator portion of a secure system is not trusted, and exists only to provide a richer operating system interface than a kernel alone would. Therefore, applications that run on secure operating systems can run on the emulator interface, or they can run directly on the kernel interface. The latter is often the case if the features provided by the emulator are not relevant to the desired application, or if the application requires very high performance.

Furthermore, some portion of a multilevel application might need to be privileged to perform its task. If this is the case, then the code must be trusted to perform its function properly, and the code must run directly on the kernel because the Emulator is not trusted.

Because of these different options for implementation of

multilevel applications, we will survey some multilevel applications that have been proposed to date, and indicate how each application would run on a secure system. Each application has either been worked on in the past, or is presently under development.

### **The guard application**

In military operations, there is a great need to be able to interconnect computers of different classification levels: evolving defense systems depend heavily on the capability of passing information between computers operating at different levels. Unfortunately, such connections are very difficult to implement in a secure manner. This problem would be made much easier if all computers had secure operating systems available, but such is not the case.

There is also a recurring need to make a subset of classified data available for use at a lower classification level. "Sanitization" and "downgrading" must be performed to do this without compromise. To better illustrate this need, consider a highly-classified computer that maintains an intelligence data base. This data base typically contains pieces of data with attributes that make them very sensitive. However, to be operationally useful, the data is needed at lower levels where command decisions are made. Thus there is a great need to be able to "sanitize" the data. Sanitization is often accomplished by removing the sources (sensors, etc.) of the data or by reducing the precision of the data. If the computer with the intelligence data base is not secure, then we cannot trust a sanitization and release function performed on the computer not to allow the release of highly-classified data at a low level.

Currently, there are several methods available to provide a sanitize and release function. The simplest involves reading the information to be sanitized from one terminal, and entering the sanitized version on another terminal. The two terminals involved are not connected to the same system; there is no electrical connection between the two systems. A more sophisticated solution involves a single CRT terminal that can be connected to either system (by means of a switch), but only one system at a time. In this mode, data from the intelligence computer is read onto the screen of the CRT and sanitized by using the local editing capabilities of the CRT. Then the CRT is disconnected from the intelligence computer and connected to another, lower level system, and the data is read into the lower level system.

The problem with these solutions is that they are time-consuming and cumbersome. The best solution would be to use a secure operating system on intelligence computer, and directly connect it to a lower-level system, providing a facility on the higher-level computer to securely sanitize data before releasing it at the lower level. This solution may not be viable however, because existing intelligence data bases are on computers for which no secure operating system exists, and which are, in some cases, not securable (because of lack of necessary hardware features).

The Guard application is an intermediate solution to this problem. The Guard is a secure minicomputer system that

acts as an interface between two computers of different security levels and allows data to flow between them in a secure and controlled manner. The Guard can provide better throughput than the switched terminal described above, and is much more flexible in its capabilities. The Guard application uses trusted processes and unlevel processes to accomplish its functions. The Guard will be described in more detail in a later section.

#### Secure database management systems

Using a secure computer system allows one to process multiple levels of data without having to overclassify the data. Using the system high mode of operation for example, all data of classification SECRET and below can be processed on a unilevel SECRET computer, but all outputs of the computer must be considered SECRET until a manual review process allows them to be downgraded. If multiple levels of information are to be organized and accessed in a meaningful manner, it makes sense to use some form of Database Management System (DBMS). However, most current database management systems do not take classification levels of data into account, so using them to process multiple levels of data would result in all of the data being processed at one level, causing some of the data to be overclassified, an adverse side effect to be avoided if possible.

Since the advent of secure system development work, there have been several attempts to incorporate multilevel security into a DBMS. These DBMS designs have relied to varying degrees on the kernel of the underlying secure operating system for protection of data in the database. Work in the design of secure database management systems has shown that although they can be designed to function in a secure environment, the environment provided by many past and present kernel designs may not be ideally suited to building a Secure DBMS. Another concern in the design of secure database management systems is the nature of the user interface to the database.

A later section will survey recent work in this area and describe some problems that still need to be solved.

#### Secure message processing systems

Another military application for secure computer systems is message-processing systems. These systems automate the task of day-to-day military message communication. These systems are in reality transaction-based database management systems, but have a much stronger requirement for good user interfaces than many other database applications if they are to be widely used by military staff.

Recently, there has been an effort to evaluate the use of such systems in a secure environment, and to design secure message-processing systems to run on secure operating systems. DARPA, the Navy and CINCPAC are conducting a Military Message Experiment to evaluate computer-aided message handling systems in an operational military envi-

ronment. MITRE's security-related role in the experiment has been to investigate the security ramifications of such systems: to identify the kernel primitives needed to implement the systems, and to identify the impacts that security imposes on the user interface.

Several message systems were developed during the experiment, and the SIGMA system developed by the Information Science Institute of the University of Southern California<sup>19</sup> was chosen for installation. SIGMA is an interactive message handling system providing computer-aided message handling services for the receipt, filing, retrieval, creation and coordination of military messages. Although SIGMA runs on the (insecure) TENEX operating system, it presents a user interface that reflects DoD security policy. A key concept in the design of SIGMA is that of a multilevel terminal: a terminal with multiple "windows" on the screen, each of which can potentially contain information at different classification levels.

If such a system were implemented on a secure operating system, it would have to be integrated closely with the kernel. Either the kernel would have to be able to deal securely with the concept of a multilevel terminal, or some kind of trusted process would have this responsibility. FACC, as part of their KSOS effort, is investigating the applicability of KSOS as a host for multilevel terminals and secure message processing systems.<sup>1</sup>

#### Secure front ends

Early in our Multics effort we discovered that to make a Multics system fully secure and able to handle multiple levels of terminals attached to the system in a feasible manner, that we had to make the Multics front-end terminal controller secure also. The front-end terminal controller has to multiplex the data streams coming from many terminals into the Multics computer, and it was quickly recognized that if this multiplexing were not done properly, untold security violations could result. We could have used multiple controllers each dedicated to a single level, but this usage of resources is wasteful and inflexible. Unfortunately, the Datanet 355 controller being used did not have the hardware features necessary to support a security kernel. The Multics project undertook, with Honeywell, the development of a secure communications processor, called the SCOMP.<sup>20,21</sup> Currently, the SCOMP hardware (a modified Honeywell Level 6 minicomputer) is complete and Honeywell is building a version of KSOS to run on the SCOMP.

Thus, front-end controllers are another major type of application for secure computer systems. Indeed, this application is not limited to terminal controllers, though. Secure front-end controllers have application in secure computer networks, also. Front-ends have many different functions and require varying amounts of security support from secure systems. Some front-ends would need much trusted code and therefore run on the kernel interface. Some more sophisticated front-end applications may also need the type of file systems supported by the emulator portion. Currently, Ford Aerospace and Communications Corporation is look-

ing into the applicability of KSOS as a base for a Network Front-End for the World Wide Military Command and Control System, WWMCCS.

#### A DEEPER LOOK AT THE GUARD APPLICATION

The Guard application described earlier is being developed by Logicon under DARPA sponsorship at the Advanced Command and Control Architectural Testbed (ACCAT) in San Diego. The Guard application is expected to run on KSOS when KSOS becomes available. ACCAT, a joint DARPA/Navy undertaking, provides an ideal environment for Guard development. The Guard application is often referred to as the ACCAT Guard.<sup>22,23</sup>

The ACCAT Guard system is a minicomputer that provides an interface between two computers or networks at different classifications. Hereafter, the computer or network of lower classification will be referred to as the LOW computer or network, and the higher classification computer or network will be referred to as HIGH.

Guard allows the two computers/networks of different classifications to communicate by providing (1) an upgrading facility to pass data from the LOW computer/network to the HIGH computer/network, and (2) a sanitization and downgrading facility to pass properly sanitized data from the HIGH computer/network to the LOW computer/network.

Two general classes of data transfers are provided by ACCAT Guard. The first is ARPANET network mail transfers. Network mail can normally flow among computers on the LOW network or among computers on the HIGH network, but cannot flow between the two networks at different classifications. ACCAT Guard allows mail to pass between the LOW and HIGH networks in a secure, controlled manner.

Second, Guard allows users on the LOW computer/network to query Datacomputer<sup>24</sup> databases residing on HIGH computers, and allows a properly sanitized response to be sent to the requesting user. Additionally, Guard accepts queries either in English or in Datalanguage, the Datacomputer database query language. English queries are translated into Datalanguage by a Guard operator.

The Guard minicomputer is connected to the LOW and HIGH networks through Private Line Interfaces (PLIs)<sup>25</sup> over the ARPANET. PLIs are encryption devices that allow a computer with a specific key to securely communicate with other computers having the same key. Thus the Guard has two distinct ARPANET connections that are at different security classifications. Figure 1 shows the connection of the Guard computer via PLIs and the ARPANET to the other computers. The LOW and HIGH computers are prohibited from directly communicating because their keys are different. They can communicate only through the Guard computer, which has two PLIs and keys to communicate with both the LOW and HIGH computers. Thus the Guard computer must control the communication between the LOW and HIGH computers. Note that there could be other computers in the network with PLIs keyed the same as the

LOW or HIGH computers. All such computers that share the same key form a secure "subnet" of the ARPANET. Thus the Guard can be viewed as an interface between two networks of different classifications.

#### *Guard operating personnel*

There are two types of personnel designated to operate the Guard system, Guard operators and Security Watch Officers. The main responsibility of the Guard operators is sanitization. A Guard system can have many Guard operators, whereas it has only one Security Watch Officer, whose function is to review all data downgraded by the Guard and approve or deny the downgrade. Thus the Security Watch Officer has responsibility for the security of the system. The specific duties of both Guard operators and Security Watch Officers are identified below in the context of each type of data transfer.

#### *Guard operation*

As outlined briefly above, Guard provides two types of communication between LOW and HIGH computers: network mail and database queries. Moreover, each of these two types of communication can be initiated by a user on a LOW computer or a HIGH computer. The operation of the Guard in handling each of these four cases is described in general terms below.

#### **HIGH network mail**

HIGH network mail is mail sent from a LOW computer and intended for delivery to a HIGH computer. No security violation is involved when sending mail from LOW to HIGH. The HIGH network mail enters the Guard system as mail through the LOW ARPANET interface, passes through the Guard Software with no human intervention, and leaves the Guard via the HIGH ARPANET interface. Thus neither the Guard operator nor the Security Watch Officer is involved in Guard processing of HIGH network mail.

#### **LOW network mail**

LOW network mail is mail sent from a HIGH computer and intended for delivery to a LOW computer. Such a transfer has a potential for a security violation if the data in the mail is classified higher than the LOW level for which the mail is intended. Therefore, LOW network mail is processed by the Guard system as follows.

First, the mail enters the Guard system as mail through the HIGH ARPANET interface. From there it is manually reviewed by the Security Watch Officer who must determine if the mail is free from information classified higher than the LOW level. If the Security Watch Officer determines that the mail can be sent, the mail leaves the Guard via the LOW

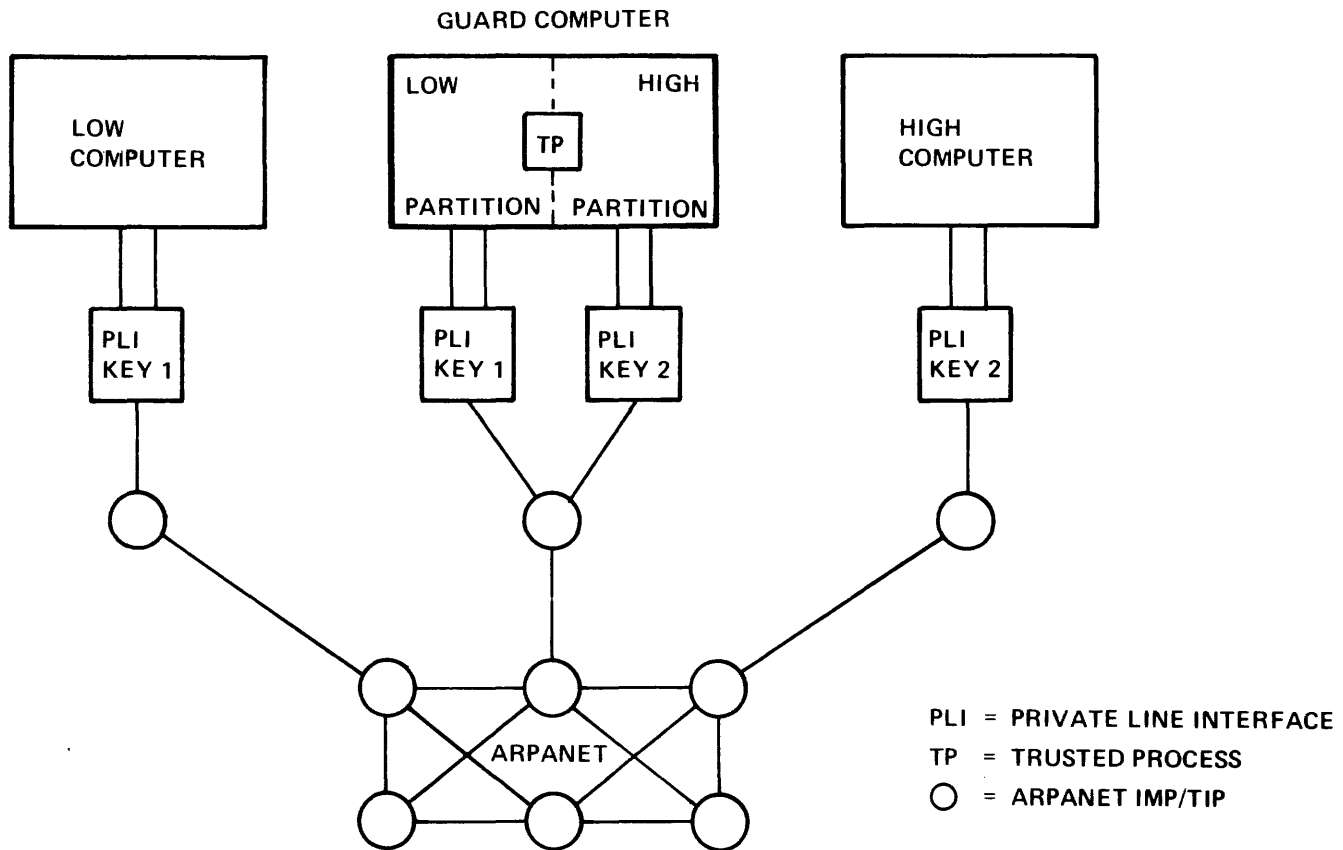

Figure 1—ACCAT guard ARPANET connections.

ARPANET interface. If the mail cannot be sent, the mail is sent back to the sender marked as rejected. Thus, only the Security Watch Officer is involved in Guard processing of LOW network mail.

#### HIGH database queries

A HIGH database query is a query originating on a LOW computer and intended for a HIGH computer database. Passing a query from LOW to HIGH does not involve a security violation. However, passing the reply from HIGH to LOW could potentially involve a security violation if the reply is not properly sanitized. HIGH database queries are processed by the Guard as follows.

First, the query enters the Guard system as mail through the LOW ARPANET interface. If the query is in Datalanguage, the query is passed through the Guard without human intervention, and passes through the HIGH ARPANET interface to the HIGH Datacomputer. If the query is in English, it is translated into Datalanguage by a Guard operator, and then passes to the HIGH Datacomputer through the HIGH ARPANET interface.

Replies coming from the HIGH Datacomputer (through the HIGH ARPANET interface) contain potentially classified information and are processed by the Guard system before passing to the requester. The replies are in Datalanguage, but when sanitized, may take on a different form. A

Guard operator reads the query and its response and attempts to sanitize the response by editing it to remove information pertaining to the nature of sources, etc. The Guard operator (sanitization officer) either sanitizes the response or replaces it with a message indicating that there was no response, and passes the query and the sanitized response to the Security Watch Officer, who must make the final determination of whether or not the response is passed on to the requester through the LOW ARPANET interface. If the Security Watch Officer decides against sending the response, the sanitization officer is so notified so he can do a better job of sanitization.

#### LOW database queries

A LOW database query is a query originating on a HIGH computer intended for the LOW Datacomputer. Passing such a query from HIGH to LOW involves a potential for a security violation if the query contains some data classified higher than LOW. However, passing the reply from LOW to HIGH does not involve a security violation. LOW database queries are processed by the Guard as follows.

The LOW database queries enter the Guard system as mail through the HIGH ARPANET interface. If the query is in Datalanguage, it is reviewed by the Security Watch Officer who allows or disallows the query. If the query is

disallowed, it passes back to the requester as mail (through the HIGH ARPANET interface) marked as rejected. If the query is allowed, it passes through the Guard to the LOW Datacomputer.

If the query is in English, it is translated into Datalanguage by a Guard operator, and then passes to the Security Watch Officer for review. If the Security Watch Officer allows the query, it passes to the LOW Datacomputer. If however the query is disallowed, the Guard operator is so notified so that he can take the appropriate action (i.e., to translate again or send the query back to the requester as rejected).

The reply from the LOW Datacomputer can pass back to the requester (from LOW to HIGH) without a security violation, and does so without human intervention. The reply is in Datalanguage.

#### *Guard design*

The programs that implement the Guard system are divided into three types of processes, LOW, HIGH, and TRUSTED. The integration of these processes with KSOS is shown in Figure 2. LOW processes have a security level

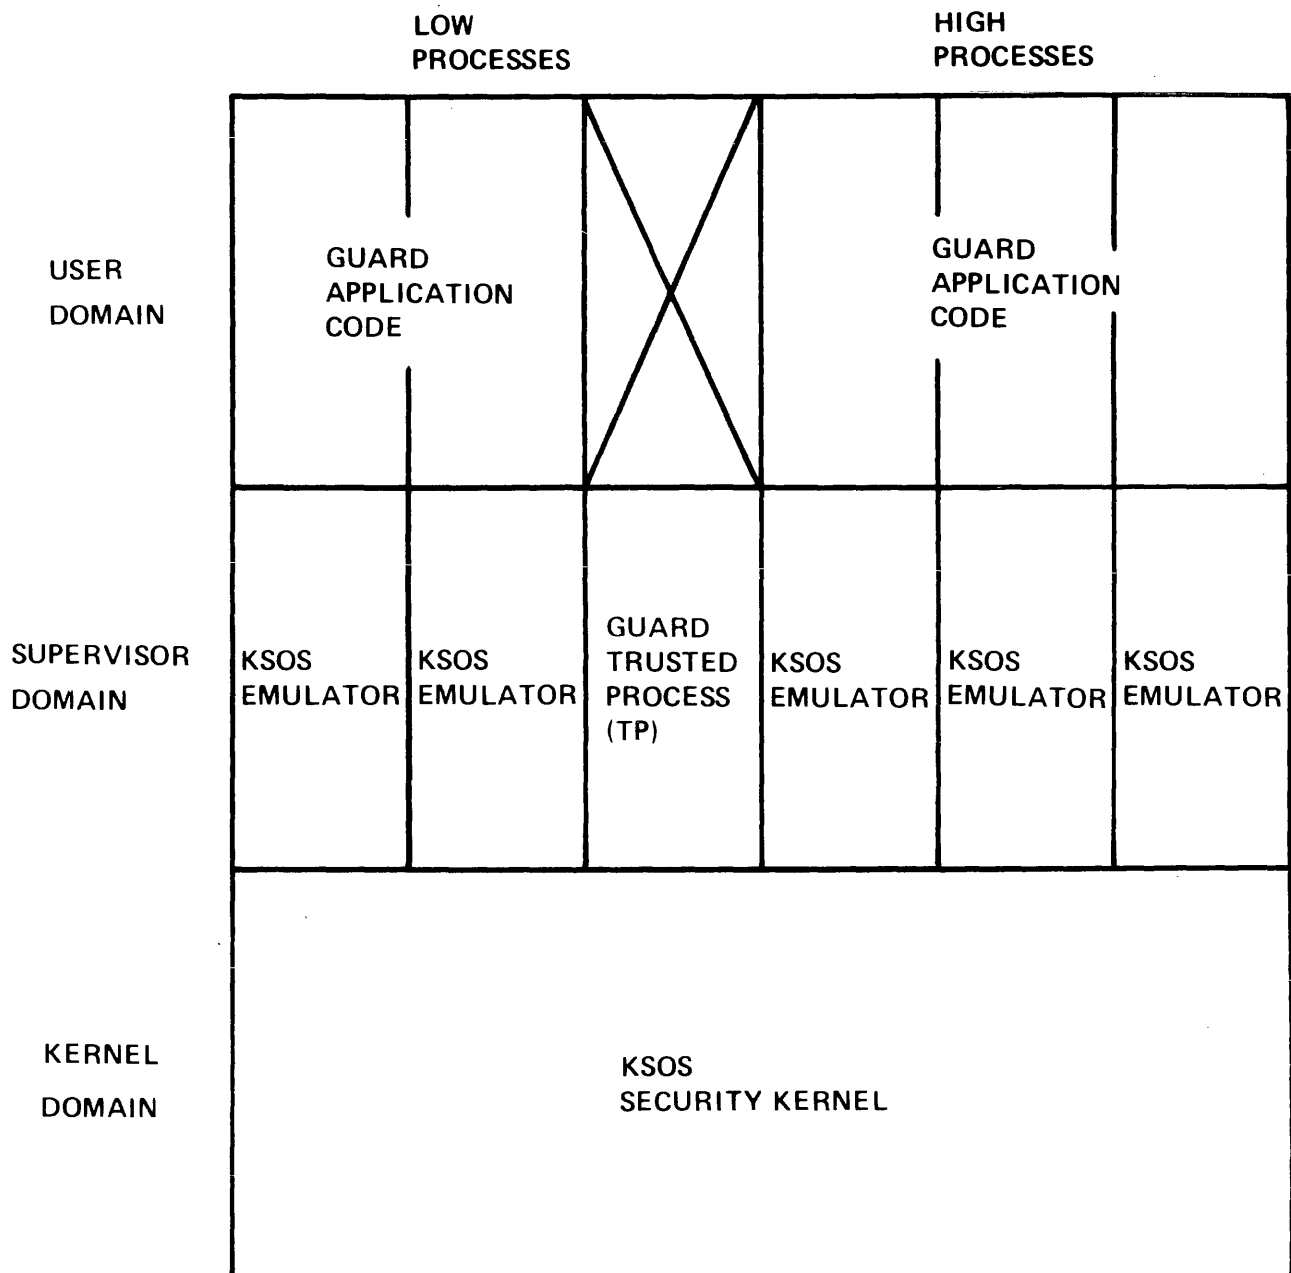

Figure 2—Integration of guard processes with KSOS.

equal to that of the LOW ARPANET connection, and have read/write access only to files at the LOW level. Similarly, HIGH processes have the same level as the HIGH ARPANET interface, and have read/write access only to files at the HIGH level. The TRUSTED processes are able to read and write both LOW and HIGH files, and therefore has the capability of passing data between LOW and HIGH processes.

The LOW and HIGH Guard processes deal with the LOW and HIGH ARPANET interfaces, respectively, and HIGH Guard processes provide the interface that Guard operators use to perform their functions of English to Datalanguage translation and HIGH response sanitization.

Just as the kernel is the encapsulation of the security-related portion of an operating system, the Guard TRUSTED processes are the security-related portion of the Guard code, and are therefore the only portion of the Guard that must be verified. The Guard TRUSTED processes run directly on the kernel, and have little or no knowledge of the environment created by the UNIX emulator. The other Guard processes run in a UNIX environment, and communicate with the TRUSTED processes via kernel-provided inter-process communication (IPC) messages.

#### The guard TRUSTED processes

Since the TRUSTED processes are the only security-related portion of the Guard application, they are the only Guard processes that we will discuss in more detail. The TRUSTED processes provide the interface to the Security Watch Officer and provide one major function, that of downgrading.

The downgrade function allows a HIGH process to send some data to a TRUSTED process for downgrading and release at the LOW level. This function is used to:

- Downgrade LOW Mail (mail sent from a HIGH user to a LOW user).
- Downgrade LOW Queries.
- Downgrade sanitized responses to HIGH Queries.

The downgrade function must be provided by a TRUSTED process because its operation violates the \*-property. When the TRUSTED process receives some data for downgrading, it notifies the Security Watch Officer, who can read the data and decide whether or not the data can be released at the LOW level. The TRUSTED process releases the data only when so instructed by the Security Watch Officer. Thus the Security Watch Officer is solely responsible for what data is released at the LOW level.

Verification of the TRUSTED downgrade function involves demonstrating that the only data allowed to flow from HIGH to LOW by the TRUSTED process is data that has been seen by the Security Watch Officer and approved for downgrading. The Security Watch Officer's terminal is connected directly to the TRUSTED process through the kernel, so there is no unverified code between the terminal and

the TRUSTED process, and hence no chance for spoofing the Security Watch Officer.

#### A DEEPER LOOK AT SECURE DATABASE MANAGEMENT SYSTEMS

As mentioned earlier, the area of secure database management systems is one that has received some attention in the past, but that has many avenues yet to be explored. In this section we review some of the Air Force-sponsored work, and present some problems yet to be solved.

The Air Force Electronic Systems Division sponsored several research and development efforts in the design, specification, and validation of secure database management systems. Of primary importance are the contributions of System Development Corporation<sup>26</sup> and I. P. Sharp Associates Ltd.<sup>27</sup> Both of these studies helped to identify and clarify the key technical issues in secure database management technology.

##### *The SDC secure data management system*

The SDC effort concerned the design of a secure relational data base management system that interfaces with the multilevel environment provided by the secure Multics Operating system. SDC concluded that a relational data base could comfortably exist within the multilevel environment. The following technical evaluation of the SDC work is taken from Reference 26.

“The objective of this work was to develop a model and design of the security-related portions of a Data Management System (DMS). The model and design effort focused on those portions of a traditional DMS which are affected by the security constraints of the operating system. The result is a design framework which provides the basis for the development of a complete DMS which only has to draw on conventional DMS design technology.

“The mathematical model of a secure DMS encompasses DoD-based security policies which the DMS is to enforce with respect to some of the basic DMS operations. The modeling effort encompasses the modeling of the various levels of the DMS and its operating system interface.

“The modeling work suggested a design for a relational data management system that interfaces with the multilevel environment provided by the secure Multics operating system. The design utilizes the protection provided by the operating system in such a manner that the DMS contains no code which has an impact on the security of the data in the system and, thus, whose correctness must be verified. The DMS is designed according to the principle of least privilege; hence, the DMS operating as part of the user's process has no privileges that are not also afforded the user.”

The DMS described in the SDC work is designed to store database information in the storage containers provided by the underlying Multics operating system: segments. In order to contain no security-relevant code, the DMS must use a number of unilevel segments, because segments are the smallest unit of protection in secure Multics.

The SDC work is important because it shows that a secure DBMS can exist on a secure system without any additional security-relevant code. However, the SDC effort does not address the additional flexibility that could be gained if smaller units of data could be efficiently protected. The SDC effort is a good example of a DBMS design around existing secure operating system primitives.

#### *The I. P. Sharp protected DMS tool*

The approach taken by I. P. Sharp is unique in that rather than working from existing kernel designs and primitives, they investigated the design of kernel primitives that would support the implementation of a family of secure data management systems. The primitives identified are referred to as the "DMS Tool." The study shows that the DMS Tool is general enough to apply to data management systems implemented as a dedicated DMS, as an application on a secure operating system, or in a computer network.

The view of the data in the I. P. Sharp work was relational.<sup>28</sup> The I. P. Sharp study recommended that each relation be assigned a single security level, i.e., the data in each relation must be considered at one level. Data from several levels cannot be gathered into a single relation and maintain their individual classifications. The resultant relations would have the classification of the most highly classified data that made up the relation.

#### *The MITRE secure INGRES system*

MITRE, working from these past studies, attempted to impose security constraints on the INGRES relational database management system, and to integrate the resultant secure INGRES system with the MITRE secure UNIX prototype.<sup>29</sup> This effort is important because it was one of the first actual implementations of a secure DMS on a prototype secure operating system. Like the SDC study, the MITRE effort worked with existing kernel primitives to investigate their sufficiency for supporting a secure DMS.

The approach taken by MITRE was also very similar to the SDC approach, in that no security-relevant code was added to the INGRES system. Use was made of the objects provided by the MITRE Secure UNIX kernel to accommodate the relations in an INGRES database.

The design of the MITRE Secure UNIX file system, like that of UNIX, is hierarchical, consisting of directories which may contain other directories or data files. In the MITRE design, data files in a directory assume the same access level as the directory. Consequently, the security level of an INGRES relation (a data file) must be at the same level as its database (a directory). Although this limitation does re-

duce the convenience of the secure INGRES system, the coordination of INGRES with the MITRE Secure UNIX necessitated the mapping of relations in this manner. Adhering to these restrictions, a user is still able to perform multilevel operations on relations in the INGRES database directory structure.

In order to use secure INGRES to process multiple levels of information, the user must create a database at each security level to be included in the database. Also, a user is able to "read" information from a file at a security level lower than his current level, established at login time. As a result, a new relation can be created by combining information obtained from relations in databases at access levels less than or equal to the level of the database being added to.

#### *Areas for future work*

There are two problems that have recurred in much of the past secure database design and implementation work:

1. The fact that protection of very small objects is difficult, and often results in relational database designs that force relations to be at the same level.
2. The fact that user interfaces to secure database management systems are seemingly difficult to design in such a way that the user is not greatly hindered by the security features.

The solution to the first problem seems to lie in the proper design of security primitives, and the implementation of protection features in the right places. For example, a DBMS can rely on the protection primitives provided by the underlying secure operating system, or it can, using trusted processes, provide its own protection, possibly at a much finer grain. Currently trusted processes are rather difficult to verify, so they are used sparingly. However, as verification technology develops, it will become much easier to design with trusted code. IBM has made a survey of many database management systems to determine the relationship between operating system and database system security.<sup>30</sup> Their conclusion is that it is most convenient to separate the design of kernel primitives and DBMS security features.

The solution to the user interface problem has been addressed in the context of message processing systems,<sup>31</sup> which are really special cases of a DBMS. The techniques proposed in this paper need to be further studied and applied to more secure database designs.

## CONCLUSIONS

Secure computer systems are moving rapidly out of the "research arena" and into the field. The KSOS effort will soon demonstrate that multilevel secure operating systems can be built feasibly and cost-effectively. Many important applications for KSOS and other secure operating systems

are being designed and developed now, and the potential for future applications is tremendous.

# The foundations of a provably secure operating system (PSOS)

by RICHARD J. FEIERTAG and PETER G. NEUMANN

*SRI International*  
Menlo Park, California

## INTRODUCTION

PSOS has been designed according to a set of formal techniques embodying the SRI Hierarchical Development Methodology (HDM). HDM has been described elsewhere,<sup>1-3</sup> and thus is only summarized here. The influence of HDM on the security of PSOS is also discussed elsewhere.<sup>4</sup> In addition, Linden<sup>5</sup> gives a general discussion of the impact of structured design techniques on the security of operating systems (including capability systems).

HDM employs formally stated requirements, formal specifications defining the design of each module in a hierarchical collection of modules, and formal statements of the module interconnections. In the case of PSOS, there is a formal model describing the requirements of the basic protection mechanism, and additional formal models of the requirements of various applications (e.g., Reference 6). HDM provides the formalism and the structure that make the formal verification of the system design and implementation possible and conceptually straightforward. This formal verification consists of formal proofs that specifications satisfy the desired requirements,<sup>6</sup> and subsequently that the actual programs for the system and its applications are consistent with those specifications.<sup>2</sup>

The design of PSOS has been formally specified using a SPECification and Assertion Language called SPECIAL.<sup>7</sup> These specifications<sup>1</sup> define PSOS as a collection of about 20 hierarchically-organized modules. Each module typically is responsible for objects of a particular type defined by that module. From the user point of view, the most important modules are those for capabilities, for virtual memory segments, directories, user processes, and for creating user defined abstract objects. Some modules are to be implemented in software, some in firmware, and some in hardware—as dictated by the efficiency required.

Capabilities provide the protection mechanism for all such objects in PSOS, and are discussed in the next section. The subsequent sections of this paper summarize the development methodology used in PSOS, present the protection mechanism provided by PSOS capabilities, exhibit its properties, show its applicability in developing data and procedure abstractions, and contrast the PSOS approach with the kernel approach to achieving secure systems. There are

many important issues relating to the use of capabilities in PSOS (and other computer systems) that are not presented in this paper. Many of these issues are discussed in the references cited here.

## PSOS CAPABILITIES

The concept of the capability has appeared in several other operating systems (e.g. References 8-13). Although capabilities are a fundamental part of the design of each of these systems, they all differ in the way they use and interpret capabilities. PSOS differs from its predecessors in its uniform use of capabilities throughout the system and in the simplicity and primitive nature of the basic capability mechanism.

Each object in PSOS can be accessed only upon presentation of an appropriate capability to a module responsible for that object. Capabilities can be neither forged nor altered. As a consequence, capabilities provide a controllable basis for implementing the operating system and its applications, as there is no other way of accessing an object other than by presenting an appropriate capability designating that object.

Each PSOS capability consists of two parts, a *unique identifier* (uid) and a set of *access rights* (represented as a boolean array). By definition neither part is modifiable, once a capability is created.

- *Unique Identifiers*—PSOS generates only one original capability for each uid. Any number of copies can be made of a given capability, but making a copy requires presenting an existing capability for which a copy is to be made. Therefore, a procedure or task that creates a new capability with some uid knows that the only capabilities that can have that uid must have been copied either directly or indirectly from the original. In other words, the creator of a capability with a given uid is able to retain control over the distribution of capabilities with that uid.
- *Access Rights*—The set of access rights in a capability for an object is interpreted by the module responsible for that object to define what operations may be per-

formed by using that capability. The interpretation of the access rights is constrained by a *monotonicity rule*, namely that the presence of a right is always more powerful than its absence. The interpretation of the access rights may differ for different objects, but the monotonicity rule must always apply.

The access rights for a segment capability (as interpreted by the segment manager) indicate whether that capability may be used to write information into the designated segment, to read that information, to call that segment as a procedure, and to delete that segment. In PSOS, a directory contains entries, each of which is a mapping from a symbolic object name to a capability. Each directory is accessed via a capability for that directory. For directories, the interpretation of access rights is done by the directory manager. The access rights for a directory capability indicate whether that capability may be used to add entries to the designated directory, to remove entries, and to use the capability contained in that entry.

A copy of a capability may be made, but the resulting capability cannot have any access rights that the original capability did not—as is seen from the following list of possible operations upon capabilities. (There are other access rights, meaningful to capabilities of all types, to be discussed under storage permissions.)

## THE PSOS PROTECTION MECHANISM

Capabilities provide the basis for a flexible protection mechanism, as follows:

### *Tagging of capabilities*

In PSOS, capabilities can be distinguished from other data because they are tagged throughout the system (i.e., in the processor, and in both primary and secondary memory) by means of a tag bit inaccessible to programs. Consequently, the hardware can enforce the nonforgeability and unalterability of capabilities.

### *Operations upon capabilities*

There are only two basic operations that involve actions upon capabilities (as opposed to actions based on capabilities, which is the normal mode of accessing objects), as follows.

`c=create__capability` creates a new capability (i.e., with a previously unused uid) having all access rights.  
`cl=restrict__access(c, mask)` creates a capability with the same uid as the given capability `c` and with access rights that are the intersection of those of the given capability `c` and the given maximum (`mask`): i.e., it creates a possibly restricted copy.

### *Store permissions*

The second capability operation described above appears to permit unrestricted copying of capabilities. For certain types of security policies this unrestricted copying is too liberal. For example, one may wish to give the ability to access some object to a particular user but not permit that user to pass that ability on to other users. Because simplicity of the basic capability mechanism is extremely important to achieve the goals of PSOS, any means for restricting the propagation of capabilities should not add complexity to the capability mechanism.

A few access rights (only one is currently used by PSOS itself) are reserved as *store permissions*. This is the only burden placed on the capability mechanism. The interpretation of the store permissions is performed by the basic storage object manager of PSOS, namely the segment manager. Each segment in the system is designated as to whether or not it is capability store limited for each store permission. If a segment is capability store limited for a particular store permission, then it can contain only capabilities that have that store permission. This restriction can be enforced by a simple check on all segment-modifying operations.

By properly choosing the segments that are capability store limited, some very useful restrictions on the propagation of capabilities can be achieved. The restriction used in PSOS is not allowing a process to pass certain capabilities to other processes or to place these capabilities in storage locations (e.g., a directory or interprocess communication channel) accessible to other processes. (Other restrictions are also possible using store permissions, such as restricting a capability to a subsystem or a particular invocation of a subsystem. For example, see Reference 1, page II-25.) More general means for restricting propagation of capabilities and for revoking the privilege granted by a capability can be implemented as subsystems of PSOS. The store permission mechanism has been selected as primitive in the system because it achieves the desired result with negligible additional complexity or cost.

## DATA AND PROCEDURE ABSTRACTIONS

PSOS consists of a collection of data and procedure abstractions constructed in a hierarchical fashion as shown in Table I. Each level in the hierarchy represents a collection of abstractions introduced at that level. Abstractions at higher (numbered) levels are implemented using abstract objects introduced at lower levels in the design. It is unimportant whether an abstraction is implemented in hardware, firmware, or software. It is reasonable that abstractions introduced at lower levels be implemented largely in hardware or firmware and that abstractions introduced at higher levels be implemented largely in software. However the demarcation between hardware and software is not established by the design, and it is quite possible that abstractions occurring throughout the system be implemented as hybrids, i.e., partially in hardware and partially in software.

TABLE I—PSOS Abstraction Hierarchy.

Level	Abstractions
16	user request interpretation
15	user environments and name spaces
14	user input-output
13	procedure records
12	user processes and visible input-output
11	creation and deletion of user objects
10	directories
9	abstract object manager
8	segments and windows
7	pages
6	system processes and system input-output
5	primitive input-output
4	arithmetic and other basic procedures
3	clocks
2	interrupts
1	registers and other storage
0	capabilities

It is convenient to group the levels of Table I into generic categories as shown in Table II. The generic categories collect abstractions satisfying similar goals. At the base of the hierarchy is the capability mechanism, from which all other abstractions in the system are constructed. Above the basic capability mechanisms are all the physical resources of the system, e.g., primary and secondary storage, processors and input/output devices. From the physical resources are constructed the virtual resources. These virtual resources present a more convenient interface to the programmer than the physical resources, permit multiplexing of the physical resources in a manner largely invisible to the user, and allow the system to allocate the physical resources so as to maximize their efficient use. Next in the PSOS hierarchy comes the abstract object manager, providing the mechanism by which higher-level abstractions may be created. As will be discussed in detail, it is possible to construct higher-level abstractions based solely on the capability mechanism; however, the abstract object manager provides services that make construction of such abstractions easier. The top two categories in the generic hierarchy include community abstractions and user-created abstractions. The community abstractions are intended to be used by a large group of users, e.g., by all the users at a particular site. Such abstractions may be simple utility routines such as a compiler, or may actually create and control access to new virtual resources such as directories. The user abstractions are those intended for use by a limited group of individuals.

Of the properties stated previously, there are two impor-

tant ones that make the PSOS capability particularly useful in the construction of abstract objects.

1. The capability serves as a *unique* name for an abstract object.
2. The capability is unforgeable.

This means that a capability can be used as a name (guaranteed to be unique) by which an abstract object can be referenced, and access to the object can be controlled by limiting the distribution of the capability.

In addition, there are several important pragmatic reasons why PSOS capabilities are useful as a naming and protection mechanism for supporting abstract objects.

1. The capability mechanism has a very simple implementation. This allows capabilities to be built into the system at the lowest level of abstraction, thus making capabilities available for the most primitive objects.
2. Capabilities are uniform in size, making them easy to manage.
3. The inclusion of access rights in capabilities permits efficient fine-grained control of access to objects.
4. Capabilities can be written into storage (including secondary storage) and retrieved from storage in the same manner as other data, and therefore have many of the properties of other data.

Capabilities serve as names or tokens for all objects of PSOS. It is because the basic capability mechanism is so simple in concept and in implementation that construction of the most primitive objects (e.g., input/output channels, processors, and primary memory) as well as the most complex system objects (e.g., directories and user processes) and user application objects (e.g., a data management system) is possible using capabilities. This promotes a high degree of uniformity throughout the system and eliminates the need for many special-purpose facilities.

Objects that have many properties and operations in common and are managed by a single program are said to have a common *type*; that program is called a *type manager*. The type manager implements operations on an abstract object in terms of operations on the more primitive objects used to represent the abstract object. The type manager must be able to determine which objects are part of the representation used to implement an abstract object denoted by a given capability. In other words, a type manager must be able to map the unique identifier of a given capability into capabilities for its representation objects. The capability mechanism of PSOS does not predispose a type manager to any particular implementation of this mapping. Different type managers will require diverse mapping algorithms, depending upon the number of abstract objects and representation objects they must manage, the desired efficiency of operations on the abstract object, the desired simplicity of the mapping algorithm, and numerous other factors. For example, the segment type manager uses a mapping algorithm that is in almost all cases extremely fast; however, the algorithm is

TABLE II—PSOS Generic Hierarchy.

Level	Abstractions	PSOS Levels
F	user abstractions	14-16
E	community abstractions	10-13
D	abstract object manager	9
C	virtual resources	6-8
B	physical resources	1-5
A	capabilities	0

quite complex, requiring implementation in both hardware and software. Extreme speed is essential to the operations of the segment type manager because the segment operations are used very frequently (at least once on every instruction). The directory type manager uses a less speedy algorithm because fast access is not essential.

Although the capability mechanism of PSOS does not prescribe a particular mapping algorithm, the system does provide some assistance in managing abstract objects. The *abstract object manager* provides a set of operations by which type managers can associate capabilities for abstract objects with the capabilities for their representation objects. The type manager can then retrieve the representation capabilities by presenting to the abstract object manager the abstract object capability. This is done in such a way that *only* the type manager program itself can obtain the representation capabilities, and then *only* upon presentation of the abstract object capability. The abstract object manager performs the mapping from abstract object capabilities to representation object capabilities, some of the bookkeeping functions necessary to implement abstract objects, and some storage allocation. Although the abstract object manager is intended to be useful and appropriate for a wide variety of type managers and does make the programming of a type manager much easier, it is only a service and is not essential to the construction of type managers.

The capability mechanism itself could have been constructed with many of the facilities of the abstract object manager included. This would have resulted in a capability mechanism that would be more elaborate and—for some applications—more efficient and easier to use. This is the approach taken by other capability systems cited above. On the other hand, such a capability mechanism would have required a more complex implementation. More significantly, the capability mechanism could then not have been placed at the lowest level of abstraction in the system design, and some of the physical and virtual resources of the system could not have been implemented using capabilities—requiring a different means for reference. Although having several different naming schemes is possible (and common in most systems), it destroys the uniformity, conceptual simplicity, elegance, ease of use, and possibly the efficiency of the system. It is for this reason that PSOS has a very simple, but fully general, capability mechanism, and that programs enhancing the use of the capability mechanism can be introduced as extensions at higher levels of the design.

As noted above, there is no clearly-delineated system boundary in PSOS. One would normally draw the system boundary at the interface to the community abstractions. However, all the programs that implement the community abstractions (such as directories or user processes) could be provided by users as user programs. The community programs have no special privilege other than claiming resources at initialization by taking possession of certain capabilities. For example, the user-process type manager takes possession of the capabilities for certain system processes which it then multiplexes to create many user processes. If the system's user-process type manager did not claim all the

available system processes, then it would be possible for a user to provide a different user-process type manager with the same or different facilities. Similarly, the abstract object manager has no special privilege at all. A user might program his own abstract object manager if he so desired.

The abstractions at or below any level in the design of Table I form a consistent and useful system. Clearly, the lower the level chosen as the "top level" of the system, the more primitive that system will be. If all of the physical resources (levels 1 through 5) are present, then the full PSOS could be reconstructed on the restricted system, but more likely, one would construct a somewhat different system. Thus, the PSOS design represents a family of systems. One can choose the level that provides the best set of resources to fulfill the needs of the desired system without having to include unnecessary facilities. Then one can augment this level with new type managers to create abstract objects appropriate to the desired applications. Writing such "system" type managers requires no additional skill or privilege other than that required to write ordinary user programs. The distinction between a "system" program and a "user" program is thus indeed blurred.

## PSOS RELATIONSHIP TO KERNELS

Several recent operating systems have been constructed using a "kernel" architecture. Such systems include the Kernelized Secure Operating System (KSOS)<sup>14,15</sup> and two precursor systems developed at MITRE<sup>16,17</sup> and UCLA.<sup>18</sup> The term *kernel* is used loosely in the literature, but for the purpose of this discussion a kernel is that part of the operating system that is both necessary and sufficient to satisfy certain requirements of the system. For example, if the essential requirement of a system is that it enforce a certain security policy, then that part of the system that enforces the security policy constitutes the kernel. By this definition, a kernel is meaningful only with respect to some requirement or some set of requirements. The kernel must contain all those parts of the system that pertain to meeting the requirements, i.e., there is no part of the system outside the kernel that can cause the system not to meet its requirements. Also, the kernel can contain only those parts of the system that are necessary to meet the requirements, i.e., the kernel should not contain anything that does not pertain to the meeting of the requirements. The reasoning behind kernel-based architectures is that since a kernel contains only that part of the system essential to meeting requirements, it can be small, compared to the system as a whole, and therefore has a better chance of being correct.

One of the main advantages of the kernel approach is the clear statement of purpose of the system. Since a kernel is meaningful only with respect to some explicit requirements, these requirements serve as the statement of purpose of the system. The other main advantage is the enhanced probability of correct operation. Since the programs that are critical to the correct operation of the system are isolated in the kernel, a great deal of attention can be paid to getting this code right, and less attention can be paid to other system

code that may be important but is not critical. The relatively small size of the kernel significantly improves the chances of applying formal verification techniques to the programs in the kernel in a cost-effective manner, where applying these techniques to the entire system would be unwieldy.

There are, as one might expect, some disadvantages to the use of kernels. Kernels cannot be casually modified because, by definition, all the code in the kernel is essential to meeting the requirements of the system, and any modification is likely to cause the system to deviate from that which is required. One must take extreme care to be sure that a change in the kernel will not compromise its correct operation.

In order to be able to construct a small kernel, the requirements must be fairly narrow and highly specific. Such requirements limit the applications for which the kernel is useful. For example, if the requirement of a kernel is to enforce a particular security policy, then only applications requiring that policy can be reasonably implemented using that kernel. It is not possible to implement another security policy that is inconsistent with the given security policy.

Yet another of the major problems with the kernel approach is the difficulty of designing a system in such a way that those programs essential to meeting the requirements are isolated from the nonessential programs. Finally, experience with the systems mentioned above indicates that kernels are still quite large. Clearly the size of a kernel depends upon the requirements it is supposed to meet, but reasonable requirements tend to require a large part of the system to be part of the kernel. Large kernels do not enhance one's confidence in the correct operation of the system.

Consider, for example, the kernels of KSOS and of the MITRE system. The requirement of these kernels is that they enforce a multilevel security policy. Upon close examination of these systems, it is seen that what is labeled the "kernel" is not really the kernel at all, but is only a part of the kernel. These systems have so-called *trusted processes*, namely programs that are internally able to violate the requirements, but whose external interface is consistent with the requirements. These trusted processes include programs for file system backup and retrieval, I/O spooling, and network interfaces. These programs are not labeled as part of the kernel because their function is in some sense peripheral to the main task of the system. However, their correct operation is as essential to meeting the requirements as any kernel program. If the system is to be proven correct, the programs that are used by the trusted processes must be formally verified. Inclusion of the code for the trusted processes into the kernel makes the resulting kernel much larger. This illustrates a difficulty in designing a small kernel.

It is a matter of judgment as to whether the advantages of the kernel approach outweigh the disadvantages. For the situation in which one has clearly defined, specific overriding requirements for which a small kernel can be constructed, then the kernel approach is ideal.

PSOS is well suited to situations in which one wants to support many applications with different or conflicting requirements. Because PSOS is highly extensible and easily supports different type managers with strong control over

access to objects and type managers, it makes possible the support of many different sets of requirements on one PSOS implementation. For example, several subsystems have been designed for PSOS that enforce different security constraints. A particular task could be constrained to have access to only one of these subsystems, but several tasks may be executing different subsystems simultaneously. In a sense, each of these subsystems can be viewed as a "kernel" for the tasks having access to them, but PSOS can support any number of such subsystems. Of course, one still has the problem of assuring the correctness of these subsystems and those parts of PSOS which the subsystems use. However, assuring the correctness of these subsystems on PSOS should be significantly easier than assuring the correctness of a stand-alone kernel, because each subsystem will be much smaller and simpler than it would be if it had to be implemented as a stand-alone system.

The UCLA system<sup>18</sup> is an interesting case in that its requirements for security are very broad and general. The UCLA kernel attempts to be like PSOS in its ability to support a wide range of security policies simultaneously. However, the resulting requirement does not permit as wide a range of policies to be implemented, and the system design is not as uniform or elegant as the PSOS design.

## SUMMARY

The capabilities of PSOS provide a flexible naming and protection mechanism that can be used to implement arbitrarily complex subsystems efficiently fulfilling a wide variety of requirements. The properties of PSOS that make this possible are summarized as follows.

1. The capability mechanism is extremely simple, with only two operations involving the creation of capabilities and none permitting the alteration of capabilities. There is no policy embedded in the mechanism.
2. The operations on capabilities can be completely controlled at the most primitive conceptual level of the system design and implemented in hardware. Capabilities are tagged and nonforgeable, and the protection they provide is not bypassable.
3. Capabilities and other PSOS facilities encourage strong modularity via the creation of data and procedure abstractions. Such abstractions are the basis of the design of the PSOS system itself and can be used equally well in application programming.
4. The capability mechanism can be used equally well for user programs, application subsystems, and system programs. There are no special protection mechanisms necessary to protect system programs.
5. The capability mechanism is fully general and can simultaneously support subsystems that implement arbitrary policies. Mechanisms for initialization, backup and recovery, and auditing for both PSOS and its subsystems can be constructed without subverting the protection mechanism.
6. The operations that can be performed on an object of

a particular type are precisely those defined by the type manager for that object. The operations permitted upon the particular object designated by a given capability are limited by the access rights of the given capability.

7. If a user is in possession of only one capability for an object, and he wishes to confer some or all of the access rights to another user (or to another program), he may create and pass a new capability whose access rights are a subset of those of the original capability. There is no way in which an additional access right can be introduced. (Note, however, that type managers must consistently enforce the monotonicity of access rights. That is, the presence of the right must be more powerful than the absence of that right. This is guaranteed for system-defined object types, and must be assured by the type managers for other types.)
8. Propagation of capabilities can be restricted by use of capability store permissions. The passage of a capability to other users can be prevented by not including process store permission in that capability's access rights.

Although no single commercially available computer has the facilities necessary to implement PSOS efficiently, each of the required facilities does exist on some computer. Therefore, the proper hardware support for PSOS can be implemented using established techniques. The formal techniques used to design PSOS make implementation straightforward<sup>19</sup> and make formal verification of correct operation possible. All of the advantages summarized here can make PSOS and subsystems implemented on PSOS far more secure and reliable than contemporary operating systems.

#### ACKNOWLEDGMENTS

The design of PSOS was accomplished by the close co-operation of several people. Outstanding among these are Larry Robinson who is primarily responsible for the development of HDM and who played a major role in the early design of the system, Karl Levitt who designed security related subsystems, and Bob Boyer who is responsible for the formal mathematical theory.

# A security retrofit of VM/370

by B. D. GOLD, R. R. LINDE, R. J. PEELER, M. SCHAEFER, J. F. SCHEID and P. D. WARD

*System Development Corporation*  
Santa Monica, California

## INTRODUCTION

The VM/370 Security Retrofit Program is a continuing research and development initiative, funded by the Defense Advanced Research Projects Agency (DARPA), with additional funding provided by the Canadian Department of National Defense. The program's primary goal is the security retrofit of a popular commercial operating system, VM/370.<sup>1</sup> Two approaches were originally planned: (1) the design of a feasible, formally verified security kernel to VM/370 and (2) a "hardening" effort to repair known VM/370 penetration weaknesses. It was subsequently decided not to proceed with the VM/370 hardening task because of the uncertainty of the end result: correction of known security flaws does not guarantee the absence of exploitable, but not yet detected, security flaws in the hardened system.

In the first year of the research program, the feasibility of adding a security kernel to VM/370 was studied and a kernel design for the system was produced. The retrofitted system is called KVM/370 (for Kernelized VM/370). The security enforcement mechanism, the kernel, must implement a reference monitor<sup>2</sup> that enforces a security policy. A security kernel is a reference monitor that:

- a. Mediates all attempts to access security objects;
- b. Is protected from the tampering attempts of either the control software or the users;
- c. Is verifiably correct.

A security policy has been evolved that will permit as general a form of controlled sharing of machine resources and classified data as possible within the constraints of defining a kernel that will:

- a. Be verifiable with respect to enforcing that policy;
- b. Have an acceptable effect on overall VM/370 performance;
- c. Require minimal rewriting or replacement of existing code in the VM/370 Control Program (a retrofit);
- d. Preserve a maximum compatibility with VM/370 applications.

Although KVM/370 has been developed primarily for the defense and intelligence communities, its security policy can

be applied to other environments as well. For example, the system can operate in a private-sector environment where privacy<sup>2</sup> safeguards are necessary. At this time, several commercial organizations as well as other agencies in the Department of Defense that are outside of the intelligence community are considering the possibility that KVM/370 may satisfy their "secure" data processing requirements.

The KVM/370 effort has been inspired by the belief that encapsulation of multiple, individual copies of an operating system under a virtual machine monitor system can provide a practical, secure operating system. SDC's experience with IBM's VM/370 supports this belief. Even though the commercially available implementations of VM/370 continue to be insecure against planned intrusion,<sup>3</sup> this system appears to have sufficient potential to warrant the present retrofit effort.

## RETROFIT STRATEGY

A methodology was developed for partitioning the VM/370 control program (VM/370-CP) into security-relevant and nonsecurity-relevant modules. The decision process is based on the principles of least privilege and least common mechanism,<sup>2</sup> defining security-relevant code in CP as that code which executes privileged instructions or the code which accesses global system data (i.e., control blocks traversing security levels). In this way, security-relevant CP modules are directly identifiable.

It was found in the first year of the project that most system data need not be truly global, but global only over the Virtual Machines (VMs) at a given security level. The VMs at a given security level\* could be supported by a combination of a formally verified kernel operating in real supervisor state<sup>8</sup> and a Non-Kernel Control Program (NKCP) executing in real problem state and consisting of all non-security-relevant VM/370-CP code. The NKCP would execute as a virtual machine, having access only to global

\* A security level {C, K} consists of a hierarchical classification C from the ordered set {unclassified, confidential, secret, top secret}, and a category K consisting of a subset (possibly empty) of the set of special access compartments (e.g. NATO, CRYPTO, etc.). The categories form a partial order under set inclusion.

system data for the virtual machines it is supporting at the given security level.

In principle, there are significant differences between a security retrofit to VM/370 and a new design of a secure VM/370. In both cases it is necessary to design and specify the security enforcement mechanisms for the security kernel, as well as to derive the set of formal security invariants the kernel must preserve over the system. It is found, however, that much of the code in an operating system that virtualizes a computer, such as that found in VM/370-CP, either has no security relevance or can be trivially modified so that it no longer has any security relevance. Hence, much of the existing code which provides functional capabilities to the virtual machines is essentially usable as it stands.

Secondly, it is observed that such code, in fact all of VM/370, could be virtualized. The strategy suggested by these observations involves designing and verifying a relatively small body of code which is just powerful enough to provide primitive virtualization and which controls all forms of I/O access with respect to the security policy. It is thus conceptually possible to run numerous copies of VM/370 atop this simple kernel, each running in virtual (as opposed to real) supervisor state. Since the kernel is the final arbiter and all access to real devices must eventually pass through it (i.e., these accesses all require invocation of privileged instructions in real supervisor state), no action of the virtualized VM/370-CP can compromise security. The users would run their programs atop the untrusted copies of virtualized VM/370. If a virtualized VM/370-CP were to attempt to perform actions contrary to the security policy, the kernel would prohibit such actions from taking place. These potential denials of service could be avoided by deleting the related code from the virtualized VM/370-CPs, but it is important to observe that these matters have no effect upon the enforcement of security since (1) the kernel was designed to enforce a specific security policy, (2) the kernel was formally verified to support the enforcement of that policy, and (3) the correctness proof of the kernel made no assumptions about any of the virtual machines running atop the kernel, particularly none with respect to an NKCP itself.

In the interest of enhancing the performance of such a kernelized system, it might be necessary to give certain system modules access to multilevel system data. These are the modules which control the sharing of real system resource among virtual machines at different security levels. In order to maintain system security, it is necessary to ascertain that such resource management modules properly utilize the privileges granted them by the added common mechanism. Such modules become trusted processes. Where possible and practical, the trusted processes are to be given the same formal verification the kernel processes receive.

Where this is not practical or possible,\*\* the trusted pro-

cesses are subject to a thorough audit for the presence of errors or Trojan Horses<sup>2</sup> encapsulated into a limited address space with restricted reading and writing privileges, and restricted so that they operate in real problem state with virtual addresses. These latter processes are known as semi-trusted processes.

## SECURITY POLICY

The KVM/370 kernel is designed to enforce a military security policy. This requires the preservation of two security properties, the "security condition," and the "confinement condition" (also known for historical reasons as the "\*-property", pronounced "star property").<sup>4</sup> These properties are described in terms of three types of entities: subjects, objects and security levels. Subjects are the active elements of the system for which data access must be controlled (e.g., users, processes). Objects are the data or data containers, access to which must be controlled by the kernel. There is a security level associated with each subject or object which describes the degree of clearance of the subject or sensitivity of the object. A partial order, called dominates, is defined on the security levels. Specific interpretations of these elements are to follow.

The security condition requires that no subject may access an object for the purpose of reading or updating unless the level of the subject dominates that of the object. The confinement condition demands that a subject may have write access to an object (permission to both read and write) only if the subject and object are associated with precisely the same security level.

In the main, subjects in KVM/370 are interpreted as the individual NKCPs. The kernel provides isolation among the NKCPs, but provides little or no additional isolation between VMs under the same NKCP beyond that already provided in VM/370. Since all VMs operating under the same NKCP act at the same security level, the kernel protects each VM from other VMs at different security levels, but not necessarily from VMs at the same level. Global processes, which must interface with several NKCPs at different levels, are also subjects.

The objects in KVM/370 are collections of data areas on direct access storage devices (DASD), or entire DASD volumes, tape volumes, unit record devices, real core pages and processes, and VM working environments (control blocks, scratch storage registers etc.).

During 1977, the evolution of United States National Security Policy was studied in an effort to make KVM/370 more responsive to the modifications that were being made to Executive Orders 11652 and 11905. The requirements of Executive Order 12065 clearly state that it is essential that computer systems not divulge information to unauthorized individuals on the one hand, while prohibiting the overclassification of data on the other hand. KVM/370 enforces the confinement condition to prevent unauthorized declassification of data, and produces detailed historical collateral classification information for every new volume created by the system in order to justify its classification as a function of the classifications of all data to which the virtual machine

\*\* The semi-trusted processes serve as schedulers and allocators of global resources and have the potential to be used as an illicit signalling path in violation of the confinement condition by modulating the global state variable, TIME. There is no known method for formally demonstrating that an algorithmically correct, Trojan Horse free, scheduler cannot be manipulated by users in such a way that the users can cause clock time to become a signal to other users.

that created it had access. This historical classification information may then be reviewed by a security officer possessing original classification authority for the data.

## OVERALL SYSTEM ARCHITECTURE

Figure 1 represents the architecture of Kernelized VM/370 (KVM/370), consisting of the following domains:

1. The kernel and verified trusted processes, executing in real supervisor state (about 6000 lines of JOVIAL);
2. The audited semi-trusted processes, having access to some global system data, executing in real problem state, but having access only to virtual addresses (about 10,000 lines of assembly language);
3. The NKCPs, one per security level, having access to system data for the supported security level only, executing in real problem state, having access only to virtual addresses (about 70,000 lines of assembly language);
4. The user VMs, each controlled by the appropriate NKCP for its security level, executing in real problem state.

It was intended that all kernel code and trusted process code would be written in a strongly-typed Pascal-based programming language such as the EUCLID<sup>5</sup> language in order to facilitate formal verification.

However, as the time for system implementation drew near, it was found that there were no available production quality compilers for EUCLID or any other thoroughly-typed Pascal-based programming language that would permit efficient system programming on an IBM System/370 base machine. The requirement that the system programming language possess the capability of addressing and manipulating IBM System/370-specific data structures is essential since the kernel must analyze, prepare, and maintain numerous tables and control blocks whose structure is dictated by the hardware. In order to provide for the future verification and certification of KVM/370, it is desirable that a maximum of detail on the manipulation of these data structures be expressed in the higher-order language rather than in assembly language. Lastly, it was essential that the compiler reliably produce highly efficient executable code, lest the performance costs of the system be impractically high. It was also necessary that the compiled code not require a run-time support package for its execution, since the run-time package could be a possible source of security compromise (e.g., Trojan horses, trapdoors, etc.).

After serious consideration of numerous languages for which compilers either existed or were proposed, it was decided by ARPA that system efficiency was of sufficient importance to permit the use of a programming language that was not Pascal-based, providing it satisfied the other exigencies for the project.

The language selected for the implementation of KVM/370 was the J3 dialect of the JOVIAL Programming Language. JOVIAL is a system programming language providing direct description of machine-specific data structures, as

well as access to the full instruction set of the machine. JOVIAL is not a verification-oriented programming language. Consequently, while the formal specifications of KVM/370 will be formally verified against the security policy enforcement criteria, the first implementation will not be formally verified. Subsequently, when a production quality compiler exists for a verification-oriented systems programming language, KVM/370 can be recoded in that language and then verified.

## DESIGN TRADEOFFS

The user's system-use expectations will have an impact on the system architecture, size of the kernel and trusted processes, overall system performance, and level of effort required for implementation and formal verification. Resource scheduling and management can be performed on either a system-global or an NKCP-local basis. If done on a system-global basis, the size of the kernel and trusted processes is increased, the interface between the NKCPs and the global processes becomes more intricate, verification becomes more difficult and costly, system modification becomes less facile, but system performance improves. If done on a local basis with most resource management decisions performed by the NKCPs and perfunctory reconciliations performed by the kernel, the opposite results hold; system design, implementation, verification and interfaces are simplified, while system performance may be adversely affected.

In terms of greatest all-around adaptability to applications, ease of implementation and verification, and best multilevel security, we concluded that:

- DASD page areas will be global
- Main page frame management will be based on global allocation with global page replacement
- Multilevel shared reentrant systems will be provided with all shared pages locked into core
- The CPU will be scheduled by the NKCPs.

## KERNEL DESIGN

The kernel and trusted processes are the only portions of KVM/370 whose formal specifications will be formally verified. The system is being designed such that there are no "upward" functional dependencies (i.e., at level of abstraction  $i$ , no function depends for its correct operation on any function from level of abstraction  $j$ , if  $i < j$ ).<sup>6,7</sup> In this way, it can be demonstrated that no trusted code depends on the correctness and non-maliciousness of any untrusted, unverified code. Further, the formal proof of correctness of KVM/370 will require only (1) the kernel and trusted processes be shown to satisfy the requirements of enforcing the security policy, and (2) a demonstration of the absence of unauthorized signalling capabilities within the semi-trusted processes.

In the case of the Start I/O request to the kernel, the entire channel control program<sup>8</sup> is copied into a portion of the kernel's domain where it is protected from modification

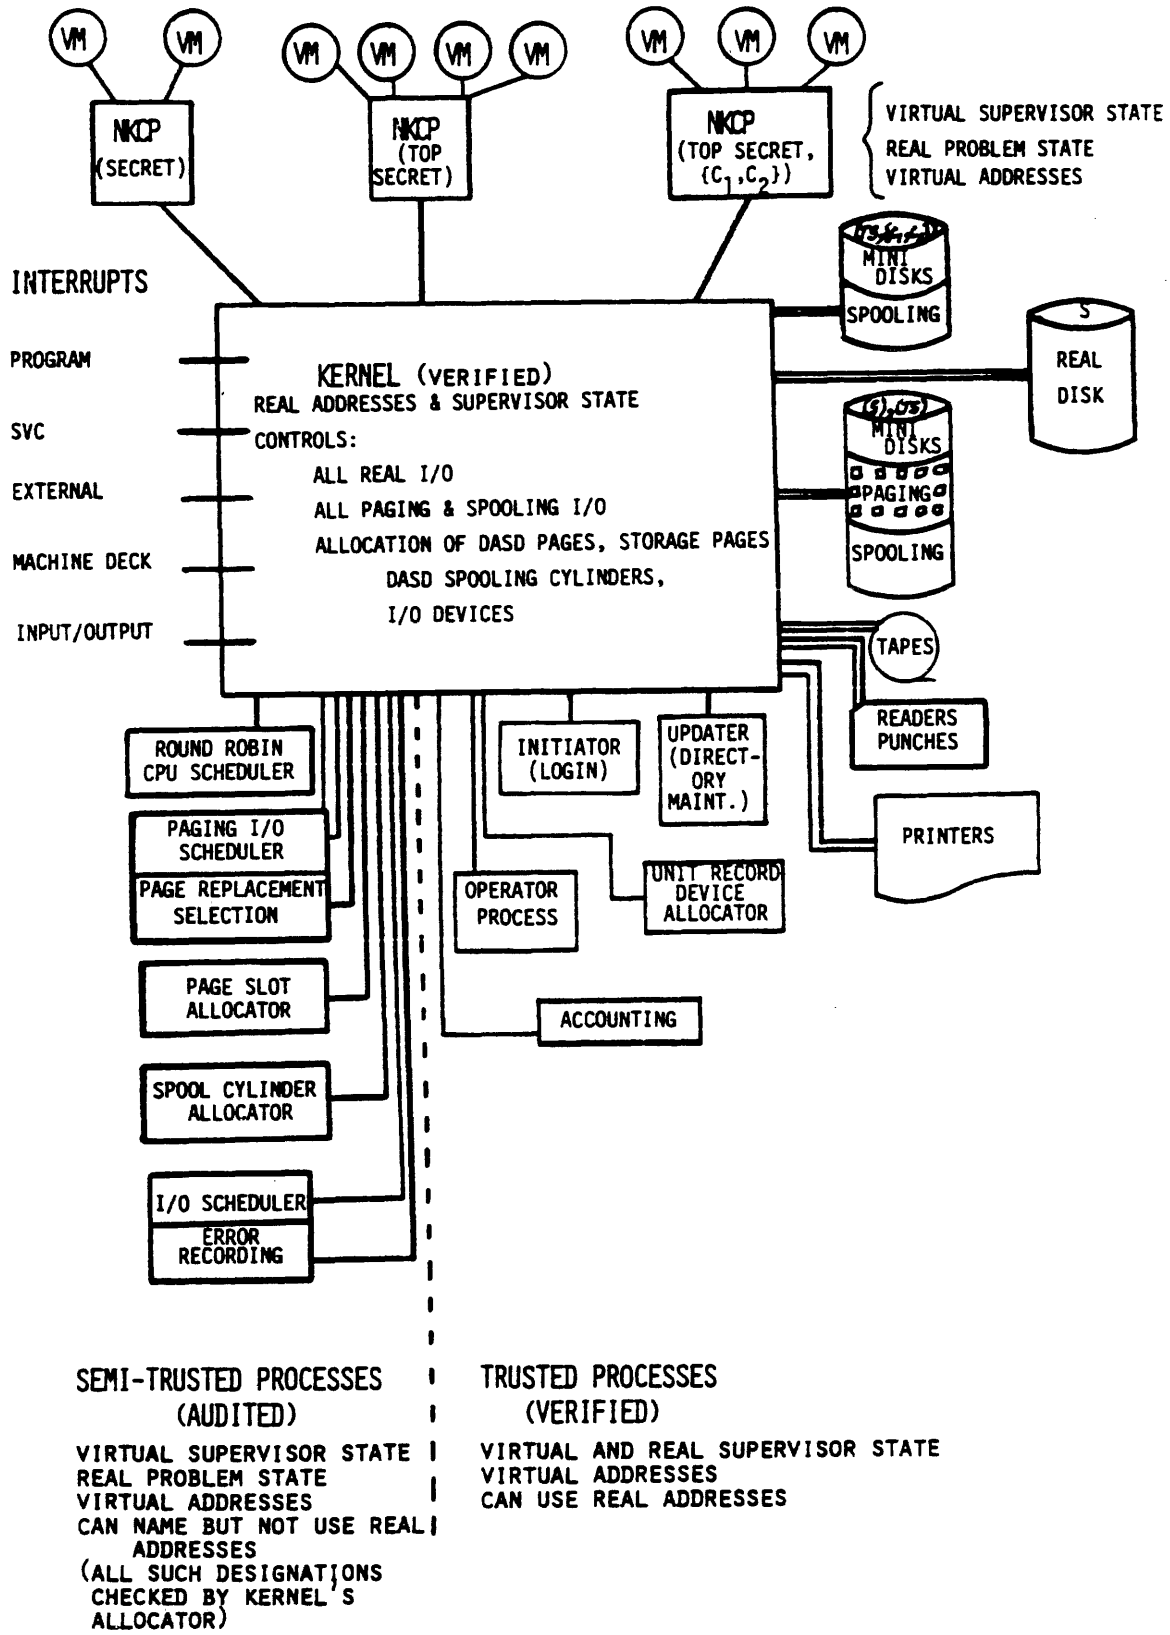

Figure 1—KVM.370 system architecture

by asynchronous attack.<sup>2</sup> Address translation is performed on the channel program. Then it is legality-checked by the kernel to guarantee that the program performs only valid accesses, that all referenced pages are locked into core, and that the channel program is not self-modifying and contains no puns or other security threats.<sup>6</sup> The I/O scheduler is then invoked and control is eventually passed to the dispatcher module, simulating a Start I/O Fast Release.<sup>8</sup> When the I/O interrupt finally takes place, the relevant pages are unlocked, and the condition code is passed as an interrupt to the appropriate NKCP.

Each security level has a unique address space for use by its NKCP. With the exception of the functions enumerated below, no NKCP can communicate outside its and its VMs' address spaces. Spool files, virtual channel-to-channel adapters (CTCA),<sup>8</sup> and inter-VM messages are handled by the NKCP and consequently cannot violate the kernel's enforcement of the security policy.

The notable exceptions are:

- Append-up for writing machine error records and accounting data which are processed at the highest security level in the system
- Read-down to obtain access to a DASD whose classification is dominated by the clearance of the user's VM.

For purposes of design simplicity, each NKCP will appear to be uninterruptible just as VM/370-CP currently is, i.e., the NKCP's critical regions will be preserved. The NKCP may, in practice, be interrupted by the kernel, but only if no NKCP shared variable (e.g. its set of active page frames or real addresses) is modified while it is servicing a user request. This constraint on NKCP-shared variables is the result of considerable effort in the area of kernel-NKCP interaction. The consequences of this design decision, as well as the considerations that led to it, are detailed in the Appendix. An NKCP terminates a critical region (a locally uninterruptible code segment) when it either schedules a VM or when it issues an I/O request.

## NKCP DESIGN

Code is security-relevant if it can influence unmediated I/O directly through the use of privileged instructions that manipulate devices or user domains, or indirectly through the use of data structures that either contain security enforcement data or can be viewed and modified by processes operating at different security levels. Data is security-relevant if it contains global information which traverses several security levels.

It appears that a considerable amount of CP code is security-relevant because it makes wide use of global system tables. Many of these tables could be distributed so that each copy contains only data relevant to a unique security level. The code manipulating these distributed tables could easily be made reentrant so that most of the code could lose

its security relevance. (Privileged instructions would still be security-relevant, however.)

An alternate approach is driven by identifying non-security-relevant code in CP and virtualizing it out of the privileged execution domain. The remainder, plus additional security enforcement code, becomes the kernel. The more code that is virtualized, the less there is to verify. Apparently, the efficiency of this system degrades as code is virtualized out of the kernel. This is because of the increased context switching between the NKCP and Kernel and the unavailability of global data required for optimal resource scheduling.

## SYSTEM VERIFICATION

Formal verification of kernel and trusted processes at the specification level will be of two kinds. These functions will be shown to correctly implement the sharing policy between subjects and objects in terms of the basic security principle and the confinement condition. This form of proof involves demonstrating that all system state transitions preserve a set of security invariants. The proof of correctness will be achieved with the assistance of an automated verification tool which enhances the credibility of the formal logical demonstration. The second phase of the formal verification process is formal proof that the trusted state transition functions themselves obey the confinement condition with respect to the system objects they read and write. The analysis techniques required for this verification involve simulated symbolic execution of source code.<sup>9,12</sup> The formal verification of KVM/370's specification has been postponed until after installation of the prototype.

## POSSIBILITY OF HARDWARE ERRORS

One of the problems considered by the project was the possibility of violations of the security policy occurring because of failure of the hardware security controls. Some possibilities considered were:

- Failure of the privileged operation protection mechanism;
- An error in address translation<sup>8</sup> or the Translation Lookaside Buffer (TLB);
- Failure of the storage protection mechanism;
- Misinterpretation of a Channel Command Word (CCW) by a channel;
- An I/O device responding to the wrong device address;
- Mishandling of a command by an I/O device.

Errors in the operation of the Central Processing Unit CPU and inboard channels are considered unlikely if the system receives proper maintenance. In addition, it appears to be difficult to guard against this type of failure. For similar reasons, we decided to ignore the possibility of an I/O device responding to the wrong address because address recognition logic on the S/370 channel is fairly simple. This left us

with the possibility of an I/O device mishandling a channel command. The most probable case of this type seemed to involve seeks on moving head devices: the possibility of a mechanical error moving the access arm to the wrong cylinder.

Questions had arisen as to the possibility that certain Direct Access Storage Devices (DASDs) were liable to incorrect seeks with a frequency that increased with their age. SDC conducted an investigation to establish hard data on the reality of these reported threats. Investigation of the logic of 3330-type devices showed a vanishingly small probability of a missed seek, inasmuch as the device controller counts the tracks electronically as they pass under the head. We also forced over 20,000 seeks of 350 cylinders and tested for an incorrect home address after each one. We found no missed seeks, nor were any seek retries reported in the error log for that day. We now believe that the redundancy checking built into the 3330 provides sufficient reliability for multilevel security applications.

Obviously, if a DASD accesses the wrong cylinder on a seek command, it is possible for a malicious user to read whatever is on the cylinder accessed, or to write incorrect information into those records. If the probability of a missed seek going undetected by the controller is as high as 0.1 percent, a user who causes a large number of seeks can reasonably expect to gain unauthorized access to data belonging to other users several times a week.

The results of the study of the 3330 have obviated the necessity of having to limit each DASD volume to a single level of security, as had been contemplated prior to the experiment. However, some installations may use older or other direct access storage devices which may not be as reliable as the IBM drives that we tested. As a result, we decided to provide a mechanism for protecting against misseeks, albeit at some cost. I/O requests are separated into paging/spooling requests and all others.

We note that all modern DASD devices can have an eight-byte key added to each paging block without affecting the number of pages which will fit on a cylinder. It was decided to write in each key the real cylinder number, track and record number, VMid and virtual page number that it contains, encrypted by a key that is determined at system start-up and unique for each security level. This would make the task of the would-be penetrator hard enough to discourage any attempt to use this mechanism.

For general I/O, it is possible to include a read-home-address CCW after each seek, and to have the kernel validate the home address on completion of the channel program. This would increase the average time required to execute a channel program by one-half revolution (about eight milliseconds). Since this represents nearly a 100 percent overhead in I/O operations, it was decided to partition devices into two classes: trusted devices and untrusted ones. A device is considered trusted if (1) it has been designated by the installation's security officer as trusted, (2) no misseeks on that device have gone undetected by the hardware (these usually result in unit-check with no-record-found), and (3) less than some threshold number of hardware-detected mis-seeks have occurred. If any of these conditions

is not satisfied, the device is regarded as untrusted. Home address verification is applied only when (1) the device is regarded as untrusted, (2) the I/O is not for paging or spooling, and (3) the I/O has been requested by an untrusted process (NKCP or scheduler/allocator).

## ELIMINATION OF KNOWN SECURITY FLAWS

There are about 30 security flaws known in VM/370. A hardened version could be produced by fixing these errors, but there might be other errors which had not been detected and the fixes might themselves introduce new security flaws. KVM/370 goes further and eliminates both known and unknown security flaws. It is instructive, however, to see how the presence of a security kernel and the constraints it places on the system design eliminate some of these errors.

Almost every known security flaw in the VM/370 system involves the input/output functions.<sup>3</sup> This is because there is no address space validation of input/output by the hardware other than that performed by the storage protection keys. Therefore, VM/370 must check the validity of all channel programs and relocate all virtual addresses. This includes both main storage addresses and DASD cylinder addresses in seek arguments and home addresses. The same I/O logic is repeated for several different requirements: virtual spooling support, virtual console support, virtual channel-to-channel adapter support, and a special VM/370 I/O interface. Each variation of this support means that errors may be present.

These errors occur in the translation of channel programs as a result of the complexity of the channel command language. For example, the same word in a channel program might be used as a command or as an operand address depending upon the execution sequence of the program.<sup>3</sup> Since the System/370 architecture allows puns in the channel program (a word's interpretation depends on whether it is received as the leading or trailing portion of a long command), it is possible to surreptitiously bypass checking by these modules, and access DASD records without authorization.<sup>3</sup>

Under KVM/370, channel command words are not permitted to take on different meanings depending on the sequence of execution. Primarily, this means that an NKCP is not permitted to submit certain channel commands with transfers or with certain modifier bits set. This does not preclude users (VMs) from constructing such channel programs, it merely requires the NKCP to put them into a standard form before submitting them to the kernel. Further, these commands will be copied into the kernel's data space and translated and modified there, preventing their modification by an NKCP between the time of translation and time of execution. Also, self-modifying channel programs will not be permitted, such as those used by the OS/360 Indexed Sequential Access Method (ISAM).<sup>1</sup>

Certain VM/370 penetrations<sup>3</sup> dependent upon simultaneous input/output and CPU execution are being countered by removing from the address space of the requestor all pages which are buffering input. This applies to both NKCP

and user VMs. In the event either an NKCP or a VM needs access to such a page, its execution will be delayed until the I/O completes and the page is made available. For example, under VM/370, careful timing of asynchronous execution could be used to exploit a bizarre oversight in condition-code checking to gain a total system penetration (real supervisor state).<sup>3</sup>

Although the treatment of storage and timing channels<sup>10,13</sup> is beyond the scope of a system such as VM/370, they must be controlled in a military system such as KVM/370. In this respect, we will thoroughly audit all semi-trusted processes for Trojan Horses since they control resources shared between different security levels. Hence, it will not be possible to transmit information over a covert communication channel at a high enough bandwidth to make such attempts worthwhile. The above discussion deals only with the security flaws that are already known. KVM/370, however, is designed around a formally specified security kernel. Once the specification is verified, there is good reason to believe that no possibility of violations of the security condition or overt violations of the confinement condition exist in the design. Further, by recoding the security kernel and trusted processes in a programming language designed for verification, a near-certainty of the absence of security flaws could be obtained by verifying the code against the already verified specification.

## CURRENT STATUS

The feasibility of performing a VM/370 security retrofit was demonstrated during the first year of project activity. An informal system design was produced, identifying the major security kernel functions. The input and output parameters were defined and their effects on KVM state variables were described.

From this, the security kernel and trusted processes were formally specified in the SDC specification language, INA JO, a strongly-typed dialect of the first-order predicate calculus. After the system data bases were defined, the coding of the NKCP and semi-trusted processes was started, and the implementation of the kernel and trusted processes was begun in the J3 dialect of JOVIAL.

KVM/370 security policy was re-examined in light of the modifications to the National Security Policy as defined in Executive Order 12065, 28 June 1978. KVM/370 security policy now takes account of both discretionary and non-discretionary aspects of security.

Integration testing of KVM/370 is in progress as of this writing.

## PLANS

It is expected that system testing and integration will conclude by late summer of 1979. At that time, KVM/370 will be installed in a testing environment within the Defense Communications Agency Engineering Center. Here, the prototype system will be evaluated on a set of selected

benchmark workloads and its performance will be tuned to the extent possible within the constraints of the security policy. In this way, the first steps can be undertaken toward determining the costs of multilevel security on an IBM System/370 mainframe. Initially, test cases will be run under varying conditions in a periods processing environment.<sup>2</sup> This will establish a basic scale against which the operation of KVM/370 can be judged. These will be followed by selected KVM/370 runs that approximate the periods processing approach: one NKCP (one color); two NKCPs (two colors), etc. Various test case workloads will be defined and specific measurements will be performed. Acceptance of KVM/370 will be made by relating dollar costs to run time, and by evaluation of the periods processing approach as it impacts user requirements.

## CONCLUSION

In this paper, we have presented a design strategy for performing a retrofit to VM/370 which will provide a multilevel secure operating environment. The strategy is heavily based on the principles of least privilege and least common mechanism. The research and development activities described in this paper transpired in the period March 1976 through January 1979. The implementation of KVM/370 is currently in progress and it is anticipated that a prototype version of the system will be installed within the Defense Communications Agency in the late summer of 1979.

## ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions and suggestions made by the following individuals: E. Book, M. Branstadt, E. Burke, W. Carlson, J. Fraley, T. H. Hinke, D. Hollingworth, A. K. Jones, H. C. Lauer, R. Lyons, C. A. Melkerson, M. Moriconi, M. Orceyre, G. J. Popek, G. Schroeder, W. M. Shasberger, D. H. Thompson, S. T. Walker, C. Weissman, J. H. Yott, and D. Zucker. We would also like to extend our sincere appreciation to our technical editor, B. L. Sargeant, and L. L. Parris, who provided typing support.

## APPENDIX A

### *A solution to the "load real address" problem*

**Background**—During the first year of the KVM/370 project, attention was paid to what is known as the "Load Real Address" problem. This problem is concerned with the fact that an NKCP needs to be able to "locate" certain pages of the VMs under its control. This is handled in VM/370-CP by the Load Real Address (LRA) instruction.<sup>8</sup> The LRA may be used for channel program translation, or to locate the operand(s) of a privileged operation that CP is simulating.

The problem which arises in KVM/370 is that the decision to "steal" a page is made by a global process, not under control of the NKCP. Consequently, there is no guarantee that the page, once "located" by the NKCP, will stay at the same real address, or even remain in main storage, long enough to be used. In order to avoid frequent and embarrassing denials of service, it is necessary to guarantee that a virtual page stays in the same place from the time the NKCP has been given its real (or "real") address, until the NKCP is no longer relying on the address given for that page. The following discussion expands on the complexities of the problem and presents what is believed to be a solution to it.

**Related Considerations**—When the problem arose, several points of view were held concerning real addresses. It would probably simplify the kernel-NKCP interface if the NKCP were allowed to access the real addresses of the pages under its control. On the other hand, there are several high bandwidth data channels involving real page addresses.<sup>13</sup> The current design calls for the NKCP to gain access to pages containing operands by having them placed in its own address space. (The kernel inserts their real addresses in the NKCP's page table.) This allows the NKCP to read and/or modify data for instructions that it simulates for its VMs,

without knowing the real addresses of the pages. For channel program translation, the NKCP will leave virtual addresses in the Indirect Address Word [IDAW] lists, which the Request-I/O handler will translate to real addresses.<sup>8</sup>

In order to simplify the kernel's handling of process scheduling, it was decided to treat NKCPs as logically non-interruptible. The kernel will refrain from presenting the NKCP with interrupts during its operation (just as VM/370-CP is designed to run with interrupts disabled). The kernel will also refrain from running any other NKCPs until the current one signals the end of its critical region.

**The Solution**—The operation of an NKCP is considered as a critical region from the time it is entered until it dispatches a VM or relinquishes the CPU. Any interrupts taken by the kernel during this period will be handled to the extent possible by the kernel and schedulers, but no other NKCPs will be dispatched, even if the current NKCP's time-slice ends. Interrupts requiring action by any NKCP, including the current one, will be stacked until the end of the critical region. Any pages swapped in at the NKCP's request or to which the NKCP gains access (by "attach page") will be placed under a temporary lock which prevents their page frames from being stolen during the critical region. The critical region (and temporary lock) will end when the NKCP makes either a Dispatch-VM or a Release-CPU kernel call. If an NKCP requires that a page be at a fixed address for a longer period of time, it must make an explicit Lock-Page call.

Note that such locks (either temporary or long-term) cannot be attached to a page which is not present or which is being used for a conflicting purpose. For example, a page that has been stolen and is being swapped out cannot be locked unless the requester can reclaim the page (this ability is not supported by the current KVM/370 design). A page which is being used for the buffering of input cannot be locked for CPU usage or output, nor can a page being used for the buffering of output be locked as an input buffer.

This approach has the following consequences:

1. No page will be stolen from an NKCP or its VMs except when the NKCP is running a VM or waiting for an interrupt. (The latter case is equivalent to the dispatcher's loading a wait-state PSW because there is no work to do). VM/370-CP always checks page status when a new request arrives from a VM by doing a LRA and/or calling the real page manager (DMKPTR). Similarly, NKCP does not rely on page locations remaining constant across such operations, so stealing a page cannot cause the NKCP to make an erroneous assumption.
2. If VM/370-CP requires that a page keep the same real address after a call to the dispatcher, it explicitly requests DMKPTR to lock the page. Thus, if the NKCP requires a page to stay in main storage across Dispatch-VM or Release-CPU calls, it must explicitly request a lock on that page. Otherwise the kernel or Select routine will be permitted to steal the page if it is the "best" page to steal.
3. Since the kernel will call other NKCPs (that is, by

invoking the CPU scheduler) only when the current process makes a Dispatch-VM or Release-CPU call, there can be no "surprise" loss of the CPU to another NKCP. This means that the kernel need not save and restore the registers in the KPROCBLOK for each process. Instead, a single level of register storage will suffice (for General registers and timers only, since neither the kernel nor the trusted/semi-trusted process will use the Floating registers). Each NKCP must be written so that it saves its own registers whenever it makes a call that invokes another process or ends its critical region. (This is not directly related to the LRA Problem, but simplifies table design.)

*Locks*—The kernel provides three types of locks to NKCPs.

1. A temporary lock is attached to each page which is swapped in at the request of an NKCP or to which the NKCP is given access as a result of an attach-page request. The lifetime of the temporary lock is the NKCP's critical region (i.e., until the NKCP releases the CPU or dispatches a VM). The temporary lock prevents the page from having its frame stolen; the NKCP may release the page, however, which cancels the temporary lock.
2. An I/O lock is attached to each page used in an I/O request. The page must be in main storage when the request-I/O call is made. The lifetime of the lock is concurrent with the I/O request (the lock is released when the requested I/O operation completes). The I/O lock can be cancelled only by cancelling the I/O operation.
3. A long-term lock is attached to a page at the request of any NKCP with access to that page. The long-term lock is permanent until cancelled by a specific request. Only the NKCP which requested the lock can cancel it. The kernel calls Lock-Page and Unlock-Page will be provided for this purpose. This type of lock can be used by an NKCP in response to an operator "LOCK" command or while gathering multiple pages (e.g. for an I/O operation) to insure that pages obtained earlier do not get swapped out while obtaining other pages.

All three types of locks protect the page from being stolen until the NKCP is finished with them. The second and third types of locks also prevent the NKCP from releasing the page until the lock has been cancelled.

If the SELECT routine (a semi-trusted process) attempts to select a page for which a lock exists, it will be re-entered to select another page. The kernel will refuse to steal a frame from a locked page. If the NKCP attempts to release a locked page (via release-page) or to swap out such a page, the result depends on the type of lock(s) attached to the page. If only a temporary lock is attached to the page, the temporary lock will be released and the request honored. If an I/O lock or a long-term lock is attached to the page, the request will be denied.

## APPENDIX B

### *A general countermeasure for quota-type leakage paths*

The allocation of objects from a global pool of finite size allows use of that limited size as a communication path for covert transmission of data. The sending process repeatedly requests resources from the pool until a request is denied. At that point the sender knows the pool is exhausted and can release the CPU and allow other processes to run. The receiver requests a few objects from the pool, then releases them. The sender releases a large number of objects into the pool to send a one, or exhausts the pool to send a zero. The receiver receives a one or zero depending on whether its requests are satisfied. Other processes may introduce noise by exhausting the pool with legitimate requests or releasing objects they no longer need. Such noise can be filtered out via normal redundancy techniques. The state of the pool is a variable shared between sender and receiver, creating a storage channel whose bandwidth is dependent on the frequency with which such requests can be made.

Analysis of the preliminary design of KVM/370 reveals a number of such resource pools:

- Disk Pages (Page Slots)
- Main Storage Pages (Page Frames)
- Spool Cylinders
- Temporary Disk Cylinders
- Kernel Table Entries
- Kernel Storage for Dynamic Creation of Tables

A number of countermeasures have been adopted to control the use of these pools as communication channels.[1] Prediction is used on page slots and entries in the KVMTABLE and PROCESSLIST. Whenever a user attempts to Log In (a relatively infrequent event), a check is made to determine whether the necessary page slots and table entries are available. The user is denied access if they are not. [2] Temporary disk cylinders are subpooled; each security level has a private pool from which it makes allocations. No global pooling of TDisk is provided. [3] Requests for main storage pages and spool cylinders are never refused. The satisfaction of a request for a page frame or spool cylinder is reported by an interrupt which may occur immediately or after an arbitrary period of time. This converts a potential storage channel into a timing channel and lowers the bandwidth. (A process which exhausts the pool is unable to free the entries it has requested until the necessary I/O has been performed).

However, some types of requests for kernel tables cannot be predicted, and their satisfaction is not dependent on I/O.

Further, subpooling kernel storage by security level would be extremely wasteful of main storage which is a precious resource. The communication channels involving these quotas are being tolerated but restricted in bandwidth. Whenever a process request is refused because of exhaustion of a kernel table or storage pool, a return code is provided

indicating to the process that some quota has been exhausted (without specifying which one). After that the process will not be permitted to make another such request for a period of time. Until that time period is over, any request by that process depending on such a quota will be denied without checking the resource pool and the return code will indicate "too soon." In this way, the communication channel is

limited to one bit per time period. By setting the time period to .1 second, these communication channels are restricted to ten bits per second.

This technique can be used on any system that has a real-time clock and can be used on any resource pool. It can be applied instead of or in addition to other countermeasures for control of quota-type data channels.

# KSOS—The design of a secure operating system\*

by E. J. McCAULEY and P. J. DRONGOWSKI

*Ford Aerospace and Communications Corporation  
Palo Alto, California*

## INTRODUCTION

This paper discusses the design of the Department of Defense (DoD) Kernelized Secure Operating System (KSOS, formerly called Secure UNIX).\*\* KSOS is intended to provide a provably secure operating system for larger minicomputers. KSOS will provide a system call interface closely compatible with the UNIX operating system. The initial implementation of KSOS will be on a Digital Equipment Corporation PDP-11/70 computer system. A group from Honeywell is also proceeding with an implementation for a modified version of the Honeywell Level 6 computer system.

KSOS will be capable of handling information at various security levels (a security level is a combination of a hierarchically-ordered classification category, like SECRET or TOP SECRET, and a possibly null set of compartments, like "No Foreign Dissemination" or specialized need-to-know compartments). The goal of the system is to provide strong assurances that it is impossible for an unprivileged user to cause an information compromise.

At its outer interface, KSOS will appear to be closely similar to the UNIX operating system.<sup>13</sup> The only changes are to tighten the security checking on some of the operating system calls, and to add several new calls which individual UNIX sites had previously added to their systems. Existing applications programs written for UNIX will run without modification or recompilation on KSOS, providing that they do not violate the security rules of the system. At last count there were several hundred application programs for UNIX, ranging from simple utilities through sophisticated compilers, data management systems, text processing systems, and powerful editors. (This paper was completely prepared on a UNIX system, as is all documentation for the KSOS project.) All of these programs should run on KSOS without modification.

This UNIX-like interface is provided by a software component called the UNIX Emulator. The UNIX Emulator

transforms the user's UNIX operating system calls into (sequences of) calls to the Security Kernel. The Security Kernel is the heart of the system. The Kernel implements the reference monitor concept.<sup>1</sup> Briefly, through a combination of hardware and software checking, the Kernel monitors every access attempt by each user process. The Kernel will be shown to make the correct decision on whether to permit or deny the access attempt.

One important distinguishing characteristic of KSOS over the prototypes which have preceded it<sup>5,8</sup> is that it contains a full range of support software. Included in this "Non-Kernel System Software" (also called Non-Kernel Security-Related Software) are components which support the day-to-day operational functions of the system: secure spooling of line printer output, portions of the interface to a packet-switched computer network, etc. Also included are components for the continuing maintenance of the system such as consistency checks of the file system, and system generation support. Finally, there are components to support the administration of the system, such as adding and deleting users, changing the security levels that a given user may access, and other functions.

The schedule for KSOS calls for its delivery in the fall of 1979 after the conclusion of a full series of testing. The KSOS development contract specifies that the system shall have a full MIL SPEC documentation package. The primary documents defining KSOS are detailed "design to" specifications which are called "B5 Specifications."<sup>3,6,9</sup> The Kernel B5 Specifications<sup>6</sup> include formal, mathematical descriptions of the Kernel written in a language developed by SRI International called SPECIAL.<sup>15</sup> SPECIAL is a formal, non-procedural language for describing the behavior of systems in the manner suggested by Parnas.<sup>10</sup> In addition, technical reports have been delivered detailing our plans for verification of the system's security properties,<sup>16</sup> for the tools and techniques to be used in implementation,<sup>4</sup> and for the long term maintenance and support of the system.<sup>7</sup>

The remainder of this paper begins with a discussion of the influences on the design. As with any design project, it is impossible to identify all of the factors which cause a given course to be taken, so only the strongest influences are discussed. Next the design itself is presented. Here the emphasis is on the more novel aspects of the design. In addition to the usual things expected from an operating

\* The work described in this paper was performed under ARPA Order 3319, Contract MDA903-77-C-0333 administered by the Defense Supply Service Washington. Various DoD Agencies are funding the work. The conclusions presented are those of the author and are not necessarily those of the Government or Ford Aerospace.

\*\* UNIX and PWB/UNIX are trademarks of the Bell System.

system. KSOS provides a number of features that aid in the creation of encapsulated secure environments. The paper concludes with a few remarks on how KSOS may be used effectively.

## INFLUENCES ON THE DESIGN

### *External design goals*

The overall design goals for KSOS are:

1. The system must provide provable security, i.e. its design and mechanization must be oriented towards the proof of its security properties.
2. The emulation of the UNIX system call interface must be as faithful as possible given the constraints of the security model.
3. The performance of the system should be "good," specifically, the performance should be comparable to that of a UNIX system.
4. The Kernel should be usable by itself as a simple, secure operating system.
5. The design should be amenable to implementation on other hardware bases.

The need for provable security had the most profound impact on the design. First, it dictated the basic structure of the system. A Security Kernel would function as a reference monitor.<sup>1</sup> The Kernel would mediate all access attempts in the system. Because the Kernel would potentially be proven to operate correctly, its behavior would have to be formally specified. Further, the size of the Kernel would have to be kept to a minimum to make formal specification and eventual verification tractable. Although only representative code proofs were planned, the Kernel would have to be implemented in a language suitable for code proofs.

Because the UNIX call interface had to be emulated faithfully and efficiently, the Kernel interface became "UNIX-flavored." However, because non-UNIX applications of the Kernel were planned, there was strong pressure to keep UNIX-specific structures out of the Kernel. As will be seen below, the Kernel has no knowledge of the format, or semantics of UNIX-specific constructs such as directories or load modules (UNIX a.out files). This knowledge is encapsulated outside the Kernel.

It was recognized that a large class of KSOS applications would not require the flexibility and added power of the UNIX interface. Rather, many of them would be built directly on the Kernel. Thus, the Kernel had to provide all of the features commonly found in an operating system. This meant that the Kernel would include somewhat more functionality than the absolute minimum.

### *Hardware limitations*

Although KSOS was intended to be a machine-independent design, it will be implemented on real machines with

various hardware limitations. The PDP-11/70 has two significant limitations. First, process switching is expensive because a large number of processor and memory management registers must be individually saved and restored. Thus, architectures which require extensive process switching are to be avoided.

The PDP-11/70 does not lend itself to the creation of virtual machine environments that include direct control of single user i/o devices. The problem stems from the granularity of the virtual address to real address mapping, and from the logical addressing of i/o registers. In KSOS on the PDP-11/70, all devices are managed by the Kernel; no attempt is made to provide devices in the user's "virtual machine."

In fairness to the PDP-11 design it should be remarked that none of these hardware limitations are especially burdensome; they merely influence the design to take advantage of the strengths, and to avoid the weaknesses of the hardware base.

### *The design methodology*

The design of KSOS is strongly influenced by the design methodology used on the project. KSOS is being designed and implemented using a blend of the "classical" methods with the formalism of the Hierarchical Development Methodology (HDM)<sup>14</sup> developed by SRI International. HDM emphasizes formalism throughout the project. The system's security requirements are formally stated as properties to be satisfied by an abstract description of the design. This design is described in a mathematical, non-procedural language, SPECIAL.<sup>15</sup> The security properties of the design are established by proving theorems that are derived from the design and the mathematical model of the security requirements. The implementation language is selected to allow its correspondence with the specifications to be proven. All of these steps force the designer to be precise and exacting in the statement of the system design. They make "kludges" very obvious at an early date. The design methodology strongly encourages a hierarchical decomposition of the design.

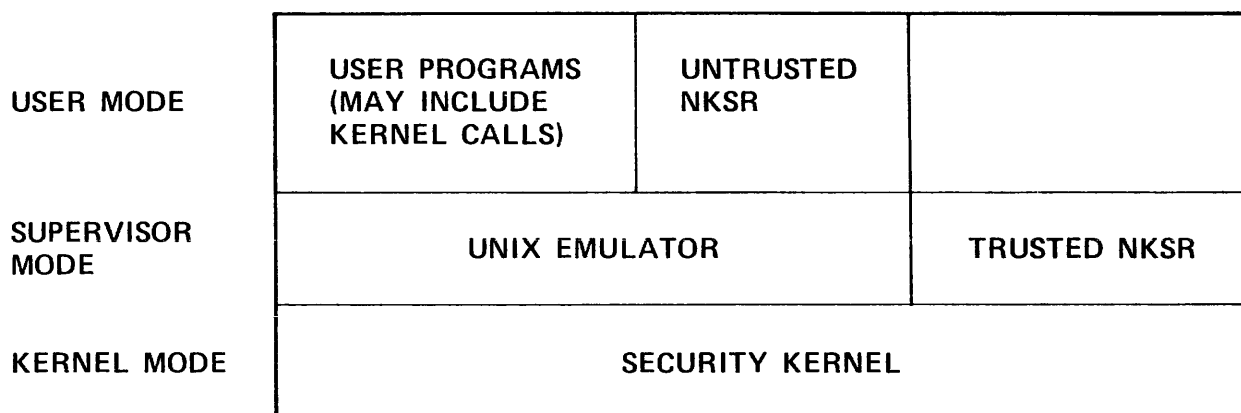

## KSOS DESIGN

KSOS is composed of three components:

1. The Security Kernel
2. The UNIX Emulator
3. The Non-Kernel System Software

The relationship of these components is shown in Figure 1.

The Security Kernel's function is to provide a simple operating system which can be shown to be secure. The Kernel centralizes the control of all the resources in the system. It mediates each access attempt by a user process and only permits those accesses which comply with the access control policy. The Kernel resides in the most privileged address space of the machine (called "kernel mode"

(NKSR: NON-KERNEL SECURITY RELATED SOFTWARE)

Figure 1—KSOS system structure.

on the PDP-11/70) where it has access to all of the raw hardware and memory management facilities.

Logically, the UNIX Emulator is a part of each UNIX process which on the PDP-11/70 resides in the "supervisor mode" address space of the process. Its function is to map the user's UNIX system calls into the corresponding Kernel call(s).

The Non-Kernel System Software is a collection of autonomous processes performing support services for the system. Like UNIX, KSOS does not have services like login embedded in the operating system. Rather, these services are performed by "trusted processes" which reside outside of the Kernel. Except for the fact that these processes have the privilege to selectively violate the rules of the Kernel, they are just like any other process. Because the Emulator is "untrusted" and is not intended to be verified, it cannot be used by trusted software; rather, such software must use the Kernel directly.

#### *The KSOS Security Kernel*

Viewed as an abstract machine, the Kernel's function is to create the objects of its interface (processes, process segments, files, devices, and subtypes) from the basic hardware resources of the system, and to mediate all access attempts to these objects.

The Kernel enforces three distinct types of access checking. The first is the enforcement of DoD security policy. This checking is the verification of that fact that the user has the proper clearance and need-to-know for reading the information (the "simple security property"), and that information cannot be downgraded by writing it to a file at a lower security level (the "security \*-property").

The second type is the enforcement of an integrity policy described in Reference 2. Integrity is a mechanism for protecting system data bases, programs, etc. against modification while allowing them to be read by any process. It is formally defined to be the mathematical dual of the security

model. We have found this integrity model to be overly restrictive, as its originator suspected. However, it does provide an additional, essential dimension of protection. Development of a more effective integrity model would seem to be a meaningful research topic.

The third type of access checking performed by the Kernel is discretionary access checking. Unlike the first two types of checking, the discretionary access checking is completely under the control of the user. The user may, at his discretion, permit or deny access by other users to the objects he owns. KSOS enforces a discretionary access policy similar to that of UNIX. For each object there are (logically) nine bits that specify read, write, and execute/search access by the owner, others in the same group as the object, and all others. We recognize that this discretionary access policy has limitations when compared to more sophisticated schemes, such as the access control lists used in Multics. However, it is simple, and requires a small fraction of the support mechanisms needed for access control lists.

The Kernel supports five different types of objects:

1. Processes
2. Process segments
3. Files
4. Devices
5. File subtypes

All Kernel objects have the same type of name called a SEID (Secure Entity Identifier). Further, every object, regardless of its type, has a block of information associated with it that includes all the information needed by the Kernel to mediate access attempts to the object. This block is called the "type independent" information. Because objects, regardless of the object type, have homogeneous type independent information, access checking by the Kernel is greatly simplified. All that must be checked is that information may flow from the source to the destination. For example, if a process wishes to read a file, the source is the file and the destination is the process. In the KSOS Kernel,

two functions perform all the access checking (one for security and integrity checking and one for discretionary access checking).

### Processes

Processes are the only active agents in the KSOS design. To adequately emulate UNIX, KSOS processes must be cheap and plentiful. For example, each UNIX command is run as a separate process. Processes in KSOS will require only modest amounts of Kernel resources. Most of the Kernel data for a process will be swapped in and out with the process, reducing the amount of locked down Kernel memory space for the process tables.

Processes may possess privileges ("trusted processes") that enable them to perform functions that require reduced checking by the Kernel (e.g. changing the classification of a file) or which may require that additional checking be performed in the process (e.g. logically mounting part of the file system). The privileges that may be given to a process have been designed following the concept of "least privilege." That is, the granularity of the privileges is quite fine, and quite specific. Many service processes possess only a single privilege, and many privileges are possessed by only one process. Thus, the KSOS Kernel is designed to create encapsulated environments for critical functions. Privileges are obtained from the process image file (load module) from which the process was initialized. Two Kernel calls, `K_invoke` and `K_spawn`, are used for the controlled invocation of privileged software. `K_invoke` functions by replacing the entire process with a user-specified intermediary process. For the invocation of trusted software, this intermediary is a trusted "bootstrap" that, in turn, replaces itself with the requested process image file, and sets the privileges of the process from the values in the image file. `K_spawn` performs the same function in a new process created as part of the `K_spawn` function. This mechanism allows knowledge of the format and semantics of process image files to be kept out of the Kernel. Thus, the bootstrap encapsulates the function of initiating trusted software with minimal Kernel support.

In addition to the `K_spawn` mechanism, new processes may be created by the `K_fork` call, which is similar to the UNIX fork call. `K_fork` creates a "clone" of the caller, a new process that is an exact copy of the caller. The only difference between the two processes (parent and child) is the return value from the `K_fork` call. Such a mechanism is required for the accurate emulation of the UNIX fork call.

Processes normally run at a single security level. The only exception to this is the part of the Non-Kernel System Software that changes the user's working security level. For inherently multi-level applications, the preferred design would be to create a trusted multiplex/demultiplex ("mux/demux") process which directs commands and i/o to processes running at each level needed. This would be preferable to having these per-level functions performed within one process which changes its level because such a process

would be larger and more complicated than the mux/demux process. Verification of the correctness of a process becomes significantly more difficult as the process size and complexity increase. One example of this preferred architecture is the KSOS network interface. A small trusted process separates the multi-level data stream from the network into several streams. Each stream has data of only one security level in it. The mono-level streams from the processes are similarly combined by the trusted process into a single, multi-level stream.

Standard UNIX is acknowledged to be deficient in the area of Inter-Process Communication (IPC). KSOS provides significant improvements in this area. The Kernel supports both an event IPC mechanism and shared segments. The event mechanism allows one process to send a message to another process, and (optionally) to cause the receiving process to be interrupted analogously to receiving a hardware interrupt. The full set to security checks is performed for each IPC attempt. That is, information must be able to flow from the sender to the recipient, and the recipient must have permitted such information flow. Finally, a process may enable and disable the pseudo interrupt mechanism, so that it will not be interrupted during some critical operation. (Shared segment IPC is discussed below.)

### Process segments

A process segment is a portion of the virtual address space of a process. The process segment is not tied to the native memory management hardware of a particular machine. The KSOS process segment may be of any size from a hardware-limited lower bound up to the entire virtual address space of a process. A process may have only some of its segments actually mapped into its address space. At its creation the segment may be declared to be sharable, in which case other processes can "rendezvous" with it and map it into their address spaces. This allows for very high bandwidth communication between the processes. Naturally, they must establish a protocol that guarantees that the segment will not be corrupted through unsequenced use. The process may elect to have only some of its segments actually mapped into its address space. In particular, several segments for the same part of the address space could exist. This mechanism is used by the trusted mux/demux processes discussed above. The data segments are shared between the trusted mux/demux and the processes servicing each logical stream. The mux/demux maps in a particular segment to a well known location and puts/extracts the data for that stream into/out of the segment.

One other use for shared segments is shared text (program) segments. It is possible to have a pure text segment shared between multiple processes, thus reducing the overall memory requirements for the system. KSOS allows a segment to be locked in memory, or to be retained in the swap area for faster accessing. The designer of the KSOS-based system is offered considerable latitude in trading space for time.

## Files and devices

The Kernel file structure is flat and uniform. That is, there are no Kernel assumptions about the internal structure or contents of files. Directories and other higher-level constructs are mechanized outside the Kernel. The UNIX Emulator creates UNIX-like directories by interpreting the contents of Kernel files. This allows a designer working directly with the Kernel to create a different type of directory structure if desired. Kernel files are accessed by blocks. There is no Kernel buffering of file *i/o*. Rather, the *i/o* is done directly into the requesting user's address space. Kernel *i/o* is asynchronous, that is, the call returns to the user as soon as the *i/o* has been internally queued. An IPC message is sent to the user upon *i/o* completion. (The inclusion of asynchronous *i/o* is a relatively late addition to the KSOS design.)

Kernel devices are like a special type of file, as in UNIX. Terminals have only the lowest level echoing support in the Kernel. Higher level functions like erase/kill processing are done outside the Kernel.

KSOS supports removable file volumes. The mechanism is similar to the UNIX mount mechanism with some significant additions for protection. Because of the possibility for removing a volume, files are limited in size to one volume. Presently the design allows for support of at least 300 Mbyte disks, with extensibility to 600 and 1200 Mbyte disks possible. These large disks may be partitioned into one or more extents, referred to as "mini-disks" which may be independently utilized as virtual disks.

## Subtypes

The KSOS subtype mechanism is one of its more novel features. The subtype mechanism is designed to allow the selective encapsulation of a class of files. Each file is a member of a subtype class. For example, "normal" files are in the null subtype class. Files which are UNIX directories are the "UNIX directory" subtype class. The accesses to files in a given subtype class may be restricted. The subtype restriction on UNIX directories is that anyone may read a directory, but only a process whose effective user ID is the Directory Manager may write them. These subtype restrictions are in addition to the other types of access checking (security, integrity and discretionary). The access restrictions for a given subtype apply to all files of that subtype.

There are many other possibilities for using subtypes. For example, they could allow "peaceful coexistence" of two separate directory structures as might occur if there were two different Emulators, say one for UNIX and one for another operating system. Subtypes could also be used to control what could be done to files that mechanized the internal structure of a data base management system. Only processes that were known to correctly manipulate the structure would be allowed to change it. The subtype mechanism provides the KSOS Kernel with a significant type extension feature in that it lets the Kernel support encapsulation and control of objects without having the Kernel be cognizant of the syntax and semantics of the object.

sulation and control of objects without having the Kernel be cognizant of the syntax and semantics of the object.

## Secure terminal interface

In the secure system it is necessary to have an "unspoofable" path to trusted services. ("Spoofing" occurs when an unprivileged user process pretends to be a privileged process. For example, a nefarious user starts a process that imitates the login sequence, and waits for an unsuspecting victim to type in his password.) In KSOS each terminal is (logically) two devices, the normal terminal device and the secure device. Only privileged Non-Kernel System Software is able to use the secure device. When the user types a reserved attention character (currently BREAK), the normal path is blocked, and the character stream is switched to the secure path. Listening on the secure path is a service process which will cause the desired secure service to be performed. Because the normal path is blocked, rather than killing off any process using it, it is possible for the user to start doing something, temporarily abandon it while requesting some secure service, and resume the activity after the secure service is completed. This is the mechanism by which the user is able to change his working security level. The Secure Terminal Interface is illustrated in Figure 2.

## Auditing

DoD security policy requires that certain security-related events be captured for auditing purposes. In KSOS this occurs in two ways, as shown in Figure 3. In the first case, the Kernel captures the events it knows about and generates an IPC message to the Audit Capture process. The second mechanism is that the Non-Kernel System Software captures the event. This second case is necessary because the Kernel cannot tell that certain significant events, like a user login, have occurred. The Audit Capture process does only a minimal amount of processing and then simply places the event record into an audit log. Although it is not within the scope of the current KSOS contract, this audit log could be processed to look for suspicious (sequences of) events.

## The UNIX Emulator

The UNIX Emulator is almost completely defined by its two interfaces. It must transform the system calls of the UNIX interface into sequences of Kernel calls. In the design of KSOS a serious attempt was made to get a good "impedance match" between the Emulator and the Kernel, while not having the Kernel be strongly UNIX-dependent.

Our view of the Emulator has evolved significantly. Initially, the Emulator was viewed as not much more than a set of subroutines that resided in a different address space. The functions performed by the Emulator were isolated to one process, except for the obvious cases of interaction with

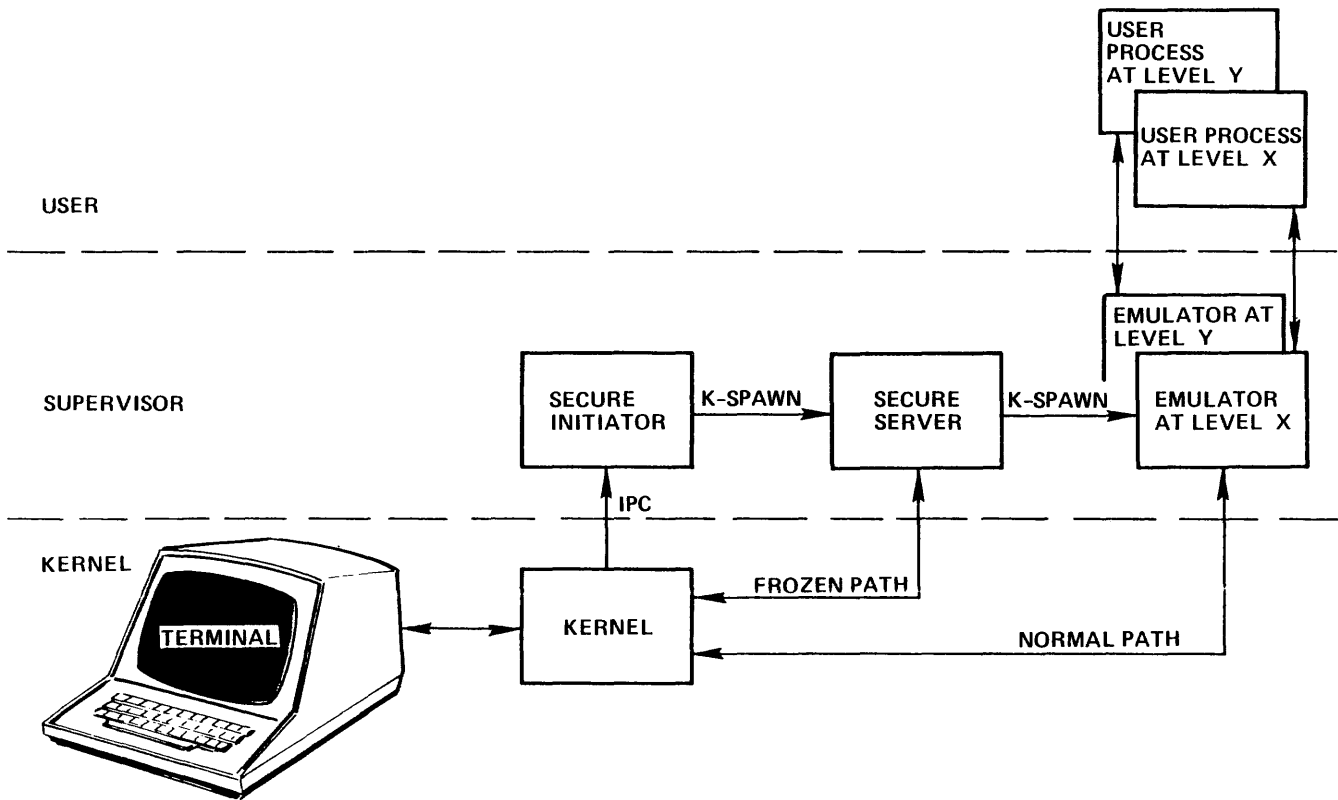

Figure 2—Secure terminal interface.

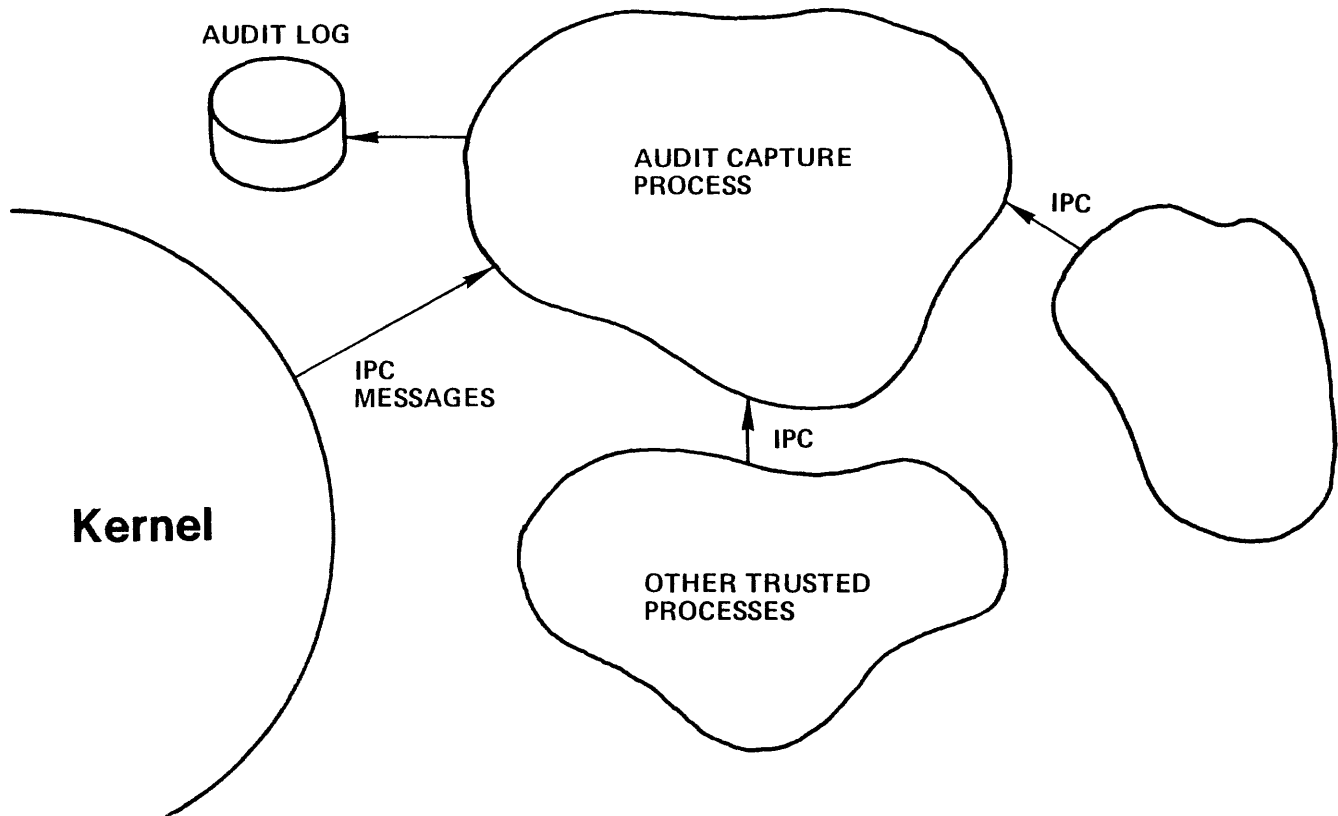

Figure 3—Audit information flow.

other processes via the UNIX pipe mechanism and the `ptrace` system call.

While this view simplifies the Emulator, it is incorrect. At the UNIX interface, a process is indirectly aware of the presence of other members of its "process family" (a process family consists of all the processes that are descendents of the process started at login for a given user). In particular, things like the seek pointers to open files are shared among the members of a process family. Our view of the Emulator now is that it provides an operating system for the process family. The Emulator not only creates the UNIX-level objects from the Kernel-level objects but also provides for controlled sharing of these UNIX-level objects.

It should be remarked that the UNIX interface is perhaps not as "clean" as one would like. There are several subtle ways in which a great deal of the internal mechanization of the system is manifest at the interface. It is debatable whether these things are "bugs" or are "features!"

### UNIX directory management

One of the major functions of the Emulator is the creation of the UNIX file system from the more primitive file system provided by the Kernel. The Emulator caches the block i/o supported by the Kernel to provide the byte stream i/o supported by the UNIX interface. The Emulator also is where UNIX directories are managed. The final design of the UNIX directory management function is the result of a long series of (occasionally heated) debates on where directories would be mechanized. Initially they were to be completely managed by the Emulator. However, this was prior to the birth of the subtype notion, and there was no way to guarantee the integrity of the directory structure. In particular, trusted software could not depend upon the directory structure. Then it was proposed to move part or all of the directory management function into the Kernel. This seemed to solve the integrity problem, but opened a new and more serious problem of making the Kernel cognizant of the structure and semantics of directory files, and thereby making the Kernel very UNIX-specific. Finally, the subtype idea was proposed. The Kernel would know that directories were "special," and would aid in the preservation of their integrity. However, the Kernel would not be aware of the internal structure or semantics of directories.

The current design has the Emulator performing all the directory interpretation functions (i.e. recursively searching for names in directories), but writing directories is only done by the Directory Manager. The Directory Manager is a program that is `K_spawned` into execution whenever an Emulator needs to modify a directory. It starts its life running as the user `dir_mgr` who owns the directory subtype. After getting permission for write access to directory subtyped objects, the Directory Manager reverts its identity to that of the requesting user. From there on, the Kernel will enforce security, integrity and discretionary access checking. Thus, the user cannot trick the Directory Manager into modifying a directory that the user cannot access. This architecture may be criticized as being too slow, since creating a new

process via `K_spawn` is moderately time-consuming. However, measurements on one of our UNIX systems in a software development environment suggest that modification of directories is a fairly infrequent occurrence.

### Computer network support

The Emulator contains the bulk of the support for the computer network interface. Initially, KSOS will "speak" Version 4 of the Transmission Control Protocol (TCP)<sup>12</sup> including the Internet Datagram Layer.<sup>11</sup> This protocol appears to be on its way to becoming a future standard within DoD.

Although no networks presently exist that can handle multiple security levels, this architecture envisages their development and is designed to support them. To support a multi-level network, the Network Daemon would be trusted, so it could handle the multi-level stream to/from the network. The remainder of the TCP functions performed by the Emulator would be untrusted, since they are at only one level.

The basic structure of the KSOS network interface was discussed above, and is illustrated in Figure 4. There is a Network Daemon which handles the Internet Datagram protocol, and enough of the TCP to separate the i/o stream from the network into separate streams for each connection. In each Emulator is the majority of the TCP functionality. All of the functions relating to sequence number maintenance, window maintenance, acknowledgment, and retransmission are in the Emulator. This is possible because these are per connection functions, and need not be globally managed. These two portions of the TCP function communicate using the Kernel-supported IPC mechanisms. The shared segment mechanism is used for bulk data passing, and the event mechanism is used for synchronization, and for "commands" to the TCP Daemon and responses from it.

### The non-Kernel system software

The purpose of this component of the KSOS system is to provide the software tools to support a KSOS system. The Non-Kernel System Software is divided into four groups:

1. *Secure User Services*—Software that manipulates the security levels of users and files. Also included in this class are all functions that require a secure ("unspoofable") path to the service.
2. *System Operation Services*—Software that performs continuing services for the system, such as the Network Daemon, line printer spooling and interuser mail.
3. *System Maintenance Services*—Software that performs occasional services primarily in the area of checking and repairing the consistency of the file system. Also included are the system generation functions. Individual KSOS sites can generate their system to suit the hardware configuration available.
4. *System Administrative Services*—Software that aids

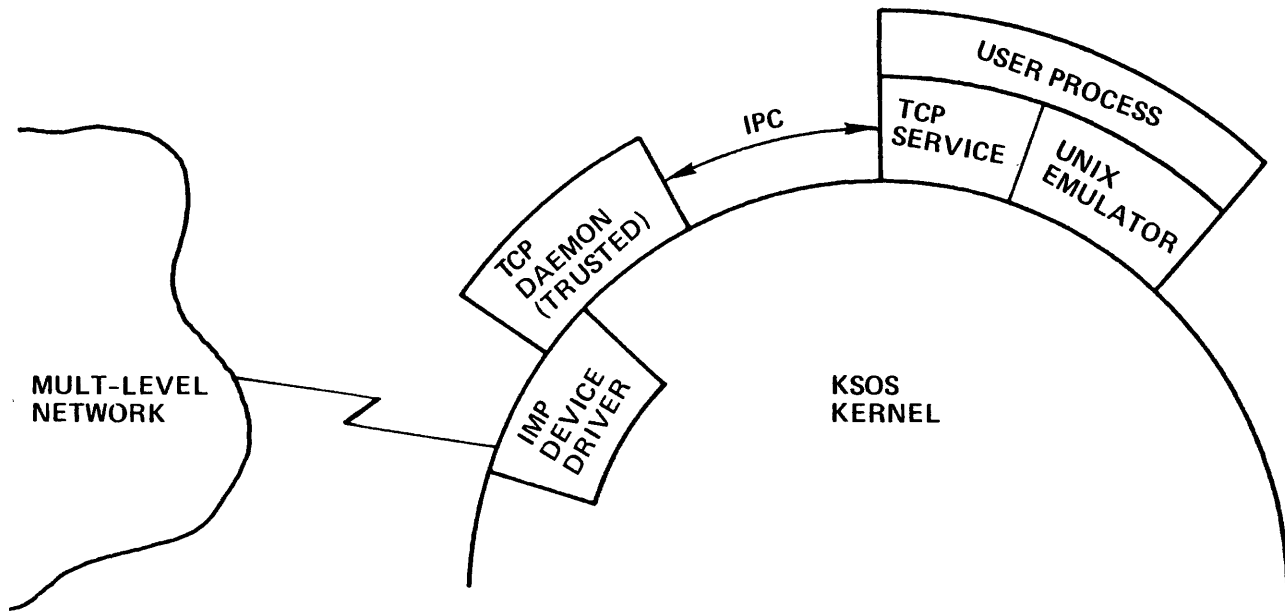

Figure 4—Network interface structure.

the System Administrator in controlling the system. Our goal has been that the System Administrator need not be a computer expert to perform his functions.

The Non-Kernel System Software described is a minimally complete set. Clearly there are large numbers of additional utilities that would be desirable. It is expected that this class will be supplemented extensively as KSOS matures.

#### KSOS APPLICATION CONSIDERATIONS

There are two broad classes of KSOS applications, each with different considerations. The first is applications that utilize the full KSOS system, i.e., applications based upon UNIX. KSOS should appear to these applications to be only slightly different than a standard UNIX operating system. Because KSOS provides a UNIX-like interface, meaningful secure applications can be built using the existing software. UNIX is one of the best systems in existence for the creation of new products by novel combinations of existing packages, and KSOS will preserve this flexibility. Such applications can, however, be made easier in some cases via the direct use of KSOS Kernel calls.

The second class of applications is those which use the Kernel directly without an Emulator. The Kernel provides many features that make it an attractive operating system in its own right. It offers excellent i/o performance, a range of IPC options, and many features that ease the design of multi-level applications. Because the Kernel is "UNIX-flavored" without being heavily UNIX-dependent, it is possible to create application environments that are an amalgamation of the features provided by different operating systems.

KSOS facilitates the creation of encapsulated environments that can be used for a variety of purposes. This

encapsulation allows objects to be manipulated only by software known to perform correctly. In many cases only a small part of a multi-level application actually deals with data at different security levels. By encapsulation of these functions in a small trusted process, it is possible to build multi-level applications that minimize the amount of trusted (and therefore expensive) code.

#### ACKNOWLEDGMENTS

KSOS is being created by an exceptionally talented and dedicated team. It is a pleasure to acknowledge their contributions. The Government team on KSOS also deserves acknowledgment for their efforts to make KSOS a reality. Finally, credit must be given to Ken Thompson and Dennis Ritchie of Bell Laboratories for the creation of UNIX. We still marvel at the sophistication and elegance of their product.

## INTRODUCTION

There has been considerable interest for some time in developing an operating system which could be conclusively shown secure, in the sense that the information stored on behalf of a heterogeneous user population was safely protected from unauthorized access or modification, even in the face of skilled attempts to do so. Early attempts to attain this goal consisted largely of auditing an existing system through attempts at circumventing the controls, and then revising the implementation code to block any successful paths that were found. Unfortunately, this approach failed to produce a secure system, largely because third generation operating systems contain so many errors that "penetration audits" followed by patches inevitably led to a system whose controls were still easily penetrated.

However, there was an even more fundamental limitation to the early approaches, frequently mentioned; testing proves the presence but not the absence of bugs. A more strictly constructive method was required, by which it would be possible conclusively to demonstrate the correctness of the security controls. It was hoped that this goal would result in a much superior system in other respects as well. The experience to be reported here strongly bears out that expectation.

The UCLA Data Secure Unix operating system is intended as a demonstration that verifiable data security with general purpose functionality is attainable today in medium scale computing systems. More specifically, the UCLA system has the characteristic that data security, the assurance that data can not be directly read or modified without specific permission, is enforced via a limited amount of kernel software. High levels of care are being applied to demonstrate that the security properties of that software are correctly implemented. In addition, the system is designed so that confinement can be demonstrated by audit of some additional, isolated code.

To achieve these goals, a number of design and implementation principles have been integrated into a single system. These include a tightly constrained base kernel, a second-level policy kernel, a well known and accepted

operating system interface, implementation in the high-level language Pascal, and application of formal, semi-automated program verification methods to the source code of both kernels.

The system interface is essentially identical to Unix as released by Bell Laboratories,<sup>9</sup> and the software presently runs on DEC PDP-11/45s and PDP-11/70s. The kernel structures and verification procedures, together with the choice of language, provide a powerful means by which the system's security and integrity can be demonstrated and assessed. Support of the Unix interface illustrates the robustness and functionality of the resulting system.

However, the kernel and verification goals imposed significant constraints on the size, complexity and general architecture of the system. The result therefore is quite different from what would have been expected otherwise. System integrity improvement results from the significant reduction in common mechanism operating on behalf of all users, a characteristic that was necessary to make verification and certification of the system practical. Nevertheless, in retrospect, we are unaware of any decision forced by these goals which has not also had the effect of simplifying the system's structure and improving overall reliability and integrity. Significant performance penalties are not expected either. The primary cost in obtaining a secure operating system appears to be found in the care required during design and development.

In the next sections we outline the UCLA Unix architecture, together with explanations for the design choices. Verification and the programming language are also discussed, and illustrative examples of the effects of Unix functionality on the system's operation are given.

## OVERALL ARCHITECTURE OF UCLA UNIX

The UCLA Unix architecture contains a number of major modules, whose relation to one another is suggested by Figure 1. The kernel should be thought of as an operating system nucleus which provides about a dozen primitive operations callable from user processes. That is, the kernel implements a number of abstract types and the valid operations on each type. It is the only module in the system empowered to execute hardware privileged instructions.

\* This research was supported by the Advanced Research Projects Agency of the Department of Defense under Contract MDA 903-77-0211.

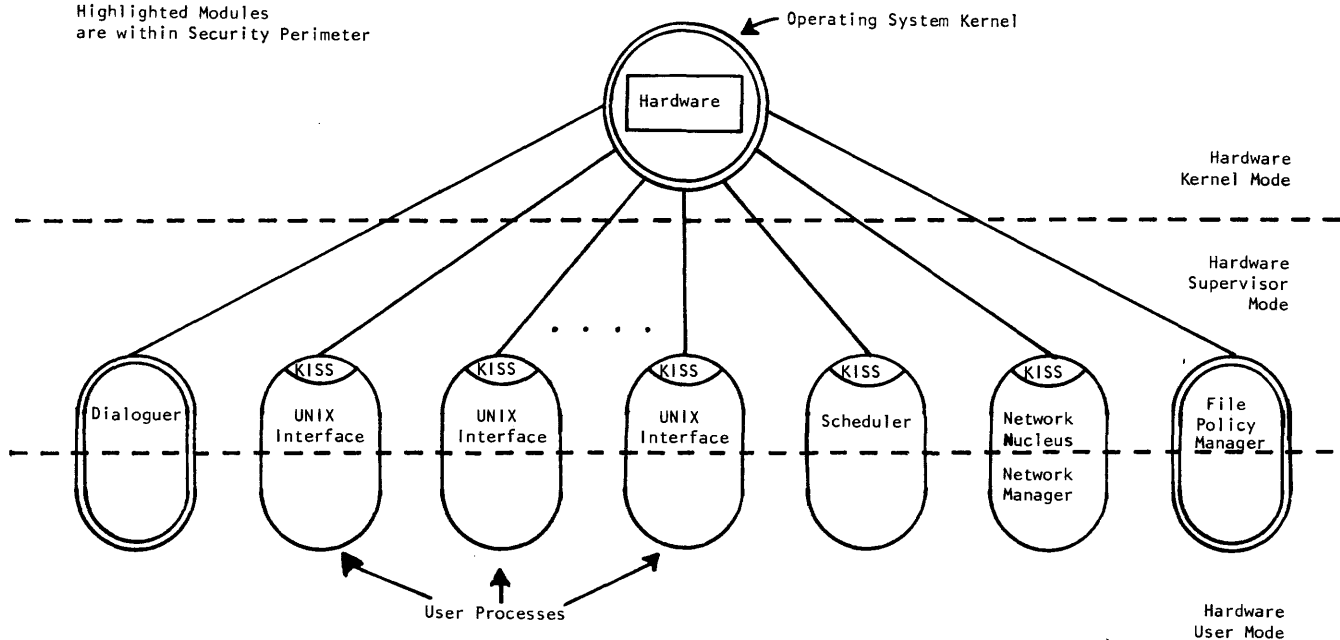

Figure 1—UCLA Secure Unix architecture.

One of the abstract types implemented by the kernel is process. A process contains two address spaces (supervisor and user mode on the large PDP-11s). An operating system interface package resides in one address space. In the other, application code is run. When an application program makes an operating system call, control passes to the O/S package which interprets the call. If necessary, the package issues kernel calls or uses kernel facilities to send messages to other processes to accomplish the needed action. All such calls or messages are controlled by the kernel. Each process is a separate protection domain. The access rights of the domain are represented by capabilities: a C-list for each process is maintained by the kernel.

There are several processes that are special, in that they perform system-related functions. Overall system security depends on the correct operation of two of them.\*\* One, called the policy manager, is the process capable of altering the data upon which protection decisions are made, and is thus the site where various security policies may be implemented. Type extensions to kernel objects, including file systems, typically would also be supported here. In the UCLA system, security policy plus suitable primitives for the Unix file system to support protection of individual files are built in the policy manager process. The second, "dialoguer," process initially owns all terminals (i.e. has capabilities for all of them) and is responsible for user authentication. It tells the policy manager what user is to be associated with a given process.

There is one further process which differs from the typical

\*\* One might say they are within the "security perimeter." Their size is not large compared to the kernel described here. It should be emphasized that the design is such that only software within this security perimeter must be correct to block system penetration.

processes employed for applications programming. However, this one, a scheduler, is not relevant to data security. It contains short-term resource management policy for CPU and main memory: process scheduling, page replacement strategies and the like. UCLA Unix is a demand paged system; when a process page faults, the scheduler is informed by the kernel so that an appropriate swap call may be issued at some later time by the scheduler. All of its security relevant actions are accomplished through kernel instructions, however.

Thus, in normal operation a user first logs into the dialoguer. That process then sends a message to the policy manager, who initializes a process for the user and moves the user terminal to the new process by issuing appropriate capabilities. Process initialization as well as normal computation take place within the domain of the given process. Additional resource requirements or file activity is accomplished through messages to the policy manager. Process switching occurs whenever a given process invokes the scheduler process, or when an appropriate clock interrupt forces such an invoke. The scheduler can then run whatever process it wishes. Page faults also force an invoke of the scheduler, so that it can initiate appropriate page swapping.

#### THE UCLA KERNEL AND ABSTRACT TYPES

The kernel can alternately be viewed as a basic, stripped down operating system or as an implementor of a number of abstract types, together with the operations on those types. One of its more notable features is the fact that a significant number of facilities, normally found in large systems, are included in it despite its very small size and straightforward structure. The basic kernel consists of ap-

proximately 760 lines of Pascal code, not including I/O support. The PDP-11 does not have any channels, so that the functions of channel programs must be written as CPU code. I/O support in the UCLA kernel is composed of two portions: a device-independent internal interface of approximately 300 lines, and as many device-dependent drivers as are required by devices present on a given machine configuration. These are quite small, and for the UCLA installation, supporting many peripherals, approximately 300 lines of code are required altogether. These numbers are relevant because it is intended the entire kernel be subjected to program verification procedures. Given current verification capabilities, and well structured code, this goal is attainable.

The UCLA kernel implements a fixed number of types, the four listed below. Type extensibility as illustrated by CAL-TSS or Hydra is not provided, although simple extensions appear feasible. The implemented types, together with the permitted operations, are discussed below.

### *Processes*

The process object is defined to consist only of the usual state variables plus one small page. It does not include the process virtual memory. As a result, kernel calls such as *Invoke* can be quite simple, merely moving data from tables to CPU registers and vice versa. All process relevant kernel calls are controlled by capabilities. It is not possible to send or receive interprocess communication, for example, unless in each case a capability is present in the process' C-list.

The process abstraction has been carefully developed to permit a large number of processes to be alive—500 on a PDP-11/70 would not be unreasonable. To do so, it is necessary that very little locked down memory be required per process, despite the fact that there are asynchronous events taking place (such as I/O completions and messages from other processes) which can occur when all the memory of a process is swapped out. The process must be informed of these events. However, the obvious solution, kernel queues, are undesirable since they increase verification difficulties, lead to overflow problems when queue space is exhausted and introduce confinement problems. The UCLA kernel avoids this problem by a number of methods, including a generalized page faulting structure and efforts to keep as much per process information as possible in swappable pages allocated to the given process. As a result, very little main storage must be reserved for an active process. Further, the complexities in two level process mappings, as suggested for Multics are avoided.

The operations available for objects of type process are as follows:

- a. *Invoke*
- b. *Initialize*
- c. *Zero-relocation-register*
- d. *Return*
- e. *Send-interrupt\*\*\**
- f. *Set-interrupt\*\*\**

\*\*\* These operations are available for all objects.

*Invoke* moves the state variables of a process into the CPU registers, after first saving those of the currently running process, mostly into one of that process' pages. *Initialize* clears the state variables of a process and grants those few capabilities needed for the process to bootstrap itself. The *Zero-relocation-register* call is used by the process to adjust its virtual memory. The process first sets a data structure in the page shared between it and the kernel to indicate the desired virtual memory page, and then zeroes the associated register, so that the subsequent page fault will cause the kernel eventually to reload the register with the desired value. *Return* is used by a process to change its current site of execution, either giving up control to the scheduler process, checking to see if any interrupts have arrived, or changing from supervisor to user mode. *Set-interrupt* and *Send-interrupt* are used in the system's inter-process communication facility. Both calls give as a parameter the name of an object with which the signal is to be labelled. *Set-interrupt* is used by a process to enable its ability to receive signals labelled with the named object, and *send-interrupt* is the associated inter-process signalling mechanism. *Send-interrupt* also passes a small amount of data, and is the means by which the system supports very low delay inter-process communication (*ipc*). High bandwidth *ipc* is done through shared pages together with this interrupt mechanism.

### *Pages*

Pages are the abstract storage unit supported by the kernel. All pages have a fixed home location on secondary storage, which is not deallocated when the page is swapped into main memory. There are two page sizes in the current implementation, with memory frame sizes set at sysgen time to minimize kernel complexity. In order to access a page, a process must first obtain a capability for the page. Then the process indicates where in its virtual address space the page specified by the capability is to appear. At that point the process can attempt to refer to the page. If it is in core, the hardware register will be loaded and the reference will succeed. If not, the process will page fault, as will be described. Since each page is a separate object, controlled sharing of individual pages is easily done.

The only operations on pages are:

- a. *Swap-in*
- b. *Reflect*
- c. *Free*

“*Swap-in*” copies the secondary storage version of a page into main memory, changing the name of the object associated with that destination page frame to the new page. The secondary storage copy is preserved. “*Reflect*” updates the secondary storage version to match main memory. Neither of these operations gives the caller access to the contents of the page, so that the operation can be issued by untrusted code. “*Free*” deletes a page from main store (only permitted if the secondary storage version is current.†)

† This (trivial) operation is present only so that pages can be moved from place to place in main store. Without “*Free*,” this movement would be more difficult, since the swap call nops when issued if the specified page is already in main store.

To simplify management of physical memory, main memory is divided into two statically allocated regions, one for each page size. That is, one contiguous region in main memory is devoted to small page frames, the other to large page frames. The portion of main memory allocated for each size can be varied at system generation time by changing a compile-time constant.

A similar situation exists for disks, except that the number of regions is variable and changeable at kernel system generation time. A given physical disk unit is broken into an arbitrary number of smaller logical mini-disks. A mini-disk is constrained to contain a fixed number of pages of a given size and object type. Mini-disks, however, are not required to be of uniform size. Hence one mini-disk might have  $X$  small pages, while another mini-disk has  $Y$  small pages. While large and small pages are not allowed to co-exist on the same logical mini-disk, they can easily exist on the same physical disk. This structure simplifies address calculation within the kernel for pages on disk, yet still allows the system manager freedom to rearrange the configuration of large and small segments on the disk to minimize disk seek and transfer times.

Pages have a home address on disk, and the name of a page can be used to determine this home address in a simple way. Main store is simply a disk cache; in-core pages are therefore merely copies of disk pages.

### *Devices*

I/O operations to all devices, including terminals, are controlled by the same capability mechanism as all other operations. However, devices such as terminals are treated as two devices—an input part and an output part. Two capabilities are therefore required to read and write a terminal, but as a result kernel internals are simplified.

Completion interrupts are handled just like any other process notification. All those processes with capabilities to receive interrupts from the device, with interrupts enabled, and with appropriate access, will receive a notification when the device generates it.

The device operations are as follows:

- a. Start-i/o
- b. Completion-interrupt
- c. Status

“Start-i/o” initiates all I/Os except swaps and reflects. The “Completion-interrupt” is the hardware generated call which typically signals completion of a previously started I/O. As an entry point into the kernel, it is little different from any other call. “Status” I/O causes no input/output operation, but returns status of the previously started I/O.

### *Capabilities*

The capability is the basic kernel representation of protection information—which objects a process is entitled to

access. Each process has associated with it a C-list containing those capabilities, stored in pages that can be swapped, but which are directly accessible only to the kernel. §

Each capability consists of four fields. First is the name of the object to which this capability refers. Second are the access rights provided. Next is a “guess” value which the kernel uses to attempt to quickly find the entry in a kernel table which maps the object indicated by the capability to a physical location. In the case of pages, the guess is the index into the kernel page table to the slot where that page entry last appeared. It in fact may have been moved by subsequent Swaps and Reflects, so if the entry does not match, a search of the table is required. That event is relatively rare however. The last field in the capability is of no relevance to the kernel, but can be set via the Grant call. The Policy Manager uses it to record the file descriptor with which the page or device is associated.

The only operation on capabilities is:

- a. Grant/revoke

It adds a specified capability to a specified slot in a specified process’ C-list. What processes can issue this call is also controlled by capabilities.

The operations on capabilities are thus quite limited. Revocation is accomplished by granting the null capability into the C-list slot that contains the capability to be revoked. There is no means by which processes can directly pass capabilities. While this fact limits what can be done with capabilities, it also greatly simplifies many issues and avoids a number of the criticisms of certain capability systems, especially the danger of not knowing how access to an object has propagated. As a result, the kernel can more accurately be viewed as containing no security policy. All such decisions regarding rights transfer, including initial granting of rights, are made only by the software running in the process which has the ability to issue Grants. The Policy Manager is the only such process in UCLA Unix.

The C-list composes a local name space for the process. This name space has two effects. First, through message exchanges with the policy manager, the user has complete control over which C-list slot contains a given capability, thereby permitting local management over the name space. Fabry<sup>1</sup> points out the significant advantages of this facility. Second, kernel names are not visible to user code. Instead, the capability contains that name. Therefore user code, being unaware of the actual object names, cannot use them as a means to breach confinement.

### *Types and operating systems*

Other authors<sup>11</sup> have noted that the usual views of abstract types to be found in programming languages are not quite suitable for operating systems because of finite resources

§ The policy manager is given read access to capability pages so that it need not keep separate track of which capabilities for pages in a file are outstanding. See the discussion of the policy manager for further information.

and circular dependencies. In Multics, for example, the process manager depends on the page abstraction, since the manager is contained in pages, while the page manager is a process and hence depends on the process manager. In a revised design for Multics, abstract types are used in a sophisticated, multiple layered manner to solve these problems.<sup>11</sup>

However, as noted by Gaines,<sup>2</sup> the method required need not involve a sophisticated solution at all, and is largely composed of static allocations. This is the approach embodied in the UCLA kernel. Processes, pages and devices are neither created nor destroyed. There are as many pages as there is space on secondary storage for them. The number of processes is fixed by the size of the kernel process table. Devices are added at system generation time. This static view is not really a limitation, since the Policy Manager reuses process "bodies" and pages by reinitializing them via kernel calls. Many systems include these size limitations anyway, although perhaps not so explicitly. As a result, the kernel type structure is exceedingly simple, and yet robust enough for fairly general operating system activity, as illustrated in the sixth section on Unix functionality. Further, the entire kernel is small enough to be locked down in main memory, in space removed from page management, blocking circular dependencies.

#### *Kernel names*

The names for kernel-supported objects were designed to maintain several important properties with the minimum of mechanisms: a) Unique names for all objects, b) clear knowledge of object types at all times, and c) avoidance as much as possible of complex name to location mappings, which must be maintained by kernel code if object protection is to be at all meaningful. Since these names are not visible to normal user processes, who see only C-list indexes, considerable design freedom was present. Therefore, names were chosen to represent the home location of the object: a page name consists of the disk device and block number. Hence no disk map need be maintained or interrogated by the kernel.

#### *Paging, segmentation and scheduling*

UCLA Unix, unlike standard Unix, is a demand paging system. All user disk I/O, including swapping of the process virtual memory space and file activity, occurs via the paging mechanism.\*

Page faulting is invisible to all processes except the scheduler, which is invoked by the kernel when a fault occurs, so that it can start a swap. There are actually two "faults" involved in accessing pages. The most significant, just described, occurs when a page is not core-resident. The other, called a register fault, occurs when the page is resident but

the relevant page register is null. This case is handled in a highly efficient way—a user map table is checked by the kernel to see which capability (and therefore which page) is desired. The appropriate value is then placed in the register and user execution continues.

All kernel calls which require swappable pages to be in core in order for successful execution first check to see if the necessary pages are indeed available. If not, the call completely unwinds itself (a trivial act, since no kernel table updates are made until all checks complete successfully), the process state is reset as described above, and the scheduler is notified as in any other page fault. Even invoking a process, which requires the page that contains the user's registers, operates in this manner. Thus page faults involving kernel-primitive instructions appear to user processes just as page faults involving hardware implemented instructions (that is, they are completely transparent).

The preceding outline suggests how the UCLA system provides a complete virtual memory and file system with only a simple set of paging primitives in the kernel. This simplicity was achieved by two major decisions. First, the virtual memory facilities were decomposed into that which had to operate correctly in order to maintain the security and integrity of the system (Swap, Reflect, and Completion-interrupt) and the rest of the virtual memory mechanism (page replacement algorithm, interaction with CPU scheduling, etc.). This decision had a significant effect on the system's resulting simplicity. Second, file activity and process memory swapping were combined into one mechanism. In standard Unix, main memory is broken into two areas—one to hold user process images, and the other for I/O buffers. Each area is managed separately. The I/O buffers are replaced in LRU order, while scheduling of process images is handled differently. All disk I/O buffers are the same size, while process images vary. The code used to handle I/O buffers is in large part different from that used to handle the movement of process images, and significant parts of both collections of code are important to the system's security and integrity.

In UCLA Unix, only one mechanism, paging, exists, and much of its support has been moved out into a scheduler which can not affect the integrity of the system. As explained earlier in the section on capabilities, the user domain also carries some of the responsibility for virtual memory management. By placing some of the responsibilities in the domain for which the action is being taken, error propagation is further limited. Application code is of course unaware of that responsibility, since the O/S interface is performing the task.

#### *Firmware implementation*

The UCLA kernel has been developed to be a candidate for firmware implementation. To be practical, it is helpful if each call behaves as much as possible as a separate instruction, with no need to be interrupted in execution, nor to issue I/O calls for which the results affect the instruction's behavior, since I/O is typically slow relative to micropro-

\* A physical disk can alternately be treated as a device, and Start-I/Os issued to it. However, a disk treated in this manner cannot also hold pages.

gram cycle speeds. These criteria are met by the UCLA kernel. Therefore, it differs significantly from architectures such as Multics or related work.<sup>6,7</sup> In both of those systems all of the operating system, including inner rings in Multics and kernel software in the case of MITRE, must be considered as part of the user process. Any process can be suspended in the middle of execution in the inner ring or kernel mode, respectively. Neither of those systems lend themselves to firmware considerations, the MITRE work because of the architecture, and Multics because of its size and architecture.

### *Verification impacts*

Verification of a full scale operating system is a multistep process, and the methods employed at UCLA are outlined by Popek,<sup>8</sup> with more detail available from Kemmerer.<sup>9</sup> The effect that the verification and certification goals had on the system architecture was exceedingly positive. Often a design choice presented itself, without any clear basis for resolution except maximizing verification ease. In retrospect this criterion was quite effective in making decisions and avoiding design pitfalls. Further, when it became clear subsequent to implementation of certain parts of the system that verification would be difficult, those portions were redeveloped. A good example of this case will be outlined in the section on I/O Interfaces.

### **Sequential code**

The current state of verification tools does not permit proof of parallel programs. Since semi-automated aids are, in our view, essential, this constraint implied a kernel design and implementation in which each call ran from start to completion without interruption, including the interrupt handlers. The UCLA kernel is built in this way, and so most of it can be proven by standard verification methods.

The cost of this design choice results from delayed servicing of interrupts which arrive while a kernel call is in progress. To minimize this problem, each call is designed to run very quickly—approximately one millisecond or less. To do so, no kernel call may do I/O of its own while in the midst of execution, since virtually all devices respond rather slowly relative to this criterion. While millisecond delays in interrupt servicing may not be suitable for heavy real time activity, it appears quite acceptable for interactive systems, which is the nature of Unix.

### **I/O Interface**

The PDP-11 does not have any significant channels: instead the device registers are wired into physical address locations and "channel" functions are executed by CPU code. Since all devices address main memory (and secondary storage) in terms of absolute addresses, I/O management is therefore necessarily a kernel responsibility. This is un-

fortunate, for several reasons. First, device semantics are quite complex and difficult to interface with the semantics of the programming language in which kernel code is written. Next, devices are probably the single largest source of changes to the kernel, since as new types of devices are added, additional verified kernel code is required to manage the device's actions. To minimize the impact of these problems, kernel I/O code was redesigned to provide a device independent level of I/O abstraction within the kernel. Code above that level is not concerned with any of the device details. Code below it implements device dependent issues, including any device dependent protection controls. The I/O abstraction level appears similar to a channel interface, with well defined opcodes and operands.

This I/O abstraction level is quite important, likely more so than the process abstractions mentioned by other authors, since at least half of the operating system kernel is concerned with I/O.<sup>11,6</sup> As a result of its use, device semantics have been isolated to the low-level drivers. See Walker<sup>12</sup> for more information.

### **THE POLICY MANAGER**

The Policy Manager is the major security relevant process in UCLA Unix. It is responsible for implementing a shared file system, for maintaining whatever security policy is to be supported by the system, and for part of the action of process initialization, which occurs every time a Unix fork operation takes place. Each of these issues is discussed below. Long term resource allocation can also be implemented in this process, but currently is not.

### *The file system and protection policy*

User code must see a file structure which is identical to the Unix tree of directories. However, one should not immediately conclude that the entire directory structure and other file support should be implemented in trusted code. In fact, one can make the following argument, largely independent of the security policy to be enforced.

Most code to be run in the user domain strictly should not be trusted to be correct, at least not to the same standards as the verified secure kernel and policy manager. However, all names, including file names, are either issued, interpreted or transmitted through that code. Therefore, it makes little sense to verify the directory-naming scheme of a file system when significant amounts of unverified code issue the names or are in the path leading to the file system. The best one can do, it appears, is to provide the user with a reliable means to specify a process profile which characterizes the categories of files to which the process is to be allowed access. Profile specification and alterations, together with the association of labels with the file on which categories are based, must therefore be done in a guaranteed reliable way if the verified protection and integrity of the entire operating system is to have any meaning. That necessary secure terminal facility will be discussed in the seventh section.

The file protection labels provided in UCLA Unix consist of a very large variety of "colors." Each file can be labelled with some number of them. Each user (principal in Saltzer's terminology<sup>10</sup>) has a fixed color list associated with him. It is understood that a user potentially can access a file only if his color list covers that of the file. The actual profile for a running process can be set to any subset of the user's color list. There is a separate profile for read and write.

Since there are a large number of colors, many of the usual protection policies can be implemented using them. Public files are labelled with the color `public` and all users have that color in their list. Denning has noted that military security policy is essentially a lattice, and that the relations of sets and subsets provides just the lattice required. Individual file names are had by assigning a given color to a single file. This color system is still evolving as experience is gained with the user protection interface, especially in the area of control over changes to color lists. Additional detail is provided by Urban.<sup>14</sup>

Given the preceding view of file system protection, one can profitably decompose its implementation into two parts, one a common mechanism relevant to security and integrity, the other executable in the domain of the requesting user process. The common mechanism can support a simple, flat file system. Files are the only significant data type, and a color list is one of the attributes of a file. The simple file system mechanism must include complete space management—disk-free lists and maps specifying which pages belong to which files, together with software to manage these data structures.

Many of the facilities normally thought of as part of the file system can be provided by software in the individual process domains as part of the O/S interface—directory structure, maintenance and searching; end of file indicators and other file status information such as usage locks. Directories are then contained in files, and access to directories is controlled in the same way as access to any other files. Assuming that the common mechanism in the policy manager is verified correct, users can affect one another only through the use of files to which they share access. Once again one expects system integrity to be further enhanced, as errors in higher level file system code are confined to the domain in which they occur.

#### *Process initialization and forking*

The policy manager must also be involved when new processes are created, since a kernel process body must be initialized and appropriate capabilities need to be granted to the new process. As much as possible however, one wishes process bootstrapping to take place within the domain of the new process. In UCLA Unix, the normal procedure for process forking is as follows. The requesting process sends a message to the Policy Manager requesting the new process as a member of the same user family. The Policy Manager records the user to be associated with the new process and issues a kernel `Initialize` call, which zeroes a process body, grants two capabilities to that process, and sets the program

counter and status to standard values. The capabilities point to a standard boot code page and the `arg-block` page respectively.\*\* A third capability is granted by the policy manager upon process request to give the process the ability to communicate with its forking parent. From here on, initialization takes place wholly in the domain of the new process. The process begins by attempting to execute its boot code, which may cause a page fault. These are handled normally. Eventually the boot code will load the O/S interface and presumably a Unix Shell into its address spaces.

#### *Other policy manager responsibilities*

In UCLA Unix, the Policy Manager is also responsible for control over access to the other kernel-supported objects besides pages—processes and devices. Devices appear as special files and inter-process communication takes place through pages (which appear as part of a file). Therefore, colors are uniformly employed for access control in these cases too.

An ARPANET connection is provided in UCLA Unix; access to it must be controlled and support for initial network connection activities is required. Capability based encryption is used to protect each connection individually. See the section on Secure Computer Networks.

## THE KERNEL INTERFACE SUBSYSTEM

Since the kernel is an operating system nucleus of minimum size and complexity, one can properly expect that it is not a convenient base to build on. Traditional systems provide a good deal of "extension" for convenience. While at first glance the O/S interface has this responsibility, it should be noted that a considerable amount of code is written to run directly on top of the kernel—the O/S interface, the network manager, process initialization, and the scheduler, for example. Each of these need basically the same extensions—capability management, inter-process communication support, virtual memory code, and some file system interfaces. Therefore we have developed an intermediate interface between the O/S interface and the kernel. The software which implements it provides a much more convenient interface to the kernel and is called the Kernel Interface SubSystem (KISS). As an extension mechanism, the KISS manages the entire environment of the process. In general, no other code in the process makes kernel calls, sends messages to the scheduler or policy manager, etc. Thus this software package has primary responsibility for maintaining a convenient "virtual machine" for the user process.

The KISS of course runs as part of the user process domain, and is architecturally contained in the same address

\*\* The boot code is actually the Kernel Interface SubSystem discussed in the fifth section. The `arg-block` page is read/write shared between the process and the kernel, and serves as the means for passing arguments and return values for kernel calls.

space of the process as the O/S interface. The KISS can be viewed as an inner ring in the sense of Multics, and if appropriate hardware were available, that would be an effective means of implementation.

## THE UNIX INTERFACE

The operating system interface has the responsibility of providing a user program interface which is as much as possible identical to standard Unix.\*\*\* It handles user system calls either by performing them itself if possible, or making the appropriate kernel calls for service requests to the policy manager to get the desired action accomplished. Parts of the Unix O/S interface are actually composed of code from the standard Unix operating system. Most of the changes consist of wholesale deletions of functions, resulting from the fact that many of those functions are redundant given the available kernel facilities and the fact that the O/S interface is essentially a single user system. All scheduling support could be removed, since scheduling is done in a separate process. A more drastic change concerns I/O buffering. In standard Unix, buffers contain significant structure to aid in multiuser and LRU operation. In UCLA Unix, most of that function disappears since it is done by the paging mechanism supported by the kernel and scheduler. I/O support is replaced in the O/S interface by code that requests file opens and relevant page capabilities from the Policy Manager, and maps those pages to the interface's virtual memory. Then the interface merely tries to reference data on the page to move it to the user, and the usual page faulting and swapping action takes place.

New code in the interface largely consists of the KISS, changes to the interface/KISS boundary, ipc support, and maintenance of the process hierarchy. This last issue will now be discussed.

### *The file system*

The Unix interface has a significant portion of the responsibility for making the user view of the file system equivalent to standard Unix. This task consists of all directory support, including searching, working directory control and the like. Once the desired logical file name is found in a directory, a file open request of the policy manager can be made using that name.† Directory searches are done by first opening the containing file, like any other. It is the responsibility of the Unix interface to manage its open files in such a way as to keep the working directory open most of the time to minimize search costs.

\*\*\* There are certain actions possible in standard Unix which will be blocked by the security policy of the secure system.

† The logical file name is essentially an inode number. (Pointer to file descriptor in the Unix file system.)

### *Forking and process hierarchies*

In standard Unix, a given user can have a process family active for him. The family is hierarchical in the sense that parents have certain rights over children. However, intra-family protection is not really effective, since any member of a family can convince any other member to destroy itself, and to take other undesirable actions, via standard Unix functions.

Therefore, process hierarchies should not be supported by kernel code, and so in UCLA Unix, members of a process family cooperate among themselves to effect family behavior. Of course, the support for process families is provided in the O/S interface, so that user software need not be concerned. This design choice simplified the kernel, and in light of the observations just made, had little or no effect on the actual protection functionality provided.

In the implementation, each process of a family has a capability for a shared page, set up by family members. In that page, data structures are maintained by the O/S interface so that intra-family relationships are properly supported. In doing so, the kernel notification facility is used to great advantage. Unix typically performs a great deal of "one to  $n$ " notification—one process issuing a signal intended for the rest of the family. The kernel Send-interrupt call is designed to support this behavior efficiently, as well as to be adaptable for other uses.

## SECURE USER INTERFACE

In order for any user to have assurance that the protection controls of a system are operating in the manner desired, it is crucial that he be sure of the values to which protection policy data have been set. Further, when login takes place, there is an issue of mutual authentication: the user wishes to be sure that he is interacting with the secure system interface, not some clever user simulation of it which collects passwords. For both of these reasons, UCLA Unix contains a small dialoguer process to which the user terminal can be reliably connected. The user causes his terminal to be switched to the dialoguer by typing a predefined sequence of break characters.§ The kernel supports the terminal switch through maintenance of a terminal state. A terminal can be thawed or frozen. Capabilities are granted by the Policy Manager giving access to terminals only when thawed, or only when frozen. When the break sequence is detected, or when a line drop occurs, the line is marked frozen. The Policy Manager grants frozen access only to the dialoguer, thawed access in all other cases. In this way, the user can move his terminal to the dialoguer, accomplish whatever change is desired, such as changing process profiles, and then move the terminal back, all without disturbing the state of computation of the process at all so that it can be continued.

§ Kernel recognition of the break sequence is not expensive since PDP-11 hardware requires character by character terminal input handling anyway.

## THE SCHEDULER

Whenever it is time for a process invocation decision to be made, the Scheduler is invoked, either directly by a user process (i.e. when it wishes to sleep) or by a clock interrupt. The kernel makes available a considerable amount of system data through a pseudo device, so that the scheduler can make sophisticated resource allocation decisions, about both memory and the CPU. Centralizing both classes of resource control permits effective coordination of allocation decisions and therefore potentially higher performance. A large class of scheduling policies can be implemented in this process. Some of them have confinement implications but provide better performance potential than those which do not. This architecture permits the system operator to make the confinement/performance tradeoff, since there is no kernel effect from scheduling policy changes.

The one potential drawback of a separate scheduler process is that it doubles the actual number of process invocations over what is really needed. This overhead is of little consequence if context switches are relatively cheap, not really the case for UCLA Unix.\*

## SECURE COMPUTER NETWORKS

When security is of concern in a computer network, encryption of the lines is generally a necessity, because those lines are not considered safe from tapping or spoofing. However, the usual approach is to encrypt and decrypt the data external to the central machine and its operating system.

It should be recognized that the software resident within the operating system responsible for managing the network is both complex and relevant to security and integrity. In standard Unix with an ARPANET Network Control Program (NCP), the NCP, operating as a common mechanism, is of comparable size and complexity to the whole operating system.\*\* Typically, one wishes to protect each network connection separately from each other connection, but the NCP manages them all, including moving data from user buffers through the NCP and out to the network interface device.

Given the availability of a secure operating system, one can entertain the idea of extending the "ends" of the encryption path deep into the operating system. For example, the user process, as it hands data over to the NCP, could be forced to cause the data to be encrypted, so the network software is treated merely as part of the insecure transmission channel. That data would not be decrypted until the receiving NCP handed it over to the destination user. If each

\* Context switches on the PDP-11 are in general fairly slow. Therefore, the scheduler is to be changed so that it is not invoked at every process switch, but instead periodically gives the kernel advice about which processes are to be run. In this way, most of the scheduling algorithms remain out of the kernel, but the additional overhead of having two context switches per (desired) context switch is eliminated. That work was not done when this paper was authored.

\*\* The NCP being considered was developed at the University of Illinois.

connection were encrypted with a separate key, then NCP errors and misdelivery within the host operating system would not affect security. If suitable error correction is incorporated with the encryption, then integrity problems can also be detected.

The main problem in this approach is the initial connection establishment protocol—how to permit users to supply the NCP with parameters telling which site and what type of connection should be established, without large confinement channels in the system. For a discussion of these and related issues, see Kline.<sup>4</sup> The method of solution outlined there has been implemented in UCLA Unix. The additional kernel code to support secure network operation was quite small. Further, most of the original NCP was kept unmodified, although its lower level was altered to match the kernel interface.\*\*\*

## PROGRAMMING LANGUAGE ISSUES

The programming language employed in software development is usually recognized to have a significant effect on that effort; however when the goal of development includes verification, the effect is heightened. The specific language issues break down here into two groups—those concerned with systems programming, and those concerned with the scale of the verification steps.

Systems programming issues arise in the same way that they occur in most high-level systems programming languages. It is necessary to be able to express details of the hardware in the high-level language, such as interrupt vectors, hardware device registers, or special instructions. These facilities must be available in the programming language, but in a way that minimizes the effect on the semantics of the rest of the language.

Virtually all the security and integrity relevant code in UCLA Unix is written in a slightly altered Pascal. Obvious verification problems were removed from the language, such as pointers, variant records and various sources of aliasing.<sup>5</sup> I/O facilities were also deleted, since we were building I/O mechanisms, among other functions. The run-time package needed to support Pascal I/O would have been useless baggage, and since it typically would be written in assembly code there would be little chance of ever verifying properties of its operation.

It was also necessary however to add features to Pascal to permit systems programming, as remarked above. Very few additions were actually necessary, and were limited to the following:

1. The ability to declare a variable to be stored at a fixed physical location (to initialize interrupt vectors, access device control registers, etc).
2. Assembly language procedures (so that special hardware instructions could be expressed as a procedure call).

\*\*\* The Illinois NCP "kernel" was rewritten.

3. The ability to have procedures which take array parameters whose length is determined at call time (to remedy the most significant limitation of Pascal).

We also developed an extensive library system to support independent compilation of program modules, and yet force type integrity across module boundaries. The compiler and library system force recompilation of modules when needed for compatibility with another module which has been altered. This facility is needed since the verification work depends on type enforcement. The language, compiler, and library system are discussed by Walton.<sup>13</sup>

There are many issues concerned with the scale of the verification effort. It is believed that over half of the original verification effort could be avoided if the language contained more reasonable controls over aspects of program behavior. One of the more obvious examples concerns the integrity of global variables. An important portion of the assertions to be verified state that most of the kernel variables have not been altered by the routine being considered. (After all, much of the statement of security concerns what is not to happen.) These assertions, in the form of a large invariant, could be simply handled by scope controls in the language, such as the Import/Export lists of Euclid.<sup>5</sup> Then compile time enforcement could be employed and the verification task correspondingly simplified. UCLA Pascal has been modified to provide Import Lists.

Another example where the verification task can be eased concerns array bounds checking. In Pascal, many subscripts can easily be out of range, and therefore potentially reference data other than the given array, violating type rules. There are four reasonable ways to deal with this problem—subscript checking could be done by hardware, by runtime software generated by the compiler, by runtime software explicitly inserted by the programmer, or it could be verified in many cases that subscripts do not get out of range. The PDP-11 hardware base does not provide any reasonable way to itself check subscript references.<sup>†</sup> The UCLA Pascal compiler does not implement array checking code. Therefore, a combination of the remaining choices were taken. The resulting assertions which need to be proven compose a significant fraction of the total verification to be done. Clearly here is a fertile area for language support or enhanced verification tools.

### ARCHITECTURAL OBSERVATIONS

UCLA Unix comprises the first verifiably secure, full functionality operating system with a fine grain of protection. The experience gained in its design and development

led us to several conclusions. Most obvious, secure operating systems are feasible to develop, although the development cost is likely to be considerably greater than if highly reliable security and integrity were not such a serious goal. However, the result is a system which appears to exhibit considerably enhanced reliability and integrity, and because of the strict modularity, is easier to modify. Performance does not appear to be seriously affected by the architectural constraints imposed by the various goals. That is, the net result of the security goal seems to be a better system in general.

It should be noted, however, that one of the central ideas to the success of the work, kernel-structured architectures, requires considerable rethinking of the usual operating system architecture views if it is to be effectively employed. Much of the standard operating system wisdoms must be reexamined, or the result will be a "kernel" that is in fact overly complex and not suitable for a rigorous demonstration of correct security and integrity enforcement.

In conclusion, it appears that the goal of obtaining secure operating systems, at least for centralized, medium scale machines, has been largely reduced to (high quality) engineering, with the most significant progress required in program verification.

# KSOS—Development methodology for a secure operating system\*

by T. A. BERSON and G. L. BARKSDALE, JR.

Ford Aerospace & Communications Corporation  
Palo Alto, California

## INTRODUCTION

The goal of the Department of Defense Kernelized Secure Operating System (KSOS) project is to design, implement and prove a secure operating system. Specifically, it is desired that KSOS be designed and proven to enforce a security model, derived from the security practices of the Department of Defense, referred to as "multilevel security."

The proof required for KSOS is rigorous proof in the mathematical sense. The necessity of preparing for proof of a program so large and complex as an operating system has led to the adaptation and, where necessary, development of design and implementation methodologies for KSOS which are departures from the usual methods of systems programming. Specifically, KSOS has required formal specification of operation system design, automatic theorem generation, automatic theorem proof, selection and use of a verifiable programming language, and verification of operating system programs. KSOS represents the first industrial application of many of these techniques, and is breaking new ground in the construction and proof of large scale computer systems. This paper describes what methods were chosen for KSOS and how they are being applied.

## BACKGROUND—THE MODEL AND THE SYSTEM ARCHITECTURE

The multilevel security model attaches a tag known as an *access level* to every object managed by the system and places constraints upon the valid relationships between the access levels of interacting objects.

The design of KSOS has been described in detail elsewhere.<sup>1-5</sup> A brief description of its architecture provides sufficient background for a discussion of the methodology. A KSOS system is comprised of

1. A kernel,<sup>2</sup> which performs operating system functions and which has the responsibility of enforcing the se-

curity policy. The object types supported by the KSOS Kernel are processes, process segments, files, devices and subtypes. The Kernel is motivated to perform actions upon these objects by sequences of calls to the routines which the Kernel provides at its interface with the rest of the system. An important mechanism for enforcing the security policy is provided by comparisons, made at kernel call time, between the access levels of the caller and of the objects the caller seeks to manipulate.

2. An emulator,<sup>4</sup> which uses the facilities of the Kernel to fabricate an (arbitrary) environment for user programs. The emulator being prepared initially for KSOS emulates the UNIX\*\* operating system.<sup>6</sup> The use of an emulator is convenient for applications which seek to exploit existing software, but is not strictly necessary. The KSOS design envisages that certain applications will make direct use of Kernel facilities.
3. Support software<sup>5</sup> to aid in the day-to-day operation of the system, (e.g. secure spoolers for line printer output, dump/restore programs, portions of the interface to a packet-switched communications network, etc). These are collectively referred to as "Non-Kernel System Software" (NKSS). Because of its varied responsibilities, portions of the NKSS must from time-to-time be allowed to violate the security model in order to operate correctly. These portions are referred to as *privileged NKSS*. To a large extent, they represent a mismatch between the idealizations of the multilevel security model and the practical needs of a real user environment. The design of KSOS allows for these violations but seeks to minimize them by providing for the economical definition of finely grained privileges and mechanism for Kernel security support of user defined extended types.<sup>7</sup>

The KSOS components for which proof is required are those which are responsible for enforcing the multilevel security model, i.e. the Kernel itself and those portions of the privileged NKSS.

The remainder of this paper is organized around a schema

\* The work described in this paper was performed under ARPA Order 3319, Contract MDA903-77-C-0333 administered by the Defense Supply Service, Washington. The opinions expressed are those of the authors and not necessarily those of the Government or Ford Aerospace.

\*\* UNIX and PWB/UNIX are trademarks of the Bell System.

for the construction of provable systems. Initially only a brief overview of the schema is presented. This is followed by an elaboration of each step of the schema, first in general terms and then in terms of its impact upon KSOS methodology.

CONSTRUCTION OF PROVABLE SYSTEMS

Figure 1 illustrates a general schema which, in principle, can be used to construct proofs that systems conform to arbitrary policies. It will be seen that the overall proof is constructed from two sub-proofs, namely

- P1—Proof that the system design conforms to the desired policy (property).
- P2—Proof that the implementation conforms to the proven design.

From these there follows

- P3—Proof that the implementation conforms to the desired policy.

Successful application of this schema requires that a great many careful preparations be made before the proofs are attempted. The various methodologies adopted for KSOS were chosen to ease the burden of these preparations. These methodologies have so far been useful in this role. In addition, the discipline of following rigorous design methodologies has yielded software engineering benefits which were unanticipated at the time the methodologies were adopted. These will be discussed in more detail below.

FORMAL STATEMENT OF DESIRED PROPERTY

Consider first those preparations involving the desired property of the design. Generally, there exists some informal statement of this property. Informal statements, written in natural language, are designed and may be adequate for human interpretation. They are however unsuitable as a touchstone for mathematical proof as they lack sufficient precision and are not in an easily manipulatable form. The informal statement of the property must therefore be con-

verted into a suitable formal statement. Great care is required at this stage to ensure that the formal statement accurately and adequately represents the intention of the informal statement.

In the case of KSOS, informal statements of the desired security property are to be found in regulatory documents.<sup>8,9</sup> These informal statements embody an intuitive notion of military security policy. They are widely applied and well understood. A mathematical model approximating this policy was developed by Bell and LaPadula.<sup>10</sup> This model has been utilized as a formal policy statement in the design and verification of a security kernel<sup>11</sup> during a project which was a predecessor to the present KSOS project. Another similar model was described by Walter.<sup>12</sup> The formal policy statement being used for KSOS was prepared by generalizing from these two models and formulating the generalization in terms amenable to proof. A informal description of the model may be found in a companion paper.<sup>5</sup> Full details of the KSOS formal statement are shown in Reference 13.

FORMAL SPECIFICATION OF SYSTEM DESIGN

The next step in construction of a provable system is expression of the system design in a fashion which is suitable for the construction of a proof. Such an expression is referred to as the system's *formal specification*. A formal specification may be viewed as a set of equations which describe the possible "states" of the system.

Viewed this way, the preparation of formal specifications is not attractive to system designers. There are two main problems. The first is that the sort of state abstraction required to formulate the equation set is not the same sort of functional or data abstraction in which the designer is trained and which (following tradition) he would otherwise use to express his design. The second problem is that adequately detailed specification of useful systems requires a large and unwieldy set of equations throughout which it is difficult to maintain consistency.

*Hierarchical development methodology*

Fortunately both problems may be alleviated by use of appropriate computer-based techniques. The techniques chosen for use in KSOS are embodied in SRI International's Hierarchical Development Methodology (HDM).<sup>14-16</sup> HDM addresses formal specification problems by providing mechanization for each of a series of steps required for system design and production. These steps are the decomposition of a design into a partially ordered hierarchy of modules, the specification of each module, the specification of the interfaces and mappings between modules and, eventually, the proof. All of these functions are performed by an integrated collection of supporting programs.

In HDM as used for KSOS, each module is considered to represent an incremental abstract machine. This is implemented upon the abstract machines coming below it in the hierarchy. Each module is specified in terms of the data

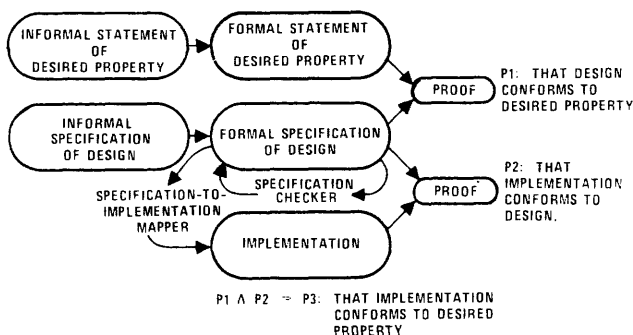

Figure 1—Schema for the construction of provable systems.

types it manipulates, and in terms of functions. There are several kinds of functions. Primitive V-functions represent the state of the abstract machine. They have a value. Derived V-functions also have a value which is computed from the value(s) of primitive V-functions. O-functions represent operations upon the state of the abstract machine by specifying how the machine's state *after* the operation is related to the machine's state *before* the operation. OV-functions combine operation and state. This model of functional decomposition follows roughly from the early ideas of Parnas.<sup>17</sup> A large reduction in the problems of abstraction is due to this model.

The abstract machines are specified in a nonprocedural language called SPECIAL (for SPECification and Assertion Language).<sup>18</sup> SPECIAL has the advantageous property that the effects of a computation may be specified independently from that computation's implementation. This is a vital precondition to design proof (P1 in Figure 1). In addition, this property allows the designer to concentrate upon the structure and functionality of his system, and to defer decisions about data representation and even algorithm choice until implementation. SPECIAL is supported in HDM by a language processor, called the Specification Checker. This provides a number of largely syntactic tests which aid the designer in maintaining consistency of definition within individual modules and throughout a hierarchy of modules.

#### Formal specification of KSOS

The externally visible design of the KSOS kernel was decomposed and specified using HDM. Twenty modules were used to establish and support the functionality of the kernel interface. The hierarchy of these modules is shown in Figure 2. Each of these modules has been specified in sufficient detail to allow all the externally visible effects of each kernel call, or of any sequence of kernel calls, to be determined by inspection of the specifications. The size of

each module is dependent upon the nature of its abstraction and the ease of specifying how that abstraction might be produced in terms of functions available from lower level abstractions.

There are 34 KSOS Kernel calls. The specification of the kernel's visible actions contains the definition of about 240 functions, comprised of roughly 3000 lines of SPECIAL. The complete formal specifications of the KSOS Kernel have been published in Reference 2, and those of the privileged portions of the NKSS in Reference 3.

A small example (the single function SEGrendezvous) taken from the Kernel formal specifications is included as Figure 3 to give the reader exposure to the style and content of the work. SEGrendezvous is part of the mechanization of shared segments. The function is a derived V-function. It returns a value computed from the values of other V-functions. It takes three parameters, pSeid, rdvSeid, and da. The names "seid," "daType," and "RdvType" are user-defined type names. The semantics of SPECIAL call for the EXCEPTIONS to be evaluated in turn. If any of them are found to be TRUE, its associated label is "returned" as an error value and no further EXCEPTIONS are checked. If all of the EXCEPTIONS are FALSE the return value, segSeid, is calculated according to the specification in the DERIVATION section of the function.

Stated in slightly different terms, the precondition of a SPECIAL function is the conditional conjunction of the negations of its EXCEPTIONS. The postcondition of a SPECIAL function depends upon the type of function being considered. In the case of derived V-functions (such as this example) the postcondition is the DERIVATION. In the case of O-functions, the postcondition is the conjunction of the function's EFFECTS.

#### Drawbacks and benefits of formal specifications

It is unfortunately true that the formal specifications of KSOS are difficult to read. This point is amply illustrated by Figure 3. Their poor reliability is due in part to the syntax of the SPECIAL language, and in part to the specification style adopted (style continues to evolve: see Reference 19). The specifications are nevertheless popular with KSOS designers and implementors. This is because they provide a medium in which design decisions can be expressed, discussed and recorded with precision and with assured continuation of design consistency. The designers and implementors communicate effectively in terms of the formal specifications. This is certainly a major benefit and it was unanticipated when the methodology was adopted.

Additional unanticipated benefits derive from the constraint of working with a hierarchical decomposition. We have found it extremely difficult to make a clean decomposition and formal specification of a kludge. On several occasions during work on KSOS, difficulty in formulating a specification for a design has encouraged prompt reexamination and subsequent simplification of that design. In other words, formal specifications help designers to understand and evaluate their product.

LEVEL	NAME	ABSTRACTIONS
19	KER	kernel call interface
18	SPF	special functions
17	PRO	process operators
16	IPC	interprocess communication
15	FCA	file capabilities, open files
14	SUB	file subtypes, type extension
13	MFS	mountable file systems
12	PST	process state
11	PVM	process virtual memory
10	SEG	segments
9	FIL	file contents
8	FST	file state
7	SMX	security model
6	PRV	privilege control
5	DIF	device independent functions
4	TII	object type independent information
3	SYL	system level
2	SEN	secure entity names, system namespace
1	DIF	device dependent functions
0	MAC	machine

## DESIGN PROOF

Consider now the next step in the provable system schema—the proof that the design conforms to the desired property. Slightly more rigorously, we wish to prove that the formal specification of the design implies the formal statement of the desired property. In practice, this inference is not proven directly. Instead, the formal specifications are processed to generate formulas relating the states of the specified design to the desired property. An attempt is then made to prove these formulas. For KSOS, the generated formulas are such that, for each specified function, the access levels of the objects manipulated are related to the access level of manipulator in accordance with the formal statement of the security policy. The formulas themselves take the form of inequalities upon access levels.

The formula generator has information about the computational model of HDM and about the "semantics" of SPECIAL. It also has implicit information about the formal model of security. An anticipated generalization of the formula generator would accommodate arbitrary formal models, perhaps expressed in SPECIAL.

KSOS exhibits considerable novelty in its use of an automatic design proof environment. During a predecessor project,<sup>11</sup> the generation of formulas and their proof as design theorems was done manually. This manual work was labor intensive and mind-numbing; it required great vigilance against error. In KSOS the cost of proof and the risk of error are reduced by utilizing an automatic formula generator coupled to an automatic general-purpose theorem prover.<sup>20</sup> To our knowledge, KSOS is the largest program for which automatic design proof along the lines sketched above has been accomplished.

Proving the published KSOS design entails the generation

and proof of about 500 formulas. This is routinely accomplished in an entirely automatic fashion. The complete process requires about 10 CPU-minutes on a DEC KL-10. This dramatic reduction in proof cost has made it feasible to include a feedback path not shown in Figure 1 whereby formal specifications giving rise to unprovable theorems are modified and the proof then retried. By this mechanism even details of the design can be coerced into conformance with the desired property.

## IMPLEMENTATION

Proof P1, that a formally specified design implies a desired policy, is a major milestone in the schema. The next logical step is to produce an implementation of that design. For this, an implementation language must be chosen. The translation from formal specification to implementation is, in part, automatable. However, completion of the task requires application of traditional inspection, review and testing methods. As the KSOS implementation effort is only just beginning at this writing, we are forced, in this section and the next on Program Proof, to discuss our plans, not our results.

### *Choice of implementation language*

The peculiar nature of operating system programming places some well known demands upon programming languages. In addition to these, KSOS places the additional requirement that the system implementation be verifiable, i.e., P2: proof that the implementation conforms to the specification.

The following are the requirements for the KSOS pro-

programming language:

- a. The language must be well defined and be supported by a stable, efficient compiler, which produces efficient code.
- b. The language must provide “modern” control structures, data structures, abstract types, type safety and machine-dependent scopes.
- c. The language must be compatible with HDM and be amenable to axiomatization.

A short list of likely system implementation languages was prepared. These were Euclid, Modula, ILPL, Gypsy, Pascal, C and Ada. Of these, the most suitable on technical grounds appears to be Euclid. However, difficulties encountered by the implementors of a compiler for Euclid have led to our choice of Modula as the KSOS implementation language.

#### *Mapping a formal specification into code*

Several levels of documentation and specification have been developed for KSOS. First, a system-level specification was produced.<sup>1</sup> Next, a design specification was developed that included both prose and formal specifications for the major components of the system (e.g., Kernel, Emulator, NKSS).<sup>2-4</sup> And finally, a product specification was developed for each of the major components of KSOS. Each of these specifications is more detailed than its predecessor and defines the implementation more exactly. In concept, each successive specification provides a refinement of the ideas presented in earlier, higher-level specifications.

Care must be taken to avoid the constant danger of inconsistency, both within a given specification level and between levels. To guard against this, we have established the primacy of formal specifications in all questions. Thus, each of the managers, designers and programmers on the KSOS project has at least a reading knowledge of SPECIAL.

There are some aspects in which any formal specifications bind their admissible implementations. Specifications written in the style used for KSOS bind the structure, functionality and local assertions of the implementation. In order to exploit this binding we plan to create and use a software tool which will map from the formal specification domain into the implementation domain, producing implementation language skeletons for use and refinement by the implementors.

There is, in principle, no requirement that a given formal specification be implementable. Neither is there a requirement that the structure of an implementation follow that of its specification. It seems to us, however, that both of these requirements increase the practical utility of incorporating formal specifications in a methodology for program development, and we therefore strive to meet them. We have shown how the KSOS formal specifications are used both manually and automatically to provide implementation guidance. The goal of decomposing the system specification into an easily implementable hierarchy was identified early in the

KSOS project. The effectiveness of this choice will not be known until the implementation is complete.

#### *Implementation environment*

KSOS is being implemented in the environment provided by the Programmer's Workbench (PWB/UNIX).<sup>21,22</sup> This program-development, management, maintenance and testing tool provides the facilities needed to carry out the complex development and maintenance activities required by the KSOS project.

The development plan for KSOS requires that several small programming teams concurrently write and test portions of the system. Configuration control will be maintained through use of the PWB/UNIX's Source Code Control System (SCCS).<sup>23</sup> SCCS will be used to control all forms of machine-readable text (e.g., design notes, formal specifications, implementations, test plans) created in conjunction with KSOS implementation. Use of SCCS will provide a complete audit trail of systems development, the ability to reconstruct any version of the evolving system and the basis for subsequent maintenance of KSOS.

#### *Inspection and Review*

The accuracy with which verified formal specifications can be implemented has been the subject of much concern to the KSOS project. How can one ensure that an implementation will perform exactly the specified function and no other? Complete code proofs (i.e. P2) of the implementation would perhaps answer this question, but they are not anticipated for KSOS.

The function of ensuring an accurate match between the formal specifications and their implementation is therefore assigned to a formal inspection process using the techniques described by Fagan.<sup>24</sup> Two levels of formal inspection are planned. The first, called Design Completion Review, authorizes release of module designs for Critical Design Review by the KSOS customer. This review takes place when the detail design has reached the level that each design statement corresponds roughly to ten or fewer statements in the implementation language. The second inspection, called Code Completion Review, is scheduled after the first diagnostic-free compilation of the complete module.

The focus of each inspection is to ensure conformity of the detailed design and implementation to the proven formal design specification. Every module must pass these two inspections.

#### *Testing for specification compliance*

The quality assurance efforts for KSOS seek to provide a series of convincing demonstrations of the security and completeness of the system. Inspection and review are two contributors to quality assurance; testing is another.

The formal specifications are a useful guide to test case

selection. In particular, test cases are selected such that there is at least one test case for:

- a. The TRUE and FALSE cases of every specified EXCEPTION condition.
- b. Both  $x=TRUE$  and  $x=FALSE$  conditions of every specified IF (x) THEN . . . ELSE.
- c. Every specified  $(x)=>Q$ .
- d. Every possible type of x in every specified TYPE-CASE (x) OF . . .

Testing of a function is based on the proven formal design specification of that function. Test cases are automatically generated from the formal specifications and are then subject to an inspection process similar to those used for inspection of design and of code.

## IMPLEMENTATION PROOF

The final step required to complete the schema for production of proven systems is to prove that the implementation conforms to the proven specification. Hoare has shown<sup>25,26</sup> how such proofs may be constructed. In practice, these proof techniques have been successfully applied to isolated algorithms (e.g. Reference 27) and have led to spectacular insights about program construction.<sup>28</sup> However, there have not been any implementation proofs of operating systems.

All the necessary methodological preparations for a complete implementation proof of KSOS are being made. There exist, of course, formal specifications. The implementation language was chosen to allow the formulation of proof rules. A theorem prover (the same one which is used for the design proof) is at hand. The KSOS contract calls for axiomatization of the KSOS implementation language and for creation of the necessary verification condition generator. However, it requires only "illustrative" code proofs, i.e. only portions of the implementation will be proved.

These proofs will not be sufficient to complete P2, proof that the implementation conforms to the design. Nonetheless, they will serve a very important function. They will illuminate the state-of-the-art in automatic program proof, providing not only experience in the necessary techniques but also quantitative data as to the tractability and economics of proving large programs. There is no doubt that an estimate of the effort required to perform a complete implementation proof of KSOS will be made, based upon data derived from the illustrative proofs.

## SUMMARY

The KSOS project is extremely significant in the field of program development methodology. It makes initial industrial use of a number of techniques which were previously used only in academic and research environments. In particular, it is novel in its large-scale use of formal specification, automatic theorem generation, language axiomatization

and automatic theorem proof. These new techniques have been successfully integrated with more traditional ones such as programming teams, inspection and review. Careful utilization of these combined methodologies allows construction of a rigorous proof that the KSOS system meets its stringent security requirements. More generally, the methodology mix and the experience gained in applying them to KSOS open the way for routine construction of computer systems whose vital properties can be convincingly proven concurrently with the development of the system.

## INTRODUCTION

### *Background*

The need for multilevel security in computer systems has become well known. In the military, lacking such systems makes costs higher than they should be because of the need either to replicate facilities or perform "color changes" (shutting down and purging systems between uses at varying levels) in order to deny less-cleared users access to highly-classified information, and desirable functions which would require the controlled intermixing of data at different security levels are simply not yet done. The Government's concern with such matters is amply reflected in Reference 9. Outside the military, it is clear that most if not all funds transfer systems, for example, would benefit from the other side of the security coin—that is, although the major military threat is compromise of data, the major financial threat is alteration of data. In both broad areas, a free-standing multilevel secure operating system would be a distinct asset. The Kernelized Secure Operating System is meant to be just such a system, and in these terms alone is of considerable interest. This paper, though, will address potential applications of KSOS in areas other than as a free-standing system.

Aside from use as a free-standing system,<sup>12</sup> it is essentially the case that all other currently-envisioned applications of KSOS will involve intercomputer network environments. Under current consideration at varying levels of intensity are the use of KSOS as a containing operating system for communications subnetwork processors ("packet switches") themselves, Network Front-Ends, Network "Front Doors" (in which case the associated Host plays a "Back-End" role), mini-Hosts (to support users at terminals), and nodes for the processing of military messages. Although only the last of these has at present been analyzed in considerable detail, all are interesting and all will be touched upon in some detail.

KSOS's use in such applications is, as the title suggests, the main theme of this paper. However, it should be obvious that the mere act of inserting a secure component into a network architecture does not mystically make the network itself secure. Therefore, another important consideration which must be addressed is that the broad issue of just how to make a network secure is a complex one, and not nec-

essarily "known" in any but the abstract sense. Not only is there little in the open computer security literature which deals with networks per se (as opposed to free-standing, single systems), but the two examples with which we are most familiar<sup>7,14</sup> are by two of the present authors—and each has reservations about the other's (fortunately, the reservations concern form far more than content). Thus, as we consider the use of KSOS as containing operating system for various network components in forthcoming sections, it will be an additional concern to keep track of how these components interrelate with the other components of the assumed or actual nets in question to effect the security of the network as a whole, and in order to do so sensibly we feel constrained to begin with what might appear to be a digression from the main theme of the paper—a discussion of security issues in networking in the abstract.

### *Security issues in networking*

#### **The problem**

As will be discussed in more detail below, the use of data communications networks in the implementation of information systems has materially increased the vulnerability of data to compromise and unauthorized modification. Substantial efforts have been made to determine the cause of these vulnerabilities and remove them. This paper will present an overview of the techniques used to ensure the security of data transiting communications networks. In a sense, the point at issue is whether a network can be said to be "secure" if (and only if?) each of its components can be said to be "secure." While the prerequisite of adequate procedural, personnel, and physical security measures is acknowledged, these issues are not addressed here. Our concern is for technical measures that can be taken, within a network, to ensure data protection in accordance with an established security policy.

#### **Security definition**

Whether for free-standing systems or for networks, information system security addresses the problem of ensuring

that protected data is accessed in a legitimate manner by authorized users. The overall security problem is generally decomposed into three related but separable concerns:

- Data security—Ensuring that protected data is not disclosed to unauthorized users.
- Data integrity—Ensuring that protected data is not modified by unauthorized users or in a proscribed manner.
- Denial of service—Ensuring that access to systems is not maliciously denied.

Current security technology has developed effective measures only for the first issue. The problems posed by data integrity and denial of service are quite difficult, with no currently accepted general solutions available. However, the means used to ensure the data security of a computer system often greatly increases the system's data integrity and service availability likelihoods. The following discussion will, though, be limited to explicit discussion of data security protection techniques.

#### Security threats and vulnerabilities

The design of secure systems explicitly assumes not only the presence of external users that may attempt to penetrate the system, but also the existence of malicious software embedded within the system that may be used to improperly obtain information. Information systems (again, whether free-standing or networked) are susceptible to penetration threats presented from two sources:

- External threats—Presented from "outside of" the system (e.g., by users at terminals or, network-specifically, by "wire-tappers" on the transmission medium).
- Internal threats—Presented from software resident within the system.

A second classification dimension considers the means by which information is compromised:

- Overt—Transmitted data is directly compromised (e.g., packet delivered to an unauthorized user).
- Covert—System control information is used to illicitly "leak" information (e.g., network-specifically, use of the packet transmission rate as a carrier to be modulated with "leaked" information).

Ample evidence is available as to the ease in which free-standing systems designed without security in mind can be penetrated by external means.<sup>4</sup> Further evidence is available as to the ease with which trusted individuals (particularly software personnel), if subverted, can embed "Trojan Horses" within software systems permitting exploitation of

internal threats. Many current systems permit mechanisms that can be exploited by Trojan Horse software to "leak" compromised information at terminal speed (100-1000 b/s) and several examples can be shown to permit even higher bandwidth.

Although the state of security kernel technology lends credence to the belief that multilevel secure free-standing operating systems are near at hand, the computer security literature does contain one interesting open problem which bears heavily on computer *network* security. This problem is referred to as the "Confinement Problem." Identified by Lampson,<sup>10</sup> the Confinement Problem deals with the possibility that unverified code (say, a compiler) invoked by a highly-cleared user might, unknown to the user, have been maliciously programmed to release to less cleared individuals classified information which it acquires while executing with the first user's access privileges. The means of releasing the information are called "channels," which fall into three classes. The first class, "storage channels," consists of files, registers, memory locations and the like. The second class, "legitimate channels," is taken to cover billing information and the like. The final, most pernicious class, "covert channels," consists of modulating shared resources such as processor usage or paging rate in a manner observable by some other, less cleared user. As Lipner observes,<sup>11</sup> proper application of the fairly well known security kernel theoretic "\*"property" can deal with the first two classes, but covert channels remain a difficult problem.

Of course, it is possible to argue that for complete security, *all* code must be verified, but this is precisely the exercise which the kernel approach is intended to eliminate. We assume it will not be the case that entire operating systems will be verified for the foreseeable future (until and unless such verification can be highly automated), and inquire instead into other means of dealing with covert channels. Here we become involved with policy considerations, for the examples cited in the literature tend to deal with rather slow channels and in some cases conscious decisions have been made not to deal with explicit blocking of covert channels in order to avoid the attendant inefficiency. Networks, however, can entail such high speeds that it is at least plausible to assume that steps must be taken to prevent them from being used as covert channels. (After all, the Host's interface to a local terminal is currently usually no faster than 1200 bits per second and it "knows" where the terminal is physically, whereas the interface even to an ARPANET packet switch is in the 100-300,000 bps range and the bits are going into another computer which may itself contain malicious software.)

As discussed in more detail elsewhere,<sup>15</sup> several covert channels may be identified that could permit hostile programs in network Hosts to communicate at military teletype speeds with hostile programs in CSNPs even if the contents of actual messages are protected by encryption and the CSNPs are kernelized. Fundamentally, the channels modulate the observable parameters of transmissions (address, length, and timing) to communicate information despite the protection of the data portions of the transmissions.

### Security countermeasures

To effectively prevent exploitation of these threats a threefold approach is required:

- Determine the security policy to be provided and enforced by the network.
- Provide the mechanisms to enforce this policy.
- Ensure that the mechanisms operate reliably and cannot themselves be subverted.

### Secure systems technology

The technology for the development of secure systems is based upon three components (the first two apply to both single systems and networks, the last is network specific):

- An effective software development methodology, thoroughly based on the constructive approach to software reliability.<sup>6</sup>
- A system architecture that completely identifies the software and hardware responsible for security, protects it from tampering, and ensures that it provides a compromise-proof execution environment for all other software (e.g., Reference 12).
- Prudent use of encryption for the protection of data during transmission through an insecure medium.

### Network security

A secure network can be considered to be composed of two elements:

- Hosts or subscribers.
- A data communications subnet.

The most common architecture for the data communications subnet is currently a network of communications switches, routing packets of data from sending to receiving Hosts via point-to-point communications lines. However, the security requirements for the communications subnet are not limited to packet switched architectures. Other subnet architectures having similar requirements include those using wideband satellite channels as a communications backbone and local networks based on communications busses or radio.

We assert without further argument that a network (Host and subnet) can be considered secure if:

- Multilevel network Hosts properly protect data while the data is resident within the Host and properly label data with its classification when submitted to the communications subnet for transmission to another Host.
- The communications subnet restricts unilevel Hosts to receive and transmit only data labelled with the classification each is permitted to process.
- The communications subnet maintains the integrity of transmitted data, particularly its classification label.

- The Confinement Problem is suitably dealt with, either by policy decision or by means detailed below.
- Communications lines are protected from compromise or modification (usually through encryption).

### ALTERNATIVE SECURE NETWORK ARCHITECTURES

One more apparent digression from the main theme seems relevant: In light of the cost of "verification" of the separate components of a network, it is tempting to consider whether a network can safely be partially verified, in the sense of verifying only the Hosts and/or their Network Front Ends (NFEs) or only the communications subnetwork processors (CSNPs), and not the other logical level. That is, can Hosts/NFEs be prevented from allowing compromise to occur, or can CSNPs be enlisted to block attempts to transfer illicitly-acquired information from compromisable Hosts, in each case without the active cooperation of the other?

#### *Host-Only verification*

By "Host-Only" we actually mean a secure network architecture wherein the CSNP level is not verified. In order to be assured that the CSNP cannot "spy" on data or deliberately misroute it, there must, of course, be an appeal to some sort of rather sophisticated encryption hardware. We note this fact here and pass on, as a discussion on encryption is well beyond the scope of this paper.

Because networks can in general consist of heterogeneous Hosts, we cannot simply assume that all Hosts will be multilevel secure. So, if only the Hosts' logical level of a network is to be verified, given that some to-be-netted Hosts cannot in principle be verified, it must be assumed that such Hosts would be front-ended by verified NFEs and that such Hosts have no access to the "outside world" except through their NFEs. (Note that from "the network's point of view" a front-ended Host is indistinguishable from a conventional Host.) The key point is that we want to be able to posit the trusted nature of the Network Control Program involved (by which we mean the network-related software which interprets the Host-Host and Host-Switch Protocols in either the Host itself or the NFE) so that we can consider whether the Confinement Problem can be dealt with by means of having the (trusted) NCP block the channels through which compromise could occur.

Taking what appears to be the strongest channel first, the use of message lengths as codes could basically be blocked by a trusted NCP's padding up to packet boundaries with null characters, which would then be encrypted and undetectable by the presumed confederate code in the CSNP. The problem with padding, of course, is that it inflicts a throughput penalty on the network in question. Also, it is not foolproof, as in networks that allow multi-packet transmissions "short" (single packet) and "long" (maximum packets) transmissions could be used as "bits." Indeed, the number of bits necessary to express that maximum number

of packets are essentially usable by a hostile transmitting program if throughput is being conserved by only rounding up to packet boundaries instead of absorbing the full penalty of rounding up to maximum length.

Blocking the timing channel is also simple in principle, but may cost even more dearly when it comes to efficiency. That is, the trusted NCP could maintain an effectively-constant rate of observable traffic by furnishing dummy traffic when it has nothing to transmit and/or by transmitting only at fixed time intervals. The impact of such measures would have to be carefully assessed for given proposed networks.

Assuming dummy traffic, the address field channel can at least be masked by the expedient of "sending" the dummy traffic to random addresses (where it would, of course, have to be detected and discarded). This tactic, too, would have an unfavorable impact on throughput. Further, close analysis by specialists would be required to determine for given circumstances just what rate of illicit communication could still be maintained through the "noisy" channel the address field would still represent.

We see, then, that the effects of attempting to block the confinement channels when the CSNP is not verified are at best conjectural. In circumstances where either the threats to the software are deemed to be acceptably low (i.e., where the Confinement Problem is dismissed as a matter of policy) or the difficulties in verifying the CSNP are unacceptably high, however, the Host-only partial verification approach would seem to be better than nothing.

#### *CSNP-only verification*

In the Host-only verification case, we did not have to look closely at the nature of the verification because the key issue was the effects of attempting to have the NCP block the confinement channels which otherwise could be used to compromise classified information. In the CSNP-only case, however, the nature of the verification is extremely important, for it has been proposed that a particular kind of CSNP verification can lead to a secure network despite the potential presence of confinement channels (cf. Reference 14).

The reasoning can be expressed as follows: Suppose a given Host contains a hostile program attempting to convey information to a confederate outside the Host. Suppose further that its CSNP contains a hostile program which will attempt to aid the Host-side program by observing the cited confinement channels and, by virtue of being within the CSNP, passing the derived information on to a human agent at some other Host (presumably an unclassified Host) on the net—a Host, that is, which would otherwise be at an inappropriate level to communicate with the first Host. If it could be guaranteed that the second act of communication can and will be prevented (i.e., that the presumed hostile program in the CSNP cannot "talk to" the agent), then it is a matter of indifference whether or not the first communication has taken place (i.e., the Host's and CSNP's hostile programs' "talking to" one another). The claim, then, is that a properly kernelized switch can indeed prevent just

such forwarding of information as is necessary to make the confinement channels work.

For Hosts without multilevel security, the CSNP must "know" the current level of operation. For Hosts with multilevel security, the Host is trusted to label each transmission to the CSNP. In both cases, the code that manages the Host-CSNP interface resides within the CSNP's kernel. Thus, any message from the Host to the CSNP will have a label representing the security level of its contents indelibly associated with it. Then, by virtue of the \*-property, any untrusted code elsewhere in the CSNP which deals with a given message (the routing algorithm, say) should be debarred from writing to any destination which has an inappropriate level (the code that manages the CSNP-to-network/communication line interface also being within the kernel). So only if there were some means of beating the \*-property within the CSNP could effective compromise occur. Although a purist might argue that finding such a means is not logically impossible, the overall case for basing the CSNP on a security kernel seems to be a strong one.

#### *Interim conclusions*

We see from the previous and somewhat sketchy arguments that it would be more desirable, from the viewpoint of secure intercomputer network architecture, to have verified comm subnet processors than verified Hosts/Front-Ends if only the one or the other could be obtained. Unfortunately, when we return to the main thrust of this paper and begin to consider applications for KSOS in networking, the a priori case for attempting to use it as the containing operating system for a CSNP turns out to be the weakest of the cases for networking applications of KSOS currently under consideration. However, it should be realized that it is only the somewhat esoteric Confinement Problem which militates against the desirability in the abstract of the more feasible "secure NFE" architecture.

#### SECURE CSNP APPLICATION

The first potential networking application we will address in some detail has already been touched upon—What of using KSOS as the containing operating system for the communications subnetwork processor (usually, but not necessarily, the "packet switch") itself? The motivation for such an application is abundantly clear, for the in-principle case for overall network security is strongest when a verified CSNP is available (with, of course, suitable encryption or physical protection of relevant transmission media).

In practice, however, the following a priori argument would have to be disproved or otherwise avoided before a KSOS-based CSNP would make sense: The most important aspect of CSNP operating systems is that they must be in some sense "minimal"; that is, as opposed to general-purpose time-sharing operating systems, CSNP operating systems must be able to display the performance characteristics of so-called "real-time operating systems" in order to

achieve the level of throughput necessary for their role in the network. KSOS, on the other hand, is specifically intended to support a general-purpose time-sharing system in its primary design role. Thus, for example, several file-system-related primitives are included in the KSOS kernel which would simply "get in the way" of real-time considerations. So there must be considerable caution exercised on the fundamental performance issue, simply because of the natures of the two sorts of beasts involved.

A nearly obvious counter-argument suggests itself, of course: Why not simply excise those portions of KSOS which are superfluous to real-time use? The answer appears to be a further question: Would doing so necessitate re-verification of the resultant system (assuming, that is, that there are no primitives missing for real-time use)? If so, then it is by no means clear that whatever "leg up" we get from the fact that a similar system has already been verified is worthwhile in comparison to the verifying of a different system which was specifically designed for real-time use. At this writing, we know of no concerted efforts to investigate these issues. However, as will be seen directly, similar questions arise in the on-going investigation of another potential KSOS application, so the situation in regard to CSNPs is not purely speculative. Further, it is an interesting theoretical problem to consider whether the verification process of original KSOS might not be arguably invariant under strict subtraction of primitives, in which case appropriate surgery could be performed "for free."

#### SECURE NETWORK FRONT-END APPLICATION

By "network front-end," we mean a separate system, closely coupled to a Host, which is interposed between the Host and a network (or networks) for the primary purpose of offloading as much network-related software as possible (including the generic Network Control Program at least, and process level or applications protocols as feasible) from the Host, for reasons of efficiency and/or implementation ease. We note that in the present context the attachment strategy may be either "rigid" (emulating a device or devices "known" to the Host—typically either a common device controller or specific terminal(s)) or "flexible" (interpreting a compact Host-Front End Protocol in both Host and NFE), despite the fact that in the general networking arena the flexible approach is theoretically far superior.

The motivation for a secure NFE (SNFE), then, would be the sum of the motivations for a conventional NFE (CNFE) plus whatever assurances of overall network security the SNFE might entail. Clearly, when one wishes to attach older operating systems to networks, not only is it desirable to avoid consuming limited space and time resources by implementing an "inboard" NCP, but it is almost inconceivable that such Hosts could be made secure in their own right. Thus, a secure NFE seems quite attractive in principle.

Architecturally, the crucial issue is what to do about the Confinement Problem. As we have already noted, without highly specialized crafting of the CSNPs it is possible that

malicious software in the Host could establish covert communications channels to malicious software in the CSNP. Presumably, were the CSNP so crafted as to defeat the confinement channels, there would be little point in interposing SNFEs anyway, as they would almost surely be less throughput-efficient than CNFEs. The implicit security architecture in which an SNFE makes sense, then, must be one involving Host-only partial verification, wherein all Hosts not multilevel secure themselves must be mediated by SNFEs. Of course, it also makes sense to require a SNFE if it is desired to outboard the NCP of a multi-level secure Host for either efficiency or flexibility reasons even in a security architecture wherein the CSNPs are verified. Also, as noted earlier, the cost of blocking confinement channels is at present conjectural, assuming that the channels are not ruled out of consideration as a policy matter.

If such provisos are acceptable, the question reduces to the appropriateness of KSOS as the containing operating system for an SNFE. As in the case of KSOS for a CSNP, the major concern is that the demands of the role are essentially real-time. It is the case, however, that limited experience with CNFEs suggests that these demands are less onerous in the NFE area than in the CSNP area.

#### SECURE NETWORK FRONT DOOR APPLICATION

By "network front door" we mean an NFE-like system with a potentially significant difference—rather than offload network software for the purpose of doing general networking, the Front Door is interposed between Host and net for the sole purpose of allowing a given application on the Host to be made available to remote users. The primary currently-envisioned application of such a "Back-End" Host would be to run a pre-existing data base management system.

The motivation for a Secure Network Front Door (SNFD) is quite apparent: It is axiomatic that "security" cannot be retrofitted to existing systems; yet forthcoming networks will make it possible for users at various security levels to access existing systems which run important applications sub-systems, particularly data base management systems (DBMSs); so if an SNFD can enable such users to access such systems with some degree of confidence that data will not be compromised in so doing, it might well be superior to doing frequent "color changes" on the relevant Hosts. It must be noted, though, that the degree of confidence is debatable. The problem is that a sufficiently penetrated Back-End Host might "lie" to its SNFD about what output is destined for which user, thus achieving direct compromise rather than the sort of indirect, Confinement Problem compromise we've been focusing on. Allowing only one user in from the net to the Host at a time might mitigate matters, but the potential difficulty remains, and, as with the broad Confinement Problem issue, must be dealt with as a policy matter.

Architecturally, the accuracy of the levels of the users must be guaranteed, either by verified CSNPs or by a model which ensures that all active access to the net is via a Host or a mini-Host with multilevel security; the Back-End Hosts

would be allowed only passive access—in the sense of being debarred from initiating logical connections “to” the net. Between the passive role of the Back-End Host (which effectively eliminates address modulation), the interactive nature of the DBMS application (which suggests transmissions will—or can—be kept short so as to minimize the likelihood of length modulation), and the consideration that no user-written code would need to be invoked in the Back-End, it can be argued that the SNFD, while not in principle leak-proof, at least does not present a particularly high Confinement Problem risk.

As to the applicability of KSOS to the SNFD, a priori concern with performance issues is certainly far less than in the CSNP and NFE cases, for we envision a user load “through” the Front Door comparable to that for free-standing KSOS use. Further, the sort of load presented—which we take to be fairly modest interpretation of the query language traversing the logical connections in order to confirm that the user is not directing the Back-End to deal with a data base access to which is not appropriate given the level of the connection—appears to be no worse than comparable to the computational load one might anticipate in the program development environment. Indeed, unlike the CSNP and NFE applications, it is at least plausible to imagine that the standard KSOS operating system emulator might also be usable for the SNFD application, thus easing implementation even more.

#### SECURE NETWORK MINI-HOST APPLICATION

By “network mini-Host” (NMH), we mean a system essentially dedicated to the supporting of terminal users whose real computational work is to be performed on the full-scale Hosts attached elsewhere on the net. The NMH is a familiar concept from existing networks, particularly the ARPANET, where the terminal support (but not the packet switch) aspects of the “TIP” (Terminal IMP) are almost exactly what’s implied by the NMH.

Motivation for a conventional NMH is largely economic. It was, after all, much less expensive to sprinkle TIPs around the countryside than H6180s, PDP10s, or whatever the full-scale Host of one’s choice is. Similar considerations would of course also apply to secure networks; but here there would also be a compelling security-architectural principle available as well. For, as has already been implied, in situations where the level of the user must be guaranteed to be accurate, it is possible to fulfill the goal by forcing all active access to the net to come through a multilevel-secure point, whether full-scale Host or NMH. (This model would be sufficient, but is not, as it happens, necessary, in that given a secure comm subnet it is possible—though awkward—to reflect “color changes” of unilevel secure Hosts and to simply multiply NMHs to the extent necessary to allow them to be unilevel too. On the other hand, for environments in which it is not feasible to have a secure subnet, it would seem that control of all entry points is a very desirable attribute.)

As with the SNFD, the NMH application would appear

to place only modest demands upon KSOS, *qua* operating system. In fact, the NMH use for KSOS seems to be the most likely of them all to come about, largely because it essentially comes “for free.” Although some fine-tuning might be necessary in order to support the rather large numbers of terminals typically associated with this sort of application, at this stage it seems likely that simply not making compilers available on NMH versions of KSOS would liberate enough capacity for doing terminal support comparable to that done on similar contemporary systems. (Given the full range of utility software, a “midi-Host” could also be envisioned.) In terms of additional programming effort implied, if the Host-Host Protocol which “comes with” KSOS is applicable, only relatively straightforward process-level protocols need be done—and at least a primitive virtual terminal protocol will be available at some level.

#### MILITARY MESSAGE PROCESSING SYSTEM APPLICATION

The foregoing applications were, for various reasons of space, time available, and point in time of writing, necessarily discussed in rather general terms. We conclude with an application the investigation of which has proceeded far enough that we can offer a noticeably more specific treatment.

##### *Introduction*

By “Military Message Processing System” (MMP), we mean an essentially free-standing system which serves as a node on a network of, at least, many such systems (and potentially on a general-purpose network), in order to process prescribed types of text messages in prescribed fashions. Thus, the network security architectural points already raised come into play here as well. For example, provided that they can be constrained to communicate only with one another, secure MMPs would be usable on unverified subnets (subject to Confinement Problem considerations), and, given verified subnets would be still more economical by virtue of being multilevel secure—in that they would obviate the necessity of unilevel replication. (We take the motivation for MMPs to be self-evident.)

Under Navy sponsorship, considerable research has gone into Military Message Processing, under the collective heading of “the Military Message Experiment.”<sup>2,8,16,17,1</sup> Military Message Processing systems are fully automated, or “third-stage” (cf. Reference 3, Table 2), message-handling systems. This means that a MMP system must be capable of complex message composition, distribution, selection, and analysis. To perform such tasks, any MMP implementation must rely on fully sophisticated and complete computer support. We believe that the KSOS Kernel provides such support in a way well suited to MMP-style communications. Without question, a MMP system could be implemented using KSOS itself as the underlying operating system (con-

sider the Mitre implementation under Tenex<sup>1</sup>). Indeed, all the required functionality, without the extra (not desired) functions and structures particular to the UNIX\* time-sharing system, are available from the Kernel alone.

### *MMP requirements and their satisfaction*

Using several documents generated by the MMP community, we have compiled a number of either mandatory or desirable properties of MMP systems. Such properties are now presented within the classifications *security*, *functionality*, and *performance*.

### **Security**

Several documents (Reference 13, p. 6, Reference 1, p. 1, Reference 17, pp. 2, 5) establish standard DoD security policy as the basis for security controls within MMP. Such policy includes the classifications UNCLASSIFIED, CONFIDENTIAL, SECRET and TOP SECRET; and the concept of information compartments such as NATO or NOFORN. Each entity within the system is considered to be at a particular security level, which encompasses one classification and a set of compartments. The security policy prohibits flow of information from a higher classification to a lower classification, or from one compartment into another. In addition to security controls, MMP systems must provide discretionary controls to implement privacy measures (Reference 13, p. 6, Reference 17, p. 2, Reference 16, p. 17). These are used to control access to information by individuals and groups.

The security area is clearly satisfied by KSOS. Not only is the DoD security policy deeply embedded in the KSOS Kernel, but also the Kernel will be verified mathematically, using proof tools developed in part by Stanford Research Institute (cf. Reference 6), to adhere to the policy. In addition, the Kernel provides UNIX-style discretionary access controls on all types of objects.

### **Functionality**

Functionality required for MMP systems is discussed in this section; where appropriate, the Kernel's satisfaction of the requirements will be indicated. First, the more primitive support functions of a system are discussed. Then the user level functions are discussed, along with their implications for system functionality.

- **Direct—Support functions**

Support of processes. The need for large numbers of processes (on the order of tens of processes per user), and for

flexible handling of them, is emphasized in several references (Reference 1, p. 5, Reference 17, p. 19, Reference 2, p. 20). Some references indicate that one or two processes are necessary for each security level classification convoluted with exact set of compartments, (e.g., Reference 17, p. 19). Specifically, the Kernel must be able to:

- a. Support many processes
- b. Allow fast process creation and deletion
- c. Switch between processes with little overhead (most processes do small amounts of work at a time)

While it is difficult to predict the level of performance of the Kernel in these aspects of process handling, there is good reason to expect it will do well. The ability to provide a satisfactory implementation of UNIX would imply at least the first two, and possibly the third. Since it is the Kernel, and not KSOS, that is under discussion, one can conceive of small special-purpose limited-context processes with characteristics suited to a MMP system, but not available under UNIX.

Corresponding to the ways messages are traditionally handled (Reference 8, p. 12, Reference 2, p. 21), inter-process communication must be available in both "message" mode and "interrupt" mode. Message mode communication places a message in a queue where it stays until explicitly read by the receiver. Interrupt mode communication preempts the receiver's execution so that the message is handled immediately. Both styles of inter-process communication exist in the Kernel as currently conceived.

Support of files and devices. Ames (p. 5) indicates that size of information objects should depend on the application itself. Ideally, then, the underlying system ought to support efficiently objects of greatly varying size. In particular, very small objects on secondary storage must be reasonable to use. The flexibility of the KSOS kernel provides for such objects.

The actual structure of a file system in a MMP system is likely to be quite different from what conventional operating systems provide. Thus, another advantage of the Kernel is its provision of a fast, simple underlying flat file system out of which an appropriate structured file system can be built.

The major security issue in device handling is providing a secure user interface, or secure terminal handling. A significant choice to be made in this regard (and regarding all devices) is whether a terminal is at a single security level at any time, or whether it may be used as a multilevel device. Also, the security level may be established externally, via established lines to limited-access terminals; or internally, via user identification. The Kernel allows single-level terminals with level established via user identification. Other important device uses are hardcopy output (line printers, etc.), and archiving and disk save and restore (magtape). Complete (level-multiplexed) handling is provided for such uses by the Kernel, as well as for secure terminal handling.

\* UNIX is a trademark of the Bell System.

- Indirect—User-level functions.

The remarks of this system indicate briefly the nature of the user interface of a MMP system. It is not possible to show point by point that the Kernel can support the given requirement. However, after thorough examination of the Kernel design while considering these requirements, we are convinced that none of them needs any capability not found in the Kernel.

**Message attributes.** Messages must be divided into sections (header, address, subject, text, comments), each of which possesses an independent security level (Reference 1, p. 3, Reference 17, p. 7, Reference 8, p. 11). A message also must possess a priority, or degree of urgency, that affects its handling.

**Sending.** Sophisticated message composition facilities are provided. External documents (files, other messages) may be referenced and included in a message without losing context. Special handling of composition is provided for responding to received messages, including direct reply and forwarding. During the composition of a message (any time until released by the composer), the classification of the message may be changed (including being downgraded). Cf. Reference 13, p. 2, Reference 17, p. 13, and Reference 8, p. 36.

**Receiving.** Received messages may be displayed and printed in various ways. Messages may be moved into user files. Messages to be examined may be selected in various ways, including order of receipt and by content. Cf. Reference 13, pp. 3, 4; Reference 17, p. 12; and Reference 8, pp. 12, 15, 20.

**Administration.** Terminals and users are identified to assure proper clearance. A specified minimum of on-line storage for messages must be supplied. An archive facility for messages exceeding on-line storage is provided. Unusual or critical events are logged. Cf. Reference 17, p. 15, Reference 13, p. 6.

### Performance

We use "performance" to mean how well the user perceives that the system does its job. In other words, given the system possesses the required functionality at all levels, does the user get comfortably fast responses, is the system's interaction with him generally comprehensible. In the user environment in which MMP systems must exist, high performance in this sense is absolutely necessary. The users do not come from computer science backgrounds, and are not likely to be tolerant of long waits, low reliability or a large amount of training in order to use the system. Of course, until KSOS is actually subjected to the test of real usage by real users, we can only conjecture about its performance in this sense, but we know of no reason to suppose it will be other than acceptable.

### Cost/Benefit summary

A major cause of inefficiency in MMP systems up to now has been the mismatch between the external requirements

and the underlying support facilities. We have shown informally that the KSOS Kernel is well matched to the needs of MMP, providing in an efficient, flexible manner the essential security, functionality, and performance. The Kernel is obviously not a MMP system in itself, but the effort to develop such a system using the Kernel is likely to be less than that experienced in other instances, also because of the suitability of the Kernel for this application. Little or no modification of the Kernel (almost surely none requiring reverification) will be required to enable its use for this application.

### CONCLUSIONS AND FUTURE DIRECTIONS

In conclusion, we observe that, based on the foregoing, there are several networking applications in which KSOS may be expected to play a role, either in whole or in part. (That is, either all of KSOS, Kernel, trusted processes, and Emulator, may be employed, or just the Kernel and, perhaps, the trusted network software). Investigations are actively under way in the Front End and Front Door areas, and the Military Message area has already been investigated to a sufficient extent to engender reasonable confidence in KSOS's utility. However, it is fair to say that none of the currently-considered application areas is at present a "sure thing." Therefore, it would seem that the most important future directions for KSOS networking applications to take lie in the following realms: the issue of removing superfluous primitives must be resolved; other efficiency areas must be investigated; closer scrutiny must be given to the overall network security implications of interposing verified components at various points in specific network architectures; and, although it was not touched upon in the body of the paper, we would be remiss not to mention the overriding open issue of secure networking—just what are the right sorts of "secure" higher-level protocols to implement in the secure components which are becoming available?

# Considerations in the employment of blind computer professionals

by JAMES A. KUTSCH, JR. and KIMBERLY B. KUTSCH

*West Virginia University*  
Morgantown, West Virginia

## INTRODUCTION

According to sections 503 and 504 of the Rehabilitation Act of 1973, employers are required to hire qualified handicapped persons and, where necessary, to provide reasonable accommodations relating to accessibility to their actual job station and to work environs—including rest rooms, recreation areas, eating facilities, etc. Further, companies holding federal contracts are required to have an Affirmative Action Program to seek out qualified handicapped individuals as potential employees.

When a person is handicapped, there is a tendency for this potentially productive person to be excluded from the work force. Yet, given opportunity and ambition, these people rise just as far as they would under more 'normal' circumstances. Why, then, are they discriminated against? Perhaps one reason is lack of understanding of the considerations necessary when employing the handicapped.

In this paper, we will deal with the problems encountered by the blind in the field of computer science.

## THE BLIND PROGRAMMER

It is assumed that we will be dealing with a singularly disabled, i.e. blind, reasonably intelligent and trained computer professional. The most immediate problem he or she will have is in handling the output from the computer. Obviously, the input to the computer is no problem, since key punches and terminals are keyboard devices. There is only a slight inconvenience involved in learning the location of the special symbols, as each device differs somewhat. This, however, is also an inconvenience to the sighted programmer.

Historically, there are many solutions to the problem of output.<sup>1-3</sup> The simplest is to have someone read the printed material. The drawback, of course, is that this ties up two people to do one job. This is, however, an adequate solution if two programmers are working side-by-side on the same problem, or if the blind programmer is acting in a consultant's capacity for a limited time.

Braille, in which any blind computer professional should

be highly skilled, is another common solution. The biggest advantage is that it allows the programmer independence. Further, several vendors produce a Braille print train, which, when installed in a standard printer, will imprint a series of raised dots on the paper. Terminal devices with Braille output are also available.<sup>4</sup>

Braille can also be produced on a conventional printer, using a software conversion program which converts print characters to a series of periods and spaces. These are printed on a printer which has a soft cushion of some sort (usually an elastic band) placed behind the paper. Thus, the periods, when printed, make dents in the paper, which when read from the reverse side, appear as raised Braille characters. The Braille characters are a matrix of dots, two wide and three high. Counting horizontal and vertical spacing between characters, 40 Braille characters would be 120 printer positions wide and four lines high when printed using this method. The disadvantages with Braille output are bulk of listings and expense of hardware print mechanisms (if that approach is taken). Further, stock printer paper is not as heavy as normal Braille paper and the Braille dots have a tendency to be flattened back into the paper, especially in very thick and heavy listings.

Morse code and musical chords have also been examined for their usefulness with varying degrees of success. If the programmer already knows Morse code and has been using it for output, it can be very useful. It requires no additional equipment as software drives the computer's alarm bell. Learning so complex a skill in order to handle output, however, is an unfair request to put on an employee. Musical chords representing letters have even less promise as a solution and in effect have never really gotten off the drawing board.

A major contribution to the problem of reading printed material was made by Telesensory Systems Inc. (TSI) when they began producing the 'OPTICON' (Optical to Tactile Converter).<sup>5,6</sup> With this system, a small camera is moved across a line of print. A tactile image of each character so scanned is presented to the reader's finger through a matrix of vibrating reeds. The user of the OPTICON can, without assistance, read a printed page. However, it takes considerable training and a high level of dedication to learn and become proficient with the device.

## READING MACHINES

The author's own research has led to the development of a talking computer terminal. It consists of a keyboard for input, a speech synthesizer for output presentation, and a microprocessor to drive the synthesizer.<sup>7</sup> The microprocessor communicates with the host machine via an RS-232 interface. The terminal can be used on any system in place of the conventional hard copy device or CRT. Input from the keyboard is sent through the RS-232 interface to the host machine. Output from the host machine, which would normally appear on the screen or paper, is processed by the software in the microprocessor and sent to the synthesizer producing spoken English output. The device can be used as a terminal on any computer system which supports asynchronous RS-232 communications.

Through one or all of the above means, the blind computer programmer can conquer the problem of computer output. It is necessary, for the employer, to discuss what methods each particular programmer utilizes and set a clear understanding of what, if any, equipment this individual will need.

## OTHER CONSIDERATIONS

A friendly and accessible secretarial staff is a large asset to a blind employee. This staff can provide valuable services by reading mail and memos, proofreading correspondence, etc. The few minutes of time necessary to glance at a memo or read the mail can increase the productivity of the programmer immensely. In an environment devoid of secretaries, a receptionist or keypunch operator could be asked to fill this need.

Another important consideration is the type of environment the blind individual will be working in. Team programming and group efforts are ideal atmospheres for very productive work. There is always someone around with whom the project can be discussed.

Finally, there is the problem of orientation. It will be necessary for someone to spend some time helping the new employee learn the location of equipment and rooms. This should take no more than a few days. Once oriented, a blind person can move about safely, freely and independently. There may be special problems pertaining to each individual. For instance, a Seeing Eye dog may accompany his master. In this case, it is necessary to locate an out-of-the-way area for the dog to be walked and to acquaint the rest of the staff with the animal. These dogs are extremely well trained and should not present any problems to fellow workers.

If the office is located in a building or complex with other businesses, it is helpful to be acquainted with the general location of these other businesses. This should require only a few minutes of additional time.

## CONCLUSION

Usually, blind computer professionals will have educational backgrounds similar to that of sighted computer professionals. However, some may have attended special schools for the blind which offer training in data processing. While a blind individual may come from a slightly different background and may require additional tools for his trade, he should be given the same opportunities and trial period as a sighted employee. Thus, he can prove his merit (or lack of it) based on his abilities and performance regardless of blindness. He can be as valuable and productive an employee as any of his fellow staff members; therefore the criterion for hiring, promoting and firing should be the same for all.

It is presumptuous to try to offer a "guideline" for hiring the blind. Each individual and each job require a different set of considerations. As an employer, do not hesitate to discuss how the new employee would be expected to function, i.e., how he might handle a batch environment compared with an interactive system.

Housing conditions in the area also bear mention. The blind employee will want to live within walking distance, on a bus or train route, or where fellow workers car pool to work without sacrificing desirability of neighborhood or school system which are important to his family. It is not necessary to be hesitant to discuss cause of blindness. Frankness and openness during the initial interview can eliminate misunderstanding or uneasiness later.

The biggest problem facing a handicapped person who tries to enter the professional work force is not his education, training, or ability but rather the education and awareness of the rest of the world in accepting the handicapped individual and realizing his potential.

# Hiring a deaf computer professional\*

by KAREN K. ANDERSON

Rochester Institute of Technology  
Rochester, New York

and

PHILIP W. BRAVIN

IBM Corporation  
New York, New York

## INTRODUCTION

The computer industry has a critical need for skilled professionals. Employers are already hard-pressed to find qualified workers and look with interest to the growing population of technically trained deaf individuals as a new source of competent employees. Interest in hiring deaf computer professionals has also been accelerated by employers' growing sense of social responsibility and their need to comply with government regulations concerning affirmative action in hiring and promoting handicapped individuals. This willingness to employ deaf professionals must be accompanied, however, by specific guidelines for the actual hiring and accommodation of such workers. This paper addresses the practical concerns of managers who wish to hire deaf professionals into their organization.

## CHARACTERISTICS OF THE DEAF POPULATION

There are 13 million people in America who have some type of hearing impairment.<sup>1</sup> About 1.8 million of these are considered "deaf," meaning that their hearing is not functional for the normal purposes of life. Since deafness is an invisible handicap, however, this group and its characteristics are relatively unknown to the general population.

Misleading terms like "deaf and dumb" and "deaf-mute" have reinforced common misunderstandings of the deaf population's intelligence and communication skills. In fact, IQ scores of the deaf follow the same normal distribution as the hearing population. Deafness does not, therefore, imply a lack of native intelligence. Neither does deafness imply the inability to vocalize. Most deaf individuals find that their speech sounds promote successful communication, especially among people who know them; but some individuals

prefer not to use their voices because their speech sounds have not proved helpful in communicating with others.

Most hearing people overestimate the ease with which a deaf person can lipread. Actually, lipreading is a difficult skill to master. Only 26 percent of all speech is visible on the lips. Even the best lipreader cannot lipread everything that is said. Familiarity of the speaker is again a significant factor in successful lipreading. The challenge of individual speech styles and facial characteristics such as flowing mustaches can be met with practice in repeated meetings.

One of the most significant results of deafness is unknown to the general hearing population. Specifically, early onset of deafness can seriously hinder language development. Although there are some deaf individuals who can read and write very fluently, others have limited reading and writing skills that misrepresent their intelligence and understanding. The facile assumption that a deaf individual's hearing and speech impairments can be easily overcome by reading and writing ignores the relationship between hearing and language development and leads many people to underestimate an individual's knowledge and potential.

"Deafness" is a generic term, since the word describes a handicapping condition with many variables such as degree of hearing loss, listening skills and lipreading and speech abilities. Other factors such as personality, education and intelligence have nothing to do with deafness *per se*. Although there is value in knowing the potential impact of deafness, it is vital to recognize the uniqueness of each deaf individual.

## RECRUITING SOURCES

There are specialized institutes within the United States that are dedicated specifically to the education of the deaf. These institutes exist because the education of deaf individuals is a challenging task. On the average the educational level of the deaf population is well below that of the general population. Only 12 percent of the population seek post-secondary education, and only six percent receive baccalau-

\* The techniques suggested in this paper reflect the collective experience of the authors and the community of deaf professionals but in no way represent policy of either author's employer.

reate degrees. Since most of the college-educated deaf now graduate from specialized schools, these schools are significant recruiting sources.

Currently there are several post-secondary schools with significant histories of educating deaf individuals. The oldest of these schools is Gallaudet College in Washington, D.C. Founded in 1864, Gallaudet is a liberal arts college for deaf students only. There is no computer science major *per se*, but degrees are granted in computational mathematics and in business with an emphasis on data processing.<sup>2</sup>

In 1969 the National Technical Institute for the Deaf (NTID) was established on the campus of the Rochester Institute of Technology (RIT) in Rochester, New York. As a college of RIT, NTID offers certificates, diplomas and associates degrees in data processing. In addition, NTID supports deaf students pursuing bachelor's degrees in RIT's School of Computer Science.<sup>3,4</sup>

Utah State University, New York University and California State University at Northridge have growing programs for the deaf in computer science.<sup>5</sup> In addition, special educational services for the deaf are becoming available throughout the country in response to Sections 503 and 504 of the Rehabilitation Act of 1973.<sup>6</sup> As access to programs opens, the number of qualified deaf graduates grows.

Employers can recruit these graduates through the placement offices of the degree-granting institutions. Deaf baccalaureate degree students at RIT, for example, are encouraged to follow the standard procedures of RIT's Central Placement Office. Colleges offering special programs for deaf individuals, however, usually augment placement services with additional services tailored specifically to their needs. These services can include special assistance during the application/interviewing process, orientation activities for the managers and co-workers of a new hire and troubleshooting consultation during the first weeks of employment. NTID and Gallaudet in particular provide a wealth of materials and personnel to assist employers in hiring a deaf professional.

Justifying the commitment required to hire a hearing-impaired person on a full-time, permanent basis can sometimes seem an overwhelming obstacle to employers. This impediment is most often an artifact of the imagined needs and problems of a deaf individual rather than accurate information about such a person. Fortunately, the desire of the employer to minimize risk with a new hire is complemented by the desire of educators of the deaf to maximize the experiential learning component of formal education. Thus, most special programs for the deaf either require or encourage work experiences as part of their programs. A summer or one or more cooperative work periods provide an excellent opportunity for employers to gauge the impact of hiring a deaf individual. The spectrum of support services supplied for permanent placement is generally available for co-op placement, also, and can help make even such short term commitments truly enriching experiences.

#### INTERVIEWING AND FOLLOW-UP

The initial contact a deaf person makes with an interested employer can occur in a variety of forms such as replying

to a newspaper advertisement, mailing in a resume, requesting an application form, or appearing in person at an on-campus recruiting interview. None of these forms of contact guarantee that the employer will be forewarned that the applicant is deaf and there is no legal requirement to that effect. Indeed, the applicant's deafness may only be revealed in his communication attempts, whether in writing or in person. An employer learning of the applicant's handicap in this way may become surprised, confused and hesitant to carry out the interviewing and recruiting process. It is imperative, however, that the employer actively proceed with the usual routine of interviewing.

Communicating with a deaf person at the initial in-person interview is, at best, an opportunity for the employer to assess the deaf person as a whole and to observe the nature of his listening and communication abilities. A good strategy for the interviewer is to start speaking slowly and let the deaf person monitor or control the pace and mode of the interview. The deaf person may indicate his inability to lipread and request that the interviewer write everything on paper. On the other hand, the deaf person may not need to resort to pencil and paper, and the interview can take place in the usual manner (i.e. communicating orally). In fact, during the course of a day when a deaf person is interviewed by several people, the deaf person may use pencil and paper with one interviewer and communicate orally with another. The interviewers should be aware of the various communication modes that may be employed. Also, it is essential for the interviewer not to show any hesitation or displeasure when asked by the deaf person to speak slower or use pencil and paper.

Another strategy to consider is the use of a sign language interpreter at the interview. It should be emphasized that the need for such a service should be specified by the deaf person, since some deaf persons do not find it necessary to have an interpreter while others may need one. If the need for an interpreter is stated, the organization should make arrangements to obtain one through a local referral or vocational rehabilitation agency that serves deaf people. One of the reasons why interpreting services are mentioned is that there are legal considerations, such as Sections 503 and 504 of the Rehabilitation Act, which create a mandate for employers to make their facilities accessible to the handicapped in general. In the case of deaf people, communication accessibility is a consideration.

The variety in the degree of hearing and speech and other communication skills must be borne in mind; but, once the communication considerations have been dealt with, the scope and content of the interview should focus on the usual issues such as the qualifications of the prospective employee, his ability to contribute to the overall objectives of the company, his ability to get along with his peers and managers and other necessary attributes required to make him a successful employee.

Finally, if the organization wants to follow up the interview by offering the prospective employee a job, indicating to the applicant that the organization could not find a suitable position, or asking for more information, it is important that the organization make such efforts directly, in writing if possible. Direct contact or writing is preferred because

the applicant may not have direct access to a telephone. Telephone communication through a third party runs the risk of misunderstanding because of distorted or abbreviated messages.

## ORIENTATION

In any new job setting the environmental barriers, whether they be social, physical, or technical, can be overcome by the orientation process. This process is simply an educational one in which the new environment is described to the new hire to make him comfortable in his new setting. In the case of a deaf new hire the orientation process is not radically different from that for a new hire who is hearing. Depending on the organization, however, the process can differ for the deaf employee's peers and his management, since they generally need some orientation in this case also. This type of orientation, in both a formal classroom and informal social setting, will be described.

The best approach to making a deaf new hire's peers and management feel comfortable and removing the mysterious aura surrounding deafness is to make them aware of deafness in general. The more they understand deafness, the more receptive they will be to the new hire and the new hire to them. This receptivity is essential because the population-at-large tends to have a stereotyping attitude toward a specific population. The process of orientation will assist in the removal of the stereotyping factor and help make the view of the person towards a new hire more individualized. In the process the new hire will blend into the work setting rather than stand out on account of his deafness.

There is a wide range of materials that organizations can use in their formal training programs for the new hire's management and coworkers. These materials can include movies, books, pamphlets and manual alphabet reference cards, to list a few. Such materials can be obtained from the colleges, institutes and organizations that serve deaf people and from appropriate personnel representatives in corporations. Some corporations may have materials they use to conduct formal training programs; others may have materials they use on an informal basis. Appendix A lists the names and addresses of several sources of orientation information and Appendix B lists the names of several corporations with experience in hiring deaf individuals.

Informal orientation is a process that is best left to the new hire, who usually takes the initiative in educating his peers about aspects of deafness that are not covered by the formal training materials. Informal training may take the form of stories and anecdotes that have a deaf theme or informal instruction in sign language or the lifestyle of a deaf person (e.g. how he "hears" the doorbell, his "telephone"). This approach usually is entertaining and goes a long way in removing the so-called environmental barriers.

The orientation process for the deaf new hire may differ only in the way information is presented, depending on the deaf person's communication skills. It should be emphasized that the deaf person should receive the full benefit of orientation programs and not be given a half-hearted treatment because of his communication limitations. The new hire's

communication skills can be inferred from the initial interview process.

As essential as it is for any organization, the orientation process may be even more important for situations involving a deaf new hire. Its value should not be minimized, for such a program implemented correctly and positively goes a long way in creating a congenial working atmosphere for the new hire, his peers and his management.

## TRAINING

In any organization heavy emphasis is placed on training and education for employees, especially in the computer field with its rapidly changing technology. This training gives the employee the opportunity to keep pace with technology. At the same time the organization maintains a group of qualified and educated people to meet its changing needs.

When a student makes the transition to the business world, a great deal of practical material must be digested before the student makes himself a useful employee. To maintain his usefulness, he must avail himself of professional development activities throughout his career.

The medium through which training is presented to the employee has greater impact on a deaf employee than on a hearing employee. To give a simple example, an audiotape is as useless to a deaf person as a videotape without sound is to a blind person. In a classroom setting there are several points to consider for a deaf person such as relevancy of the subject matter, the size of the class, and the communication skills of the deaf individual. In any case the deaf individual should make his needs known. They can take the form of preferential seating, notetakers, or even a sign language interpreter. Some deaf people may find that none of these aids are necessary, and others may find some or all of them necessary.

There are an increasing number of courses offered in both audiotape and videotape forms. For a deaf person the audiotape does create significant problems. The deaf person can receive the full benefit of the tapes by having a sign language interpreter interpret the tape, by having a secretary transcribe the contents, or by getting a copy of the script that was used to prepare the tape. The latter method is most practical, and such scripts are usually available. Videotape has similar ramifications for a deaf employee because it is harder to lipread a TV screen than to lipread in person. Thus, although the employee may benefit as his peers from the visual aids that are incorporated in videotape training, he will not necessarily do much better with the "talking face" type presentation than with an audiotape. Finally, voice-over presentations are fundamentally as difficult for the deaf person to follow as audiotapes.

Other media through which courses are offered include computer-assisted instruction and programmed instruction (self-paced instruction) as well as training in the form of reading manuals. These media are ideal for deaf persons.

If an organization acknowledges the value of training programs, it should be able to guarantee that the deaf employee receives the full benefit of these programs.

## MEETINGS

Meetings usually provide a forum for people of a given organization to share relevant information. Meetings take many forms—one-on-one, small groups of three to nine people, groups of 10 to 20 people, and an assembly type group of more than 20 people. The deaf person may require specific consideration in each of those settings. It should be emphasized, however, that there are no universal solutions for a deaf person in any setting. Useful strategies vary from one deaf person to another, depending on communication and listening skills as well as the group of people involved. The deaf person's problems are less acute if the group contains people who are familiar with the deaf employee.

In a one-on-one situation the communication process usually requires a simple adaptation. In some cases the person meeting with the deaf individual may know sufficient sign language, may talk at a speed appropriate for him to lipread, or may write down everything for him to read. In response the deaf person may write, speak, or even use sign language, if the person he is communicating with can read sign language.

In a small group the communication problems become somewhat more complicated since more people are involved. At this point written communication may be more difficult but can still be used. The deaf person may need to depend on one person in the group to follow the conversation, or he may be able to follow everything by lipreading alone. If the deaf person is the presenter, the environment differs and will depend greatly on his communication skills. The deaf person may have sufficient speech skills to conduct the meeting. On the other hand he may prepare a text or some notes for his co-workers to present for him. Communication in this kind of a setting is usually not a critical problem for a deaf person since the group is small enough for the deaf person to monitor.

The problem becomes more acute when the group is bigger. There are more personal relationships and communication links to take care of. If the deaf person has good lipreading skills, he may still run into problems at this type of meeting. For example, when one person stops talking, the deaf individual must find the next person who is talking. By the time he finds the speaker, that person may already be half-way through his statement. Similarly, if more than one person tries to speak at once or if someone interjects a parenthetical remark, the deaf person will not be able to follow them. If the meeting contains critical information for the deaf person, it may be necessary for the meeting to be controlled carefully. For example, it may be necessary for each person to raise his hand and be acknowledged before speaking. If the deaf person doesn't have adequate lipreading skills, he may need to depend on a notetaker or, if one is available, a sign language interpreter. In many cases a notetaker would suffice and could be a co-worker or secretary.

In an assembly-type setting the deaf person with adequate lipreading skills should be seated preferentially or, if he prefers, have a notetaker or sign language interpreter seated next to him. In any case the importance of the meeting will

determine whether a sign language interpreter is justifiable. The sign language interpreter is usually able to interpret the speaker's comments word-for-word, while a notetaker can at best give a good abbreviated summary of what has happened. Furthermore, the sign language interpreter can also reverse-interpret, i.e., repeat the deaf person's sign language statements or questions orally. In a setting of 500 people or more lipreading can be impractical, since it ceases to be effective when the speaker is more than eight to 10 feet away. In such situations a notetaker or an interpreter would be necessary.

## WORK ASSIGNMENTS

It is not appropriate to attempt to identify specific work assignments that deaf employees can or cannot handle. The skills and interests of deaf employees are as varied as those of their hearing counterparts. An appropriate match between employee and task must be made by considering the training and qualifications of the individual. Managers are urged to be aware of their own stereotyping tendencies when considering work assignments. Many of their tendencies are vestiges of outmoded or changing work environments. For example, the increasing orientation toward terminals for interacting with the computer reduces the number of communication barriers between the programmer and the computer. In addition, the terminal becomes a handy device for aiding communication among deaf and hearing co-workers. The recent push for documentation produces real-time rather than after-the-fact documentation, and the introduction of efficient, graphical documentation tools such as HIPO and data flow graphs also ease communication among deaf and hearing. Deaf individuals have worked in essentially every capacity within a data processing environment. There are deaf data entry personnel, deaf computer operators, deaf programmers, deaf systems analysts, deaf project leaders and deaf managers. Sensitivity to the uniqueness of each deaf person and willingness to modify the work environment slightly to accommodate him can permit that person to function and grow in accord with his own interest and abilities.

## CONCLUSION

The growing population of college-educated deaf individuals provides a new source of skilled workers to satisfy the critical need for computer professionals. There are specific, cost-justifiable techniques that can be used to overcome the communication problems that a deaf employee will face on the job. Schools, institutes and organizations serving the deaf offer materials and personnel to assist the employer in accommodating the deaf worker. Employers are urged to draw on this pool of competent professionals. They will find an increasing number of graduates who can be significant contributors to their organizations.

# MIS effects on managers' task scope and satisfaction\*

by DANIEL ROBEY

Florida International University  
Miami, FL

The impact of computers on organizations has long been a topic of special interest to management and organization theorists. Opinions vary widely on the nature and importance of information technology's influence on the structure and process of organizations. For every ounce of technical optimism created by computer scientists, a pound of social pessimism is generated by behavioral scientists suspicious of technological impacts. Over the past 20 years much dialogue has raged in emotional and speculative tones without substantial progress made in our understanding of the issue. The armchair theorists who project less human organizational life because of the computer have generally operated without the benefit of research findings. The purpose of this paper is to shed some empirical light on one hotly debated issue: the impact of management information systems on managers' tasks and their evaluation of computer-induced changes in tasks.

Speculative arguments differ in their predictions of task impacts. Leavitt and Whisler<sup>7</sup> forecasted the removal of meaningful content from middle managers' work and the resultant alienation of managers from their jobs. They suggested that need fulfillment would only be found off the job, and drew an analogy between middle management and blue collar workers, whose jobs have been affected by mechanization to the point of removing craft elements.

A counter argument by Anshen<sup>1</sup> forecasted enhancement of the manager's job because of the computer. He contended that the machine would relieve the manager of tedious routine and make more time available for creativity and unstructured problem-solving. The result would be greater job satisfaction, not alienation.

In either of these contrasting arguments, the motivational assumptions are not hard to trace. Both positions depend implicitly on the same model of Man as first offered by humanistic psychologist Abraham Maslow.<sup>9</sup> This model posits that man is motivated by a hierarchy of needs. Basic physiological, safety, and social needs motivate behavior initially, and when they are satisfied the higher-order or ego needs motivate behavior. Needs for achievement, recognition, growth, and self-actualization are said to be important

motivators for those not driven by hunger or basic survival. Through the work of Douglas McGregor<sup>10</sup> Maslow's theory of motivation has had enormous influence over management thought since the late 1950s. Other theories of work behavior with close ideological links to Maslow's work are Herzberg's<sup>6</sup> Motivation-Hygiene theory, Likert's<sup>8</sup> System 4, and Argyris's<sup>2</sup> personality-maturity theory. While details of these approaches differ, they all project man as motivated by the intrinsic satisfactions of meaningful work and as possessor of needs for achievement and professional growth.

The importance of task scope to management motivation is clear under these models of work behavior. "Enriched" tasks, which provide challenging problems and opportunities for achievement, are more motivating than those devoid of challenge or achievement possibilities. Recent work has identified tasks with greater variety, autonomy, identity, and feedback as ones with greater "motivating potential."<sup>5</sup> While research support is inconsistent, it is clear that such a viewpoint underlies the predictions of computer impact on tasks and satisfaction. Briefly, we are led to expect that *if an information system reduces task scope, managers will be less motivated and satisfied. On the other hand, if a system increases task scope, managers should react positively with greater motivation and satisfaction.*

It is important that these notions receive empirical testing if we are to move away from pure speculation. With this in mind a research project was formulated to address this question and others. The study was conceived as an exploratory project because few standard hypotheses or research methods have been generated toward answering questions about the computer's impact on organizations. The next section of this paper briefly describes the overall project and the specific approach to assessing changes in tasks and managers' reactions to them.

## THE CISM PROJECT

The project from which this research is drawn is titled Computer Information Systems and Management (CISM). Over a five-year period research teams in Denmark, Austria, England, West Germany and the United States have collected data in eight organizations which have recently installed computer-based management information systems.

\* This paper is based in part upon research supported by the National Science Foundation under Grant No. MCS77-22486. Any opinions, findings, and conclusions or recommendations expressed in this paper are those of the author and do not necessarily reflect the views of the National Science Foundation.

Each of 130 system users spent approximately four hours in interviews and questionnaire completion. In addition, unstructured interviews with other managers, systems designers and subordinates were conducted in an effort to describe the impact of the information systems on managers and their organizations. A host of variables were measured, including managers' tasks, interpersonal relations and formal structure. The major output of the project is currently being assembled and will consist of an examination of different themes, each focusing on a particular area of computer impact. In addition, each national team is producing detailed case reports of the companies they studied.

Nine questions about the impact of the system on tasks were asked of each user. For the sake of analysis these task characteristics may be grouped into three categories:

- *Enriching factors*—which reflect intrinsically satisfying aspects of work.
  1. Degree of complexity in the task
  2. Number of problems recognized within the task
  3. Possibility of developing new ideas or methods
  4. Feedback on decisions
- *Structure factors*—which reflect rigidity and routine in the task.
  1. Degree of routine of the task
  2. Standardization of codes or terminology in the task
- *Load factors*—which reflect work pace and its variations.
  1. Work pace in the task
  2. Variations in work pace in the task
  3. Work load within the task

Each respondent was asked to indicate whether each item had increased, decreased, or remained the same as a result of computer introduction. In addition, where changes were reported, respondents were asked to evaluate the change as an improvement or deterioration in their jobs, or state that the change made no difference.

Most of the questions directed to members of the CISM sample sought changes in two managerial tasks. Because some managers performed only one primary task, data on both tasks were not uniformly available. Furthermore, some respondents chose not to complete the section of the questionnaire described above. Nonetheless, data for at least one of the two tasks were obtained from 85 respondents, and data analysis is based on this group. The sample is heterogeneous with regard to type of system used, employer, and nationality. The common experience among respondents is their familiarity with a pre-existing task as well as the new computer system for performing their jobs. Our sampling thus controls for possible extraneous sources of variance and enables a direct assessment of the computer's impact on tasks and users' evaluation of those impacts.

## RESULTS AND DISCUSSION

Changes in the enriching factors are shown in Table I, where changes are cross-tabulated with evaluations on each

TABLE I—Changes in *Enriching Factors* and Managers' Evaluations of Them

Degree of Complexity in Task:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased complexity	2	4	37	43
no change*		22		22
decreased complexity	1	0	19	20
<b>totals</b>	<b>3</b>	<b>26</b>	<b>56</b>	<b>85</b>

Number of Problems Recognized:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased number	8	6	29	43
no change*		23		23
decreased number	1	0	11	12
<b>totals</b>	<b>9</b>	<b>29</b>	<b>40</b>	<b>78</b>

Possibility of New Ideas or Methods:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased possibility	0	3	52	55
no change*		25		25
decreased possibility	3	0	0	3
<b>totals</b>	<b>3</b>	<b>28</b>	<b>52</b>	<b>83</b>

Feedback on Decisions:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased feedback	0	1	54	55
no change*		25		25
decreased feedback	1	0	0	1
<b>totals</b>	<b>1</b>	<b>26</b>	<b>54</b>	<b>81</b>

\* Where "no change" in the task characteristic was reported, the evaluation response was automatically coded as "makes no difference."

item. The total number responding to each question in this and following displays fluctuates between 78 and 85 because of missing data, but this does not seriously affect the results. The frequencies are also reported here without supporting chi square statistics because expected frequencies are too small in too many cells to make the test statistic useful. However, the results come through clearly without statistical testing. A large percentage of respondents perceive increases in enriching factors and evaluate these changes as improvements. On two dimensions, complexity and number of problems, a substantial minority of respondents perceive decreases and evaluate them as improvements. On the whole, however, increases in these challenging aspects are noted and considered to be improvements.

These findings seem to suggest that predictions from the Maslow theory are correct—that system users react favorably to work that increases challenge and opportunity for achievement. However, we must also examine changes in

task structure. Here the motivation theories predict decreased satisfaction if task scope is effectively reduced through computer changes.

As Table II shows, respondents overwhelmingly see greater routine and standardization in their tasks as a result of the computer systems. However, in contrast with our expectations, users react positively to these changes. On task routine, 50 percent evaluate the change as an improvement and almost 50 percent say the change made no difference. Responses are not quite as favorable for the standardization aspect, although only ten report that their jobs have deteriorated because of increased standardization.

In explaining results which run contrary to theoretical predictions, one often turns to alternative theory. One explanation of these results lies in expectancy theories of work motivation.<sup>11</sup> A version of expectancy theory for information system user is shown in Figure 1.<sup>12</sup> It shows the vital role that performance and both extrinsic and intrinsic rewards play in the motivation process. If an information system increases users' ability to perform, perhaps through more standard routines, and if rewards follow performance, users will be more satisfied and exert more effort. While our data do not test this proposition directly, many of our research personnel report informal comments from users which indicate the benefits of increased rationality in tasks. Standardization and routine remove chaos from the job and permit better performance. Therefore, these aspects are evaluated as job improvements.

Our final set of task dimensions involve load factors. Here

TABLE II—Changes in *Structure Factors* and Managers' Evaluations of Them

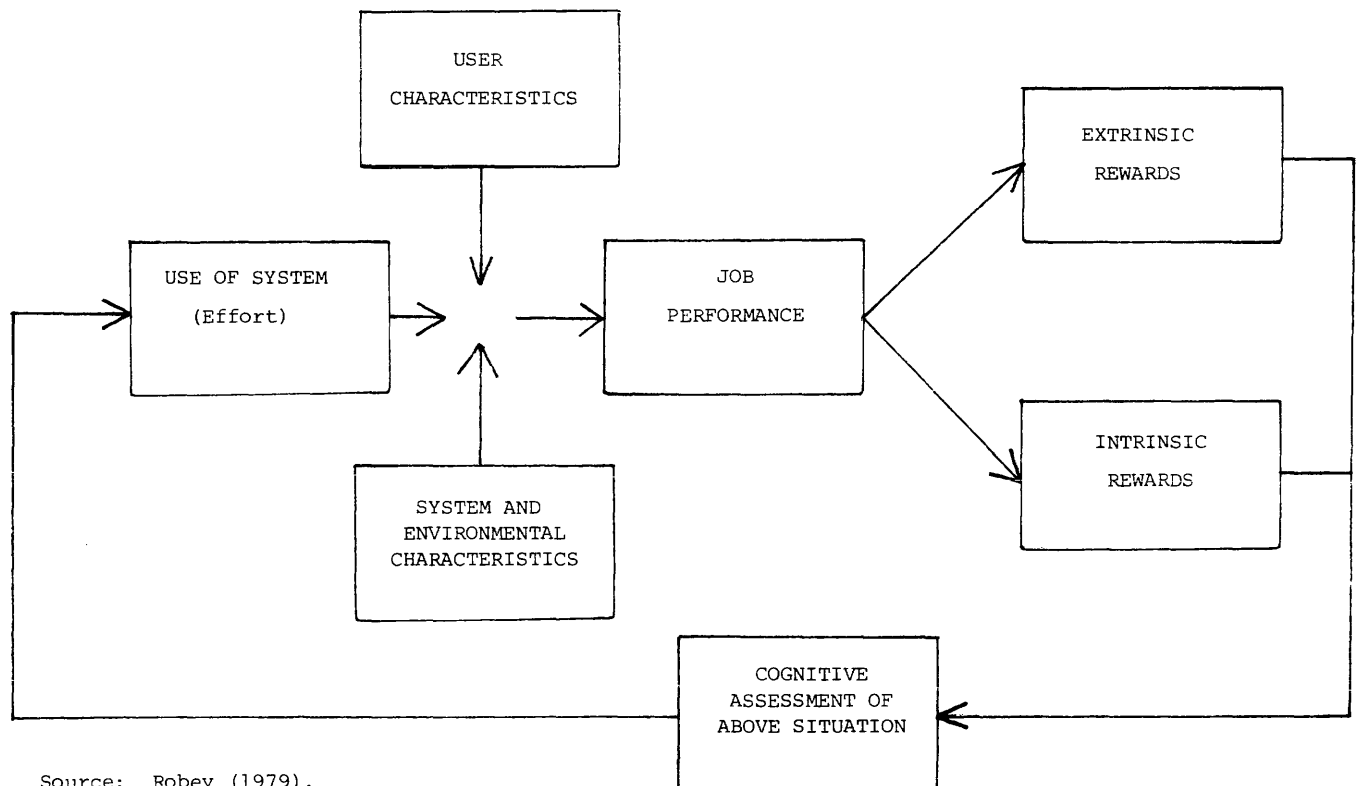

Degree of Routine of Task:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased routine	0	5	35	40
no change*		31		31
decreased routine	2	2	5	9
<b>totals</b>	<b>2</b>	<b>38</b>	<b>40</b>	<b>80</b>

Standardization of Task:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased standardization	10	15	22	47
no change*		37		37
decreased standardization	0	1	0	1
<b>totals</b>	<b>10</b>	<b>53</b>	<b>22</b>	<b>85</b>

\* Where "no change" in the task characteristic was reported, the evaluation response was automatically coded as "makes no difference."

it is expected that users will evaluate increased load and load variations in a negative light. The data in Table III show that increases in work load and pace generally outweigh decreases, and that variations in work pace increase substantially. The evaluation of these three changes is not

Figure 1—Model of user behavior.

TABLE III—Changes in *Load Factors* and Managers' Evaluations of Them

Work Pace in the Task:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased pace	9	7	24	40
no change*		32		32
decreased pace	0	1	9	10
<b>totals</b>	<b>9</b>	<b>40</b>	<b>33</b>	<b>82</b>

Variations in Work Pace:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased variations	19	10	19	48
no change*		26		26
decreased variations	3	1	3	7
<b>totals</b>	<b>22</b>	<b>37</b>	<b>22</b>	<b>81</b>

Work Load in the Task:	Evaluation of Change makes no			totals
	deterioration	difference	improvement	
increased load	9	3	17	29
no change*		35		35
decreased load	1	0	18	19
<b>totals</b>	<b>10</b>	<b>38</b>	<b>35</b>	<b>83</b>

\* Where "no change" in the task characteristic was reported, the evaluation response was automatically coded as "makes no difference."

terribly negative, although users are most negative about variations in work pace. However, a substantial number of respondents evaluate increases in work pace and work load as task improvements, and this is in contrast with our expectations.

In explaining the findings on load factors we are led again to consider the expectancy model in Figure 1. Respondents may be responding favorably to increased work load because the computer systems permit them to achieve this additional work. While performance pressures have increased, users now have the tools to reach these higher output standards. Both intrinsic and extrinsic rewards may follow and increase the satisfaction and subsequent motivation of users. Part of the price for this greater productivity may be the increased variability of the work pace. In batch systems in particular users are forced to accept discontinuities in work pace to satisfy data processing schedules and machine availability. This aspect may reduce some of the improvements perceived to be related to increased output.

Some further insights into these findings might be gained by disaggregating the data. For example, on-line and batch users could be compared on the variability issue. Elsewhere, we have looked at task uncertainty as an intervening variable.<sup>4</sup> These further analyses are beyond the scope of this paper, which has attempted to use as large a sample as possible to examine basic task effects. Disaggregation results in comparisons between much smaller subsamples, and we do not have the capacity to do too much sample-splitting

because our total sample is not large. Future CISM publications will show more detailed data analysis to the extent that it is warranted.

## CONCLUSIONS

Our overall findings may be restated quite directly: information systems increase the presence of enriching factors, task structure and task load. All of these changes are evaluated favorably by users. An explanation of these results requires that we go beyond a Maslow-based motivation theory, which predicts only the first result. Satisfaction with increases in task structure and task load are better understood by adopting an expectancy theory model of user motivation.

In moving toward the broader implications of these findings, it is interesting to note that apparent counteracting changes have occurred in the tasks we studied. The computer does make organizations more bureaucratic in the sense that routine and standardization have increased. But it also generates nonbureaucratic changes: it increases task complexity, and enables users to apply new ideas and methods to a wider array of task problems. It appears possible that both changes can occur simultaneously, which suggests that many earlier arguments linking computers to task changes were grossly oversimplified. Our results show a complex combination of impacts, which serve to enrich as well as standardize the job. There is no logical conflict in this statement if we assume that jobs are composed of several independent dimensions. Unfortunately, task research has not isolated standard measurable dimensions which could be used in research like this.<sup>3</sup> It does not appear, however, that the computer's impact on tasks can be fully understood by employing a simple, one-dimensional concept of task.

Of further interest is the pattern of evaluative responses by users. Even where tasks do become more bureaucratic (standard and routine), the change is not perceived as deterioration. The white collar worker is not alienated by the introduction of computer systems which increase task routine. Quite to the contrary, the middle manager has enthusiastically embraced the new technology largely, we feel, because it helps him improve his job performance. The computer removes guesswork, ambiguity, and structures the task so that it can be done more effectively. The user is not a loser in this transition, at least not in his own eyes. Very few respondents, even in companies with older tenured employees, regard the computer negatively. Nor are they particularly fascinated by it or treat it as a magnificent toy. It is simply a tool which permits work to be accomplished more effectively than before. To the extent that managers share the benefits brought about by better performance, they feel that their jobs have improved.

# Some neglected outcomes of organizational use of computing technology—And their implications for systems designers

by M. LYNNE MARKUS

Case Western Reserve University  
Cleveland, Ohio

## INTRODUCTION

Twenty-five years after the first commercial application of computers, it now seems possible to assess their consequences on the basis of user experience. Until recently, most assessment was done on the basis of early predictions inspired by the technological capabilities of computers. But these predictions have missed the mark considerably. Not only did the technology of computing fail to stand still, but it has been demonstrated time and again that just because a capability exists does not mean that it will be used as intended.

The predictions were dramatic: increased centralization, reduction in the number of middle managers, decreased personal autonomy on the job.<sup>16</sup> But the research findings were not dramatic: few structural changes occurred in organizations using computers, usually only those reflecting the creation of EDP departments.<sup>23,11</sup> If anything, the findings have shown that the effects of computing are "subtle, limited and complex in their patterns."<sup>14</sup>

This subtlety and complexity makes computer impact research difficult to do. Consequently, not much is done, especially inside organizations. One manager of management systems in a major industrial corporation recently told me: "We go through all sorts of gyrations to justify our systems development efforts—cost benefit analysis, ROI calculations and so forth. But we have yet to go back to see whether we achieved the benefits we expected. We know that the benefits are too difficult to measure and too difficult to trace back to their causes." Academic research has begun to fill the gaps in knowledge about computer impact on organizations, but the research has sadly neglected some important types of outcomes.

## RESEARCH FROM THE IMPLEMENTATION SCHOOL

Two general philosophies pervade the academic literature on computing use in organizations. One stream of research focuses on the factors contributing to success or failure of

computerized information systems. The second focuses on computer-induced changes for the individual employee or for the organization as a whole.

A number of researchers have tried to identify what factors influence or determine the success of information systems and management science projects. To call this rather diverse collection of operations researchers, management scientists and management information systems specialists the "implementation school" may be stretching a point. But writers such as Bean, et al.,<sup>3</sup> Schultz and Slevin,<sup>22</sup> Lucas,<sup>17</sup> Gibson,<sup>8</sup> Ginzberg<sup>9,10</sup> and Alter<sup>1,2</sup> share a common focus, first, on individual information systems and, second, on a specific type of outcome.

Both focal points of the implementation school distinguish it from the organizational school, to be discussed shortly. The first focal point, individual information systems, is a significant asset for the implementation school, because research has shown that different types of systems applications have different outcomes,<sup>23,11</sup> and that there is something in the nature of application types which affects organizational outcomes.<sup>10</sup> The organizational school, in contrast, tends to lump all types of applications together into indices of computerization for an entire organization, ignoring the previously-cited research and the fact that some parts of an organization may be unaffected by computing.

### *Limitations of the implementation school*

The second focal point of the implementation school, however, puts significant limitations on the research of this school. This is the school's focus on one particular type of outcome, namely, what happens when the systems designer turns the system over to the user ready to be converted or used. Different researchers in the school have used different measures of this outcome: Some have used the success or failure of the system to be implemented, others have used rates of use, still others have used the satisfaction/acceptance or dissatisfaction/resistance of users. But almost all call their dependent or outcome variable "success of the information system," and almost all measure it at a point in time before the users have had a chance to use the system.

This focal point of the implementation school has led to some serious limitations on its research. The first limitation relates to time. The startup of a new or modified information system is roughly analogous to the startup of a new plant. One does not simply flip a switch and begin to use the new technology. There are false starts, glitches and occasional trips back to the drawing board. Many systems designers and users I have interviewed express the opinion that working the bugs out of a new system takes anywhere from six months to two years. One major implication of this is that the "permanent" effects of an information system in an organization may not be felt by users or observable by researchers until some six to 24 months *after* the system is installed, that is, after users have some experience working with it. And, because of its focus on success defined at the point in time when the system is installed or turned over to the user, the implementation school has not been able to examine outcomes of information system *use*.

#### *Neglected organizational outcomes*

There is another limitation resulting from the implementation school's focus on "success of the information system." This is the failure to recognize the organizational consequences of information systems. In the effort to construct measures of success or failure of computerized systems, defining and redefining "usage," "utilization" and "user satisfaction," implementation researchers have left the search for organizational outcomes to researchers who did not distinguish in form or content between payroll systems and investment analysis programs. Almost totally ignored by implementation researchers have been the outcomes which relate to social and political aspects of organization functioning.

One manifestation of this organizational "ignorance" is the implementation school's definition of the "user." Systems designers interested in researching the success of their systems have typically, and not unreasonably, been most concerned about the satisfaction or acceptance of the person or group who commissioned the new system and who may have also paid for it. Therefore, the client of the systems designer is often designated the user of the system. The problem comes in when there are other, hidden users of the system, maybe those who only supply data to it. Often these other users have different perceptions of the success of the system, different feelings of satisfaction with it, from the client group. Including these might radically alter the researchers' measures of system success.

A financial information system which I have recently studied illustrates this point. This system consolidates financial data from the divisions of a large, decentralized corporation. In response to my question, "Who are the users of the system?" I was told that the main users were members of a corporate staff accounting group. Further questions revealed that divisional accountants provided the data to the system and maintained it.

"Aren't the divisions also users of the system?" I asked.

"Well, actually, the divisions don't use the system as

much as they could. We're disappointed that they haven't used the variable report writing facility to generate new types of financial analyses."

Interviews with corporate accountants identified a long list of benefits with which the new system provided them: automatically consolidated financial statements, decreased workload, faster month-end closings, standardized input from divisions, more and better management information, greater flexibility around external reporting, decreased disruption of financial activities caused by internal organizational changes. In contrast, divisional accountants found the system to be an obligation with few or no benefits to them: "Creating and maintaining the database for this system were huge jobs. Our division already had a smooth-running system for providing this information to Corporate, and it took two years to iron all the bugs out of this one. Also, it doesn't do a thing for me. The data in it is not at a level of detail where I can use it, even if I did have a staff of programmers to help me use the report writer. So I need to maintain a dual system for my own internal reporting needs."

This example illustrates that not all users of an information system see the system in the same way and if the people in this organization had taken a more inclusive view of users than just the corporate accounting group, *they* would have seen a distribution of outcomes, of costs and benefits, of satisfactions and dissatisfactions, associated with the system. This distribution is influenced by the social and political factors in the organization, factors previously neglected by most implementation researchers (with the notable exception of Gibson<sup>8</sup>), who most often focus on the system itself and the psychological attributes of client-users.

#### RESEARCH FROM THE ORGANIZATIONAL SCHOOL

The second research stream, which I'll call the organizational school, includes the studies of organizational theorists and sociologists like Whisler,<sup>24</sup> Hoos,<sup>12</sup> Kraut,<sup>15</sup> Blau,<sup>4</sup> Stewart,<sup>23</sup> Reif,<sup>20</sup> Hofer,<sup>11</sup> Robey<sup>21</sup> and Pfeffer.<sup>18</sup> The organizational school examined the effects of computing on a full range of variables reflecting psychological and psycho-technical outcomes for individuals. The effects of computing on job task, autonomy, stress, satisfaction with work and employment patterns are some examples. But early on, the organizational school began to concentrate efforts on variables reflecting changes in the organization as a whole. And the area of impact which attracted the most attention was the effect of computing on power, authority and influence in the firm.

The first published predictions about computer impact on organizations had raised this issue. Leavitt and Whisler,<sup>16</sup> in 1958, saw the potential of computing technology to store, process and analyze large quantities of data in a single place. They reasoned that access to this information would give managers the power centrally to control dispersed business activities. Managers had formerly had to delegate some of their authority, because of their limited ability to gather and digest information. The increased centralization of control

brought about by computer use would, they believed, reduce autonomy of middle managers and lower job satisfaction. Also, many middle management positions would be eliminated, replaced by computer applications.

The wave of research which followed these predictions did not significantly support them, however. Some industries, like insurance and banking, did appear to become more centralized, but researchers are still debating the issue. What they are debating, though, is how to study it, not whether the issue is important. The major contribution of the organizational school has been to identify changes in power, influence and control as potential effects of computing use and to legitimate the area of study. It made this contribution in spite of its tendency to focus on outcomes for the organization as a whole rather than on the more clearly delimited set of organizational outcomes which result from individual computerized information systems.

#### *Outcomes for organizational power and influence*

Recently, research in the area first investigated by the organizational researchers has begun to pay off. A number of studies, which may represent the beginnings of a third major school of research, have appeared in the last several years using the focus on individual information systems of the implementation school and the focus on outcomes for organizational power and influence of the organizational school.

Kling<sup>13</sup> found "that computer-based systems reinforce the existing distribution of power in American municipalities. They provide differential support to mayors and city managers in smaller cities and to departments in the larger cities."

Bjorn-Andersen and Pedersen<sup>5</sup> found that computing use in the business organizations they studied contributed to shifts in power among affected groups. By changing the basis of power of various organizational members, that is, by changing aspects like one's position of centrality in the flow of work through the organization, one's expert knowledge and one's access to up-to-date information, use of computing technology has created "winners and losers in the fight for influence."

Incidentally, Bjorn-Andersen and Pedersen noted that the early organizational research may have failed to identify these subtle changes, because the concept "centralization" is "too crude and only covering parts of the very complex interpersonal relationships potentially to be altered by the introduction of computer systems."<sup>5</sup> Pfeffer<sup>19</sup> lends weight to their observation. According to Pfeffer, real changes occurring in organizational processes of power and influence may not be immediately reflected in measures of organizational structure, like degree of centralization.

#### CASE ILLUSTRATION—ORGANIZATION AND SYSTEM OUTCOMES

A recently published case study by Conrath and du Roure<sup>6</sup> illustrates two points I have been making; first, that benefits

from, and incentives for, using computing technology vary across user groups, and second, that the success or failure of the information itself is related to and perhaps secondary to organizational outcomes, such as changes in power and influence among user groups.

Conrath and du Roure's case describes the implementation of a comprehensive logistics system in a branch of the U.S. military. The new system provided on-line access to up-to-date status information for all materiel for which the branch had responsibility. Unfortunately, the case does not tell us who initiated the system, who supported its development, and who bailed it out with an expensive redesign when it was close to failure. We are, however, told the outcomes and some details of the organizational arrangements into which the new system was introduced.

Prior to the development of the new system, all data were collected into a monthly report for senior officers. On the average, the report was a month out of date. Consequently, it was not well used in the logistics decisions of the branch. Requests for materiel were routed to junior officers, who forwarded them up the chain of command to an officer of high enough rank to handle the request. Information about the requests was obtained by telephoning those believed to possess the information.

The new system collected all relevant information automatically and made it available to junior officers through on-line terminals. No telephone calls were required to obtain information. Furthermore, the system determined the optimal way to transport materiel from one point to another, minimizing distance.

When the new system was first used, "the greatest impact was a change in the effective structure of the organization. It went from one which had been very hierarchical, very vertical, to one which was primarily horizontal. . . . The chain of command almost seemed to be superfluous." The new system enhanced the power base of junior officers by giving them access to information. This started to erode the power bases of senior officers.

But then the reaction occurred. "The commanding officer (three-star rank) demanded that the old system be continued in parallel with the new. The roles of the more senior officers were to be maintained. The argument given was that the computer-based system was not yet sufficiently reliable. The underlying reason, however, was the effect that the information-communication system had on the perceived value of the authority structure. In fact, once the old system was reinstated, the stress on supplying all the required data to the new system was relaxed, and the new system did become less reliable. The cause-and-effect relationship, however, was the reverse of the way it was presented."

The senior officers had discovered that the new system eroded their power base, a trend which, if continued, would have undermined their authority. The parallel system allowed them to maintain their traditional position. But if the dual system had continued very long, the technical advantages of the new system would have been lost. Someone decided that this should not happen and authorized the redesign of the system to include "a monitoring system designed to provide the perception of participation and control to the

more senior officers, but a system which was computer-based and integrated into the original information-communication system."

## CONCLUSION

The organizational school discovered that changes in power and influence are one major class of computing use outcomes. Research in this tradition, however, has generally failed to consider differential effects of different computer applications. The implementation school has had almost the reverse set of strengths and weaknesses: a focus on individual applications but a failure to consider power and influence.

The focus of implementation researchers regards as the user the person or group who requested system development. This, in turn, has encouraged implementation researchers to search for black-and-white outcomes, success or failure, within a single user group. This paradigm cannot distinguish between, for example, a system which failed because users did not have the appropriate cognitive style to use it and a system which failed because the initiating user imposed it upon other users who had sufficient power to sabotage it or to get around it in some way. Surely, these two causes of system failure would lead to different prescriptions for improving the activities of systems designers.

In the second instance, the organizational outcomes of the new system, namely, an undesirable imposed change, had a secondary effect on the information system itself, namely sabotage. The failure to recognize the interaction between consequences for the organization and consequences for the information system has been a limitation of implementation research that may be hindering the improvement of system design practice.

Sabotage is one kind of interaction between organizational outcomes and system outcomes. Maintenance of parallel systems is a second. Making changes to the information system itself after installation may be a third. Requests for changes to already implemented systems sometimes reflect user reactions to changes or disruptions in their organizational practices brought about by using a new computerized information system. This is clearly what happened in the Conrath and du Roure case just cited.

If the best aspects of both schools are combined, the application focus of the implementation school and the power and influence outcomes variables of the organizational school, the neglected outcomes are brought into focus. It then becomes possible to perform what can be called computer/organizational impact analysis. In this type of analysis, one traces organizational outcomes of computing use back to their causes. Changes in power and influence among various user groups can be traced back to the interaction of new system designs with existing organizational arrangements, as in the case by Conrath and duRoure. These same organizational outcomes can then be projected forward into probable consequences for the success or failure of the information system itself.

If systems designers performed computer-organizational

impact analysis before they designed and installed new systems, they might anticipate information system failures and learn to avoid them by manipulating aspects of system design and implementation with a view toward eliminating undesirable organizational outcomes.

Computer/organizational impact analysis might also help managers in organizations create desired organizational changes. Galbraith<sup>7</sup> and Pfeffer<sup>19</sup> have shown that computerized information systems can be used to change the structures and processes of organizations. However, the research has yet to tell us how to design computerized information systems to make these desirable organizational changes possible. Computer/organizational impact analysis may fill this gap, by shedding light on some of the neglected outcomes of computer use.

## PROLOGUE

Education is a versatile animal. After belonging exclusively in the domain of the home for millenia, public education in the United States became institutionalized about 1800. Today, the school system in many cultures is often equated to "the" educational system. However, industrial institutions are also becoming acutely aware that education is a vital component of their structure, and in some cases, of their market.

I believe that education is vital in all three of the above institutions: home, school, and industry. If a role of education is to help us learn new ways, as well as to understand current and past concepts and events, then we are in for a great deal of education in the future. It hardly seems possible that Toffler's *Future Shock* is already eight years old, as we observe and share in rapidly changing lifestyles and institutions constantly today.

## THE ACADEMIC

It is my deep conviction that a large part of education can occur in a framework other than in a formal classroom setting. In such a formal lecture/testing situation, students are most often evaluated on a basis of comparison with other people who happen to be in the class. The resulting attitudes are ones we've all seen or experienced: the confident, bright, fast-learning top 10 percent, the slower-learning bottom 10-20 percent who consider themselves "dumb" or "stupid," and the large majority in between—not really understanding much, but content to receive a "C" and get out.

It was attitudes such as these which prompted me several years ago to investigate alternative modes of education. The alternatives involved evaluating students on the basis of mastery of definable objectives, and not on how well or poorly or rapidly their classmates performed. I first investigated computer-based education (CBE) over ten years ago, became disillusioned with the quality, and left. When PLATO became viable in the early 1970s, my interest and activity were rekindled. Shortly thereafter, a friend intro-

duced me to Keller's Personalized System of Instruction (PSI). Combining CBE and PSI in a university framework proved very useful in eliminating many of the attitudes mentioned earlier.<sup>13-16</sup> Then, a few years ago, I introduced explicit cooperation into these courses, lest students become too isolated.<sup>12</sup> The primary cooperative efforts were: study partners for PSI units, design of a computerized personal data base by a small group, mutual design and use of interactive programs, use of cooperative exercises and parties.

Approximately the same time as the last papers were published, the personal computer revolution began in earnest. The seeds were thus sown for a major professional transition: a long-abiding interest in the home, a career in higher education, professional training in computer science, and the personal computer. After balancing these for a year or two while continuing to teach in the university environment (and encouraging all my students to investigate machines for home use<sup>11</sup>), I made the decision to return to the computer industry after a 13-year hiatus.

## THE ATTRACTION OF INDUSTRY

Texas Instruments (TI) is a very natural professional home at this time. It has a long-standing interest in the individual consumer; it can deliver high-technology personal products at affordable prices; mini- and microcomputers are current offerings of the company; it has made a commitment to using an extremely well structured programming language (Pascal); a large educational effort is underway to deliver this tool; and most importantly, it actively encourages creative solutions to challenging problems. Consequently, my active interests in personal computing and CBE/PSI educational systems could be naturally joined to help deliver a useful, fun and challenging tool to homes everywhere. "Computing power to the people" became an area where contributions were definitely possible. In fact, TI received top billing in an excellent recent article on CBE, where the author stated: "... it is not wise to underestimate the ingenuity of the private sector in harnessing mass production to perceived consumer needs, whether in the home or in the

school."<sup>19</sup> He then goes on to describe the popular Speak & Spell (TM) product of TI.

Texas Instruments has made a substantial effort to improve the scope and calibre of on-the-job education for its employees. And because of the diversity of employees in such a company, it is an ideal site for applying CBE/PSI principles developed in academia. Lessons learned in this environment can be utilized as TI also actively pursues a market beyond its own confines. This market is the general populace which can make fantastic creative contributions if given a versatile, well-designed home computer capable of educating *and* of becoming "educated" itself. An excellent article in a recent issue of *Computer* is a well balanced overview of some of these contributions and how they might come about in the 1980s, according to a group of experts.<sup>8</sup>

The ability of machines to become "educable" is my requirement for personal computers. They must be able to perform many useful and fun tasks. Pick up any copy of *Creative Computing*, *Personal Computing*, *Byte*, *People's Computers*, etc. for a vast array of marvelous application areas. But the same computers must also be able to be told how to do new things—no amount of ROM is adequate here. Historically, we have told the machine how to do new things by creating a new program for it. I doubt very much if the general public will program in the same ways you and I have for 20 years, but we must make it possible for them to "teach new tricks" to their new helper and game-player. Our natural language researchers in artificial intelligence should be a big help here. Smalltalk at Xerox PARC is an excellent start.<sup>9</sup>

#### POTENTIAL CONTRIBUTIONS

Both CBE and PSI, after a relatively sheltered life in academic institutions, hold great promise in other institutions, notably the home and industry. Control Data Education Company and others are deeply involved with CBE in industry.<sup>5</sup> And it is rumored CDC is even looking at the home market.<sup>6</sup> PSI, on the other hand, is almost exclusively used in schools. Therefore, one of the potential contributions is to formulate a strategy to maximize the effectiveness of both tools in an industrial environment. They have proven themselves to be viable in their original settings. Now we are in a position to respond to numerous calls for cooperation between the university and industry.<sup>4,17</sup>

Upper-level management at TI has decided that the widely-recognized superiority of Pascal for many programming tasks will be acknowledged within a majority of future TI products. Consequently, they have funded the effort to produce the first industrial version of Pascal, called TI Pascal. The language, in both its sequential and concurrent forms, has been formally released.

Now formulating the (few) extensions to Pascal and implementing the associated compilers, interpreters, and run-time support systems is no mean feat. However, the educational effort required for widespread use of this tool is also considerable. The universities have been a great help here as they continue to replace their introductory courses

oriented to Fortran and assembly language with ones emphasizing Pascal and associated reliable design techniques. A recent issue of *Byte* contains many readable articles on Pascal.<sup>7</sup> Textbooks are also rapidly appearing.<sup>2,3,18</sup>

Within TI then, we are experiencing many of the problems associated with university classes: "too many" students for only a few instructors, not enough individual attention, time conflicts, student travel time, multiple entry levels, etc. In addition, there are some unique concerns. In particular, student time is worth money! This is a revolutionary concept in school, but a vital consideration in industry. Moreover, students do not really receive a letter grade. Rather, it is *assumed* that, after they have attended a Pascal course for *n* hours, they know Pascal sufficiently to be able to read and write Pascal programs.

#### A POSSIBLE SOLUTION

One of the possibilities under consideration by TI for delivering some courses involves both CBE and PSI. The following is one option.

1. Develop CBE materials using off-the-shelf hardware, and pieces of courseware, if available.
2. Use the product for a few classes until the majority of the major errors are removed.
3. Concurrently, develop TI software and hardware designed for a well-engineered CBE interface, relying on experience gained in the current system by users and authors.
4. Transport currently developed courseware to the new distributed TI system permitting interterminal communication.

At this point, students will take a lesson (or course) near their site at a TI system. User consultants will be available on-line in prime time, with a notes feature used at other times.

The course will usually consist of several units as in PSI, where each unit contains an introduction, objectives, suggested procedures (involving reading, program writing, taking CBE lessons, etc.), sample exercises and a multiple version unit test. Unit mastery will be demonstrated by passing the unit test at 80-90 percent competency, where each question will relate to a unit objective and be categorized by Bloom's educational cognitive taxonomy.<sup>1</sup> For readers unfamiliar with PSI, the excellent paperback by Keller and Sherman is recommended,<sup>10</sup> in addition to earlier referenced papers of the author. Briefly, PSI is characterized by five attributes:

1. Mastery-based
2. Self-pacing
3. Non-lecture
4. Written materials
5. Proctors

The argument in favor of PSI runs something like this.

Students can gain in self-respect, and justifiably so, when they demonstrate they can master the material (a). But since students grasp material at widely varying rates, such mastery will occur only if the students are primarily responsible for pacing themselves (b). However, if they pace themselves, there is no way any lecturer could possibly speak to all students at their individual points of progress (c). But if the information is not transmitted verbally, how can it be done? Written material provides a partial answer (d). With the widely varying rates of progress through a course, there is no way one instructor could manage the evaluation process for 30 students working on 20 units of material, each with its own multi-version unit test. Hence, proctors become invaluable (e). They each, including the instructor, take responsibility for about ten students. That is, they go over the unit tests, answer questions, suggest resources, etc.

The first unit test will be graded on-line at the student's convenience by an instructor. If competency is not demonstrated, suggestions for further study will be given and another version of the test taken later. This will continue until mastery is achieved, and then the student will start the second lesson. For latter units, either the instructor or another student who had passed the unit earlier (internal proctor) will grade the test and make suggestions. This proctor can be at the same site as the student taking the test or at another TI site. In either case, the proctor can see the student's quiz and carry on a full dialogue.

Course mastery will be demonstrated by passing all units at mastery level. Statistics regarding completion times, number of unit test retries, proctors, comments on lessons taken, ill-stated questions or objectives, etc., are easily gathered in the proposed system and can be released to authorized personnel. For example, a cost center manager might wish to see how much money should be budgeted for students to take the TI Pascal course.

## A FUTURE

I would expect that, should TI decide to try the preceding alternative to current course development and delivery, the company will also market a similar product eventually. A home computer can be utilized for educational lessons with dial-up access to instructors or proctors who might become widely-scattered friends over time. Components of the lessons can use the many exciting peripherals forthcoming: touch panels, audio output and input, video disks, synthesizers, etc. as well as our best and most versatile resource: people. If a student has difficulty understanding something, cooperation is encouraged! I think we are here to help one another, not to compete continuously.

## SUMMARY

I have suggested that the institutions of home, school, and industry have much to gain by cooperation with one another.

My interest in providing computing power at an individual level has led me on an odyssey from industry to university life, and now back to a computer industry vitally involved with personal computing. Lessons learned in the university about how students learn better are suggested as viable options in the industrial environment. In particular, CBE (computer-based education) and PSI (Personalized System of Instruction) are conjoined to offer flexible courses internally. And from these efforts, modified ones can be made available to the public, permitting learning to occur wherever people happen to be, perhaps just finishing up with a rousing game of interterminal "Star Trek" or "Oregon Trail!"

# Recent developments in computers and society research and education

by RICHARD H. AUSTING

*University of Maryland*  
College Park, Maryland

and

GERALD L. ENGEL

*Old Dominion University*  
Norfolk, Virginia

## INTRODUCTION

Since the advent of computers, there has been concern about the impact of computers on various aspects of society. Thousands of articles and numerous books have been written in the general area of computers and society. Computer professionals have been instrumental, though perhaps not always significantly enough, in the development of policies and legislation affecting the use of computers in the public domain. Studies have been conducted; courses have been introduced, primarily at the college level; seminars directed to computer professionals have been held; and public information programs have been sponsored, mostly on a local level.

While much of this activity is continuing, a number of developments during the past few years suggests that new (or renewed) emphasis is being placed in certain areas, particularly in research and education.

## RESEARCH

One indication that research activity in any area is increasing is the establishment of a journal or section of a journal for publication of results. Research papers in computers and society have been appearing regularly in the *Communications of the ACM* since January, 1976 when "Social Impacts of Computing" was made a separate Technical Department with its own editor (R. Kling, University of California at Irvine). Also, the conference ACM 78 which was held in Washington, D. C. in December, 1978 included two sessions on research in computers and society. Six papers were featured in these sessions.<sup>1</sup>

Books have appeared which give more stress to issues in the area of computer impact on society and analytical perspectives of the subject matter rather than expository treatments of applications as found in many works. Examples of the former are books by Arbib, Gerberick et al., Gotlieb and

Borodin, Hoffman, Mowshowitz, and Weizenbaum.<sup>2-8</sup> These kinds of books are useful for computer professionals as well as for upper division or graduate students in a computer oriented degree program.

## EDUCATION

Recent curriculum recommendations from ACM's Curriculum Committee on Computer Science (C<sup>3</sup>S) include an advanced-level course in Computers and Society. The report "Curriculum 78: Recommendations for the Undergraduate Program in Computer Science"<sup>9</sup> specifies that the course at least be strongly recommended and should be required of all computer majors if sufficient material is not included in other required courses in the program. This recommendation constitutes one of the major differences between the report "Curriculum 78" and the same committee's report ten years earlier<sup>10</sup> which did not include a course on computers and society.

Another recent development within ACM is also worth noting. The Elementary and Secondary Education Curriculum Committee, in December, 1978, began work on recommendations for material on computer impact to be taught in elementary and secondary schools. It is too soon to comment on this development, but the effort itself is significant.

## CERTIFICATION

The Institute for Certification of Computer Professionals (ICCP), established in 1973, has exercised concern over the societal responsibilities of computer professionals in a variety of ways. In 1977, ICCP offered the Certificate in Computer Programming (CCP) examination which attempts to test minimum knowledge requirements for persons holding senior programmer positions. The content outline for the examination contains a section on computers and society.

ICCP also offers the Certificate in Data Processing (CDP) examination which is oriented toward management positions. Anyone who passes these examinations is expected to subscribe to codes of ethics and good practice (which were developed by ICCP) in order to obtain the certificate. Although relatively few (less than 20,000) persons hold the CDP and only several hundred hold the CCP, there is active discussion on the use of these examinations (and examinations for other positions under consideration by ICCP) as part of the minimum requirements for appointment or promotion to certain positions. This issue is a complex one with ramifications that are not subject matter for this paper. However, the institution of such requirements as criteria for obtaining a job title or, more importantly, for carrying out the duties of a position, will increase the awareness of computer professionals of their societal responsibilities.

For example, consider the development of an automated diagnosis program. A number of them have been implemented and more sophisticated ones are likely. Some of these programs have resulted from the interaction of medical personnel who knew relatively little about computers and programming and one or more programmers who knew relatively little about medical applications and who may not have known as much as one would like about programming, data structures, and relevant techniques. Who is to blame if a patient suffers because of a wrong diagnosis? Does the programmer have any responsibilities in this regard? Should a programmer be required to pass an examination such as the CCP before being placed in charge of the programming project? Certainly, there is no guarantee that persons will be more aware of societal responsibilities because they obtain a new title, but the intent would be to make them more accountable, hence, we hope, more concerned.

## CODES

Within the last few years, codes of ethics, conduct, or good practice have been established by a number of computer societies (e.g., ACM, ICCP) which suggests the memberships' growing awareness and concern over the impacts of computers on society. Members are expected to subscribe to the codes, but computer societies have found it difficult if not impossible to enforce their codes. In an attempt to remedy this problem, the ACM Council at its meeting in June, 1978, adopted enforcement procedures for its Code of Professional Conduct after extensive discussion both at this meeting and at previous ones. The text of the procedures was published in the August, 1978 issue of the *Communications of the ACM*.<sup>11</sup>

## NSF GRANT TO ACM

In 1974, work began on a project of ACM's Education Board funded by NSF and entitled "A Study of Computer Impact on Society and Computer Literacy Courses and Ma-

terials." The project had three basic objectives:

1. To review and catalog materials related to computer and society courses and programs and to provide methods for dissemination of such information.
2. To identify minimum-knowledge-level requirements for computer literacy.
3. To develop behavioral objectives for various types of computer and society courses as well as develop decision mechanisms for materials for such courses.

## Bibliography

The project committee's efforts to achieve the first objective resulted in 1976 in an annotated bibliography of over 2000 selected entries (dated, for the most part, after 1968) which was intended to provide resource material for teachers of both computer impact on society and computer literacy courses. A hierarchical information storage and retrieval system was developed and implemented under Charles H. Davidson at the Engineering Computing Laboratory, University of Wisconsin—Madison. Entries were coded by area, function, approach, level and type. Retrieval of all entries satisfying combinations of these categories was possible.

A review of the kinds of material written in the area of computers and society, and included in the bibliography, can be found in Austing, Cotterman, and Engel.<sup>12</sup> Briefly, the review indicates that over 90 percent of the material was expository in nature, ranging from the wonderment (e.g., computers are superior to humans) and fear (e.g., computers will cause vast unemployment) found in earlier literature to the more detailed discussions of applications found in later material. A very small percentage of the literature contained technical perspectives. We hope this percentage is increasing as suggested by the examples cited in previous sections.

While the bibliographic work was underway, the project committee participated in panel sessions and held open hearings at conferences, in addition to discussing ideas and experiences of interested and knowledgeable professionals from education, industry, government and selected groups from the public-at-large. These efforts provided substantial input relative to course content, educational level, minimum requirements and objectives of courses in computer impact on society and computer literacy.

The second phase of the project, also funded by NSF, began in July, 1977 and will continue into 1979. The following three activities were specified:

1. Further develop and refine the bibliography and the information storage and retrieval system supporting it.
2. Organize and conduct a workshop on computer impact involving individuals other than computer professionals.
3. Develop and disseminate a collection of position statements in the area of computer impact by various concerned professionals.

### *The workshop*

The workshop played a major role in the approach to the other two activities. It was held on July 17-19, 1978 in Williamsburg, Virginia. The 33 invited participants represented as diverse a group as possible, the only common bond being an expressed interest or experience in one or more aspects of the societal impact of computers. Austing and Engel report on the organization, content and results of the workshop.<sup>13</sup> Some of the results and recommendations lend emphasis to the fact that there are renewed efforts lately in the area of education regarding computers and society.

Specifically, a list of topics was developed from which course material could be used. This list did not constitute a taxonomy, nor was one expected at this stage. However, whenever a topic is selected for presentation, it is necessary to determine the level (impart knowledge, instill an attitude, develop a skill), audience and approach (lecture, discussion, examples only, technical aspects, project, etc.). Further, when developing material possible emphases must be considered, such as

1. Skills citizens need for coping with the computer impact.
2. Computer impact on work patterns and relationships within organizations.
3. Degree of high technology comprehensibility of professionals.
4. Computer impact on the political/economic/legal process.
5. Inherently socially problematic nature of computer technology.

The growing interest and public support for the computer literacy concept was cited as a reason to consider including suitable material at the pre-college level. More strongly, the workshop participants recommended that *all* high school graduates be computer literate. The rationale focused on the necessity to learn about computers before formal schooling is completed because computers do (and will continue to) permeate our society. To achieve the desired computer literacy, graduates should have knowledge of the following:

1. Historical perspective of computing.
2. Computer anatomy (includes parts of a computer, how computers work, algorithms, problem solving, system capabilities).
3. Uses of the computer (both types of uses such as information storage, simulation, DP, communications and areas such as business, science and technology, education, health care).
4. Social implications (such as careers, organizational changes, privacy).
5. Futuristics (for example, trends in artificial intelligence and robotics, innovation and new technology, communications).

6. Introductory level skill in algorithm design and programming (only if adequate access to computers is available).

At the college level, two kinds of courses were specified, one for the general education requirement (designed as a survey type course) and one for the computer science major (designed to help students learn to carefully analyze the social settings in which computing is used, to understand what social and historical forces give rise to different systems uses and designs, and to realize the impacts and value conflicts upon users and non-users of computers). The workshop participants recommended that a Computers and Society course, or equivalent knowledge, be a part of the education of every college student. Rationale cited the imperativeness for college-educated persons to have more than a superficial knowledge of computers and their impact because of the technical/information explosion and the corresponding expansion in computer usage, the need for the corresponding expansion in computer usage, the need for awareness about computers in consumer life and the need for a more informed citizenry in decision making where computers are involved.

Imparting knowledge to computer professionals and reaching them are two problems addressed by workshop participants. Delivery mechanisms (e.g., courses, professional development seminars, tutorials) must be intensive, be appropriate to the job environment and be geared to very specific groups. Computer professionals have a difficult enough time trying to keep up-to-date in their specific area. They will not always find the time to attend courses or seminars for the purpose of keeping abreast of the impact of computers in such wide-ranging areas such as transborder data flow, electronic funds transfer, communications and health care. They need a set of principles rather than broad knowledge to apply to societal impact issues relevant to applications in which they are involved. These principles can be developed through a highly-concentrated approach to a specific issue, possibly by means of a case study approach or by simulations and role playing.

The general public needs to be educated about computers but effective means are difficult to identify. Every computer professional can play a role in educating the public and, by so doing, put into action various aspects of social consciousness that would otherwise just be words. The public is inundated by computer applications (e.g., charge accounts, graphics on TV, advertisements, electronic games). Computer professionals could not only offer continuing education courses to transmit correct information to portions of the public, but also exert whatever influence they have (possibly through computer societies and associations) on business and government to promote policies encouraging proper use of computers where the public is involved. Workshop participants identified a number of specific information media and suggested uses of media groups for disseminating material about computers to the public. However, no readily available solutions were found.

One of the outcomes of the workshop was to broaden the base of material in the bibliography developed in the first phase of the grant by incorporating references from fields other than computer-oriented ones (e.g., philosophy, health care). The bibliography was also updated by adding more current references and, in some cases, deleting some which have been superseded or which were not as good a source as another reference. The bibliography now contains over 3000 entries and is a much more valuable resource to anyone intending to offer a course in the computer impact on society or computer literacy. After the termination of the grant in the spring of 1979, ACM will begin maintaining the bibliography. Information concerning its content and use can be obtained through ACM.

## CONCLUSION

The activities previously described indicate the kinds of efforts underway in the area of the computer impact on society. They are at the level of affecting professional organizations of computer people and having an impact on schools, especially elementary and secondary ones. Research results are being disseminated more widely than before which, in turn, should encourage more creativity and development by people concerned with societal issues. All of these are hopeful signs of renewed emphasis on important issues in computers and society.

# Interactive monitoring of computer-based group communication\*

by KATHLEEN SPANGLER, HUBERT LIPINSKI and ROBERT PLUMMER

*Institute for the Future*  
Menlo Park, California

## INTRODUCTION

Biofeedback is a procedure for monitoring unconscious or involuntary bodily processes and making them perceptible to the senses. The objective is to increase consciousness and therefore control of the bodily processes as a means of improving health. This paper is not about health or biofeedback, but it does describe a procedure that is perhaps analogous to biofeedback—the interactive monitoring of group communication through computers.

Over the last decade, a number of computer programs have been developed to support small-group communication; these include PLANET, EIES, PARTYLINE & DISCUSSION, CMI, CONFER, MINT and RIMS.\*\* Since these programs act as a kind of gatekeeper for the communication process—directing participants to appropriate “activities” and ordering their “messages”—they can easily be extended to record important features of the group’s communication patterns. For example, during its development phase, the PLANET system included monitor software that collected and analyzed information about the time users entered and left a PLANET activity, the number of public and private messages sent, the number of words in public and private messages, the use of commands, the typing time and the number of computer resource units used, among other statistics. This information was used to evaluate the impact of the medium on group communication and it revealed several different styles of computer conferencing among users of the system.<sup>2,3,4</sup>

The information from the PLANET monitor software was not available to those who were participants in PLANET conferences during their discussions. However, there is no technical reason why such information could not be made available to users of computer conferencing. It could then serve as a kind of biofeedback about the group communi-

cation process, increasing the group’s consciousness of its communication patterns and thereby giving them more control over those patterns.

An interactive monitor would allow the group to spot possible communication barriers—nonparticipants, isolated subgroups and poor access to important resources, for example. The group leader or the group as a whole could then determine whether some intervention would reduce these barriers. An interactive monitor could also provide insights into the efficiency of the group communication process; it could display to the group its volume of communication, the timeliness of information exchange, and the cost of communication. Over a long period of time, such a monitor could chart the history of the group, displaying informal changes in the group’s organization that may suggest the need for formal changes. In short, an interactive monitor could be used to evaluate and alter the group’s communication process.

## IMPLEMENTING THE MONITOR—THE HUB SYSTEM

At the Institute for the Future, we have begun to implement this concept for groups with a specific communication purpose—the construction of large-scale policy models. We have designed a communication system known as HUB. The HUB system, which resides on the Bolt, Beranek and Newman PDP-10 computer in Boston, is a four-part communication system. The four parts include

- A computer conferencing facility that uses the PLANET program.
- A graphic communication facility (the “shared visual space”) that allows users to create graphic images from picture primitives and to comment on these images.
- A “program workspace” that allows users to run a variety of computer programs and to discuss them while they are being seen or to comment on them later.
- A “document workspace” that allows a group of users to develop a document jointly by making changes on a single version and annotating those changes in comments.

A HUB “switcher” makes it easy for users to access and

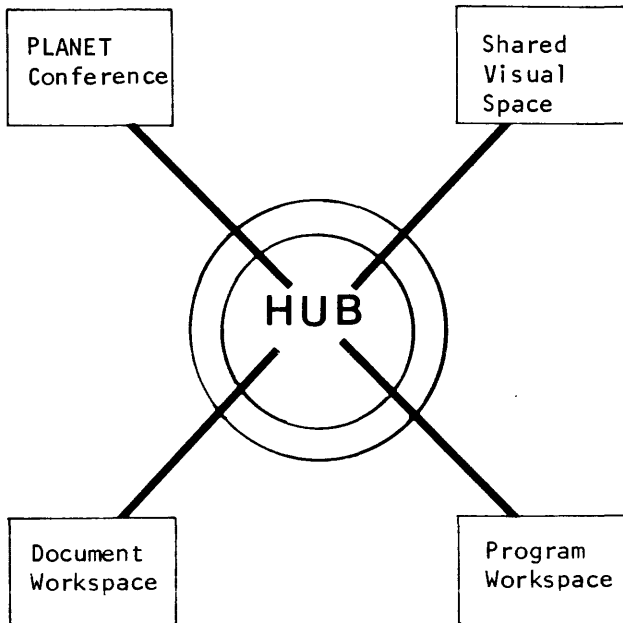

Figure 1—The HUB system.

move among each of these four systems, as illustrated in Figure 1. It is in this switcher that the HUB monitor is located and it is here that users interact with it.

#### IMPLEMENTING THE MONITOR—WHAT TO MONITOR

In designing the monitor, of course, one of the central questions is, What should be monitored? To answer this question, we began by considering the complex set of variables that combine to shape group communication. One useful way of grouping these variables is according to three categories: (1) group process, (2) individual communication styles and (3) task performance.\*\* These categories suggest an outline for identifying the kinds of information that may be useful to a team of modelers in the course of a HUB conference.

Consider first the *group process* variables. One of the most important issues for groups of all kinds is participation. The level of participation of various group members reflects leadership patterns, productivity of the group, and the availability of resources to the group. It can also reveal subgroups who may have certain unique communication needs, but also unique problems in communicating with the larger group. In a HUB conference, we imagine that the following information about participation would be useful:\*\*\*

- Volume of communication per day, week, or month for

\*\* For a review of taxonomies of group communication through electronic media, see Reference 5.

\*\*\* Obviously, this list is not exhaustive; it does, however, include the major patterns that can be collected or calculated automatically.

the entire group (in both comments and words), for the entire system and for each part of the system (i.e., PLANET, program workspace, etc.).

- Length of comments in each part.
- Distribution of participation over time.
- Distribution of participation within each part and across parts of the HUB system.
- Dominant participants for each part; for the system as a whole.
- Percent synchronous participation for each part.
- Cost of communication per unit time.

Each *individual* in the group will have his or her own characteristic style of communication. The monitor should be able to provide a profile of this style. Many of the variables in such a profile are similar to those for the group as a whole. For example, the profile should probably include

- The volume of communication generated by the individual compared to the volume of the group as a whole.
- The individual's frequency of communication.
- The changing position of the individual in the distribution of participation over time and across parts.
- His/her use of programs compared to others in the group (number of runs initiated in the program workspace).
- Percent time spent in synchronous interaction.
- His/her private communication network (in PLANET).
- The "accessibility" of an individual to others in the group.†
- His/her cost to use the system per unit time, compared to the total group.

The *task performance* variables are perhaps most specifically related to the unique communication problems of modeling groups. These problems include a lack of communication between builders and users of models due to organizational barriers, perceptual barriers and different levels of skill in working with computers and mathematical concepts; a tendency for individual members of the modeling team to "do their own thing" rather than to work in a collaborative style; problems of documentation; and problems of confidence in the model due to difficulties in interpreting results, in understanding the model structure and in recognizing factors that are not considered in the model, all of which lead to questions about the validity of the model.§

Much of the information that would be useful in diagnosing and correcting these problems cannot be easily collected by an automatic monitor.\* However, since the various parts of the HUB system are really designed to facilitate different

† "Accessibility" in a HUB conference can be measured by the time lag between the sending of a message and its receipt by any particular individuals. The longer the average time lag, the lower the accessibility.

§ For a full discussion of communication problems in the modeling process, see Reference 6.

\* For example, an indicator of difficulties arising due to perceptual or disciplinary barriers is the use of specialized jargon by subgroups. A content analysis of the transcript would reveal such a pattern; however, it is not done easily by an automatic monitor.

tasks, the usage patterns for each of these parts provide a task-related profile of the group's communication. For example, the volume of activity in each part is likely to change as the focus of the project shifts from one task to another. These shifts can be monitored over time; individual participation patterns can be overlaid on these volume patterns. Such information would demonstrate who is involved in what types of activity at any point in time.

It will also be useful to collect specific data for each of the subparts to clarify issues of task performance. For example, it will be useful to know

*For the shared visual space:*

- The number of versions of each graphic image.
- The ratio of comments to graphic commands.
- The length of time to produce a completed graphic image.
- The frequency of use of graphic commands.
- The cost to produce a completed graphic image.

*For the program workspace:*

- The number of runs for each program.
- The number of comments per run.
- The number of synchronous runs.
- The number of times each run is reviewed.
- The number of unique input files.
- The ratio of program lines to comment lines.
- The cost of each run.

*For the document workspace:*

- The number of text changes over time.
- The ratio of text changes to comments.
- The number of times a document is printed in full.
- The average line length of text changes.
- The number of synchronous text changes.
- The number of reviews of text changes.
- The cost per text change (including and excluding comments).

In addition to this information, the group can evaluate its overall task performance by considering some of the data about the "time effectiveness" of information exchange in various parts of HUB. Thus, the HUB monitor should collect statistics on the length of time between any program run and its review by any other participant; between any graphic change and its review by any other participant; between any document change and its review by any other participant; and between comments in any of the four parts and their review by any other participant. Such measures will provide a very dynamic view of the communication process.

Many of the communication variables in these four categories are related; in fact, all of them can be calculated from a relatively small number of statistics, which the HUB monitor is designed to collect. In addition to these statistics that are collected unobtrusively, the monitor files include space for two other types of information: (1) hand-coded information about the message and (2) responses to structured

questions. Thus, it would be possible, for example, for someone to content-analyze a series of messages (e.g., for the use of jargon) and hand-code this information into the monitor to be displayed with network patterns for the messages. The second feature—responses to structured questions—would allow the conference organizer to poll the users' feelings about the group process, which would then also be available to supplement the statistics on communication patterns.

## IMPLEMENTING THE MONITOR—HOW TO DISPLAY

The procedures for collecting monitor statistics are quite simple. The procedures for displaying them to the group are more complex. First, there are choices about how to represent information about all of the communication variables noted above. Some of these can be shown as simple ratios, but most of them call for some form of graphic display. Some of these, such as network graphs that must be constructed to show the strength of links, can be quite complex. Second are choices about how the users interact with the monitor—Do they automatically get a display of 20 or 30 pre-set graphs and figures or do they specify what they want to see? And if they specify what they want to see, how do they know what they can display? Closely related is a third question about how much control users have over what can be displayed. On one hand, there may be only one fixed representation for each major variable. On the other, the users might be able to manipulate the representation to emphasize certain aspects of it, or they might even be able to combine two or three variables to suggest correlations. Finally, there may be certain variables that are pre-selected as significant; in this case the monitor could automatically notify the group when this variable reached some critical level.

Because we are still in the process of developing the HUB monitor, we have not made all of these choices. However, it seems clear that the way in which the variables are displayed could make a significant difference in the impact of the monitor data on the group. Furthermore, it seems clear that there are a number of creative ways to display the information that might speak directly to problems that plague modelers. For example, labeling people by some label other than their names could provide some interesting insights. If a graph showing distribution of participation were labeled by disciplines rather than names, it might become clear, for example, that subgroups are developing along disciplinary lines. The group could then assess whether this pattern is appropriate for the phase of the activity or whether some important insights are being lost due to lack of effective communication between the subgroups. Thus, it seems that a primary criterion for decisions about how to display the monitor data should be flexibility to design displays that do, in fact, address particular problems that the group may have.

#### AFTER IMPLEMENTATION—THE IMPACT ON COMMUNICATION

We have suggested that an interactive monitor could have an effect on the group communication process that is comparable to that of biofeedback—namely, that it can increase consciousness and therefore control of the group's communication patterns. But we can now speculate about some more specific impacts—both negative and positive—of the type of monitor that we are implementing for the HUB system.

One possible effect is that there will develop a new role in the communication process for a group facilitator. We have already noted the tendency for such a role to develop in PLANET conferencing.<sup>3</sup> In a HUB activity, this role might include responsibility for checking the monitor regularly and interpreting the results for the group. The facilitator might use the private message mode to counsel individual group members about their participation patterns or might use the displays in group sessions to consider the implications of the patterns for complaints or difficulties that the group may be experiencing.

A second likely effect of the monitor would be to encourage more experimentation with group structures. As the group becomes more conscious of its communication patterns, it may wish to intervene in these patterns by tinkering with roles and responsibilities and then following the monitor to observe the effects of the experimentation.

It seems very likely that such a monitor could and would be used to evaluate the group's performances and the performances of individual members. Certainly, it would make an individual's contribution to the group more apparent; it would also provide a reading on the more elusive measures

of performances, such as ability to get along with one's colleagues. Such an evaluation tool may indeed seem attractive to someone who is faced with objectively evaluating a group of people; however, there are also real dangers here. First, there is the possibility that the very existence of the monitor will inhibit some communication, and it may actually discourage the participation of some people altogether. Also, the monitor may encourage some people to "perform" for the monitor, to alter their behavior just to show up well in the monitor data. Finally, the use of the monitor could encourage evaluation of the *wrong* aspects of performance, particularly if the data that are easily collected are not the best data for evaluation.

The way that the HUB monitor will be used by groups and the effects on modeling communication remain to be assessed. Our plans call for field tests of HUB over the next two years. The role of the monitor will be an important focus of this evaluation.

# The status of women in health science computing

by LYNN L. PETERSON

*The University of Texas Health Science Center at Dallas*  
Dallas, Texas

The computing profession is now just over 25 years old. During this 25-year period, women increased in the labor force from 34 percent of all women ages 16 and over in 1950 to 46 percent in 1975.<sup>1</sup> Since computing developed during the period when females became a larger proportion of the work force, the question arises as to whether women are equitably represented in this profession. The present decade has brought a consciousness-raising with respect to woman's role in the professions in general, with an interest in the role of women in the computing profession following naturally. The health care industries have become an ever more important and visible component of the U. S. Gross National Product, resulting in increasing scrutiny of the conduct within the health care professions. With this background, the question of the status of women in Health Science Computing appears to be a logical one to consider.

The ACM-SIGBIO Symposium on Health Computing Careers was held in June 1977 to provide a broad survey of present and future health computing careers. A basic understanding was that Health Science Computing was not just computer science practiced and applied in a Health Science Center setting, and it was not just medicine utilizing computers as one of the many specialized tools at its disposal. Health Science Computing was seen as combining capabilities of computer science and medicine and emerging as a discipline of its own to address areas of patient care, research, education and service.<sup>2</sup> However, if our concern is women's role in Health Science Computing, we can gain both knowledge and perspective by examining the two major components of its root—computer science and medicine.

## COMPUTER SCIENCE AND WHERE WOMEN FIT

To look at those who are in the process of preparing for a career in computer science, we refer to a study done in the fall of 1975 by Mamrak and Montanelli.<sup>3,4</sup> Their findings show clearly that the number of students enrolled in computer science programs has increased dramatically since the early 1970s. They also show a small but statistically significant increase in the enrollment of women in computer science at the bachelor's level during the period from 1971-1975. But a look at the numbers of students in bachelors, masters and doctoral degree programs shows a moderate decrease in the percentage of women enrolled and graduating as the degree level increased. It is possible that one of

the reasons for this is the lack of role models to encourage aspiration to higher-level career attainments. For the 1971-75 time period, the sex distribution of computer science faculty indicates a clear lack of availability of women role models in the higher academic ranks.<sup>4</sup>

Next, let us look at those who are actually engaged in computing as a career. In 1975, women made up 39 percent of those in the labor force.<sup>1</sup> At the same time, they comprised approximately 31 percent of those employed in computing at all levels.<sup>5</sup> In the data entry positions, 99 percent were women. In programming and analysis, the percentage of women holding these job titles was no higher than 20 percent. An explanation of this situation could be the one offered by Weber and Gilchrist. Approximately 34 percent of the baccalaureate degrees awarded by American colleges and universities in 1971 went to women. If letters, nursing, fine arts, applied arts and home economics are excluded, the percentage of women drops to 26 percent. It is possible then that not enough women are receiving baccalaureate degrees in fields appropriate for entry into the computing profession to raise the percentage significantly through the mechanism of providing qualified applicants.

Another view of the role of women in the computing profession involved a survey of 425 women (77 percent responses) in data processing conducted in 1975 by Asprey and Laffan to determine how women felt about their status and their potentialities.<sup>6</sup> The survey showed that 68 percent felt they had equal status with their colleagues in pay, promotions and overall. Some 70 percent of the respondents felt they had opportunities to advance to a senior level and more than half (actually 56 percent) felt opportunities to hold highly responsible management positions were available to them as women. The survey showed that the availability of part-time employment or of work on a contract basis made the computing field attractive to women with family responsibilities. Betty Maskewitz, now Director of BCTIC at the Oak Ridge National Laboratories, is quoted as saying "computing is a wonderful field for women—an exciting field for anyone regardless of sex or any other stupid qualifier."

While the computing field received a rather positive subjective evaluation by women employed in it, one might wonder if this field of endeavor is then hospitable to all. A recent *Datamation* article<sup>7</sup> shows that the computing profession is clearly not for everyone, that those individuals who are

attracted to computing as a career do not represent a cross-section of working professionals. A survey reported in the article shows that data processing people show a strong need for personal accomplishment, for learning and developing beyond where they are, for being stimulated and challenged; in short, a high "growth need." In fact, of all the professions surveyed, computing professionals showed the highest level of "growth need." At the same time, data processing people show a negligible need to interact with others, the lowest "social need" of all professions surveyed. In fact, it is felt that, if asked, most programmers would probably say that they preferred to work alone in a place where they couldn't be disturbed by other people. Computing professionals then do not merely represent a cross-section of the work force, but have some distinctive characteristics. In the absence of arguments to the contrary, we can assume that these personality traits are represented in both sexes.

#### MEDICINE AND WHERE WOMEN FIT

A look at medicine, the other major component of the root of Health Science Computing, shows that women in academic medicine, the area of medicine most likely to be in contact with Health Science Computing professionals, do not fare as well. Judith Braslow of the AAMC staff stated<sup>8</sup> that of 48,500 faculty members in the nation's medical schools, 15 percent were women. Furthermore, of the 38,973 full-time faculty, 10 percent of the M.D.s and 15 percent of the Ph.D.s were women. Subjectively, their situation was felt to be improving. These women felt freer to move as career advancement dictated than was previously the case, and many were willing to make the sacrifices involved in moving to administrative positions. Many were now being asked to serve on committees where the female point of view was desired but as a result were being greatly over-committed. However, they felt that in spite of the progress made there was still a dearth of women faculty role models.

#### MEDICAL COMPUTER SCIENCE

In order to qualify for many of the positions in the computing field, one is required to have the capacity for logical thinking instead of a specific preparation. Furthermore, for computing people such as data entry personnel, computer operators and junior programmers without a defined specialty, training in a specific applications area of computing is not required. It is, however, when we address the preparation of professionals in the specialty area of Health Science Computing that we are led to more academic considerations.

The academic training grounds of many Health Science Computing professionals are programs called by such names as Medical Computer Science, Medical Information Science, Medical Informatics or any of a variety of terms. In 1977, a survey of existing training programs in Medical Computer Science was conducted to update an earlier published study.<sup>9</sup>

An interim report on this survey,<sup>10</sup> presented at the SIG-BIO Symposium on Health Computing Careers, is available from, and will be kept current by, The University of Texas Health Science Center at Dallas. This survey shows that, according to Medical Computer Science practitioners and educators, job opportunities in health computing abound for adequately trained individuals. This situation shows no signs of slackening in the near future. The survey showed there were 92 percent as many students enrolled in Medical Computer Science programs in 1977 as had graduated since 1970. The 358 people enrolled were to be thrust into the job market in the succeeding years, each having up-to-date training in medical computer science. However, they account for less than one-sixth of the projected requirements for biomedical computer specialists.<sup>11</sup> Computer applications in medicine seem to be on the increase without a commensurate increase in the development of programs in Medical Computer Science to supply the personnel. If the projected need is accurate, this situation will have to change or else the bulk of the personpower recruited for medical computer science positions will have to be trained on the job. Thus, whatever route is used to approach jobs in medical computer science, job opportunities seem bright whether resulting from the growing requirement for accurate information posed by various programs of utilization of health care and assessment of the quality of health care, or resulting from the increasing clinical applications of the computer.<sup>12</sup> Thus, for the foreseeable future, people with specialized training in Medical Information Science or Health Science Computing will have every expectation of finding employment which makes good use of their background.

#### STATUS OF WOMEN IN MEDICAL COMPUTER SCIENCE TRAINING PROGRAMS

In an attempt to investigate the status of women in the Medical Computer Science training environment, a pilot survey was conducted. A complete survey of the Medical Computer Science programs with respect to women's role is planned as a follow-up to the 1977 survey mentioned above. Those Medical Computer Science programs identified in the 1977 survey will be contacted with the intention of collecting data on the number of men and women currently enrolled in M.S. programs, in Ph.D. programs, in Post-doctoral programs, already graduated from M.S. and/or Ph.D. programs and currently serving on the faculty. The survey is planned for the spring of 1979 with results to be presented at NCC 79.

Since the number involved in the pilot study was small, impressions only from the pilot survey can be given, with more objective data to come from the survey itself. It can be seen from even this limited sample that, within Medical Computer Science departments, the role of women in these programs covers a wide spectrum. One program has no women faculty; one, representing the other end of the wide spectrum, shows a two-to-one male-to-female-faculty ratio. Several programs have no female graduate students: one, representing the other end of a wide spectrum, estimates

that its student population has a one-to-one male-to-female ratio. In one program, all graduates have been male; in another, all have been female.

From these limited glimpses, it appears that a program's openness to women depends heavily on the individual graduate program and that generalizations over all Medical Computer Science graduate programs will not apply. A comment from one spokesperson suggests that a program's openness to women depends also on whether the individual women want to give what it takes to meet the challenge of the graduate program. In speaking with representatives of various graduate programs, it was interesting to find frequent mention of a man or men who gave encouragement to a number of women during various stages of their academic development. Such individuals should obviously be recognized and encouraged. While female role models may be lacking in many areas, this type of person can serve a role model for both sexes.

#### ENCOURAGING GROWTH OF WOMEN'S ROLE IN HEALTH SCIENCE COMPUTING

These glimpses of women in computer science and in Medical Computer Science Training Programs shed some light on what might be done to encourage the growth of women's role in Medical Computing. Some positive suggestions:

- Encourage women who are inclined toward an interest in fields preparatory to computing to pursue that interest and get good high school and undergraduate training. Sex stereotypes which suggest that girls should not be good in math, for example, should not be perpetuated.
- If you are a woman in the field of Health Science Computing, consciously serve as role model whenever possible. Be visible. Talk about the problems and possibilities of women in this field. If you like your work, say so.

- Finally, be the very best you can in what you do. Don't shy away from a challenge—enjoy it!

By these means, and ones which others will, we hope, continue to suggest, we may ensure that qualified, interested women are not discouraged and/or prevented from engaging in careers in Health Science Computing.

# Women and minorities in the computer professions

by HELEN M. WOOD

National Bureau of Standards  
Washington, D.C.

## INTRODUCTION

Generally, while full equity may not have been achieved by women and minorities in computer occupations, the belief has been that their employment status was better and conditions were more favorable for full utilization of skills due to the relative youth of the computer field. The federal government, in particular, has been involved in computers since their beginnings, and in addition has taken a stance in support of both equal employment opportunity (EEO) and affirmative action.<sup>19</sup> This position has been backed by laws (e.g., Civil Rights Act of 1964) and Executive Orders (e.g., E.O. 10590 and E.O. 11375) prohibiting discrimination on the basis of race, color, religion, sex, national origin, or age in federal employment. Accordingly, it is reasonable to assume that women and minorities would have more opportunities within the federal government, especially within the federal computer-related professions.

This report examines available statistics in order to assess the status of women and minorities employed in computer-related professions, both in the U.S. labor force, in general, and the federal workforce, in particular. The intent is to provide "gross" indicators of the current situation and perhaps stimulate additional analyses. The focus is on labor market experience (e.g., employment and unemployment rates, relative salaries), rather than the utilization of women and minorities from a human resources perspective. This paper will primarily address labor market-related issues. For a report on utilization of women and minorities in science and engineering, including an examination of such factors as science abilities and the relationship between career plans and career outcomes, see Reference 14. Overt or covert discrimination and societal, cultural or other causal factors which have been addressed elsewhere (e.g., References 7 and 8) are outside the scope of this report, as is any attempt to identify determinants for improvement.

Due to varying data collection and tabulation techniques, tabulated figures contained in this report may not add to totals. Likewise, totals may not necessarily agree across reports cited.

## U.S. WORKFORCE

The minority portion of the total 1974 U.S. workforce was approximately 11 percent. Women comprised nearly 40 per-

cent of the workforce.<sup>14</sup> The next section will examine the composition of the U.S. scientific and engineering workforce.

### *Scientists and engineers*

The NSF studies show that in 1974 the scientific and engineering population of the United States was almost two million in size, or just under 1 percent of the total U.S. population.<sup>13</sup> Of this total, which included individuals not in the active labor force (e.g., retired scientists), 1,100,000 were engineers and 900,000 scientists. Of the total population of scientists and engineers (S/E), about 1.7 million people were in the labor force (i.e., employed or seeking employment). Table I describes U.S. S/E employment by sex and race.<sup>13</sup>

In 1974, there were approximately 185,000 women trained in the S/E fields. Almost one-half of these women (89,000), however, were not participants in the labor force. That is, they were not employed and were not seeking employment. Those women who were in the labor force (about 96,000), represented six percent of the total number of employed scientists and engineers in the United States. The large number of women in S/E who were not in the labor force contrasts sharply with the figures for all male scientists and engineers. Only 12 percent (222,000 out of nearly 1.8 million) of all male scientists and engineers were not in the 1974 labor force.<sup>13,14</sup>

Of the women not working, 20 percent had retired. The others were unemployed due to family responsibilities, ill health and "other reasons." Some of those "other reasons," including perceived career roadblocks and discrimination, were among the issues discussed at a 1977 American Association for the Advancement of Science symposium on covert discrimination and women in the sciences.<sup>15</sup> Additional insights into factors contributing to low female labor force participation may be found in Kreps' report on American women in the work force.<sup>7</sup>

In 1974, minorities comprised less than five percent of all scientists and engineers (about 87,000). Minority scientists and engineers had a higher rate of participation in the labor force, however, than their non-minority counterparts. While about 15 percent of the non-minority scientists and engineers were not in the 1974 labor force, the figure for minorities was 8.5 percent.<sup>14</sup> The higher labor force participation rate

TABLE I.—Employment of Scientists and Engineers, by Sex and Race: 1974

Field	Total	Sex		White	Total Minorities
		Male	Female		
Total	1,662,000	1,566,000	96,000	1,583,000	79,000
Physical scientists	156,000	141,000	14,000	147,000	8,000
Mathematical scientists	45,000	38,000	7,000	42,000	3,000
Computer specialists	122,000	101,000	21,000	116,000	5,000
Environmental scientists	44,000	42,000	1,800	43,000	1,000
Engineers	999,000	993,000	5,000	963,000	29,000
Life scientists	136,000	118,000	18,000	129,000	7,000
Psychologist	61,000	46,000	15,000	57,000	4,000
Social scientists	100,000	87,000	13,000	86,000	14,000

Note: Detail may not add to totals because of rounding. Source: National Science Foundation, Manpower Characteristics System.

for minority group scientists and engineers is somewhat surprising since a greater portion of minority scientists and engineers were women (one in five) than was the case for nonminorities (one in 10). These figures led the NSF to suggest that "the high labor force participation rate for minorities may reflect more favorable career opportunities for minority group scientists and engineers vis-a-vis minorities in the general population because of equal employment and affirmative action legislation. Also, given historical patterns of discrimination, it may reflect a greater commitment to gainful employment in science and engineering among minority group scientists and engineers."<sup>11,14</sup> However, other factors such as the age, experience and reasons for non-participation in the labor force of both the minority and non-minority groups must be considered before any real conclusions can be drawn from these figures.

Now that general employment figures for scientists and engineers have been examined, it is meaningful to discuss the status of employment in the computer sciences.

#### *Computer specialists*

Recent attention has been accorded the status of women and minority computer science faculty and students.<sup>9,11</sup> In a report on women in the computer industry,<sup>20</sup> Weber and Gilchrist examined employment figures for computer manufacturers and computer-user industries. The data they presented suggested "... that women are not receiving equal pay for equal work and may not be sharing equally in the opportunities for advancement." Some improvement was noted. For example, figures indicated that the percentage of women employed by manufacturers of electronic computer equipment was showing significant improvement, although still below the national average.

The NSF reports on S/E employment found that the second largest group of scientists in the U.S. 1974 population were computer specialists, numbering 125,000. Chemists ranked first at 138,000.<sup>13</sup> In the NSF reports the term "computer specialist" was used to include

1. College faculty in the computer sciences
2. Computer programmers

3. Computer systems analysts
4. Computer scientists
5. Other computer specialists

In 1974, of the six percent of all employed scientists and engineers who were women, the largest proportion (22 percent) were categorized as computer specialists.<sup>13,14</sup> Furthermore, 88 percent of the female computer specialists in the S/E population were employed, compared to, for example, 53 percent of the life scientists and 23 percent of the total scientists. This relatively high ratio between the number of female computer specialists in the population and their employment as computer specialists led the NSF to suggest that this could indicate more favorable employment opportunities for all computer specialists. This appears likely, as the employment figures for men and minorities were both approximately 100 percent in this field. The NSF also observed that the computer field is relatively new, having grown so rapidly that demand frequently exceeds supply. It was also speculated that "since traditional barriers to employment tend to fall in the face of a skill shortage, women may have found employment as computer specialists because they had the educational background and were available for employment."<sup>13,14</sup>

The demand for computer professionals is further illustrated by data on the transition of scientists and engineers from school to work,<sup>14</sup> which indicates that most of the women who planned careers and had degrees in the natural sciences and who did not work in those fields worked instead in the computer field.

A recent nationwide NSF survey shows that the numbers of men and women, respectively, working at or above the systems analyst level in the computer science area were 138,700 and 33,600 for 1975 and 134,900 and 31,300 for 1973.<sup>16</sup> The apparent under-representation of women in the computer field in general could be attributable in part to a shortage of women receiving college degrees in the fields required by the computer industry.<sup>20</sup> The same might be true for the low representation in the more highly skilled computer positions.

Current figures from the National Center for Educational Statistics show the total and proportion of Bachelor's, Mas-

ter's and doctoral degrees awarded from 1970-1 through 1975-6.<sup>17</sup> As shown in Table II, the number of degrees awarded to women in computer and information sciences continues to be fairly light. (Data is available on women and minority Ph.Ds and on science and engineering doctorate supply and utilization.<sup>6,12</sup>

As indicated by Table III computer specialists were among the scientific fields reporting median ages under 30 years.<sup>14</sup> The median age for women computer specialists was five years less than for men in the field. In fact, women scientists and engineers were in general younger than males with a median age of 27 and 38, respectively.

In Weber and Gilchrist's review of the status of women in the computer industry,<sup>20</sup> they concluded that "the available data suggest that women are not receiving equal pay for equal work and may not be sharing equally in the opportunities for advancement." While the annual salary differential between men and women is actually less for computer specialists—a difference of \$2,300—than for any other S/E field examined in the NSF study,<sup>14</sup> this figure alone is not in itself a sufficient indicator that the situation is improving. Likewise, the fact that medical scientists had the largest salary differential (\$5,800) does not necessarily imply that greater inequities exist in that particular field. Salary differentials should instead be viewed as percentages of gross salaries, for clearly a small absolute differential could

TABLE II.—Total and Proportion of Bachelor's, Master's and Doctoral Degrees Awarded to Women 1970-71 Through 1975-76 By Broad Discipline Division

	Degrees Awarded 1970-71 to 1975-76

\* Too few cases to compute a median.

represent a large percentage of total salary, depending upon the average salary for the field.

Salary differentials reflect many variables, including type of employer (e.g., business, government), age (note the difference in median age reported earlier), work activity (e.g., R&D, management) and job experience. For example, in the U.S. workforce, a greater proportion of men than women were engaged in management and administration—the work area which typically has the highest salary. This was certainly the case for S/E fields surveyed in 1970, as is shown in Table IV.

Salary surveys made by the College Placement Council and cited in Reference 14 reveal an apparent narrowing difference in starting salaries for women and minority scientists and engineers. For individuals in computer science in particular, the national average monthly salary offers made to bachelor's degree candidates during the periods 1973-4 and 1975-6 were \$920 and \$1,035, respectively, for men and \$895; \$1,045, respectively, for women.

TABLE IV.—Median Annual Salaries of the 1970 Science/Engineering Labor Force, by Field and Work Activity: 1974

	Work Activity		
	R&D	Management or administration	Teaching
Total	\$18,400	\$22,600	\$19,200
Physical scientists	19,000	24,500	19,000
Mathematical scientists	21,400	24,200	18,000
Computer specialists	19,100	20,700	18,900
Environmental scientists	20,100	22,900	18,900
Engineers	18,300	22,600	20,400
Life scientists	17,900	19,000	18,500
Psychologists	19,500	22,200	18,700
Social scientists	20,200	23,100	19,800

Source: National Science Foundation, Manpower Characteristics System.

This (at best) elimination or (at worst) reduction of the gap in starting salaries, coupled with such factors as the relatively small number of women scientists and engineers and their younger median age, are likely to result in a reduction in average salary differential for men and women.<sup>14</sup>

Age and detailed salary information relating to minority scientists and engineers was not included in the NSF reports.

## FEDERAL WORKFORCE

Recent Civil Service Commission statistics show that the federal government is well ahead in overall employment of minorities in professional, administrative, technical and clerical jobs. The private sector, however, has higher percentages of women and/or specific minority groups in some categories. These figures also show some increase in the proportion of minorities and women in both middle and upper level jobs, although Civil Service Commission Chairman Alan K. Campbell noted that the rate of progress has been slow.<sup>4</sup>

As of November 1977, minorities represented 21.6 percent of all full-time federal civilian employees. Women held 30.7 percent of those positions. Since 1975, minority full-time employment has steadily increased by an average of 1.2 percent per year, in spite of an overall decline of 0.2 percent for the full-time federal work force for this period.<sup>5</sup>

### *Scientists and engineers*

As illustrated in Figure 1, in 1974 the federal government ranked behind business and industry (37 percent) and educational institutions (27 percent), by employing only 12 percent of all scientists. Most women engineers were employed by business and industry. The federal government, along with nonprofit organizations and State and local governments, each accounted for about 10 percent of the women scientists.

Figures compiled by the U.S. Civil Service Commission show that as of 1974 there were few minority and women employees in some of the "pure science" occupations. For example, the percentages of women and minorities respectively were Physics—2.4 and 3.7, Nuclear Engineering—0.6 and 3.5 and Chemistry—14.3 and 2.4.<sup>2</sup>

### *Computer sciences*

Federally-employed computer professionals are divided into several different job classifications (e.g., computer scientist, computer specialist, general physical scientist). This makes it extremely difficult to collect statistics and to make comparisons with the U.S. workforce totals. Consequently, this section will present selected figures which should at least provide a "snapshot" of the current situation in this area.

In 1976, total employment for federal computer specialists showed 24,521 full-time permanent employees. (Full-time permanent employees are those federal workers who have career—three or more years of continuous service—or career conditional—less than three years—appointments and work a full-time—40 hours per week—work schedule.) Of those employed as Computer Specialists, 19.4 percent were women and 11.0 percent were minorities.<sup>3</sup> These numbers are up from the corresponding 1974 figures of 19.1 and 10.1 percent.<sup>2</sup> Table V shows average General Schedule (GS) pay categories ("grades") and percentage figures for all federal employees, women, minorities and non-minorities in several scientific occupations.<sup>3</sup> Comparing the statistics for computer specialists with corresponding figures for federal chemists, a field with a General Schedule employment of 7,599, we find a somewhat lower percentage representation for women (15.2 percent) and a slightly higher representation for minorities (12.8 percent). Average grade for all employees in chemistry was 11.63. The average for women and minorities was (10.37 and 11.27), respectively.<sup>3</sup>

In the computer-related occupations, as well as for many other federal scientific fields (e.g., chemistry, physics, meteorology, metallurgy, astronomy), the average pay grades for women and minorities are less than the average for all employees. Furthermore, the average grade for women is less than that for minorities in each field examined.<sup>3</sup>

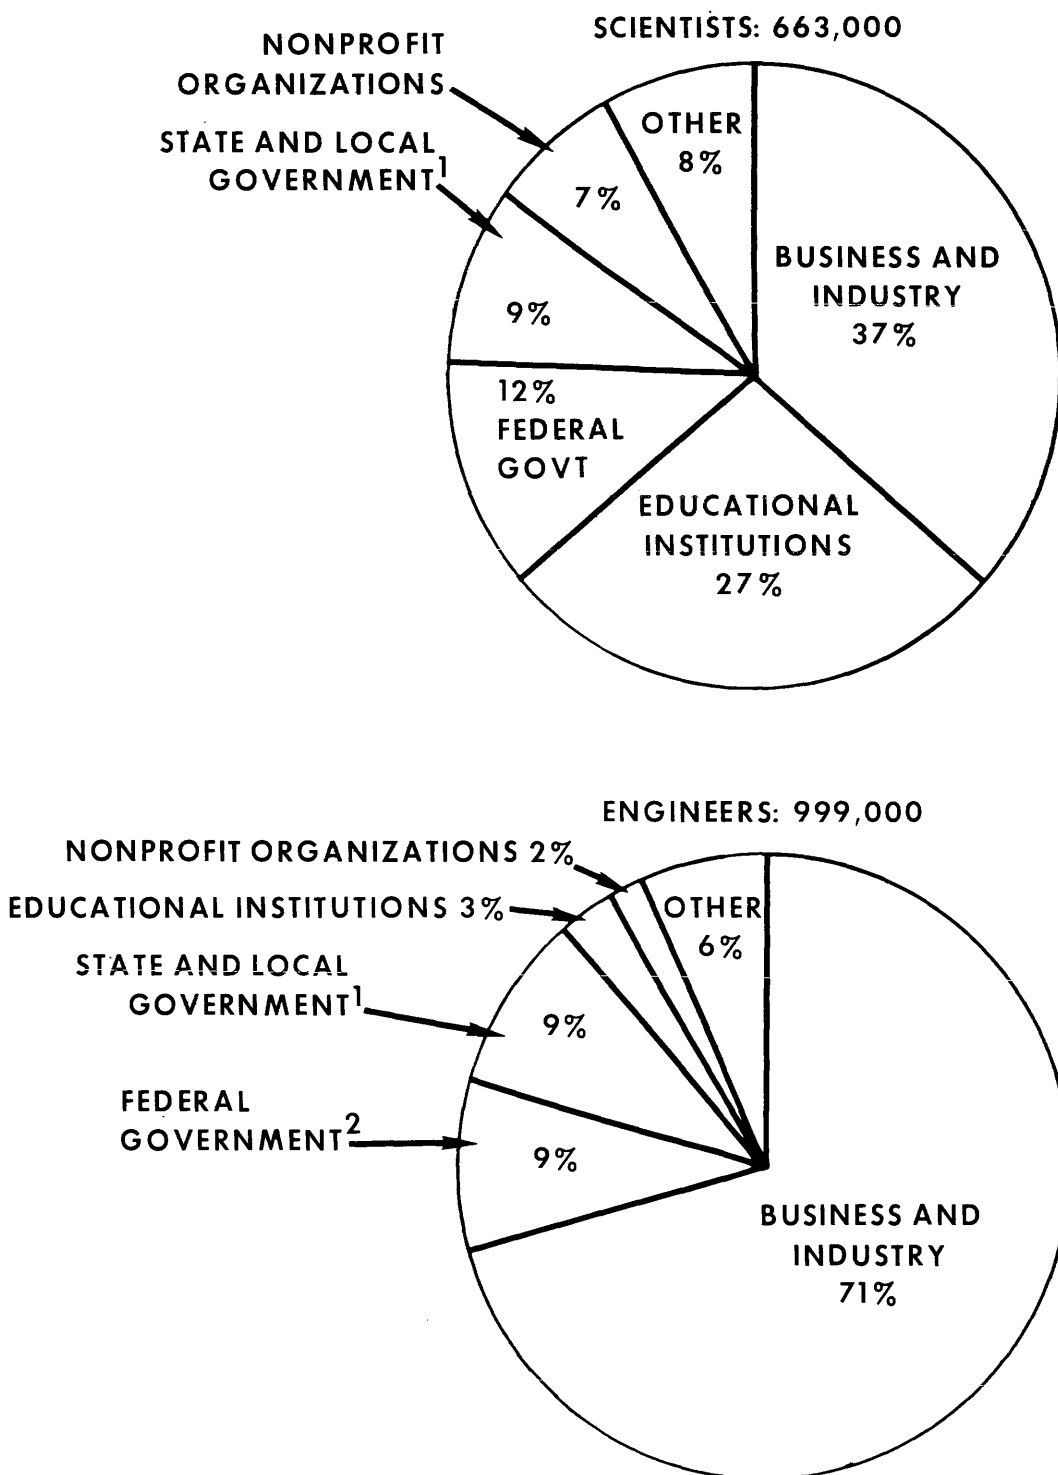

As was brought out in the earlier discussion of factors affecting salary differentials, more information is needed in order for the full implications of these figures to be judged. Age, education, availability and job experience, for example, must be viewed in conjunction with average grade and representation.

## SUMMARY AND CONCLUSIONS

The available data do not provide sufficient information to support any surprising conclusions about the current status of women and minorities in computer-related professions. Meaningful analysis of the data is also hampered by the fact that more information was available relating to the employment of women than for minorities. Certainly it would appear, based upon the previously-cited employment rate and other statistics, that the computer field is in general a "healthy" field. Accordingly, one can expect to find better

TABLE V.—1976 Federal White-Collar Employment—Selected Fields

	Average Grade				
	All	Women	Minorities	% Women	% Minorities
Digital Computer Administrator	12.80	10.79	11.88	11%	9.3%
Computer Specialist	11.39	10.58	10.99	19.4%	11.0%
Chemistry	11.63	10.37	11.27	15.2%	12.8%
Mathematics	11.69	10.82	11.38	19.1%	11.0%

Figure 1—Scientists and engineers by type of employer: 1974.

employment opportunities for all, and hence for minorities and women, there than in other scientific and engineering occupations.

Recent reports of the National Science Foundation (NSF) on the status of women and minorities in the sciences and engineering<sup>13,14</sup> have concluded that there is and has been an under-utilization of women in the sciences and engineering, both in terms of their entry into these fields and their utilization within the scientific workforce. For minorities, data indicate that Blacks and Hispanics appear not to have developed those background skills considered important for careers in the sciences to the same extent as other racial groups and women. Consequently, it is suggested that this may have caused an under-utilization of these minorities in science and engineering. Information on utilization of women and minorities in the computer field was not cited. Further analysis in this area would be useful.

As noted by the NSF report on women and minorities in science and engineering,<sup>14</sup> "... available data indicate that there are relatively few women scientists and even fewer engineers, and considerably fewer minority scientists and engineers of either sex." Data gathered also indicate that relatively few women and/or minority scientists and engineers are unemployed. However, data on labor force participation and salary differentials show possible problem areas. The fact that the labor force participation rate of female scientists and engineers is significantly below that for males in S/E may reflect actual or perceived lack of job opportunities. If one considers the histories of women, both minority and non-minority, who are considered "successful" in the sciences, then it may be more easily understood how some women might become discouraged and "drop out" or lower their expectations.<sup>8</sup>

Many women in the federal government do not feel that there is much difficulty in progressing to the top of a career ladder once they get into the career series. However, they perceive attitudinal barriers preventing them from advancing into supervisory and managerial positions. The fact that real obstacles to advancement remain is illustrated by a recent Civil Service Commission study which reported that women with college degrees are one to three grades behind men with the same educational level.<sup>10</sup> Recent reports indicate, however, that the federal workforce is changing and that some progress is being made in the employment of both women and minorities.<sup>18</sup> We hope future analyses of em-

ployment and utilization statistics will reflect accomplishments of current equal employment opportunity and affirmative action programs of both the public and private sectors.

# Computers in judicial administration

by CHARLES L. AIRD and BARBARA H. TODD

*Supreme Court of Virginia*  
Richmond, Virginia

## INTRODUCTION

The number of computer installations in the courts has increased rapidly in the past ten years. This trend indicates an enthusiasm in the courts to acquire the scientific and industrial technology that the business community has successfully used. The computer is recognized as being a major tool of technological development and for its tremendous capability for upgrading the quantity and quality of a wide variety of functions and services. However, while looking in ecstasy at the new horizons of computer technology, we must realize the computer's dependency upon man. Computers are unlike any other machine. Switch on a water pump and water is pumped, but switch on a computer and nothing happens unless precise instructions have been prepared.

Today's courts are similar to businesses. They are complex organizations which store large amounts of detailed information. Court files require precise methods for processing and retrieving this information.

Modern computer technology is well suited to the task of accomplishing the repetitive job of maintaining accurate up-to-date information that is easily retrievable. The computer can also create access to information which was previously too costly to assemble.

The courts now using automation experience improved record-keeping efficiency. Computers provide timely and effective management information to individual courts as well as to the Supreme Court and other criminal justice agencies.

The potential capabilities of systems technology can provide the courts with standardized reports and services. Computers can provide this wide range of services in far less time than manually possible. The services and reports that can be produced for the courts are numerous.

Basic docketing and indexing services are typical services. The docket, listing cases to be heard in specific courts on specific dates, can be generated. The computer can retrieve cases or records based on a particular piece of data such as the name of the defendant, docket number, summons number, type of case, date, or other piece of identifying information. This permits the court to make direct inquiry into case records and to update records by visual display terminals located in individual courts.

Cases can be listed by judge, by attorney, and by docket number to keep track of case and schedule conflicts. Particular cases which require follow up or review for specific reasons are listed as exceptions. Notices are automatically prepared as required by the court. These capabilities improve case flow management and reduce the amount of paperwork needed to maintain records and administrative activity. Periodic statistical reports are generated on caseload and courtroom activities for individual courts.

Improved statewide caseload information can be provided to judges, clerks and the Supreme Court on a regular basis. Information on caseload, case age, pending cases, hearings, dispositions and workload forecasting are by-products of computerized record-keeping. This, too, can be used for effective judicial management.

Successful implementation requires careful study by local courts and the Supreme Court. Implementation depends upon long-term cooperation during the necessary trial-and-error process in the initial stages of development.

## CONTRIBUTIONS AND PROBLEMS

The trend toward computers is due to the increased workload of the court. Traditionally, the measure of judicial workload has been filings. As filings increase, the complexity of the court and clerk's office operations increases. Computers were solicited to cure inefficiencies. The computer is solving major problems by reducing backlog and delay, improving scheduling and reducing redundant tasks.

Computers will continue to make substantial contributions to court administration. However, automation is not a total panacea. Technology can do little to reduce backlogs and delays stemming from strategy, not procedure. It will not expedite courtroom proceedings established by due process. The computer is an aid to management but is not a substitute for such things as judicial selection, discipline and sentencing.

Even though there are many admirable automated judicial systems throughout the country, judicial computerization on the national, state and local levels faces difficulty. Several reasons exist which indicate the depth of the problem. Vendors have oversold their products. Sales techniques have been more successful than applications. The judges who run

the courts are not businessmen. They are easily influenced by a smooth sales pitch. However, once stung by an expensive, inefficient application, they will not be sold again.

Funding has been a major problem also. Computerization costs money and budgets are usually controlled by the executive branch at all levels of government. The judiciary is sensitive to invasion by the other government branches and may not pursue funding. The most popular solution is to share the expertise and hardware of the executive branch. Court processing is not easily understandable. Lack of communication and scheduling priority conflicts often doom joint projects. The judicial branch is very sensitive with respect to privacy and security.

If these problems are resolved, and actual design of a system begins, the lack of in-house expertise becomes a hurdle. More failures than successes were produced in early judicial data processing projects. This was due to inadequate planning, poor scheduling and insufficient testing. Projects were generally too big and not implemented in stages.

Even with growing caseloads, the computer is not necessarily the solution. Most courts have not reached the point where adding more people does not solve the problem. Only the urban courts are overburdened. The practical solution to increased caseload may be better manual techniques, forms design, specialization of tasks, elimination of duplication and word-processing equipment.

The final problem encountered in the courts has been resistance to change. The courts are the most conservative of the three branches of government. Many courts use the same record-keeping procedures implemented in the English courts and imported to the colonies.

CATEGORIES OF AUTOMATION

Considering the problems, it is surprising that the courts have considered any automation. In many instances, the

courts have not had a choice. Caseload in urban-centered courts has reached overwhelming proportions and so has the paperwork. Therefore, three categories of systems at two levels have been developed. The three categories are administrative systems, case record and trial systems and legal research systems. The two levels are at the court and the administrative.

Administrative systems are payroll, personnel, budget, inventory and financial record systems, that is, the routine business systems. Statistical systems allow for caseload management of the courts. Case record and trial systems deal with case tracking, docketing, indexing, case scheduling, jury selection and management and information systems exchange with other criminal justice agencies. Some systems are useful at only one level. Others perform at both and still others serve as a means of communication between the two levels.

VIRGINIA'S SYSTEMS

In reviewing Virginia's computerized systems, it is beneficial to keep in mind the structure of the judicial system. The District Courts were unified under the state in 1973. Prior to that time, they were municipal courts and independent. These are the lowest level courts and have the greatest volume, most cases and the need for computerization. The Circuit Court clerk's offices are local and totally independent. There is no standardization and low volume. The average number of commenced cases per circuit judge in 1977 was 1,100 or approximately one case every two hours. The Supreme Court stands at the top of the judicial branch. There are numerous computer applications at the District Court and Supreme Court. Only one Circuit Court currently has or is developing a system.

ginia Supreme Court handles the administration of the General District and Supreme Courts in total and the Circuit Court Judges. The OES is also responsible for 426 magistrates. Personnel and payroll systems are centrally handled by the OES. The budgets of each court with revenues and expenditures are tracked by an automated budget tracking system (ABTS). The ABTS produces a financial analysis statement for each court on a monthly basis, generates a summary of state and local revenues and state expenditures, and provides the basis, justification, and documentation for the judicial budget (Exhibit 1).

Certain individual courts keep automated financial records. These are the earliest and most successful applications. These courts track fine payments, support arrears, support check writing and support accounting.

The OES maintains statistical systems. These systems

summarize caseload and measure judicial workload. The results are used to obtain federal funding from the Law Enforcement Assistance Administration (LEAA), determine the number of judgeships and personnel for individual courts and to justify budgets.

There are two schools of thought concerning statistical systems. One school supports case-by-case statistics. This involves the collection of all critical information on a particular case plus any decision points and change of status. All statistics needed are generated from the data bank. Such a system is very flexible and produces many results; exception reporting, sentencing disparities, continuance studies, and case tracking. These are balanced against the negative consequences of tremendous amounts of paperwork, time consumption for clerical personnel, very large computer files, and great expense. The developmental cost is several million

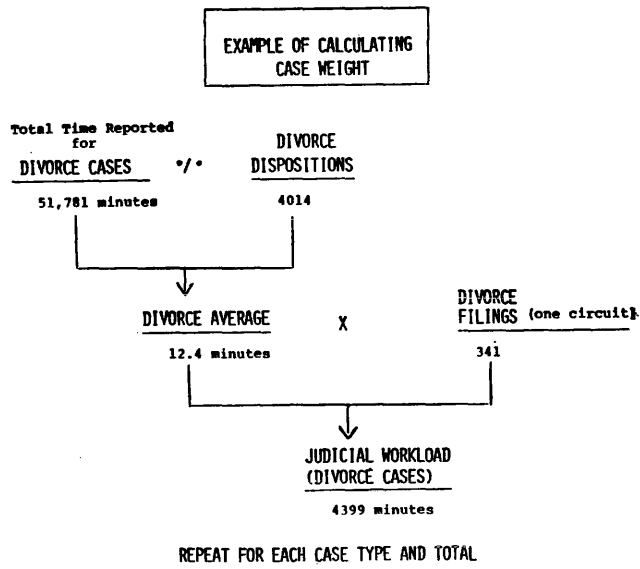

Exhibit 8

minutes for each case type are sampled. Using a statewide average time for each category of cases multiplied by the number of cases for a particular court, the amount of judicial work is calculated for that court (Exhibits 8 & 9). The "normal judge year" is administratively determined and used to calculate the number of judges needed to staff the court. Clerical workload uses a similar procedure. Weights are determined by spot-checking the time spent on case-related work.

The Circuit Court Caseload Reporting and Judicial Workload System is also a case-weighting system. The basic caseload summary gives the categories of civil and criminal cases. Also included are jury data and case aging information (Exhibits 10 & 11). The basic caseload counts of filings and dispositions will be weighted based on the average judicial time per case. Judges are timed to determine the amount of time each of the general categories of cases takes for disposition. Exhibits 12 and 13 are the forms used for sampling workload. Weights are based on both bench time and case-related chambers time (Exhibit 14).

dollars plus operational maintenance costs of \$500,000 annually.

The second method is to collect summary statistics. The design incorporates what is needed and is collected on a summary basis from the courts. The advantage of summary systems is the reduction in paperwork and expense. A summary statistical system can be developed for \$150,000 and operated for \$25,000 per year. Neither approach is successful unless a strong and supportive Chief Justice and Court Administrator control the Courts. The capture of the data elements must be an integral function of the clerk's office. Exhibits 2, 3, 4, and 5 give an indication of the large amount of data that must be included for case by case statistics.

Virginia has three caseload reporting systems:

1. Uniform Docketing & Caseload Reporting System—District Courts.
2. Circuit Court Caseload Reporting and Judicial Workload Systems.
3. Magistrate Statistical System.

These are batch-operated systems. They are programmed in COBOL and run on an IBM 370/158 (2) system under OS-VS2 with 1024k storage.

The Uniform Docketing System is divided into two sub-systems. The first part is used in the clerk's office to standardize case scheduling and indexing in the District Courts. The second part of the system has three purposes: to count basic cases, to determine judicial workload and to indicate clerical workload. Monthly summary reports (Exhibit 6) are completed using the tearoff from the Uniform Docket (Exhibit 7).

Counts of cases are not enough to determine workload. The different types of cases do not take equal amounts of time to process or hear in the courtroom. There is a need to weight cases depending upon their complexity. The bench

**CASE RECORD AND TRIAL SYSTEMS**

Case record and trial information systems at the court level aid clerical staff with redundant clerical efforts. Such systems increase the accessibility of records and provide the most complete records possible. These systems have certain common characteristics. Each case is one record including basic case and individual information and status. Multiple indices are established which are typically manual, single directional. Automated indices expand the court index to systems similar to those in a library. The number, name, attorney, judge, status, offense, or disposition may be used

to find the case records. These systems feed statistical systems and transmit data to other agencies.

The TRACER system in the Norfolk Court is an excellent system. It is an on-line criminal justice information system functioning for multiple agencies including Police, Jail, Commonwealth Attorney and Probation/Parole Department, as well as the District and Circuit Courts. The components of the system are a person master file, arrest/offense trailer records, and the index accessible by name, alias, social security number, Police I.D., etc. The reports generated by this system are docket, custody status, jail history, arrest record, and court caseload statistics (Exhibits 15 & 16). Other court information systems are in Fairfax County for all courts, Portsmouth—an automated traffic system, and Richmond—arrest system and juvenile records. The Juvenile Justice Information System, a time-sharing system, was a failure in the Tidewater region. Richmond Juvenile and Domestic Relations Court has installed a minicomputer which tracks support cases and performs docketing tasks. Frederick, Winchester, Roanoke, Portsmouth and Virginia Beach have implemented systems to automate some functions of the clerk's office and at the circuit court level to provide for juror management. Juror management includes selection, notification, and payment of trial juries.

## CRIMINAL JUSTICE INFORMATION SYSTEMS

LEAA has established its Comprehensive Data Systems (CDS) Program to coordinate and accelerate the development of comprehensive state criminal justice information systems. Two components of the CDS are Computerized Criminal History (CCH) files and Offender-Based Transaction Statistics System (OBTS). The CCH files form a central report source for the important events in the cases of individuals charged with serious crimes. Virginia has developed

the Central Criminal Records Exchange (CCRE) for the state-level reporting. The CCRE is maintained by the State Police. Courts contribute disposition information, but although extensive files exist, little is done with the information except for police use (Exhibit 17). Since 1973, the OBTS has been in the development stage under the Secretary of Public Safety.

Many states are in a similar position to Virginia's. Partial systems are underway, yet none are fully satisfactory. There are three primary reasons. While the cost of development is funded by LEAA, operating costs are not. The annual running costs of such systems may amount to several million dollars. For the same cost, there may be alternatives which are more flexible and less risky. The second problem is that the more comprehensive a system, the more the quantity and quality of data input. This takes large amounts of time. Current laws also prohibit the replacement of the manual systems now in existence. If the manual systems are not replaced, the workload is significantly increased.

## LEGAL RESEARCH

Legal research systems are under development or have been implemented by several commercial vendors. Basically these systems involve computer-assisted text look-up using keyword search and text selection algorithms. The LEAA-sponsored organization, SEARCH Group, Inc., has evaluated the practicality of computerized legal research for multiple criminal justice agencies and the three systems currently on the market. SEARCH is a non-profit consortium of states involved in criminal justice research and "dedicated to improving the administration of justice in the U. S. by applying advanced technology to justice systems." The projects include development of national standards and goals for criminal justice agencies, state judicial information sys-

tems (recently transferred to the National Center for State Courts), strategy for implementing privacy and security regulations, etc.

The three legal research systems studied were LEXIS, WESTLAW, and JURIS. LEXIS was developed by Mead

Data Corporation, WESTLAW by West Publishing Company, and JURIS by the U. S. Justice Department. JURIS was evaluated in Virginia for a six-month period. It was not successful since it contained federal cases not directly applicable to state law.

plan to identify the areas in which computer development should be achieved. The plan will consider what systems currently exist, what functions of the court can be effectively automated, hardware needs of the judicial system, and the cost/benefits and feasibility of a statewide judicial computer network.

New court computerization will result from continual balancing between the ideal system and the practical constraints of the judicial branch of government. Each system will be carefully weighted and subjected to critical analysis in light of decreased federal funding. Contending needs will be addressed—needs for increased quality of and improved

information, simplicity and usability of systems, consideration of the judiciary's independent status, and flexibility to accommodate future needs. New systems must meet enunciated goals. They must have a sound basis on which more

complex systems can be built. Constant review and evaluation during development, implementation and operation will be required to ensure that the needs of the Courts are met.

# Police and computer technology—The expectations and the results

by KENT W. COLTON

*Brigham Young University*  
Provo, Utah

## THE EXPECTATIONS—THE CHALLENGE OF THE PRESIDENT'S CRIME COMMISSION

In July, 1965, in the face of dramatic rises in reported crime and delinquency rates, the President's Commission on Law Enforcement and the Administration of Justice (sometimes called the Crime Commission) was created. One area selected for special attention in the Commission's final report was the potential contribution of science and technology in the generally labor-intensive field of law enforcement. Because criminal justice agencies must process enormous quantities of data, the use of computer technology—electronic computers and new techniques such as systems analysis, operations research and computer modeling—seemed particularly promising, and the use of computer technology by the police has expanded significantly since the mid-1960s.

A variety of factors have fueled this growth. The first was the report of the Crime Commission. The recommendations of such a distinctive group drew instant attention and outlined high expectations: "Modern technology can provide many new devices to improve the operations of criminal justice agencies, and particularly to help the police to deter crime and apprehend criminals."<sup>1</sup> The Commission's recommendations were fortified by the addition of large-scale federal resources to the police area through the Law Enforcement Assistance Administration (LEAA). The pressure from vendors to sell their product—enhanced as the Vietnamese War was ending and technology-oriented industries sought to increase their domestic market—also contributed to the expansion of the computer-related innovations. According to one study, \$143 million, or 11.5 percent of the total LEAA block grant budget, was spent for law enforcement telecommunications during the three-and-one-half years between July 1, 1971 and January 1, 1975, and this figure did not include matching money from the states.<sup>2</sup>

The Crime Commission report was filled with enthusiasm and raised high expectations about the possibilities of such innovations. Advocates felt that computer technology would allow for the rapid processing of information, expand police capabilities and improve law enforcement services, for example by reducing response time. Some hypothesized that

aspects of the technology might even improve apprehension rates, thus deterring criminal activity and reducing crime rates.

The use of computer technology by the police has expanded rapidly since the mid-1960s, undoubtedly aided by the Crime Commission's report and federal funding. However, there is disagreement as to the utility of such computer use. Whereas proponents seek for the benefits noted above, critics claim that much of the money has been wasted, that such innovations have not increased the efficiency or effectiveness of crime control, that the proliferation of such systems represents a potential infringement on civil liberties, and that the money could be better utilized on less technical approaches to the crime problem.<sup>3</sup>

Although there has been a lot of dialogue regarding the purchase and application of computer technology in law enforcement, there has been relatively little research or evaluation since the Crime Commission concerning the actual uses, difficulties, and diffusion of computer technology by the police. Despite prestigious recommendations, the process of introducing change requires more than directives from the top. Important behavioral and power relationships are involved in the actual implementation of the technology. A decade has passed since the Crime Commission selected computer technology as an area of potential significance. The purpose of this paper, then, is to begin to evaluate what we have learned since the mid-1960s and to address the consequences and diffusion of innovation.

The paper is based on the results of research efforts which have transpired over a period of six years. The research has included two national surveys of U.S. police departments in 1971 and 1974 (designed by the author and administered by the International City Management Association [ICMA]) and a series of seven case studies in different police departments around the country.<sup>4</sup> The four sections which follow will 1) review the results of "routine" and "non-routine" applications of police computer technology, 2) discuss some of the lessons we have learned and the reasons for the disappointments and problems that have arisen, 3) outline a new focus for the diffusion and application of police computer technology, and 4) discuss the change in expectations for the future.

## THE RESULTS—THE EXPERIENCE OF THE PAST DECADE

### *The use and evaluation of police computer technology*

The first real-time police computer system in the U.S. was installed in the St. Louis Police Department in the mid-1960s. Since then the growth of computer technology within police departments has been widespread. However, the surveys conducted as a part of this study in 1971 and 1974 revealed that implementation has been slower than expected. The 1975 survey was mailed to all U.S. police departments in cities with populations over 50,000. Of the 326 (80 percent) that responded, 193 (56 percent) were using computers. Although this was an increase of 12 percent over 1971 responses, it was only about half the growth predicted by the earlier survey.<sup>5</sup>

Some of the difference may be explained by a slight variation in response rate between the two studies and by varying interpretations of survey questions. But, more important, estimates of future growth tend to be overly optimistic. The slower rate may also indicate that some police departments are taking a more careful and sophisticated approach to computer use.

When surveyed, police departments with computers were asked to identify which of 24 applications they were using. The 24 applications were grouped into eight areas: police patrol and inquiry, traffic, police administration, crime statistical files, miscellaneous operations, resource allocations, criminal investigation and command and control.

In evaluating use and impact, it has been useful to draw a distinction between "routine" and "non-routine" applications of computer technology.<sup>6</sup> Routine applications involve the relatively straightforward, repetitive manipulation and inquiry of prescribed data, often by means of a definite procedure. The same manipulation was usually done by hand before the advent of the computer. Technology simply makes the process quicker and easier. For example, although police patrol and inquiry applications were technically advanced and provide rapid retrieval of information to the field officer, such inquiry systems are relatively straightforward and the tasks can be labelled routine. Other routine application areas comprise traffic files, crime statistical files, police administration and miscellaneous operations.

In non-routine applications the machine becomes a tool for decision-making, strategic planning, and person-technology interaction. There are no absolute methods for handling problems, either because the area is complex or because they require custom-tailored treatment. The human decision-maker plays a vital role in judgment, evaluation and insight. Non-routine application areas in law enforcement include resource allocation, investigation of crime, and command and control—including computer-aided dispatch and automatic vehicle monitoring. (See Figure 1.)

Rather than view routine and non-routine categories as sharply distinct classifications, though, they should be regarded as delimiting the two ends of a continuum. As applications move toward the non-routine end of the continuum, systems design becomes more intricate, and

behavioral, personality and organizational considerations become more significant. Several applications fall between the two extremes. The best example is crime statistical files, which though generally routine in collection and processing, provide the basic data for a number of non-routine activities, such as resource allocation. Command and control applications also have both routine and non-routine dimensions.

*As the use of computer technology has evolved since 1960, successful implementation has often been limited to the routine areas.* Traffic, police administration, and crime statistical files have all remained important; and the expansion of police patrol and inquiry records—especially in the late 1960s and early 1970s—has been almost phenomenal.<sup>7</sup> *In the non-routine areas, though, results have been far more disappointing.* For example, in the previously referenced 1971 survey, 61 departments predicted they would implement a computer-aided dispatch system. However, only 15 such systems had been installed by 1974—less than one percent of the computer applications reported in the 1974 survey.

Resource allocation has been the only non-routine computer use where the number of applications actually implemented has exceeded expectations. The 1971 survey results indicated that in three years 12 percent of all computer allocations would be in the resource allocation area; the actual percentage was 16. An additional question in both the 1971 and 1974 surveys asked police departments to rank the relative importance of different computer allocations. There was little shift between the two years, and in both 1971 and 1974, resource allocation applications were ranked first.

Although the actual level of implementation has been below earlier expectations in a number of areas, the computer, with all its interesting implications and problems, has unquestionably become a permanent part of law enforcement technology after a decade and a half of use. The issue now is not will computers be used, but how and with what impact?

### *Computer impacts*

**The impact of routine applications.** Although experiences vary from city to city, there is evidence that routine computer applications provide a number of benefits, particularly when benefits are defined in a narrow, technical sense. For instance, numerous police patrol and inquiry applications and crime statistical files are working around the country today. Seven-second retrieval of information to the officer in the street has been a reality in Kansas City, Los Angeles, and other police departments for a number of years. In terms of "technical impacts"—benefits resulting from improvements in the input, processing, and output of information—the technology has provided a number of positive advantages. In at least some departments, extensive amounts of new or better information are available more rapidly for broader distribution, although results again vary among police agencies. Further, if one views the service delivery impact of such routine applications from a more narrow "process"-oriented perspective, a number of routine applications have improved service to the public and have been

Routine	Non-Routine
Police patrol and inquiry (including --> warrant, stolen property, and vehicle registration files) <sup>b</sup>	
Traffic applications (including -----> traffic accident, citation, and parking violation files)	
Miscellaneous operations (including ---> intelligence compilation and jail arrest records)	
	←--- Command and control (including computer aided dispatch and automatic vehicle monitoring)
	←--- Criminal investigation (including automated field interrogation reports, modus operandi and automated fingerprint files)
	Crime statistical files (including crime offense, criminal arrest, juvenile criminal activity, and offender based files)
Police administration (including -----> budget analysis and forecasting, inventory control, vehicle fleet maintenance, payroll preparation, and personnel records)	←--- Resource allocation (including police patrol allocation and distribution, police service analysis, and traffic patrol allocation and distribution)

Figure 1—Routine and non-routine uses of police computer technology.\* The terms "structured" and "unstructured" have also been used to draw a similar distinction. See, for example, G. Anthony Gorry and Michael S. S. Morton, "Management Decision Systems: A Framework for Management Information Systems," Working Paper No. 458-70, Alfred P. Sloan School of Management, MIT, April 1970. Also, Herbert A. Simon originally used the terms "programmed" and "unprogrammed" to make a related characterization. See Herbert A. Simon, *The Science of Management Decisions*, New York, Harper & Row, 1970, p. 6.

\* The dotted arrows reflect the fact that routine and non-routine categories are not sharply defined classifications. Rather, they should be regarded as converging from opposite ends of a continuum.

shown to be cost-effective, though full-scale analysis of costs and benefits were not covered in this project. For example, in Tulsa, Oklahoma, an additional \$180,000 in estimated revenue was returned after the first year's operation of a new automated traffic citation system. In Long Beach, California, membership in an automated want/warrant system in the Los Angeles area increased the number of 1970 warrant arrests 31.5 percent over 1969 figures.<sup>8</sup> In Kansas City, Missouri, the ALERT (Automated Law Enforcement Response Team) system was installed in 1969, and the num-

ber of monthly inquiries per police officer concerning stolen cars or wanted persons rose from 36 in January to 90 in May 1971, and in 1975 police officers were averaging 250 inquiries per officer per month. In Oakland, California, after digital computer terminals were installed in half the patrol cars in 1971 and 1972, units with terminals in their cars made more than seven times as many information requests, received more than three times as many "possible hits," and were three times as productive in warrant arrests and vehicle recoveries as nonequipped units.<sup>9</sup>

However, when one examines the actual service results or outcomes of such routine applications the benefits of the technology are more uncertain and unexpected impacts and influences begin to emerge. For example, a former Kansas City Chief of Police reported that after installing their ALERT system, one of the most advanced police patrol and inquiry systems in the country, the police department experienced an overload of police officers making stolen car checks, thereby creating a potential manpower drain and shifting concentration from other vital police tasks such as preventive crime patrol.<sup>10</sup>

Further, as far as service impacts are concerned, it seems that routine computer uses by the police have almost entirely been devoted to the crime control and law enforcement functions of the police.<sup>11</sup> By over-emphasizing the application of technology to crime control, law enforcement agencies may neglect possible applications to social service activities; for example, computer files to assist with referral information, medical assistance, or listings of agencies and names of people who might provide social service assistance.

Finally, large resources from the LEAA have in some cases served as a "seductive stimulant" for police departments to get involved with computer technology in the absence of an intrinsic desire for understanding. As one police data processing manager put it, "Millions of dollars have been spent, but there's still an awful lot of garbage coming out of police computer systems." Although no one knows how much waste and misuse exists, police computer hardware has undoubtedly been sold to police departments that don't know how to use it, or for nonessential applications.

**The impact of non-routine applications.** Although the service and power shifts of routine computer applications raise certain questions and concerns, overall a number of routine applications have been successful, especially in terms of operational performance and technical impacts. However, non-routine uses of computer technology bring greater complexity both in terms of implementation and evaluation. In this study, case studies have been conducted in two areas of non-routine use—resource allocation and command and control. Each will be discussed.

As noted above, in surveys in both 1971 and 1974, police departments considered *resource allocations* to be their most important areas of computer use. Resource allocation was also the only area in which the number of applications reported in the 1974 survey actually exceeded 1971 predictions. All police departments must make deployment decisions and the interest in the use of technology to aid in this allocation process is growing. However, the interest in automated police deployment should be placed in the context of a realistic understanding of the law enforcement environment. The resource allocation applications noted in surveys generally refer to using tabulations of crime statistics to determine deployment, not to more sophisticated models.<sup>12</sup> Even where modeling work has been tried, many of the efforts have met with only limited success as the three cases examined as a part of this study indicate.<sup>13</sup>

In St. Louis the use of a computer model that was implemented in the late 1960s is purely optional as of 1977, and

district captains no longer request computer-generated reports. The command staff and the Board of Police Commissioners are essentially doing nothing to encourage use of the system by other commanders. In Boston, efforts were made to implement a computer simulation model in the early 1970s but the proposed deployment techniques were dropped entirely in 1973, and questions have even been raised within the police department concerning the manual resource allocation procedures that were implemented in 1974.

Of the three cases reviewed in this paper, the Los Angeles Police Department (LAPD) has the only resource allocation system utilizing computer technology which is actually operating and established as a part of its deployment process. The first level of evaluation—having a working system—has been met. However, even there, the objectives of the resource allocation project were substantially modified. The original LEMRAS/ADAM deployment model<sup>14</sup> was dropped in 1974 to be replaced by the ADAM historical reporting system which was implemented in June, 1975. The current ADAM package no longer includes forecasts of future needs, and deployment recommendations are based on manual calculations using computer-generated reports of historical data. The LAPD has achieved technical benefits in terms of reducing the manpower required to analyze workload and to calculate deployment plans, but many of the service impacts are still unclear. For example, conflicts arose between the strategy for allocation implicit in the deployment model and team policing, an alternative strategy for police work. Finally, one of the original service objectives of the initial allocation system, improved crime prevention, has been virtually abandoned as one of the factors considered in the current ADAM historical reporting system.

Efforts in police departments to utilize computer technology in resource allocation go far beyond the St. Louis, Boston, and Los Angeles case studies. The modeling techniques used in these three cases are now outdated, and improved models have been developed. For instance, a number of projects are currently underway to implement two more recent modeling efforts: the Patrol Car Allocation Model (PCAM) and the Hypercube Model.<sup>15</sup> These models allow the user to identify a wide range of performance measures—i.e. mean travel times to various locations, workload balances, response to call-for-service and other dispatching strategies—and based on the relative importance of these various measures, alternative deployment strategies are provided. As a consequence, some of the objections in St. Louis and Los Angeles—that those modeling efforts did not consider enough of the relevant factors—have been overcome. The actual results of most of these efforts still must be evaluated, though. Further, the implementation problems encountered in the three cases discussed in this paper do not seem to be isolated instances. Rather, there is strong evidence that such difficulties are commonplace.

According to a 1975 report by the RAND Corporation that examined a number of attempts to implement computer models in the criminal justice area: "Through a series of interviews with model builders and personnel in agencies that attempted to implement models, a picture of the implementation process was obtained. In general, criminal justice

models have failed to achieve any notable level of use for policy decisions.<sup>16</sup>

The potential for automating aspects of *police command and control* were first pointed out by the Crime Commission in 1967. Computer-aided dispatch (CAD) systems provide the framework for bringing together many of these new tools through the partial automation of the call-answering and dispatch process. Other command and control technological changes that have been considered or tried include mobile and portable digital terminals to allow officers in the street to communicate digitally with headquarters, automatic vehicle monitoring (AVM) systems to keep track of the location and monitor the status of police units, and 911 emergency telephone services. A CAD system may include an AVM system, 911 telephone service, or mobile digital terminals.<sup>17</sup> Some of these innovations in command and control are routine: the technology basically replaces a previously manual activity such as with digital terminals or the automated transfer of information from the telephone operator to the dispatcher. However, CAD also provides the framework for a number of non-routine activities, such as tracking and monitoring vehicle location, automatically timing the lengths of calls and raising a "flag" if a call takes over a specified time (say 30 minutes), or providing new information to be used for management. Command and control as discussed in this report, then, relates not only to dispatch deployment, but to the ability of police administrators to control and modify the manner in which police operations are conducted.

In the study providing the basis for this study, three cases were examined in the command and control area, and in San Diego and New York City working systems have been developed, although in Boston the problems of introducing the new technology have been more significant.<sup>18</sup> The success and failures of these three cases provide certain insights for the future. First, it is possible to establish ongoing, operational CAD systems. The SPRINT system in New York City has been working since 1970, and the CAD system in San Diego has been operating since 1975. Both cities have achieved technical benefits from CAD such as the availability of new and better information, rapidity in matching addresses with geographic location, the effective transfer and recording of data in the dispatch process, and the retrieval of data from the dispatch process.

Secondly, both cities have experienced positive service impacts in terms of process-orientated measures. Some of these process service benefits include: telephone calls are answered and serviced more rapidly (telephone talk time in San Diego has dropped from three minutes to 77 seconds, and the average time required to answer the telephone is 2.5 seconds); standards can be set for communications and field backlogs (New York City has met its standard of answering 98 percent of telephone calls within 30 seconds, and radio airtime and field backlogs are monitored and recorded daily); and the workload has been more evenly distributed within communications divisions.

Thirdly, when it comes to measuring the actual service "results" attributed to CAD, the findings are inconclusive. In the New York City and San Diego police departments

there is a general feeling that dispatch time has been reduced, but the data are inadequate to prove or disprove such a hypothesis. In fact, to the extent that data exist, they seem to show that the impact on response time has generally been negligible or modest at best.<sup>19</sup> Further, the police departments have essentially not analyzed the influence of the CAD systems in such areas as improving police productivity by enabling patrol officers to respond to more calls per shift or providing a better match between police service needs and available resources.

The question remains, then, as to whether the benefits of CAD justify the costs. Although the expenses of much of this technology seem high, when placed in the overall context of the costs of police operations, the comparative magnitude of the dollars seems to diminish. In New York City, for example, the annualized costs for developing and operating the SPRINT system are about \$2.7 million. Because the 1975 police budget in New York City was approximately \$625 million, only 0.4 percent of the annual budget was devoted to the CAD system. Stated in another way, the costs of operating SPRINT are roughly equivalent to maintaining 10 police patrol units on an annual basis.

In both New York City and San Diego, technical and service benefits have been achieved to help offset such costs, and it seems highly likely that the use of CAD systems will continue to expand. Whether their full potential is achieved, though, will depend on the skills of the management personnel. Both New York City and San Diego provide a wide range of new information for managers. However, police chiefs have seldom considered themselves as managers in the past; rather, their responsibility has been to balance pressures within and without the city and to promote the need for law enforcement and police resources. Consequently, it is still unclear as to whether they or their assistants will be able to channel the potential technological talents of the computer to do more than simply perform routine operations.

#### THE CRIME COMMISSION REVISITED (OR SOME OF THE REASONS WHY THE RESULTS OF POLICE COMPUTER TECHNOLOGY HAVE BEEN MIXED)

When the Crime Commission issued its report in 1967 it was optimistic about the use of science and technology in law enforcement. It set forth a far-ranging program of application and experimentation. Some of these experiments have worked, but a number of others have failed, and whether explicitly or implicitly, the Commission oversold the potential impact of such innovations on reducing crime and increasing arrests. It also seemed to assume that innovation would occur automatically from the top down, that little attention was required for the diffusion process, and that the only motives for implementation would be altruistic, and that vendors of technology would be neutral and pressure-free in their "unbiased advocacy." Finally, they recommended so many possible experiments that it was difficult to select and focus priorities and to follow through. What

have we learned from our experience over the past decade and what recommendations can be made for the next few years?

*Firstly*, it should be clear that it is extremely difficult to measure the effectiveness of technological innovations in confronting crime. In a number of cases, particularly as reported in the overall study report, allocation and command and control projects failed to demonstrate clear improvements in a department's patrol performance, particularly in the area of crime control. Perhaps the greater failure was the original expectations which were built in the 1960s that we might be able to establish such linkages. Criminal activities are based on a wide range of factors only a small portion of which are influenced by police activity. Changes in deployment patterns or response rates may have some modest influence, but criminal statistics are far too imprecise to measure these differences or to isolate the portion of the change attributed to police allocation or technology as opposed to changes, for example, in the weather or the unemployment rate.

*Secondly*, it should be apparent that a number of the original specific objectives of the Crime Commission will not be met, and expectations for the future must be altered. The best illustration of this is related to response time. Based on the evidence to date it would be a mistake to maintain hope that response time benefits will justify command and control and resource allocation technological innovations. As noted earlier in this report, the CAD system did not achieve response time benefits. Further, in St. Louis tests of a Phase I AVM system, it was found that AVM did not bring the expected reduction in response time. In fact, although the question will be examined again closely in a Phase II experiment, current findings lack any evidence to suggest that travel time reductions due solely to AVM will significantly improve police operations or reduce costs.<sup>20</sup> The entire response time system includes a number of components, not the least of which is the time it takes the victim to call the police after a crime has occurred. In the past, excessive attention has been focused on the elements of the response system which can be influenced by technology. In fact it seems after reviewing the evidence of this report that response time is primarily a personnel and human issue rather than a technical problem. If response time is to be improved, people who have been victimized will need to call the police more rapidly, or a department will need to reorganize *both* the flow of the technology *and* the flow of people related to their communications system. Technology alone will make little difference.

*Thirdly*, the experience of police departments in using computer technology to date has forcefully demonstrated the importance for performance guidelines in the diffusion of such innovation. The relationship between the user and the vendor must be clearly defined and performance guidelines specified. In San Diego there was a very clear set of vendor specifications in their request for proposal for the CAD system, and this was invaluable in achieving the desired product. The Boston proposal for CAD lacked the same clarity, and misunderstandings inevitably developed. In the long run, both the police and the vendors of technol-

ogy will benefit from a clear framework and set of standards and specifications. In fact, it is the conclusion of this report that effective implementation necessitates such standards, and the Law Enforcement Assistance Administration, or its sequel, should play a central role in developing such guidelines.

*Finally*, it seems that at least one of the major reasons for the disappointment of the Crime Commission was its failure to recognize many of the complexities and motivations concerning the implementation of technology and the interaction between the context and nature of police work and the technology. Police organizations have a number of characteristics that are quite different from those of other public and private institutions. In most industrial organizations and public bureaucracies, movement to higher levels of power and status is accompanied by greater discretion or freedom of choice in decision-making. Complexity of task increases with responsibility. By contrast in police bureaucracies, the lowest-ranking officer—the patrol officer—is often given the greatest discretion, being forced to continually make decisions without direction from superiors, and consequently the administrator's ability to control and influence police behavior is severely limited.

A further complication in understanding the police is the local and fragmented nature of law enforcement and the fact that police departments have a variety of different tasks and styles of operation. The popular conception of police work, often supported both by news media and by movies and television, is one which assumes that the bulk of a policeman's time is devoted to the exciting and dangerous job of crime-fighting. In fact, a comparatively small part of a policeman's time is devoted to *crime control and law enforcement*. Instead, *service activities* and *order maintenance* occupy the largest portion of police time,<sup>21</sup> and different police departments have different styles of operation depending on whether their orientation is, for example, *legalistic* (identified by strict interpretation and enforcement of the law and strong centralized authority), *watchman* (characterized by a more traditional approach, greater discretion and weaker centralized authority) or *service-oriented*.<sup>22</sup>

In summary, then, the eventual influence and impact of technology in policing will not come from the technology per se, but from an interaction between police work, the nature of a particular department, and any specific innovation. When the Crime Commission set forth its recommendations in 1967, it apparently assumed, at least in part, that police administrators would have strong centralized control and that the diffusion of innovation in the form of computer (and other) technology would be primarily an act initiated from above with effective communication from higher to lower echelons of the police department providing the linkage for implementation. The primary problem recognized by the Commission was monetary,<sup>23</sup> and in failing to more specifically address the diffusion of technology, many of the obstacles such innovations have met over the past decade were overlooked. Given such factors as the fragmented nature of police work and the variety of police departments around the country, the use of technology may have an important influence on power and prominence within orga-

nizations. Behavioral factors have proved essential in achieving acceptance and success, and the nature of innovation and change is a long-term and deeply-rooted process. With this in mind, the next section of this paper will examine a new focus for the diffusion of police computer technology.

#### THE DIFFUSION OF POLICE COMPUTER TECHNOLOGY—SOME DIRECTIONS FOR THE FUTURE.

There is a human tendency to seek direct solutions and to try to classify actions as either failures or successes. When it comes to the diffusion of technological innovation there seems to be no single prescription that will guarantee success. It is possible, though, to identify what not to do, particularly with the benefit of hindsight. Based on such hindsight and the analysis of the cases noted above, a series of "necessary-but-not-sufficient" conditions in the implementation process have been identified. The factors can be divided into two categories—those related to the nature of the environment of the innovation, and those related to the project management of the innovation. In essence, they are built upon and serve to summarize many of the common themes which have emerged from the case studies: the need for understanding the environment and motivations for change, the long term nature of innovation, vendor pressures and the temptation to oversell or overestimate a project's potential, the necessity of setting priorities and outlining clear performance guidelines in advance and the importance of human and behavioral considerations such as the continuity of personnel and the involvement of police officers at all levels to the extent possible. Listed in Figure 2, they serve as a "check list" for future consideration—not as a magic formula for success.

Obviously, it is impossible to expect that all of the factors relating to the nature, environment and project management of change can be achieved whenever computer technology is implemented. There is no simple answer to assure success. It is clear, though, that in the past we have failed to devote adequate attention to the implementation and diffusion of innovation not only in law enforcement but in almost all areas of urban service delivery. While trying not to raise our expectations beyond reach, it should be possible to concentrate our efforts at more effective evaluation and transfer, where appropriate.

The diffusion of innovation basically involves four steps:<sup>24</sup>

*Inventing*—The creating of ideas, technologies, models, etc.

*Informing*—Publicizing the technology and educating the law enforcement community concerning the technology and its possible advantages and disadvantages.

*Implementing*—Introducing the technology into a law enforcement agency.

*Integrating*—The overall social and economic acceptance and adjustment to the innovation by the agency.

In developing a more realistic and productive outlook and direction for the diffusion of law enforcement technology, and for that matter, diffusion related to all urban services, all four deserve consideration.

#### *Inventing—The need for better technology*

Although this report has neither the space nor the capacity to be too specific, "better technology" improvements can and should be made in the quality of law enforcement computer applications. For example, in the modeling area we must build better models. Over the last decade, progress has been made. The Hypercube and PCAM Models offer better options to police users than those available six or seven years ago. Further, it may be possible, within the professional community of computer technology, engineering and operations research, to establish high standards and criteria by which inappropriate innovations can be weeded out.

#### *Informing—The need for "truth in technology"*

One of the greatest failings related to computer technology in the past decade is the tendency to overpromise. Expectations have been raised only to be dashed, due to a whole range of technical and behavioral factors. The primary change agents in law enforcement technology are vendors. However, they have a vested interest in selling their product and this interest has sometimes tended to focus sales literature on the advantages of technology as compared to the drawbacks. As noted earlier, the time is ripe to develop realistic performance guidelines and to try to assure that in the informing and educating process that the costs of technology, as well as the benefits, receive ample publicity.

#### *Implementing—The need for "policy management"*

The implementation process is not simply a matter of policy choice, but a process of conflict resolution requiring the understanding and management of different values and perspectives. It has become apparent in analyzing the implementation of law enforcement technology, that a new breed of police officers is emerging. These are officers who have "come up through the ranks" and have, therefore, "paid their dues" and are respected within the policy community. At the same time, they have had some experience with both the advantages and limitations of new technology and may be helpful in this process of conflict resolution. Rather than try to teach outside engineers about police work, it may be profitable to cultivate this inside set of "police technology experts." As long as they maintain this independence they could become a "pool of resources" to aid in the diffusion process.

1. Conditions related to the nature and environment of the innovation:

A clear and realistic understanding at the outset of the project of the policy issues involved. Multiple, even conflicting objectives are often involved. For example, when Los Angeles first began the LEMRAS project, they failed to appreciate the policy conflict between the model and team policing.

A perceived need for change among those influenced by the innovation -- both police administrators and officers in the street. Effective change must usually build from within an organization. If innovation becomes an "idea in good currency," its chances for success will rise significantly. One of the indicators of this perceived support is a willingness to pay for change. Both San Diego and New York City "used their own money," when installing CAD systems. Although projects funded from the outside may still succeed, often there is less commitment and support than in self-funded efforts.

Effective timing and system design so as to meet user needs and resist the temptation to oversell and therefore build impossible expectations. The first attempt at CAD in San Diego failed miserably because those involved in the design failed to identify the needs of users. The second effort focused special attention on user concerns and was implemented at a time when change seemed essential. The outcome was far more successful.

The proper selection of priorities in implementing computer technology. The most important formula seems to be to start with routine innovations that assist the officer in the street; more nonroutine innovations can be developed later to serve a more narrow range of officer needs. Also, the focus has been on crime and law enforcement activities. Perhaps if greater attention were devoted to service or order maintenance objectives, acceptance would increase.

2. Factors related to the project management of innovation:

Establishment of a clear set of performance guidelines at the beginning of a project. Such guidelines serve as a framework for clear understanding between the vendor and user. They were invaluable, for example, in San Diego, and their absence in other cities has been at the root of many difficulties.

A long-term framework and perspective. Eight years were spent in the implementation of the ADAM historical reporting system in Los Angeles, and the New York City SPRINT CAD system has evolved significantly within a seven year period. Such projects inevitably take longer than initially planned, and if an adequate time-frame is not allowed, frustration and rejection will ensue.

Emphasis placed on human-computer interaction. There is sometimes a tendency to consider computer technology as a replacement for people. This is both unrealistic and inefficient. One of the most critical variables for the efficient operation of any computer system is the development of the proper balance in the interaction between people and machines.

Effective training, education, and information dissemination. The process of communication is often at the heart of effective innovation. Carefully designed training programs provide an important link in such communication. However, innovators must be careful not to oversell and be prepared to listen to feedback. The dialogue process must be two way.

Continuity of personnel. Experience has shown that, as advocates for technological innovation move, the innovation often dies. Change in personnel is inevitable, but at the same time, a certain degree of continuity must be maintained.

Involvement and quality of top-level leadership. Police departments tend to be fairly rigid organizations with well established chains of command. Understanding, involvement and support from the top is essential if technological innovations are to be implemented and used. More than support from the Chief is required, though. In addition, a core of agency leaders is necessary if commitment is to be maintained over time.

Involvement of other police personnel. Besides the top commanders, police at the operating level must be involved in the design and development of computer technology. One reason the resource allocation system faltered in St. Louis was because the field officers strongly resisted a shift of only one hour in their daily schedules because it would have required them to commute to work during the normal rush hour traffic.

Caliber of computer systems and technical staff. Individuals are required who have both technical skills as well as a broad perspective which will allow them to see beyond computer technology to law enforcement needs and to communicate successfully with the police department. In order to attract such individuals, cities must be willing to pay competitive wages.

Unbiased evaluation. A careful (and, if possible, independent) evaluation should be an integral part of any implementation effort.

Figure 2 (continued)

*Integrating—The need for the internal motivation and integrity of change*

One of the most critical elements for implementation success is that the desire for change must come from within, not without. Better evaluation and guidelines for performance can help educate police departments as to the advantages and limitations of technology, and "pools of resources" from within and without the law enforcement community might establish a two-way communication to facilitate diffusion. Still, the final desire for change and the specific design and implementation of alternatives must come from within the police department involved. Openness and meaningful communication are required, and although it is difficult to maintain such behavior constantly, it is essential in helping to bring about effective innovation.<sup>25</sup>

CONCLUSIONS—CHANGING EXPECTATIONS FOR THE FUTURE

There are a range of views about the use of computers and technology in our society. At one extreme are those who see the increasing movement towards a technological society as dangerous, a movement that will take us away from the "good life." Scientific rationality and technological progress may have questionable results and set up a chain reaction which we may not be able to reverse. At the other extreme are the technologists and the vendors who sell their products. They argue that the benefits of technology outweigh the costs and tend to oversell their products and to promise more than they can deliver. It is the opinion of this author that the truth lies somewhere in between. On the one hand computer technology has become a part of law enforce-

ment activity. Given this reality, the most useful orientation is to realistically evaluate current needs and progress and to promote change where it is appropriate. On the other hand, we must admit that many of our efforts at technological innovation have failed. Promises have been overextended, expectations have not been met, and resources have been wasted. The answer to our problems does not lie in hardware; it lies in basic value judgments and in people. In talking about a computer application in his police department, one police sergeant astutely remarked:

"The computer terminal in the car is an effort by the police department to professionalize from a hardware approach. This is O.K., but the more we concentrate on hardware, the farther we move from the basic people issues. The real police problems don't have technical solutions. Instead, it's the people who are screwed up, and we need more people-to-people type efforts in police departments, such as improvements in communication, improved motivation, productivity modifications, better interpersonal relations, etc. In short, instead of hardware solutions, we need policy resolutions of the basic issues of the police force. The result of the computer may be to take our minds off what are the more important issues."<sup>26</sup>

In summary, most arguments against the computer are made on the grounds that too much money is currently being spent on law enforcement technology, particularly when it is not clear that the benefits of such technology justify the costs. However, this study has found that in many routine applications the benefits *can* justify the costs, particularly if benefits are defined in narrow, process-oriented terms. Further, this efficiency may continue to develop with time as computer technology becomes more sophisticated and police departments get better at handling the organizational and behavioral problems which often accompany the introduction of technology and the implementation of change.

More importantly, though, there are other issues surrounding the use of the computer that have greater significance than questions of costs and benefits. The use of computer technology by the police must be placed in perspective. Although many aspects of computer technology in law enforcement are well established and expanding, it would be a mistake to think such innovations will play a major role (at least in the short run) in revolutionizing the police or many of the issues they face. Police work, to a large extent, is determined by the conditions of our society and its people. Crime and law enforcement have a momentum of their own. Computer technology may have a marginal role in influencing and shifting relationships, but the major law enforcement issues must be resolved in the context of society as a whole. For example, some of the most pressing law enforcement questions at this time are to define the basic task of the police, to identify how the officer's time is really being spent, to determine the correct allocation of resources and to determine if current recruiting and training practices complement the basic needs and priorities of the police. The computer (along with proper analysis) may help in a small way to resolve these sorts of issues, but until such

questions are addressed the implementation of the computer may also serve to reinforce the status quo, to lock in and substantiate our present approach, and to indirectly countermand other innovation.

The greatest strengths of computer technology seem closely related to its greatest weaknesses. Computers have the potential to aid in criminal justice activities through rapid communication, accurate and complete information, and perhaps a more rational approach to decision-making. We must realize that there are limits to this technology, though, and not overestimate the potential. These very benefits, if not properly controlled or planned, may result in misuse, unintended consequences, wasted resources and frustrations. Expanded computer use by the police is at a crucial point and now is the time to point to a new direction, one slanting toward attention to evaluation and implementation, stressing performance standards and transfer, and realizing that police play a broader role in society than simply fighting crime. Such a new direction requires careful consideration so that the strengths of technology can be judiciously marshalled and the weaknesses and potential risks prudently forestalled.

## NOTES

## INTRODUCTION

In the search for speed and computing power, many researchers in computer science have turned to networks of computers as a possible solution.<sup>1,5,8,14,9</sup> These networks consist of minicomputers connected by links across which communication between processors occurs. In homogeneous networks, the computer at each node is identical to the others, with the possible exception of peripherals. Each processor has its own local memory, does not share memory with any other processor, and communicates with other processors via message passing. In order to fully utilize the speed and power inherent in a network, emphasis must be placed on the development of parallel (as opposed to sequential) algorithms.

In this paper, we will investigate concurrent algorithms designed to impose a logical structure on top of the physical computer network, such as a pairing of the processors along communication lines. These algorithms are interesting not only for their relationship to parallel algorithms in general, but also because the resulting structure may be used as a basis for writing other parallel algorithms. We restrict our attention to algorithms that have the following properties:

1. Initially, each processor knows only of its neighboring processors in the network.
2. All processors have the same program to execute.
3. Messages sent between neighbors may take an arbitrarily long amount of time to arrive.
4. Messages between any two connected processors will always arrive in order.
5. No assumptions are made about the physical interconnection pattern except that it is connected.

The algorithms we will discuss form three types of structures on the network. These three problems have been chosen because their results are dependent upon the physical

network configuration and because they apply to the solution of other network problems. *Pairing* algorithms match each node of the network with a direct neighbor. Since a pairing is not always possible, as in the case of an odd number of nodes, a good solution should leave a minimum number of "single" processors at the end of the algorithm. *Spanning tree* algorithms impose a tree on the network so that a unique path exists between any two processors in the network. The last problem considered is that of forming *hierarchies* of processors. One step in developing a hierarchy is the formation of processor cliques. Each clique should be of a certain size and one processor in each clique is designated as the "leader." A good solution should try to minimize the average radius of each clique.

The assumptions made earlier about the behavior of messages and about the program each processor runs give rise to several problems. The problem of *agreement* is that each processor must make consistent decisions with regard to the rest of the network, possibly based on widely differing local information. (For example, in the pairing algorithm, two nodes should not simultaneously believe they are paired to the same third node. In particular, the final state of the computation must not exhibit this behavior.) Each processor makes independent decisions about its future role in the resulting structure. Therefore, any decisions a processor makes that might affect its neighbors' decisions must eventually be communicated to those neighboring processors.

*Synchronization* is the problem each processor encounters when it is about to finish a phase of the algorithm. Since information about the rest of the network is usually incomplete at each node, the algorithm must be designed so that each processor can make its own decisions based on little information. (For instance, in the pairing algorithm, a processor should not decide to halt its active participation and assume that a neighbor is its mate unless it knows that the neighbor will agree.) In particular, it is hard to decide whether a current local state is final or not. In part, this problem results from the assumption that messages between processors may take a long time to arrive. A processor cannot stop participating unless it knows that no later mes-

\* This research was supported in part by United States Army under contract #DAAG29-75-C-0024.

sage can force a change in its state. Although messages never get lost, they may arrive quite late, and provisions for handling or preventing these messages must be made.

The above two problems just mentioned have an easy solution if we allow ourselves the luxury of a central controlling processor. Such a central control would, however, become a bottleneck as the size of the network grows. We feel that more general solutions can be derived by avoiding this central control. Certainly, any known methods for sequential solution of these problems could be carried out by the central control.

In developing these algorithms, we have totally ignored low-level aspects of message passing. Low-level protocols and the problems of lost or garbled messages are the responsibility of the underlying network implementation. Some research has already been invested into these problems.<sup>7,10</sup> It is our intent, however, to study the fundamental problems of parallel algorithms themselves.

We have examined the performance of these algorithms by simulating a network in order to obtain sample results. Different network configurations were used, and comparative performance between different configurations varied, but the relative performance of each algorithm remained the same for each configuration. The configuration used most often was a square grid of varying sizes. We schedule the time of the receipt of a message on a time line, and assume that the computation at each node takes negligible time. The time for a message to be delivered is selected from an exponential distribution with mean 1, truncated to lie between 0.50 and 1.50 time units. In this way, many actions may occur "simultaneously" in simulation. The programs were written in Pascal<sup>6</sup> and executed on a PDP 11/40 and a PDP 11/45.

Each of the following algorithms operates in the following manner: Upon receipt of a message, a processor executes a program segment that depends upon the processor's state and the message received. In this program segment, the processor may save whatever information it wants from the message, send out new messages, and change its internal state.

## PAIRING ALGORITHMS

To achieve a pairing, each processor must agree either to become paired with a neighbor or to become single. A correct solution is one in which a paired processor and its mate agree that they are paired, and no neighboring processors are both single. An optimal solution is one in which there are a minimum number of single processors, which may require some analysis of the network configuration to derive.

We will start with a simple algorithm, called Algorithm A, and then suggest improvements. The basic pairing algorithm has four states. A processor in the *idle* state has not yet started the algorithm. When it is *waiting*, a processor expects a reply from its chosen mate. *Paired* means the processor considers itself paired, and *single* means it considers itself single. There are five messages—*awake*, which starts an idle processor; *query*, which indicates that the sender

wishes to pair with the recipient; *agree*, which tells a waiting processor that the sender agrees to become paired with it; *disagree*, which indicates that a processor's chosen mate is itself awaiting an answer from its own intended mate; and *refuse*, which indicates that a processor's intended mate is already paired with another processor.

At the start, each processor is idle, and one awake message has been sent to it. (It is not important to this discussion how awake messages are generated.) Initially, all direct neighbors are potential mates. If the processor receives the awake message in its idle state, it chooses a random neighbor from its list of potential mates as its intended mate, sends it a query and changes state to waiting. This query may reach the neighbor before any awake message. In this case, the recipient chooses to become paired with the sender and returns an agree message. This case, when the recipient of a query is in its idle state, is the only one in which an agree message is sent. Since agree, disagree and refuse messages are sent out only in response to a query, and queries are not sent out by idle processors, we only have to consider these two cases when the processor is idle.

If a processor is in its waiting state, many different actions may occur. Any processor in the waiting state must already have seen the one awake message directed to it. If a query is received, a disagree is sent back if the query is not from the intended mate; otherwise, the processor becomes paired. No agree need be sent in the latter case; since the sender of the message is this processor's intended mate, a query was sent to it and the mate will take the same action. If an agree is received from the intended mate, then the processor also becomes paired. If a disagree is received from the mate, then the processor chooses a new intended mate, sends it a query and remains in its waiting state. The new intended mate may be the same as the first one. If the processor receives a refuse from its chosen mate, it removes the sender from its list of potential mates, chooses a new intended mate and sends it a query. If there are no more potential mates, the processor becomes single. A single processor should not receive any messages at all, since no query is outstanding and all neighbors have refused, implying that they are paired. Finally, if the processor is paired, it can receive either a query, in which case it sends back a refuse, or an awake, which it ignores.

If we examine Algorithm A, we see that once all of the processors are started, a processor and its intended mate must choose to query each other before they can become paired. Many false starts may happen before this pairing actually occurs. In an effort to reduce contention, Algorithm B begins by sending only one processor an initial awake message. If an idle processor receives an awake or query message, it sends out awake messages to all of its neighbors except the sender of the received message. Simulations show that the number of singles left remains about the same for Algorithm B as for A regardless of the network structure, and the elapsed time (simulated time, not running time) becomes progressively worse as the size of the network increases. This behavior implies that contention is not really time-consuming. Also, the time needed to activate the processors across the network from the originally started pro-

cessor begins to override any extra time that contention might produce. Concurrency, it seems, has definite, although not dramatic, time advantages.

Algorithm C is a modification to Algorithm A designed to provide each processor with earlier information concerning the state of its neighbors so that it can make a better choice of intended mate. Since the refuse message indicates that the sending neighbor is already paired, queries can be forestalled by broadcasting refuse messages to all direct neighbors (except the mate and those neighbors known to be already paired) as soon as a processor becomes paired. This modification has three parts. First, whenever a processor becomes paired, it must send out refuse messages to the appropriate neighbors. Second, if a processor receives a refuse from a processor other than its intended mate, it removes the sender from its potential mate list. Finally, a paired processor that receives a query need not respond, since it has already sent out a refuse. The observed saving in elapsed time is quite dramatic, and the number of singles left also seems to decrease. The amount of information available, then, appears to make a considerable difference in performance.

Since concurrency and early information both improve the speed of the algorithm, we tried Algorithm C, activating all of the processors at the same "time." The previous algorithm sent the broadcast awake message to all processors at the same time, but that message arrived according to our message-delay distribution. Again, the elapsed time performance improves, but no real conclusions can be made concerning the number of singles left. In fact, the number of singles may increase for larger networks.

Of the two, more information makes a greater improvement in the performance of the algorithm than concurrency. In order to follow this idea further, Algorithm D provides an individual processor with still more information about its neighbors. A new message, *neighbor-list*, is introduced. This message contains the size of the potential mate list of the sender. These neighbor-list messages are sent out to all potential mates upon receipt of a refuse message, which changes this number. When a processor receives a neighbor-list message, it enters the new data in a table. When it comes time to choose a mate, each processor picks a random neighbor from among those with the fewest potential mates. One expects that the number of singles will decrease, because better choices can be made. For the smaller networks, the new approach seems to make no difference, but for the larger networks, significantly fewer singles result. Algorithm D also performs faster than Algorithm C for all network sizes.

Perhaps we could do better with a different choice of a neighbor to query. Instead of choosing a neighbor with the fewest potential mates, Algorithm E chooses a neighbor with the most. The results justify the intuition that choosing the neighbor with the fewest potential mates leaves fewer singles. Surprisingly, however, Algorithm E is still an improvement over Algorithm C, in which an intended mate is randomly chosen, both in elapsed time and number of singles. Again, increased information creates an algorithm that performs better.

Since none of these algorithms guarantees an optimal solution (that is, one in which the number of singles is minimal), we introduce a second phase to the basic algorithm during which singles migrate, eventually to meet and pair. All the previous algorithms have the property that each processor knows when its active participation in the algorithm is over. In the subsequent pairing algorithms, termination is not locally discernable.

Algorithm F introduces a *break* message that is sent out by a single to a randomly chosen neighbor. This neighbor, if still paired, will then send back an agree, send an *eloped* message to its old mate to indicate that they are no longer paired, and become paired with the single that sent the break message. The recipient of a break message may be waiting or single, though, since processors can now become paired and unpaired an arbitrary number of times. If the recipient is waiting or single, and its intended mate is not the sender of the break message, it then sends back a disagree. Otherwise, the recipient becomes paired, much as in the previous case when two processors send queries to each other. If a disagree message is received by a single processor, then the sender of the disagree is added to the potential mate list, the processor enters the waiting state and a new query is sent out. When a single processor receives an agree, query or break message from its intended mate, it becomes paired. Eloped messages are ignored if they do not come from one's mate, since the message can be late, but must be handled otherwise. They are treated as a refuse in response to a query, which means that the receiving processor must now become single or waiting, depending upon the state of its potential mate list. An appropriate message (break or query, respectively) is also sent. The algorithm has halted (in simulation) when all of the processors have become paired, or the minimum number of singles is left for the given network.

The simulated time to execute phase two is much higher than that for phase one, and varies widely in different test runs. Of course, this phase allows little concurrency, since only those processors near singles are involved. Moreover, networks that cannot be completely paired fare better during phase two than networks of similar size that can be paired, since more singles are migrating throughout the network. We tried Algorithm F in conjunction with both Algorithms A and C, that is, with refusals both broadcast and not broadcast. The results were a bit puzzling at first—Phase Two time increases when refusals are broadcast. The cause is probably that the potential mate list becomes more of a hindrance than an aid in the second phase, since it restricts the choices a processor can query before it must become single. In addition, the average path length, or number of break messages per single at the end of Phase One, also increases when refusals are broadcast.

In an effort to reduce the time spent by singles that migrate randomly throughout the network, Algorithm G includes a homing signal for the singles so that they might find each other more easily and directly. Whenever a processor becomes single, instead of immediately breaking a random neighbor's pairing, it broadcasts a homing signal containing some random number. This message is passed on by every processor until some other single receives the signal. This

single will then break the pairing of the neighbor who relayed the signal. In this way, one hopes that single processors will meet and pair much sooner, since they can move toward each other directly. One also hopes that the signal broadcast messages will not seriously affect performance.

Unfortunately, the phase two performance of Algorithm G turns out to be seriously worse than random migration. First, broadcast messages take up some time, since every processor must receive each signal twice before the message is squelched. More importantly, breaking the pairing of a neighbor in the direction of another single does not necessarily place the new single any closer to the originator of the signal. In a square matrix configuration, for example, there is a two-out-of-three chance that the new single would be just as far away, as shown in Figure 1. Only a better understanding of the configuration of the network at each processor will allow a more intelligent break message to be sent after a processor becomes single.

The pairing algorithm is an excellent medium for studying parallel structure-producing algorithms. We discovered that concurrency, even if it does increase conflict among the processors, decreases the elapsed time of the algorithm without seriously affecting other aspects of performance. Also, gathering greater amounts of information leads to faster and more accurate results. Finally, the network configuration cannot be totally ignored in the development of an algorithm; an algorithm that ignores configuration information will do worse than one which incorporates the data into its "solution."

As a passing note, we also tried our algorithms on different connection patterns for the network. The algorithms perform consistently better on square matrix configurations than on any of the "flake" configurations of similar sizes with respect to the number of singles. (See Reference 3 for a definition of "flake" network configurations.)

Figure 1—S<sub>1</sub> is a single generating a homing signal detected by S<sub>2</sub> and relayed by P<sub>1</sub>, which is paired to P<sub>2</sub>. In each case, S<sub>2</sub> will pair with P<sub>1</sub>, and P<sub>2</sub> will become a single. Only in the first case is the resulting single closer to S<sub>1</sub> than before.

### SPANNING TREE ALGORITHMS

A spanning tree is a subset of the physical links of the network such that there exists a unique path along the selected links from any given processor to any other processor in the network. An algorithm to produce a spanning tree should select appropriate links in such a way that each node agrees with its direct neighbors as to which of the connecting links are in the tree. A useful algorithm by-product is a routing table at each node associating destinations with locally-selected links. We will examine two algorithms for this problem.

In Algorithm H, each processor can be in one of three states—*idle*, *working* or *done*. *Awake* and *known-nodes* are the only messages. *Awake* starts an idle receiving processor. Each *known-nodes* message contains a list of those nodes the sender knows it can reach through selected links other than the one on which the message is sent. Each processor associates each direct neighbor with those nodes it thinks that neighbor can reach, according to the most recent information passed to it via *known-nodes* messages. A list of selected links is also kept.

Upon starting, each processor tells its direct neighbors that it can reach itself. When a processor receives a *known-nodes* message, if the connecting link is currently selected, and nodes newly reachable through it could be reached through other links in the spanning tree, then the link to the sending neighbor is de-selected. If the newly reachable nodes do not conflict with any current information, then the link to the sending processor remains in the tree. On the other hand, if the connecting link is not currently selected, and if the reachability set the neighbor has sent does not conflict with the current set of reachable nodes, then the connecting link is selected. Whenever a *known-nodes* message arrives, it may show that some links have been removed from the spanning tree, so the receiving processor also checks if any of the other connecting links can now be selected. Finally, the new information about its status of reachable nodes is sent to all of the receiving processor's direct neighbors, unless no new information is to be reported (the last message sent to each neighbor is saved to facilitate this decision). A processor can determine when its role in the algorithm is finished when it chooses not to send any messages to its neighbors, and all nodes in the network are reachable through selected links. In order to perform this test, each processor must know the names (but not the locations) of all nodes in the network, which can be supplied in the *awake* message.

It is easy to prove that this method will produce a correct solution. First, if a link is selected by a given processor when it has terminated, then the set of nodes reachable through that link is the complement of the nodes reachable through the other selected links, by the termination condition. If the neighbor on the other side of the link has not selected the link, and has also finished, then it must think it can reach the first processor through another selected link. If this is the case, it would have told the first processor so. The first processor could not then have selected that

link, because it causes a conflict (a processor can always reach itself without going through any links). So the neighbor must also have selected that link. Second, the sets of nodes reachable through each of the selected links will be disjoint, so any path along the tree will be unique. Finally, all of the processors are in the tree when the algorithm halts. A major drawback to Algorithm H, however, is that the computing time required for each action and the amount of space required to maintain the appropriate information at each node are both large.

A second method, Algorithm I, sacrifices some concurrency for ease of computation. The idea is based on the pairing algorithm. During the algorithm, every processor belongs to a partial spanning tree, and each tree is controlled by one of the member processors. Partial trees merge using a version of the pairing algorithm, with the controlling processors representing the trees.

At the start, each processor starts as its own spanning tree. Partial trees are built by repeatedly asking other processors to join. Each controlling processor keeps track of which nodes are in its tree, and asks only those nodes not in the tree. If the controlling processors of both trees agree (i.e., the "trees" have queried each other as in the pairing algorithm), a combined tree is formed, and one of the two controlling processors is chosen as the new controller. Each controlling processor has an associated random number; whichever has the higher one becomes the controller for the combined tree. Processors that no longer control a tree relay messages to their controlling processor. As soon as one transaction is complete, the surviving controller initiates the next one, until the set of neighbors not in the current tree is empty. This algorithm does not require any advance knowledge of which processors are in the network, since the set of tree neighbors can be calculated from the set of nodes in the tree and the set of neighbors of nodes in the tree. When the set of nodes neighboring those that are in the tree is a subset of the nodes in the tree, the entire tree has been formed.

Algorithm I can be sped up in two ways, resulting in Algorithm J. First, when one controlling processor becomes chosen by another, it informs all of the nodes in its tree which processor is now controlling the tree, so that messages can be relayed directly. The second idea provides a major improvement, because it increases the concurrency of transactions. When a controlling processor,  $\alpha$ , receives a query from another controller,  $\beta$ , that has a smaller associated random number, and  $\alpha$  is also waiting for an answer from a third tree,  $\gamma$ , then  $\alpha$  sends an acceptance, not a disagreement, to  $\beta$ . Processor  $\beta$  is destined to lose its position as controller in any case. Update messages are now required, however, since the controller  $\gamma$  may be the surviving controller of the transaction between  $\alpha$  and  $\gamma$ . That controller will not be aware immediately that other nodes have joined  $\alpha$ 's tree in the interim, since such information is normally passed along with the queries and  $\gamma$  may therefore generate an indirect query to itself, delayed by some relays. Update messages enable this processor to rectify such a situation.

These two improvements together decrease the elapsed time of Algorithm J until it is comparable to the time of Algorithm H. In addition, it seems that the simulated time increases more slowly with the size of the network for Algorithm J than for Algorithm H.

It is obvious, however, that Algorithm H is much cleaner and that it derives its speed from its inherent concurrency. In Algorithm J, all chosen processors are idle except when relaying messages, and the speed is derived primarily from the lack of conflict. If Algorithm J could be changed to distribute the decision process, then perhaps it could become a more powerful solution. On the other hand, the number of messages sent in Algorithm H grows significantly faster with the size of the network than in Algorithm J. Therefore, for larger networks, Algorithm H may prove impractical since message passing may become a bottleneck. In general, though, it is much better because it does not rely on random numbers or shortcuts to derive its speed, although a good way to terminate the algorithm may be harder to develop.

The previously-mentioned algorithms were developed solely under the assumption that more than one processor can begin within a short amount of time (much shorter than that required to complete the algorithm). If only one processor is started, then Algorithm K, a much simpler method, may be used: When a processor receives an awake or query message and it is idle, it selects the link over which the message came and responds with agreement. It then sends out its own queries along the other links. It only selects those links across which agreements are received. In order to allow each node to determine termination, disagreements can be sent to all subsequent requestors. When all neighbors are accounted for, the node is finished. This procedure is clean and simple, but requires that exactly one processor be started. Running time is directly proportional to the diameter of the network and to the maximum degree of the nodes.

## HIERARCHY ALGORITHMS

The final class of algorithms investigated are those designed to form a hierarchy of processors. The major step is to form cliques of processors, with one processor chosen as the head of the clique. The hierarchy can then be built by repeating the clique-forming algorithm on the heads of the cliques formed in the previous step. Therefore, we shall only look at algorithms that form cliques. A correct solution is one in which each clique is well formed—there is exactly one head, and all of the processors in the clique agree that they are in the clique. An optimal solution is one in which the average radius, as measured from the head of the clique in message links, is minimal. A constraint is the acceptable range of sizes (number of nodes) per clique.

We will discuss two algorithms. The first assumes that all the processors are started within a short time of each other, whereas the second assumes that a central controller directs the algorithm. In Algorithm L, each processor is in one of two stages—*head* and *chosen*. Each processor begins as a

head and tries to form its own clique. It keeps asking processors not in the clique to join. Each head also keeps track of how close it is to its goal. Chosen processors are those that think that they are members of some clique. When a chosen processor receives a query from another clique's head, it relays the request to its own head. The head either denies the request or tells the processor to switch allegiance to the other head. The chosen processor then sends back a disagree or an agree, respectively, to the requesting head. If a head is itself queried, it decides either to abdicate or to disagree. If it abdicates, the head tells its chosen processors to start all over and sends an agree to the requestor; otherwise it sends a disagree. The head stops asking new processors to join its clique when it feels that the clique is of the correct size. In order to minimize the average radius of each clique, the head prefers to query those processors that are closer. This algorithm requires decision algorithms for selecting potential members, freeing current members and abdication. We could not produce very good hierarchies with Algorithm L with the various decision algorithms tried.

Algorithm M is a variant of one developed by Larry Wittie.<sup>13</sup> In this method, one clique at a time is formed, and a central control is needed to ensure that the algorithm terminates. The algorithm operates in two stages, the first of which informs each processor of all the other nodes in the network and their distances in message links. This preparation can be done by a straightforward modification of Algorithm H.

The second stage of Algorithm M forms the cliques. The central control sends a message to an arbitrary processor in the network ordering it to form a clique. This processor chooses and queries the right number of nodes, sending along the calculated radius of its proposed clique. If one or more of these chosen processors can form its own clique with a smaller radius, it responds to that effect. Otherwise, the chosen processor sends back an agree. If, when all of the chosen processors have replied, at least one has sent back a better radius for its proposed clique, the querying processor chooses one from among those with the best radius for a proposed clique, and tells it to try and make a clique. If all processors respond with agreements, then the querying processor becomes the head of the clique and sends messages to the chosen processors indicating that they are now members of the clique. It then chooses some processor not in any clique and tells it to form its own clique from among the other processors that are not in any clique. When as many cliques as possible are formed, the algorithm halts. Algorithm M is not very concurrent, but does produce fairly good hierarchies. It is also possible to devise a network for which this algorithm cannot produce an optimal solution, since the algorithm uses local hill climbing. If concurrency could be added, this algorithm would be very powerful indeed.

It appears to be more difficult to design good distributed algorithms for forming processor cliques. Either some heuristics are needed so that the different cliques forming simultaneously do not interfere with each other, or concurrency needs to be sacrificed. Some further study into the

basic nature of the problem appears to be required in order to find a good, concurrent clique-forming algorithm.

## CONCLUSION

We set out to develop parallel algorithms for globally structuring networks of processors. We discovered that although concurrency is an important aspect of the performance of these algorithms, the amount of information about the problem available at each processor plays an essential role. We also found that the nature of the particular problem has to be examined for sources of concurrency.

In future research, we hope to examine not only other problems and algorithms for concurrent solutions, but also problems for which the associated solutions will use the imposed network structures produced by the algorithms in this paper. Since processor networks appear to be emerging as an important computing resource, it is essential that research into the design of distributed algorithms be continued and expanded.

# The tree-structured distributed network front-end processor architecture

by ROBERT M. MONROE, RONALD J. SRODAWA and FRANKLIN H. WESTERVELT

Wayne State University  
Detroit, Michigan

## INTRODUCTION

Contemporary front-end processors, such as the IBM 3705,<sup>1</sup> Memorex 1380,<sup>2</sup> Burroughs Data Communications Processor<sup>3</sup> and the MERIT Communications Controller,<sup>4</sup> share the same general architecture depicted in Figure 1. Communication lines are associated on a one-on-one basis with line adapters. These are connected in small groups (clusters) to the local processor, and perhaps to the local memory, through line interface bases. In a similar manner, the host system input/output channels are associated on a one-on-one basis with channel adapters which are connected to the local processor and memory. The architecture can be thought of as a minicomputer system in which the channel adapters and line interface base/line adapter subsystems are input/output devices. In fact, many front-end processors are configured in precisely this fashion.

There are many design parameters which can be varied to affect the maximum aggregate data rate, cost, and services-rendered characteristics of front-end processors. The number of line adapters per line interface base and their relative complexities are an example. The line interface bases might interrupt the processor for every character or transfer entire records by means of direct memory accesses. The channel adapters might connect directly to the host system channels or through some other standard interface such as a channel-to-channel adapter or high-speed communication line. Generally channel adapters utilize direct memory access features because of the high aggregate data rates they sustain.

All of the intelligence of a typical front-end processor is located in the single local uni-processor. This uni-processor must handle all the interrupts from the line and channel adapters. In effect it is multiprogrammed across all of the data streams to provide front-end services such as line editing, character code translation, and message formatting. Saturation of the local processor limits the kinds of services that can be provided and the aggregate data rate that can be sustained.

We describe here a front-end processor architecture in which the single local uni-processor, memory, line interface bases and line adapters are replaced with a network of microprocessor systems as depicted in Figure 2. The network

is tree-structured with the root microprocessor system connected to the channel adapters and local direct access storage devices (DASD). At the same time the leaf microprocessor systems replace the line interface bases and line adapters. The low cost of microprocessor systems makes such a network economically feasible. Each communication line has a dedicated microprocessor and the computational power of the network easily exceeds that of the local uni-processor in the traditional front-end processor configuration. It is reasonable to expect that more sophisticated services might be provided or that higher aggregate data rates might be sustained. Data movement between the communication lines and the host system channels is accomplished by store and forward message routing through the tree of microprocessors. The tree-structure network organization was chosen because it correlates well with the hierarchical organization of the hardware system.

The remainder of this paper begins by describing the network topology and the configuration of the nodes in abstract terms. Next, a description of the prototype configuration is given followed by a description of the proposed production configuration. The cost of a typical production configuration is established and compared to that of a similar configuration using a commercially available front-end processor. Finally, arguments are given supporting the advantages of a tree-structured distributed network architecture for a front-end processor.

## NETWORK TOPOLOGY

As briefly described earlier, the topology of our front-end processor is a distributed network of microprocessor systems arranged as a tree-structure depicted in Figure 2. Each node (microprocessor system) of the tree is loosely coupled only to those nodes to which it is connected by edges. The network is a loosely-coupled microprocessor system—the interconnections consist of loose input/output couplings rather than tight couplings such as shared busses.

There are three functional types of nodes. The leaf nodes connect on a one-on-one basis to the communication lines.

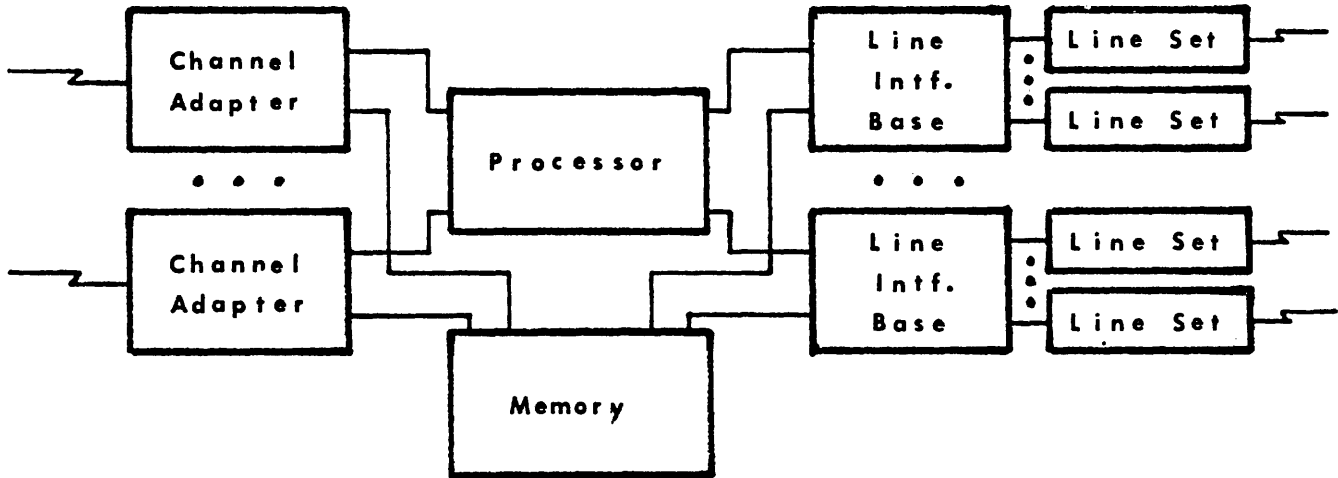

Figure 1—Front-end processor general architecture.

These are the nodes which take over the function of the line adapters. A leaf node provides the front-end services-rendered to the associated communications line. To the user, the leaf node appears to be a microprocessor system located within the communication link between his terminal and the host system and dedicated to his personal use. For this reason it is called the personal processing link (P<sup>2</sup>L) and the entire front-end processor is called the Personal Processing

Front-end Processor (P<sup>2</sup>FEP). The root node connects to the host system channel adapters and local DASD. It gives the network its voice to the host system and maintains a local database. Each of the intermediate nodes connects the subtree below it to the next level closer to the root. The intermediate nodes function as store and forward message handlers. The term link control (LC) refers to a node which is either the root node or an intermediate node.

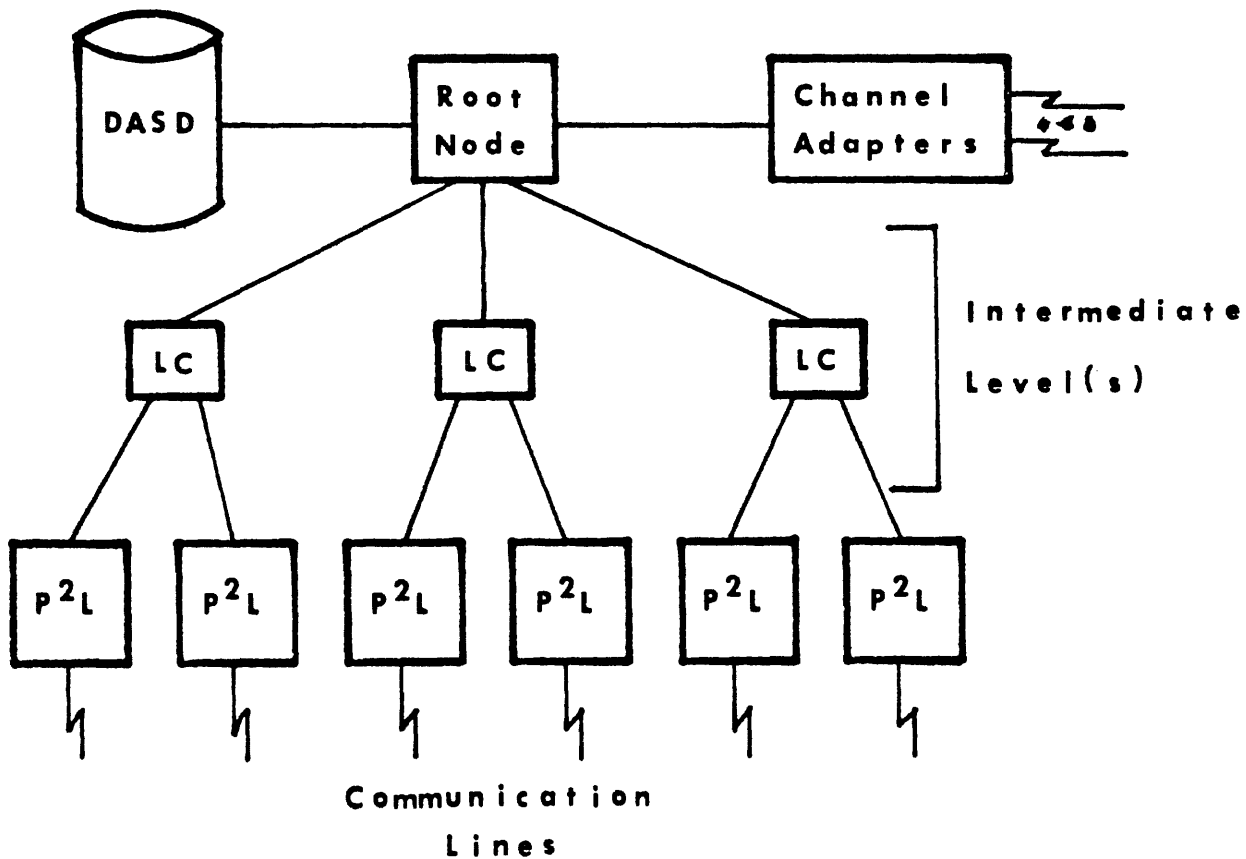

Figure 2—Personal processing front-end processor.

### Leaf node (P<sup>2</sup>L) architecture

Each P<sup>2</sup>L consists of a microprocessor system with four interfaces as depicted in Figure 3. The communication line interface connects the P<sup>2</sup>L to the communication line associated with the leaf. Generally this is a serial interface following either RS-232-C<sup>6</sup> or 20 ma current loop<sup>7</sup> conventions. Adequate support of modems on the dialable telephone network implies a careful adherence to the full RS-232-C set of conventions. The *break/disconnect monitor* (BDM) interface allows the adjacent link control to monitor the communication line for break and disconnect status. This interface is necessary to assure system integrity if users are allowed to execute arbitrary programs in their personal processing links. Most microprocessor systems contain protection mechanisms insufficient to prevent arbitrary programs from capturing the P<sup>2</sup>L. Furthermore, an original design goal was to allow the user of a P<sup>2</sup>L to execute any code that could be executed on a comparable microprocessor system under the complete control of the user at his/her local site. This includes being able to completely "wipe out" one's local program and then recover by a local "reset." The BDM interface provides the ability to perform the "reset" even though the P<sup>2</sup>L is, obviously, not local to the user's site.

The *non-maskable interrupt* (NMI) control line allows the adjacent link control to interrupt the P<sup>2</sup>L into its ROM program nucleus even in the presence of a non-cooperating user program. This together with the BDM interface assures the integrity of the P<sup>2</sup>L.

Finally, the *data* interface allows data to be shared between the P<sup>2</sup>L and its adjacent link control. The *data* interface could be either serial or parallel depending upon the

Figure 3—Leaf node (P<sup>2</sup>L).

Figure 4—Link control node (LC).

manufacturer's standard card configurations. A full duplex *data* interface allows simultaneous data movement in both directions and reduces the complexity of message protocols.

### Link control (LC) architecture

Each link control node (intermediate node or root node) consists of a microprocessor system with a varying number of interfaces as depicted in Figure 4. The precise configurations of interfaces depend upon whether the link control functions as the root node, intermediate node, or intermediate node adjacent to the P<sup>2</sup>Ls. In small configurations more than one function can be supported by a single node.

Each link control connects to all of the nodes immediately below it on its branches. There are two types of interface bundles, depending upon whether these branch nodes are leaf nodes or other link controls. If the link control in question connects to P<sup>2</sup>Ls, then each interface bundle consists of the BDM, NMI, and *data* interfaces described above. If the link control connects to other link controls, then each interface bundle consists of NMI and *data* interfaces similar to the interfaces of the same name described for the P<sup>2</sup>Ls. In either case, there are as many interface bundles as branches from the node in question.

Each link control (other than the root node) connects to one link control in the next level closer to the root. This connection is made through a NMI interface and *data* interface. The NMI interface is used to propagate gross system

events such as resets. The *data* interface is used to move messages comprising the data streams one level between the P<sup>2</sup>Ls or root node.

The root node interfaces to local DASD and the channel adapter instead of a link control at the next level. The root node replaces the NMI and *data* interface bundle with interfaces to the channel adapters and local DASD. The channel adapter interface connects the root node to the host system channels thus giving the front-end processor a voice to the host system. The DASD interface gives the front-end processor and indirectly its users a local file system independent of the host system.

## PROTOTYPE SYSTEM

The prototype system consists of two P<sup>2</sup>Ls and one link control node. The link control node serves both as the root node and the intermediate node adjacent to the P<sup>2</sup>Ls. The prototype is constructed from standard Zilog cards. MCB, RMB, SIB, and IOB cards are used.

Zilog MCB cards consist of a Z-80 CPU, a serial universal synchronous/asynchronous receiver/transmitter (USART) with both RS-232-C and 20ma current loop interfaces, a parallel interface supporting 16 bi-directional lines, and a combination of ROM and RAM memory.<sup>8</sup> Zilog RMB cards supplement the ROM/RAM on the MCB card to provide up to 64K bytes of memory.<sup>9</sup> Up to 16K bytes may be non-volatile ROM, PROM, or EPROM components. Zilog SIB cards provide four serial USART components with RS-232-C interfaces.<sup>10</sup> Zilog IOB cards provide four parallel interfaces, each supporting 16 bi-directional lines.<sup>11</sup>

Each P<sup>2</sup>L of the prototype system consists of two cards—one MCB and one RMB. The total memory configuration is 64K bytes with 8K bytes non-volatile. The USART supports the communication line interface. The *data* interface is supported by the parallel lines, with eight lines in each direction to provide full duplex transmission.

The root node of the prototype system consists of four cards—an MCB, RMB, SIB, and IOB. The USART of the MCB connects to the host system through a high-speed RS-232-C interface. (This interface was chosen to remove the need for a channel interface hardware design). The *data* interfaces from the P<sup>2</sup>Ls are supported by 32 parallel lines of the IOB card. The NMI interfaces of the P<sup>2</sup>Ls are each driven by a parallel line from the IOB card. The BDM interface from the P<sup>2</sup>Ls are supported by two USART components from the SIB card. The prototype system contains no direct access storage in its original configuration. It is wired to accept the Zilog floppy disk controller card (MDC).

The prototype system consists of eight cards assembled in a Zilog unwired 9-slot card cage. Each card contains a 122-pin edge which plugs in the backplane. All pertinent interface signals are available on the backplane. The backplane is wired as three independent systems—the root node and the two P<sup>2</sup>Ls. For example, there are three independent address busses, each interconnecting the cards of the respective systems. All loose couplings between systems are likewise implemented through backplane wiring. External

Figure 5—Prototype P<sup>2</sup>FEP card arrangement.

interfaces (three RS-232-C interfaces and the disc controller interface) are accomplished by wiring from the individual card pins to interface areas along the periphery of the cage. Ribbon cables with 100 mil spacing pin connectors at one end and standard RS-232-C connectors on the other effect the interface. Figure 5 depicts the cards of the prototype system in the card cage.

## PROPOSED PRODUCTION SYSTEM

At the time of this writing the production system configuration is not yet frozen. Factors such as the recent announcement of new card configurations with improved component mixes and the anticipated availability of Z8000 components and cards in the near future account for this indecision. We shall describe here the general design philosophy, using the subsystems of the prototype configuration as building blocks.

The production system will be structured around 18-slot unwired rack mountable card cages. Since rack mounted modems are also available, one can anticipate a system in which the front-end processor card cages and modems are mounted in the same rack as in Figure 6. This configuration minimizes the wiring between modems and personal processing links.

One 18-slot card cage can hold a link control (six cards) and six P<sup>2</sup>Ls. The P<sup>2</sup>Ls are configured as in the prototype system. The link control is augmented with another SIB card to handle the BDM interfaces and another IOB card to handle the *data* and NMI interfaces of the six P<sup>2</sup>Ls. The link control nodes, in turn, are connected to either the root node or intermediate nodes through 17-line parallel interface (full duplex *data* and NMI).

The root node (or intermediate link control node, depending upon total configuration size), is housed in a separate card cage within the cabinet. It must have sufficient IOB cards to support the 17-line parallel interfaces of its branches. If it is an intermediate link control, it must have an additional 16-line parallel interface to the next level link control. However, the root node requires interfaces to the local DASD and the host system channel adapters.

## COST ANALYSIS

To estimate typical system costs, let us assume a configuration supporting 96 low-speed asynchronous lines. Assume that rack mountable modems are packaged 16 modems

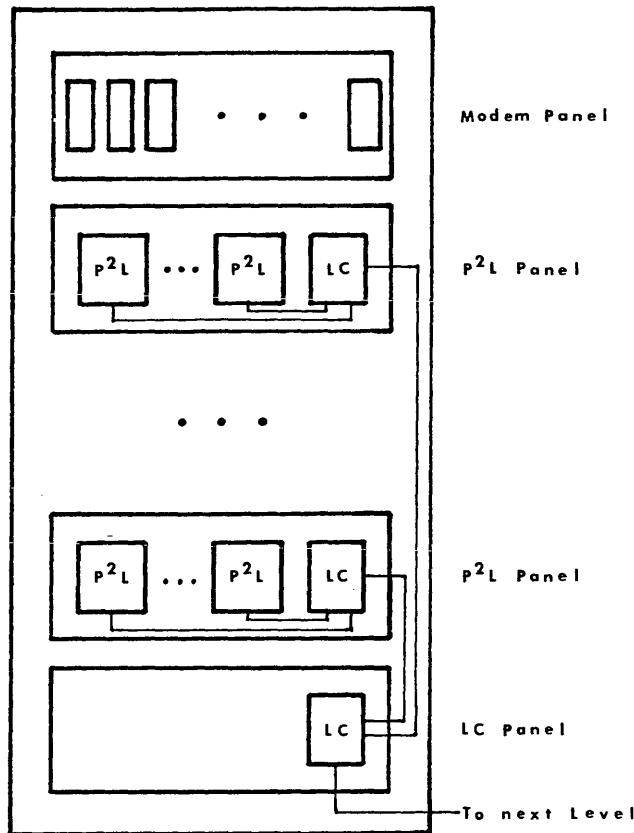

Figure 6—Typical production P<sup>2</sup>FEP cabinet.

per rack panel. It makes sense to package one modem panel, three personal processing link panels, and one link control panel per cabinet. (This leaves two personal processing links without modems—P<sup>2</sup>Ls without modems can be assigned to monitor an interactive line under program control when a user disconnects. This provides a very powerful extension of the VM/370-CP *disconnect hold* command<sup>12</sup> in which automatic responses can be generated under P<sup>2</sup>L control.) Ninety-six lines are housed in six cabinets. A seventh cabinet (or extra space in the original six) houses the root node, channel adapters and DASD storage and controllers.

The configuration just described is a tree containing four levels. The root (Level 1) is connected to each of the link control panels in the six cabinets (Level 2), which are connected to the link control systems in each personal processing link panel (Level 3), which are connected to the personal processors of the panel (Level 4).

The system contains 25 card cages, 133 MCB cards, 133 RMB cards, 44 IOB cards, and 36 SIB cards. The system cost is estimated to be approximately \$350,000.

Memory is the most expensive component of the given configuration—each of the 133 microprocessor systems has 64k bytes of memory, giving a system-wide total of over eight megabytes. Halving each system memory size to 32k bytes reduces the system cost to approximately \$225,000. Quartering each memory size to 16k bytes removes the need

for the RMB cards altogether and reduces system costs to approximately \$150,000. (For comparison, a 96 asynchronous line IBM 3705II lists at approximately \$150,000). A mix of memory sizes would have a system cost somewhere between the two extremes and would have unusual processing services available to its users.

## ADVANTAGES

The Personal Processing Front-end Processor offers several advantages over traditional front-end processors. These generally accrue from the compute power inherent in the multi-processor network, the network architecture, and the properties of the components. Each advantage is as follows:

### *Host system offloading*

One advantage offered by all front-end processors is offloading of the host system. Generally offloading is in the areas of code translation, record editing (e.g., backspace interpretation), recovery from transmission errors, and record formatting. Offloading with the P<sup>2</sup>FEP is expected to be significantly higher due to the additional services provided by the P<sup>2</sup>L including file editing, input/output record filtering, source program compilation for some languages, and execution or interpretation of programs.

It is quite clear that a significant load can be removed from the host facility when one considers the following facts:

1. The density function of the CPU requirements over all interactive user service requests shows a typical exponential decay curve.<sup>13</sup> This indicates that a significant amount of CPU time is expended to satisfy small requests for a large number of users.
2. The frequency of use of host system components such as the context editor and BASIC, which are strong potential candidates for offloading to the P<sup>2</sup>Ls, is quite high—indicating that a significant CPU load could be in fact offloaded.
3. A significant amount of CPU time is expended processing each input or output record between the host system and the interactive terminals—this CPU time vanishes when the user is conversing with a program resident in his P<sup>2</sup>L.

Offloading of whole interactive conversations has a greater beneficial effect than just the cumulative processor time required for the offloaded computations. Input/output record transfers between the host system and the front-end processor are eliminated which also eliminates the many trips through the host system interrupt handlers that would have been necessary otherwise. This causes the operating system overhead to be reduced. Since interrupts have a deleterious effect on hardware instruction lookahead algorithms, host system performance may increase with sophisticated host hardware possessing this feature.

Time-sharing systems incorporate short quanta times in

their CPU scheduling algorithms to reduce the average response times to requests requiring low CPU requirements. This biases system response time to favor requests requiring low CPU requirements. Since many such requests are processed in the P<sup>2</sup>L rather than the host system, it may be reasonable to increase the length of the quanta used in scheduling the host system. This further reduces the number of trips through the host system interrupt handlers.

#### *Cost reductions*

Programs offloaded onto a personal processor cost less to use than their counterparts on the host system. It is appropriate to charge users for *connect time* to the personal processor regardless of the work performed. These connect charges, since they need only recoup the front-end processor acquisition and operating costs, are relatively low.

#### *Uniform short response times*

Response time to user interactions with offloaded programs will not depend upon total system load and should be significantly less than response time with equivalent host-system programs under heavily loaded conditions. Again, the offloading of the processing of trivial requests from the host system ought to improve the responsiveness of the host system to those requests that are not filtered out by the P<sup>2</sup>Ls.

#### *Increased availability*

The P<sup>2</sup>FEP may be available even when the host system is unavailable. At these times users can still accomplish useful work provided it can all be done by the P<sup>2</sup>L. Examples include local file editing, local language program development and execution and the staging of host system jobs for automatic submission when the host system becomes available.

#### *Microprocessor program development*

As the usage of microprocessors increases, the user community will need to develop programs for eventual execution upon offline microprocessor systems (e.g., in laboratory apparatus). If the microprocessor hardware systems are compatible, it is possible for users to develop these programs utilizing services provided by the P<sup>2</sup>FEP and perhaps even unit tests program modules in the P<sup>2</sup>Ls.

#### *General communication protocols*

The LSI devices which microprocessor manufacturers market for driving data communication equipment are very general. These drivers generally adapt to synchronous and asynchronous protocols; switched lines, leased lines, or di-

rect attachment of equipment; a variety of character or message formatting conventions; and any practical rate of transmission under program control. It is possible with these devices to dynamically determine the proper communication parameters at the time the user initiates his session with the system. Many commercially available front end processors do not possess this flexibility.

#### *Input/Output filtering*

It is possible for the user to interject a program in his P<sup>2</sup>L between the host system and his terminal. This program can then function as a data filter. A general macro-processor is an example of such a program. This is reminiscent of the chained processes concept in UNIX.<sup>14</sup>

#### *Job staging*

The local DASD and editor can be used to prepare jobs or portions of jobs for submission to the host system. This can be done whether or not the host system is available at that moment. With this feature the P<sup>2</sup>FEP can act as a programmers' workbench.<sup>15</sup>

#### *Maintainability*

The P<sup>2</sup>FEP is easy to maintain on a card replacement basis. It is reasonable to stock replacement cards on-site because of its construction from a few card types, each occurring in large quantities.

Hard faults are relatively easy to isolate because of the inherent tree structure. By sending echo requests and timing responses, the root node can isolate a fault to a single node. In a similar manner a P<sup>2</sup>L can isolate a fault on its path to the root to a single node. Once a fault is isolated to a single node, a complete card swap of that node can be performed to put the P<sup>2</sup>FEP back in operating condition. The faulty cards can be tested later in a standalone configuration.

## CONCERNS

There are three concerns due to the tree-structured architecture of the system. One is that the aggregate data rate increases as one moves toward the root node. The second is that the fraction of the system affected by an error increases as one moves toward the root node. The third is that the amount of work that must be performed by the root node might saturate it.

The potential increase in aggregate data rate poses no problem. Offloading, since it eliminates the movement of data between the P<sup>2</sup>L and the host system, reduces the aggregate data rate. Furthermore, the maximum aggregate data rate of contemporary front-end processors such as the IBM 3705 (500,000 bytes/sec) and the Memorex 1380 (100,000 bytes/sec) is within the capabilities of microprocessor systems.

A failure in a P<sup>2</sup>L affects only the single user serviced by the failing P<sup>2</sup>L. A failure in a LC affects all nodes in the subtree beneath the failing LC. The fraction of the system affected by a failure increases the closer the failure is to the root node. The only effect of a LC failure is to sever communications between the nodes in the subtree beneath it and the root node. Message timeouts can be used to detect a failure in a node along the path to the root. The previous section outlined the maintenance strategy for the P<sup>2</sup>FEP, which is to isolate the failure to a single node quickly, then repair immediately with a complete card replacement of the node. We anticipate that this policy will yield acceptable reliability. If this should prove not to be the case, it is readily possible to provide redundancy distributed throughout the tree structure to obtain the necessary "fail-soft" characteristics.

The root node is obligated to provide service for high levels of activity. Besides performing store and forward message processing between the host system and its branches, the root node maintains the local data base. It is possible that the level of activity might saturate a single Z80 in larger configurations. There are, fortunately, at least two alternatives. One is to use faster components such as the Z8000 in the root node. Another is to distribute the workload of the root node across more than one loosely-coupled microprocessor system. The division of effort might be along functional lines. For example, the root node might be structured as three systems, one communicating with the other nodes of the P<sup>2</sup>FEP, the second servicing the channel adapters connecting the P<sup>2</sup>FEP to the host system, the third maintaining the local database.

## ALTERNATIVES

An alternative to the P<sup>2</sup>FEP described here is a number of decentralized microprocessor systems, each with local DASD and terminals, and perhaps a communication link to the host system. Decentralized systems of this sort might be user-programmable or supported by the manufacturer for a special purpose, such as word-processing. Many vendors, including Sykes, Wang, and Vydec, for example, market such products. There are good justifications for a centralized FEP rather than a number of decentralized systems. These are as follows:

1. *Higher utilization.* The P<sup>2</sup>FEP naturally experiences a higher utilization because it is shared among all the host system users. Decentralized systems are generally associated with a single individual or group of individuals. The "macro cost" is lower for the P<sup>2</sup>FEP because a smaller number of units are required to satisfy peak demands. The cost to individual users is decreased because a simple connect-time charge replaces the significant cost of a personal system.
2. *Economy of scale.* The P<sup>2</sup>FEP with its large number of loosely-coupled microprocessors located in close proximity to one another leads to certain economies, such as rack-mounted systems, shared power supplies, and quantity discounts. These tend to make the single large system cost significantly less than the equivalent number of smaller systems.
3. *Sharing of peripherals.* The close proximity of the individual P<sup>2</sup>L systems allows peripherals such as DASD to be shared among all the P<sup>2</sup>L systems. This again results in a more economical system. It also may lead to the use of larger, more reliable devices than those normally used with microprocessor systems.
4. *Centralized software responsibility.* Just as their larger cousins, microprocessor systems require expensive nurturing by a competent systems programming staff. Centralized hardware also makes it possible to centralize the software responsibility effectively. In contrast, a decentralized set of (possibly incompatible) microprocessor systems will lead to competition for the available systems programming expertise to the detriment of all.
5. *Franchise.* The P<sup>2</sup>FEP is available to all host system users, even though budgetary limitations might prevent them from securing their own microprocessor systems. (It is a fact of life that decentralized systems are often budgeted by the local unit.)

## CONCLUSIONS

The tree-structured distributed network front-end processor architecture appears to offer several intriguing advantages and few significant disadvantages. It may provide a most reasonable method for realizing the advantage of distributed logic or intelligence to a large number of users without incurring the significant disadvantages of distributed maintenance and software development costs. The prototype module is nearing the system test phase and the results of these tests should prove to be most interesting. If successful, it may be possible to provide very low cost, transparent access to a hierarchy of increasingly powerful computing resources for a very large number of users in a novel and highly reliable way. The results of these tests will be reported later.

# Analysis of real-time control systems by the model of packet nets

by MOHAMED GAWDAT GOUDA

*Honeywell Corporate Technology Center  
Minneapolis, Minnesota*

## INTRODUCTION

During the planning stages of a real-time control system, the planning team is more concerned about the global aspects of the system rather than the details of its different components. The first questions that have to be resolved are, What are the basic processes (or modules, or tasks) in the system? What are the data flow rates between these processes? and What are the memory and processing rate requirements of each process? Also of prime concern is how to select a suitable computer architecture to host the system and how to decompose the system on a selected distributed architecture.

In order to be able to address these questions in a systematic and formal way, we introduce a model, called Packet Nets, for real-time control systems. The model is based on the concepts of data flow;<sup>4,12,11,3</sup> but unlike other data flow models, this model focusses on the global system characteristics and hides the details which are not needed during system planning. The model is intended as a tool to represent real-time control systems in an implementation-independent fashion. Moreover, it can be used in estimating the values of some basic system parameters such as data flow rates between system components and the processing rate requirement of each system component.

The model of packet nets is introduced in the next section following the introduction. In the third section, we present a systematic method to compute data flow rates between the different processes in a packet net. Then in the fourth section, a technique to estimate the processing rate requirement of each process in the net is outlined. In the fifth section, the memory requirements of packet nets are discussed. In the final section, we discuss some issues concerning the decomposition of packet nets on distributed computer architectures.

## PACKET NETS

A process in a real-time control system performs three basic operations in a cyclic fashion—receiving (or input operation), execution and sending (or output operation). The process first receives a ‘‘packet’’ of data from another proc-

ess in the system or from the external world (e.g., sensor data coming from a sensor). Then the process executes some internal functions on the received data and finally it sends the results as a data packet to the next process in the system or to the external world; then the cycle repeats. The process is halted temporarily if its input queue is empty during a receiving operation, or if its output queue is full during a sending operation.

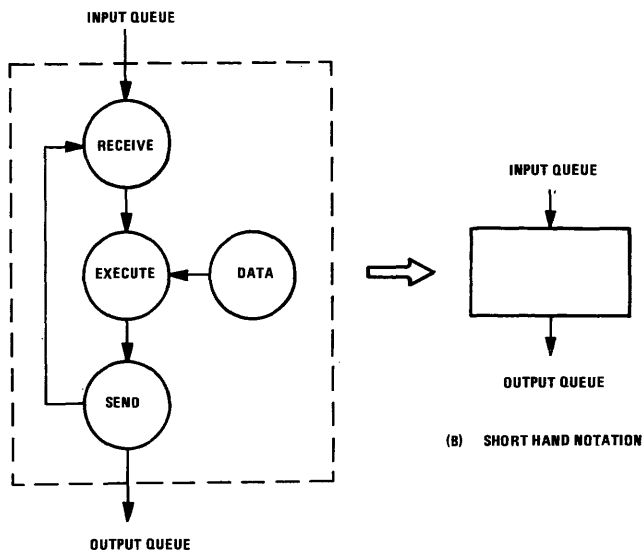

Graphically, a process can be presented as a directed cycle (Figure 1a) with three types of nodes—a receiving node, an execution node and a sending node. Attached to the receiving node is an input queue via which the incoming data packets are received. Similarly, an output queue is attached to the sending node to send the result packets to the next process. The internal memory of the process is represented as a data node attached to the execution node. Using a short-hand notation, a process can be also represented as a single node (Figure 1b) with input and output queues.

The model in Figure 1 is restrictive as each process can receive data packets from only one process and can send data packets to only one process. To remove these restrictions, we extend the model such that a process can have more than one input and one output queue. As shown in Figure 2, the different input queues of a process are controlled by an OR-receiving operation or by an AND-receiving operation. Similarly, the different output queues are controlled by an OR-sending or an AND-sending operation. These four sending/receiving operations are defined (informally) as follows.

To execute the OR-receiving operation, the process waits until one of its input queues has at least one packet. Then, the process removes one packet from this input queue and proceeds to process it. To execute the AND-receiving operation, the process waits until there is at least one packet in each input queue. Then, the process removes one packet from each input queue and proceeds to process them.

To execute the OR-sending operation, exactly one of the associated output queues is selected (arbitrarily) to put the sent data packet in it. To execute the AND-sending operation, one data packet is put in each output queue. The sent packets are not necessarily identical.

A process with an OR-receiving operation and an AND-

(A) DETAILED DEFINITION

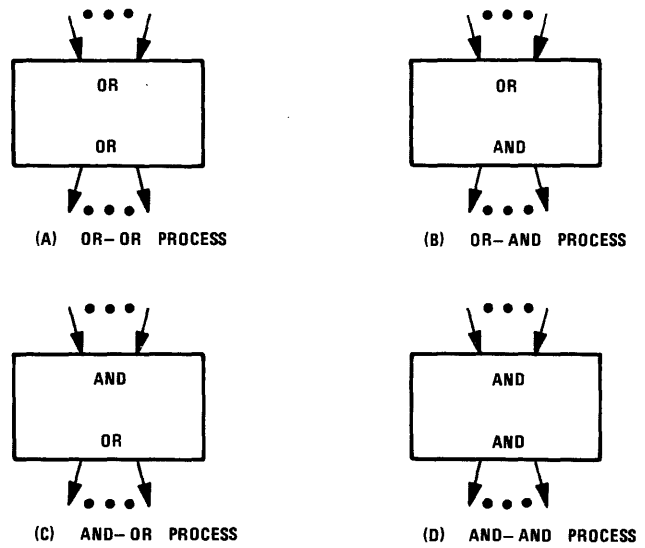

Figure 3—Different classes of processes in a packet net.

sending operation is called OR-AND process. Similarly, OR-OR, AND-AND and AND-OR processes can be defined. A short-hand notation for the different processes classes of processes in a packet net is shown in Figure 3. Observe that if a process has a single input queue, then an OR-receiving operation becomes equivalent to an AND-receiving operation. Therefore, we use the convention that if a process has a single input (or a single output) queue, then it has an OR-receiving (or OR-sending respectively) operation.

To give an example of a real-time control system and its packet net, consider a radar scheduling system.<sup>6</sup> The system receives requests to use the radar. It orders these requests based on some priority scheme, then delivers the ordered sequence (called frame) of requests to the radar to serve them in order. But since the radar cannot accept any frame unless it satisfies some constraints, the system has also to examine the generated frame against all the constraints (imposed by the radar) before delivering the frame to the radar.

Figure 4a shows the outline of a radar scheduling system. Arriving requests are of three different classes. Each request has its own local priority such that requests of the same class are ordered according to their local priorities. The partially sorted requests are sent to the framing process to be ordered in a time frame based on some global priority. The frame is then sent via a frame modification process to a number of checking processes. Each checking process examines (in parallel with other checking processes) whether or not the frame meets some radar constraint. The individual decisions for the frame are then sent to a final decision process to decide whether the frame is accepted or rejected. Accepted frames are sent to the radar, while rejected frames are sent back to the frame modification process to be corrected before being examined once more. The packet net for this system is shown in Figure 4b.

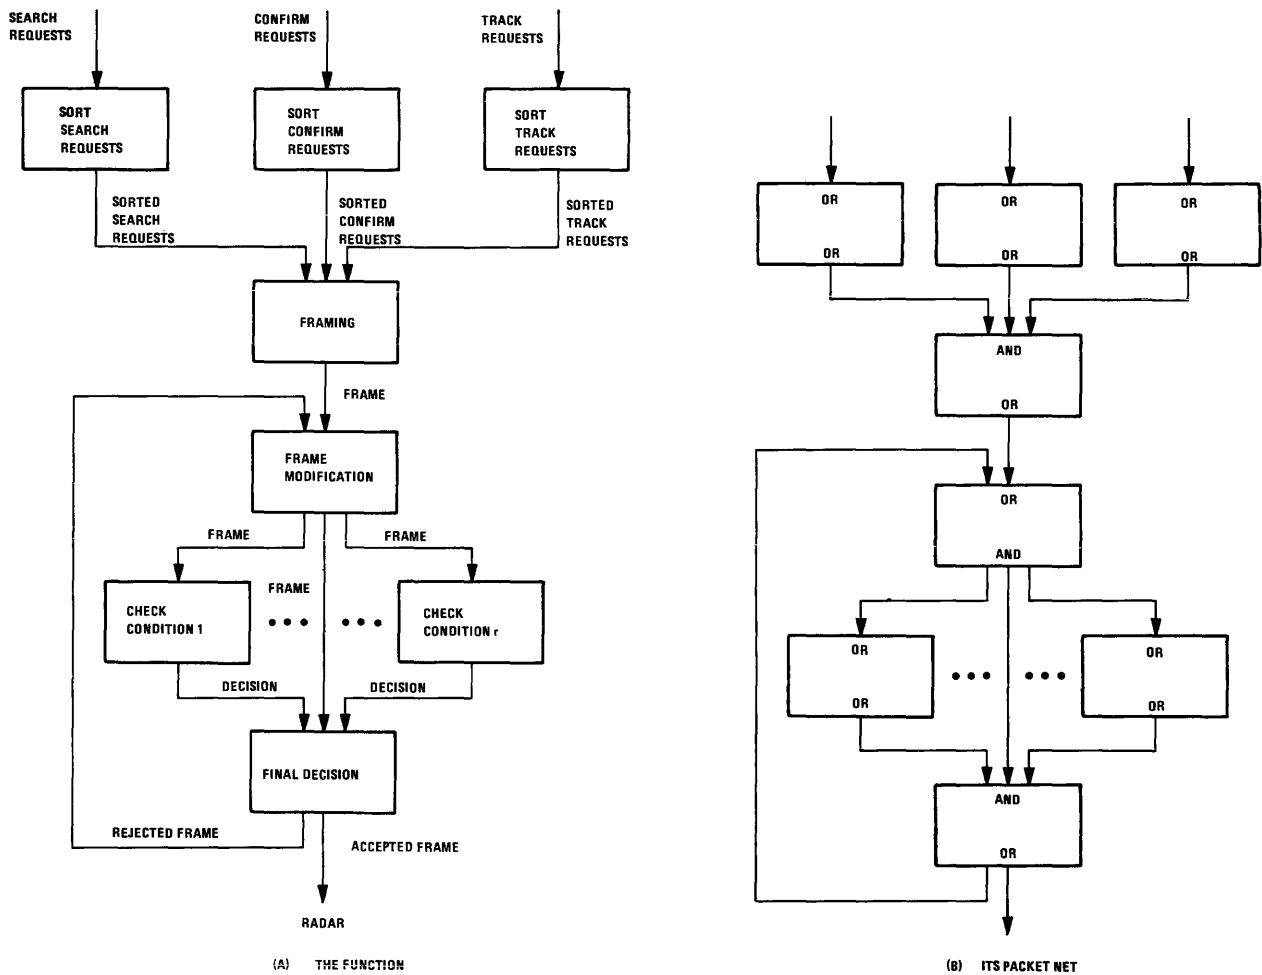

Figure 4—A radar scheduling system.

PACKET FLOW RATES

Part of the analysis of a real-time system is to compute the rates with which the data flow between the different system components. In the packet net model, this corresponds to compute the packet flow rate in each queue in the net. To make this computation, the flow rate (in packets/sec.) in each external input queue should be estimated from the application (e.g., the rate with which the sensor data arrive to the system). If an input flow rate changes with time, an upper bound for its value should be estimated. Also, the probabilities with which each OR-sending operation distributes the output packets among its output queues should be estimated from the application.

As an example, consider the packet net in Figure 5. The external input flow rate to the net is estimated to be 10 packets/second. The output queues of OR-OR Process 1 are labelled with the probabilities .2, .1 and .7, while the output queues of OR-OR Process 2 are labelled with the probabilities .5 and .5. The variables *t*, *u*, . . . , and *z* are associated

with the different queues in the net; each variable is defined to be the packet flow rate in its associated queue. The problem, now, is to evaluate these variables. Next, we present the equations to evaluate the packet flow rates in any well formed packet net.

Consider the OR-OR process shown in Figure 6a. The input packet flow rate to that process equals  $\sum_{j=1}^m x_j$ . This flow is distributed among the *n* output queues according to their associated probabilities. Thus, the packet flow rate *y<sub>i</sub>* in the *i*th output queue is evaluated as follows:

$$y_i = p_i \sum_{j=1}^m x_j \quad i = 1, \dots, n$$

Similarly, the packet flow rate *y<sub>i</sub>* in the *i*th output queue of an OR-AND process (Figure 6b) is evaluated as follows:

$$y_i = \sum_{j=1}^m x_j \quad i = 1, \dots, n$$

Consider the AND-OR process shown in Figure 6c. Be-

Figure 5—A packet net.

cause of the AND-receiving operation in this process, the flow rates in all input queues should be equal. Assume that the flow rate in any input queue equals  $x$ . This flow is distributed among the  $n$  output queues according to their associated probabilities. Thus, the packet flow rate  $y_i$  in the

$i$ th output queue is evaluated as follows:

$$y_i = p_i x \quad i=1, \dots, n$$

Similarly, the packet flow rate  $y_i$  in the  $i$ th output queue of an AND-AND process (Figure 6d) is evaluated as follows:

$$y_i = x \quad i=1, \dots, n$$

For any packet net, we can write the flow equations using the general forms just discussed. By solving these equations simultaneously, the packet flow rates in each queue in the net can be determined. For example, the flow rate equations for the net in Figure 5 can be written as follows:

$$\begin{aligned} t &= .5 u \\ u &= .2 (t+10) \\ v &= .1 (t+10) \\ w &= .7 (t+10) \\ x &= .5 u \\ y &= w \\ z &= x=v \end{aligned}$$

Thus, the flow rates can be determined:  $t=v=x=z=1.11$ ,  $u=2.22$ ,  $w=y=7.78$ . All dimensions are in packets/second. If the packet sizes (in bits/packet) for each queue can be estimated, then the flow rates can be computed in bits/seconds.

For many packet nets, the flow equations are inconsistent; thus produce no solution. For example, if the output probabilities of Process 2 in the packet net in Figure 5 are

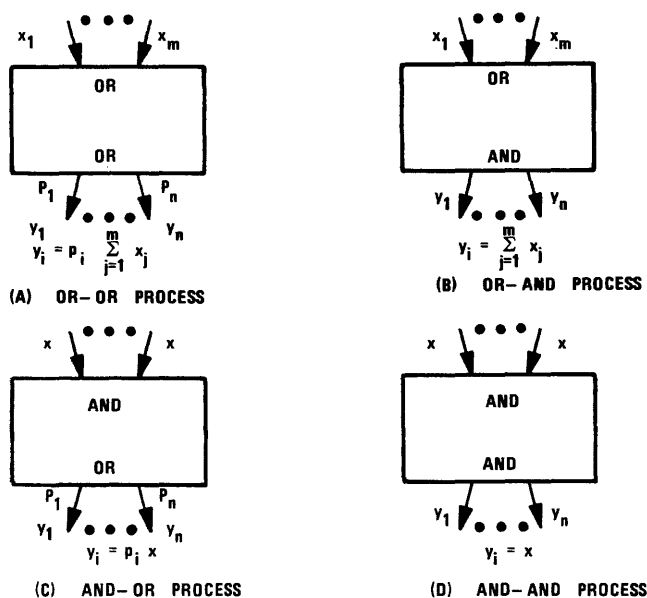

Figure 6—Data flow rates in the output queues of a process.

changed from .5 and .5 to .4 and .6, we get the following flow equations:

$$\begin{aligned}
 t &= .4 u \\
 u &= .2 (t+10) \\
 v &= .1 (t+10) \\
 w &= .7 (t+10) \\
 x &= .6 u = .12 (t+10) \\
 y &= w \\
 z &= x
 \end{aligned}$$

From the third and fifth equations, we have

$$v \neq x$$

This contradicts the requirement that  $v$  and  $x$  should be equal since they are AND inputs to Process 4 in the net.

A packet net is said to be well formed only if its flow equations are consistent and produce a single solution to the flow rates in the net. Obviously, the packet net in Figure 5 is well formed; but if we change the output probabilities of Process 2, the resulting net is not well formed.

The consistency of flow equations for a packet net depends on the net structure, and the estimated output probabilities for the processes in the net. Therefore, inconsistent flow equations imply that either the net "structure" is intrinsically inconsistent, or that our estimation of the output probabilities is inconsistent. In the previously-mentioned example, we illustrated how an inconsistent estimation of the output probabilities can lead to an inconsistent set of flow equations. Next, we give some examples of intrinsically inconsistent packet nets.

Figure 7a shows a part of a packet which consists of a cycle with  $n$  OR-AND processes. The  $n$  flow equations for such cycle are as follows:

$$\begin{aligned}
 x_1 &= x_n + I \\
 x_2 &= x_1 \\
 &\vdots \\
 x_n &= x_{n-1}
 \end{aligned}$$

From these equations, we get  $x_n = x_n + I$  (which can be true iff  $I=0$ ). Thus, in Case  $I \neq 0$ , this cycle is intrinsically inconsistent.

As another example, consider a cycle of  $n$  AND-OR processes (Figure 7b). The flow equations for this cycle are as follows:

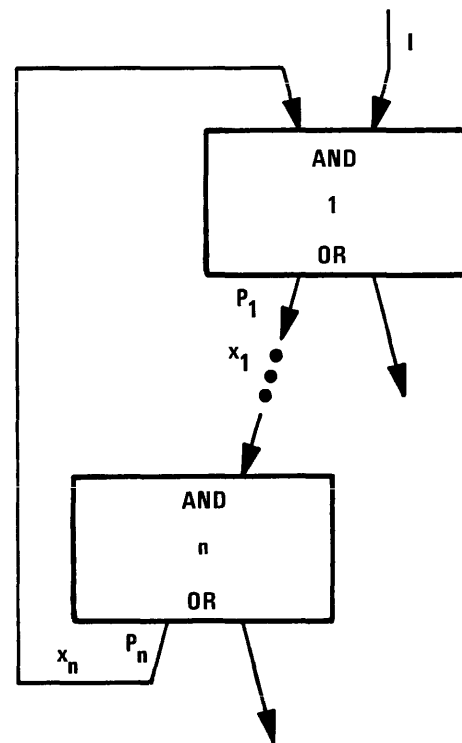

$$\begin{aligned}
 x_n &= I \\
 x_1 &= p_1 x_n \\
 x_2 &= p_2 p_1 x_n \\
 &\vdots \\
 x_n &= p_n p_{n-1} \dots p_2 p_1 x_n
 \end{aligned}$$

which can be satisfied iff  $p_1 = p_2 = \dots = p_n = 1$ ; i.e., each process should have exactly one output queue. If any process has more than one output queue, then the cycle is intrinsically inconsistent.

From these examples it is clear that a packet net should not contain a cycle whose nodes are all OR-AND processes,

(A) A CYCLE OF  $n$  OR-AND PROCESSES

(B) A CYCLE OF  $n$  AND-OR PROCESSES

Figure 7—Examples of packet subnets.

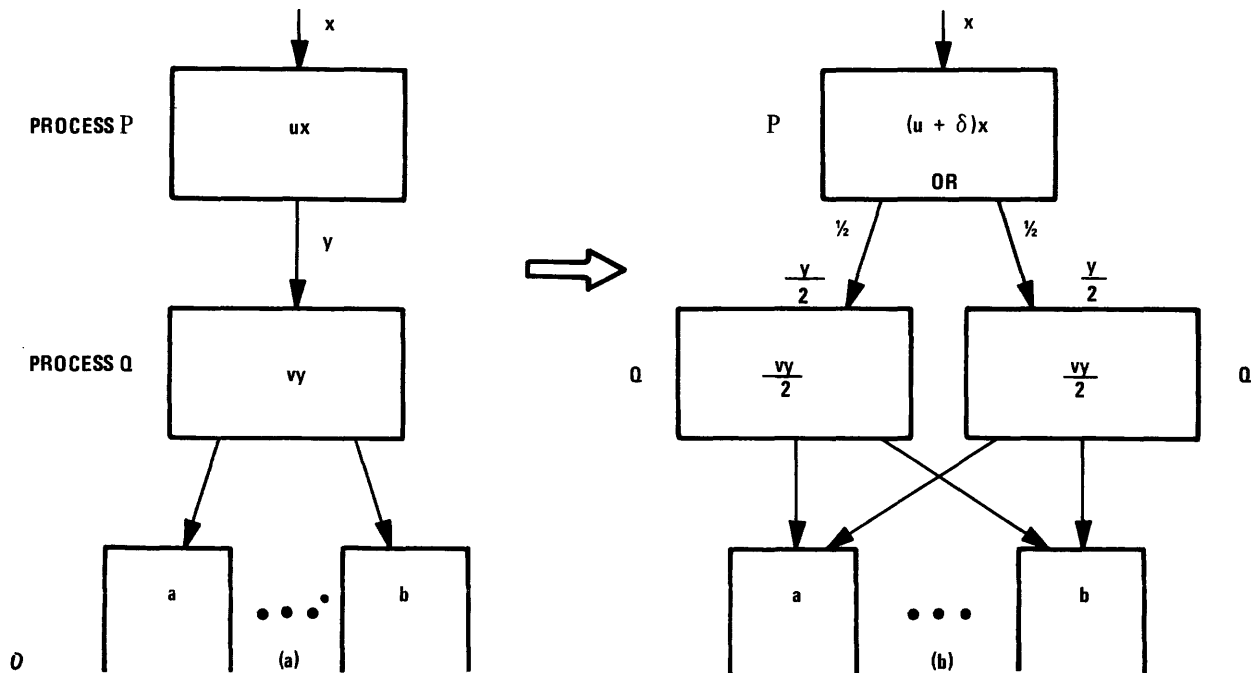

Figure 8—An example of adding extra copies of a process.

or whose nodes are all AND-OR processes. It is also clear that flow equations are useful in designing well formed packet nets.

### EXECUTION RATES

Another part of the analysis of a real-time system is to compute the execution rates (in inst./sec.) for all the processes in the system. In order to make this computation, the number of instructions in the main cycle of each process (see Figures 1a and 2) in the net should be estimated.

Assume that the input packet flow rate to a process  $P$  is  $\sum_{i=1}^m x_i$  packets/second. Therefore, the cycle of  $P$  should be executed  $\sum_{i=1}^m x_i$  times per second. If the cycle of process  $P$  has  $r$  instructions, then the required execution rate of  $P$  is  $r \sum_{i=1}^m x_i$  inst./sec. Observe that the above computation does not depend on the process type (e.g. OR-OR, OR-AND, . . .).

The required execution rate of a process can be reduced by adding extra copies of the same process to the packet net. For instance, Figure 8a shows an arrangement of two processes  $P$  and  $Q$  connected by a queue (from  $P$  to  $Q$ ). Assume that the input packet flow rates to  $P$  and  $Q$  are  $x$  and  $y$  respectively. Thus, the required execution rates for  $P$  and  $Q$  are  $ux$  and  $vy$ , where  $u$  and  $v$  are the number of instructions in the main cycles of  $P$  and  $Q$  respectively. Assume that an extra copy  $Q'$  of process  $Q$  is added to this arrangement, as shown in Figure 8b. This requires that process  $P$  becomes responsible for equally distributing its output packets to both  $Q$  and  $Q'$ . In other words,  $P$  becomes an OR-OR process with output probabilities of .5 and .5. The

input packet flow rate to  $Q$  (or to  $Q'$ ) becomes  $y/2$ ; and the execution rate of  $Q$  (or  $Q'$ ) becomes  $vy/2$  half the original amount. On the other hand, process  $P$  has more responsibilities; and the number of instructions in its cycle increases with the amount of  $\delta$ . Hence, its execution rate will increase to become  $(u + \delta)x$  inst./sec.

In the previous example, the distribution of data packets between the process copies is handled by an already existing process in the net. In some cases, however, a new process is added to the net to perform this distribution function. We call such a process a distributor. Figure 9 shows how  $(k-1)$  additional copies of one process and a distributor are added to a packet net to reduce the process execution rate by a factor of  $1/k$ . Observe that the distributor execution rate  $\delta y$  is "small" since there is a "small" number of instructions (namely  $\delta$ ) in its cycle.

Another advantage of adding extra copies of the same process to a packet net is to increase the overall system reliability and availability. At any rate, whether the extra process copies are added to decrease the execution rate requirements or to increase the system reliability, the implied assumption is that no two (or more) copies of the same process should be assigned to the same processor in the host hardware. The problem of assigning processes to processors is discussed in more detail later on in the sixth section; but first we need to discuss the memory requirements of packet nets.

### MEMORY REQUIREMENTS

Memory is required for a packet net to store its processes and its queues. The required memory to host one process

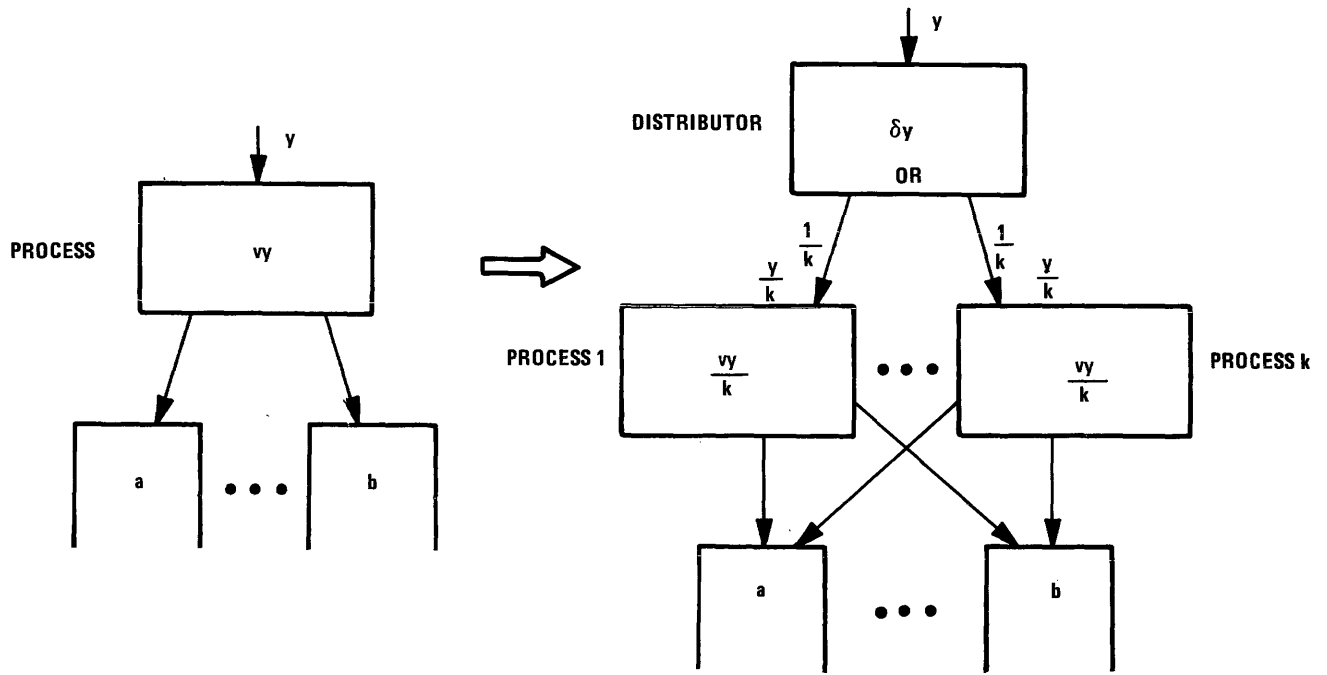

Figure 9—Adding an extra  $(k-1)$  copies of a process to decrease its execution rate by a factor of  $1/k$ .

in the net depends on the control and data structure of that process; i.e., it depends on the size of its program and its data file(s), if any. An upper bound for the required memory of each process should be estimated from the application so that the total memory requirements can be calculated.

The required memory to host the queues of a packet net depends primarily on how this memory is organized and how it is managed. We next describe one scheme for the organization and management of such a memory. Other attractive schemes are not discussed in this paper because of the space limitation. For convenience, we define an OR process to be either an OR-OR process or an OR-AND process, i.e., it is a process with an OR-receiving operation. Also, we define an AND process to be either an AND-OR process or an AND-AND process.

Consider an OR process  $P$  with  $m$  inputs (Figure 10a). To allow both  $P$  and its input processes to proceed concurrently, the input queues of  $P$  should be implemented as one packet pool which can hold up to  $m+1$  packets (Figure 10a). When one input process (say,  $Q$ ) finishes the assembly of a new packet (say,  $p_1$ ) in the packet pool, and  $P$  finishes the processing of an old packet (say,  $p_2$ ) from the packet pool, then  $P$  initiates a packet interchange with  $Q$ . Thus,  $Q$  starts to assemble a new packet in place of  $p_2$ , while  $P$  starts to process the packet  $p_1$ .

Similarly, if  $P$  is an AND process with  $m$  inputs, then the packet pool between  $P$  and its input processes should hold up to  $2m$  packets (Figure 10b). When each input process finishes the assembly of a new packet, and  $P$  finishes the processing of the  $m$  old packets, then  $P$  initiates a packet interchange which causes  $P$  to get the  $m$  new packets and assigns each input process a space for one packet.

In this static memory allocation scheme, the storage capacity of any cycle in the packet net is fixed. Thus, it is possible that packets may continue to flow into some cycle in the net until the cycle is completely full. At this instant, the cycle processing stops and a deadlock situation arises. The remainder of this section examines such deadlocks in more detail. In particular, we introduce some sufficient conditions for deadlock avoidance.

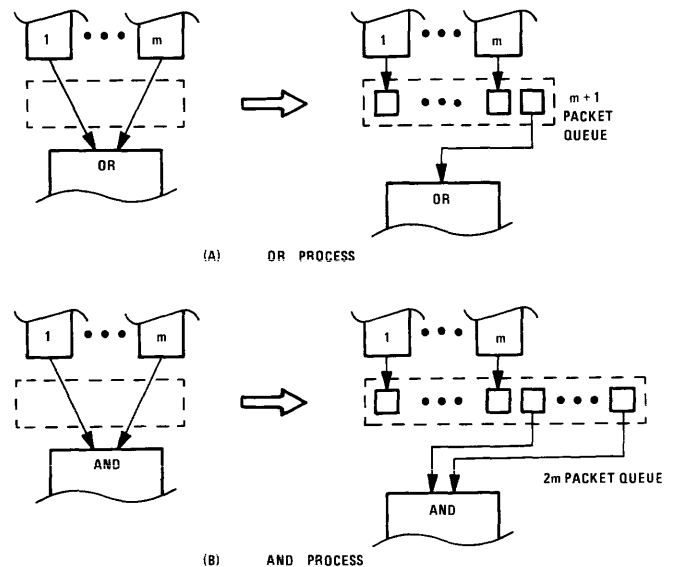

Figure 10—Queue requirements in packet nets.

Deadlocks arise in a packet net whenever one or more cycles in the net become full of packets. But, because AND processes can never increase the number of packets in any cycle (as illustrated in Figure 11), they can never contribute to deadlock situations. Therefore, we need only to consider OR processes in a packet net, the OR processes can fill the cycle with packets causing a deadlock. In order to avoid such a deadlock, we need sufficient conditions to prevent the OR process from filling their cycles with packets. Next we present such a set of conditions; but first we need to define "cycle queues." A cycle queue is a queue which exists in one or more cycles in the packet net.

The following three conditions on the structure and operation of OR processes are sufficient to avoid deadlocks in packet nets:

- cond1*—Each OR process has at most one input cycle queue (Figure 12a). A packet which arrives to the OR-process via the input cycle queue is called a cycle packet; otherwise it is a non-cycle packet.
- cond2*—If there are one cycle packet  $p_1$  and one space  $p_2$  for a new packet in the packet pool of an OR process  $P$ , then  $P$  initiates a packet interchange such that  $p_2$  is assigned to the input cycle queue to assemble a new cycle packet, and  $p_1$  is assigned to  $P$  to be processed. However, the processing of

$p_1$  will not start until there is one packet space in each output queue of  $P$ .

- cond3*—If there are one non-cycle packet  $p_1$  and one space  $p_2$  for a new packet in the packet pool of an OR-process  $P$ , and if there is one packet space in each output of  $P$ , then  $P$  initiates a packet interchange such that  $p_2$  is assigned to the input non-cycle queue (via which  $p_1$  has arrived), and  $p_1$  is assigned to  $P$  for processing. The processing of  $p_1$  can start immediately after the packet interchange.

Observe that both *cond2* and *cond3* do not restrict the structure of packet nets in any way; they merely enforce some order on the packet processing by the OR processes. On the other hand, although *cond1* does restrict the structure of packet nets, we feel that the restriction is not severe; the packet net in Figure 4b satisfies *cond1*.

The processing of cycle packets can never increase the number of packets in any cycle in the net; thus, it can never lead to a deadlock. For this reason, *cond2* implies that the processing of cycle packets should proceed whenever possible (Figure 12b).

The processing of one non-cycle packet by an OR process can generate at most one extra packet in every cycle which contains the OR process. Therefore, the third condition *cond3* implies that the processing of one non-cycle packet

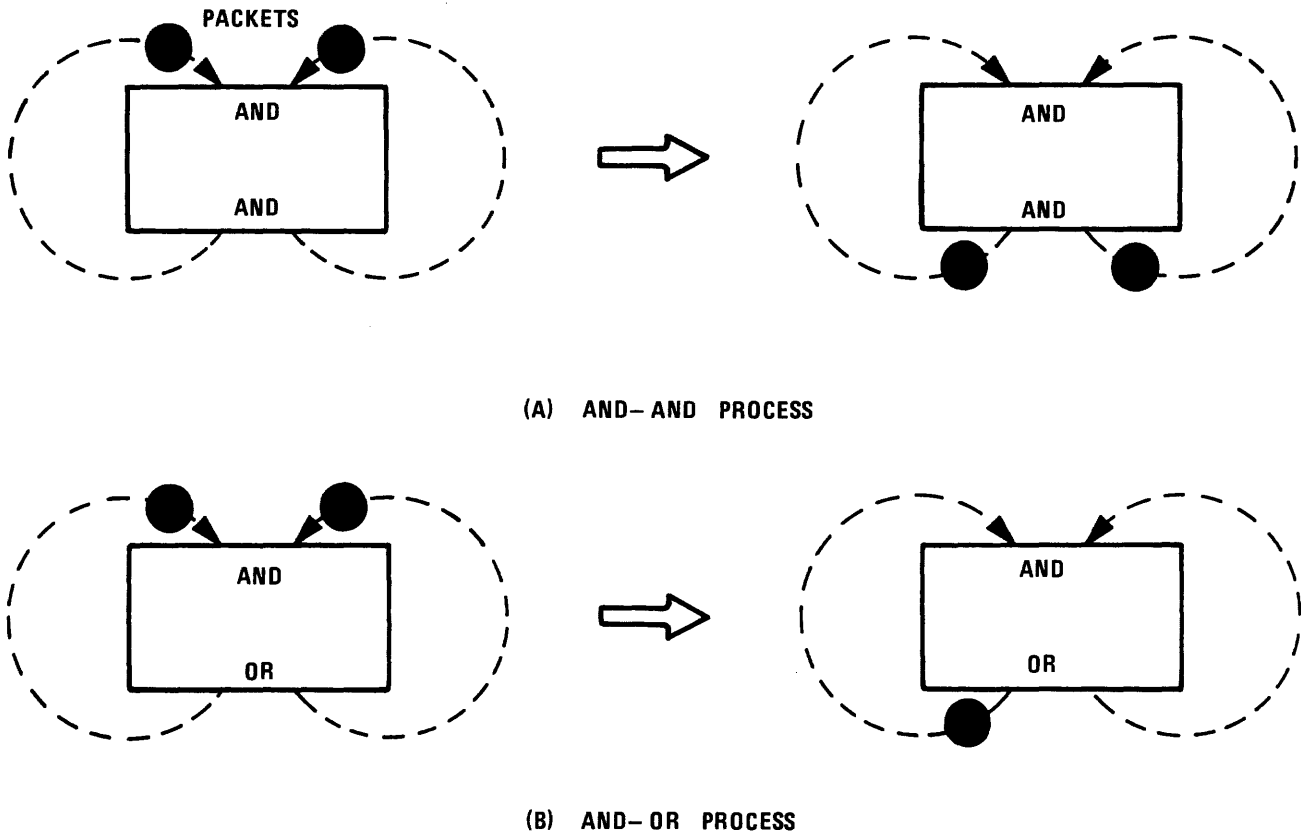

Figure 11—AND-processes do not increase the number of packets in cycles.

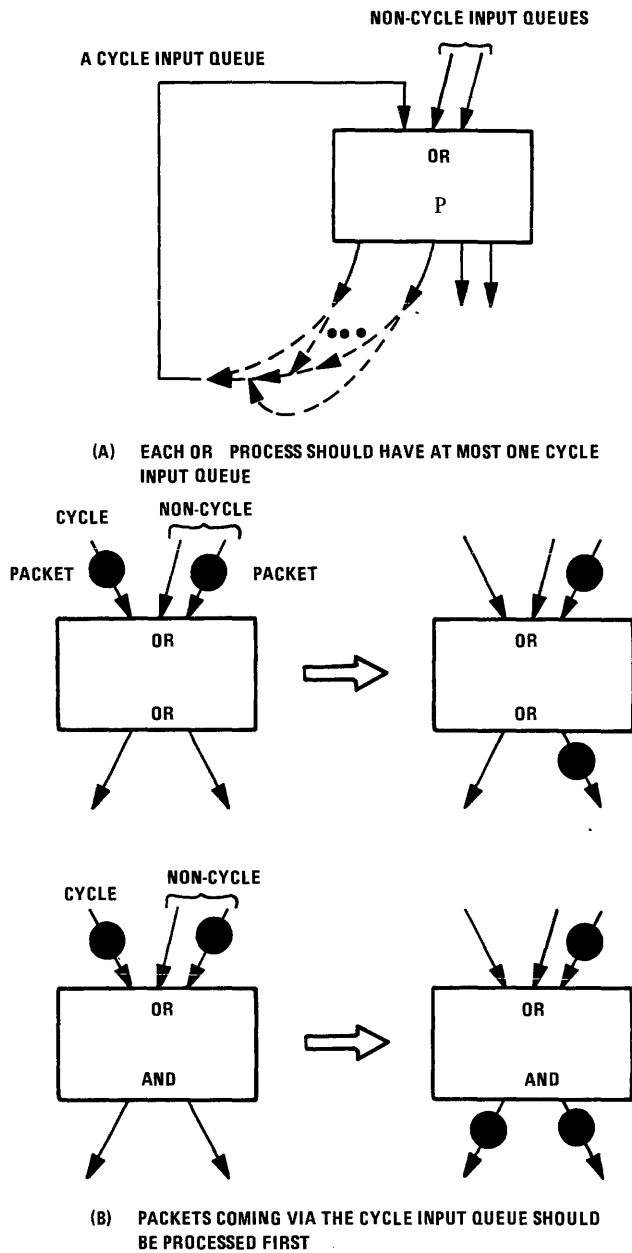

Figure 12—Avoiding deadlocks in packet nets with OR-processes.

shouldn't start unless the OR process "sees" two available packet spaces in each cycle which contains the OR process. This is the case when the OR process has one packet space in its input pool, and has one packet space in any of its output pools. Under this condition, the processing of non-cycle packets can never make any cycle full of packets.

Because of the space limitation, the discussion in this section has been limited to static memory allocation where each queue has been assigned a fixed memory size. We acknowledge, however, that static memory allocation can be unaffordable in some applications. The solution for these applications lies in dynamic memory allocation where

queues can grow and shrink in size as their needs change with time.

DISTRIBUTED COMPUTER SYSTEMS FOR REAL-TIME CONTROL

In this section, we investigate some of the problems associated with designing distributed computer systems for real-time control. Our bias toward distributed computer systems stems from our conviction that these systems provide high degrees of extensibility, integrity and performance<sup>10</sup> which are most needed in real-time environments.

In the previous sections, we have discussed how to calculate the following quantities:

1. The data flow rates (in packets/second, or equivalently in bits/second) between the net processes.
2. The execution rate (in instructions/second) of each process in the packet net.
3. The memory requirements (in words) of each process in the net.

These quantities are needed for the design of a distributed computer system to host a packet net (i.e., a real-time application). For that reason, these quantities are recorded on a graph, called the system graph of the packet net. The nodes in the system graph correspond to bi-directional communication between processes in the packet net. As an example, Figure 13b shows the system graph for the packet net in Figure 13a.

Each node  $i$  in the system graph is labelled with two quantities  $(e_i, m_i)$ , where  $e_i$  (in instruction/second) is the execution rate of the corresponding process, while  $m_i$  (in words) is the memory requirement for the corresponding

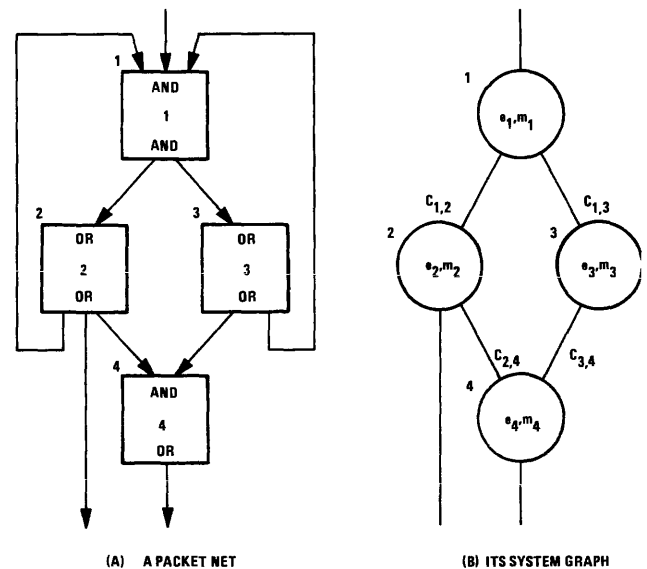

Figure 13—The relationship between a packet net and its system graph.

process and its input buffer. Each edge  $(i, j)$  in the system graph is labelled with a quantity  $c_{i,j}$  (in bits/second) which is the sum of the data flow rate from process  $i$  to process  $j$  and the data flow rate from process  $j$  to process  $i$ .

The system graph of a packet net contains all the needed information to design an "optimum" distributed computer system to host the packet net. In Reference 7 we outline a design methodology of distributed computer systems based on the model of system graphs. In this methodology, a system graph is used to generate a set of possible distributed architectures which can host the packet net. Then, from these generated architectures, an "optimum" architecture is chosen based on cost and reliability considerations. This approach still needs more research and more design automation support before it can be utilized in a practical way.

A more practical approach is to begin with a ready-made distributed computer system which can host the packet net. Then, find the "optimum" assignment of the packet net processes to the system processors.<sup>2,5,8,9</sup> This optimization problem can be expressed and solved in terms of system graphs as illustrated by the following example.

Consider the shared bus system shown in Figure 14. It consists of some processors; each of them has its own private memory and its own Bus Interface Unit (BIU). The processors communicate only by sending and receiving messages via the global bus which they control in a decentralized fashion. In this architecture, the global bus is the limiting resource.<sup>1</sup> Thus, on assigning processes to processors in this architecture, the object should be to minimize the bus traffic.

Assume that a shared bus system with  $r$  processors is to host a packet net. The optimum process assignment can be reached by finding at most  $r-1$  minimum cuts for the system graph of the packet net. These cuts should satisfy the following two conditions:

*cond1*—The cuts partition the nodes in the system graph into at most  $r$  partitions such that for each partition:

$$\sum_{\text{partition}} e_i \leq E$$

$$\sum_{\text{partition}} m_i \leq M$$

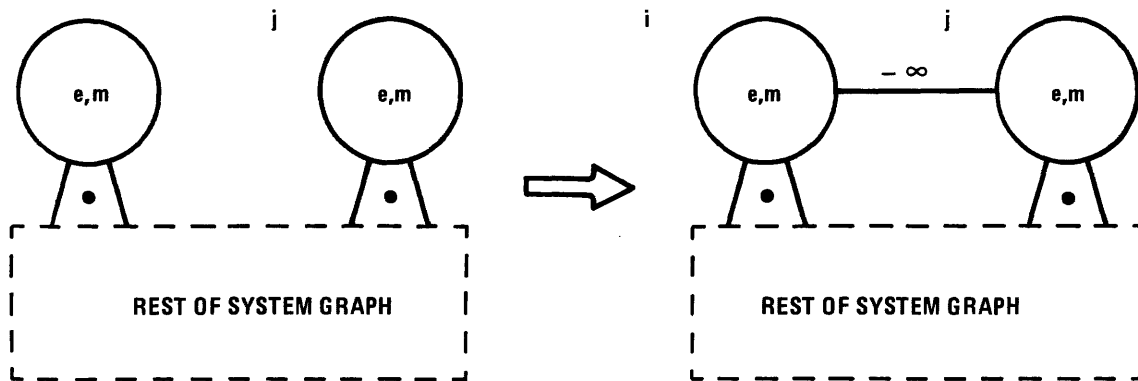

Figure 15—Assigning two copies  $i$  and  $j$  of same process to different processors.

Figure 14—A shared bus system.

where  $E$  is the processing rate which can be devoted to the application by one processor in the system, and  $M$  is the memory which can be devoted to the application by one processor in the system.

*cond2*—  $\sum c_{i,j}$  is minimum  
 $i$  in one partition,  
 $j$  in another partition

Finding these minimum cuts may require, in general, an exhaustive search among all possible cuts.

It has been mentioned in the fourth section that for reliability reasons, different copies of the same process should be assigned to different processors. To make sure that the minimum cuts technique will produce this assignment, we add an edge to the system graph between any two nodes which correspond to copies of the same process. These edges will be labelled with  $-\infty$ , as in Figure 15; thus, the minimum cuts must cut through all of them.

Sometimes it is required (e.g., for input/output considerations) to assign some processes to specific processors. To make sure that the minimum cuts technique will produce these assignments, the following additions should be made to the system graph:

- 1.—A node labelled  $(0,0)$  should be added for each processor which needs to host specific process(es).
- 2.—An edge labeled  $-\infty$  should be added between any two processor nodes.
- 3.—An edge labelled  $\infty$  should be added between a processor node and a process node iff it is required to assign the process to the processor.

An example is shown in Figure 16.

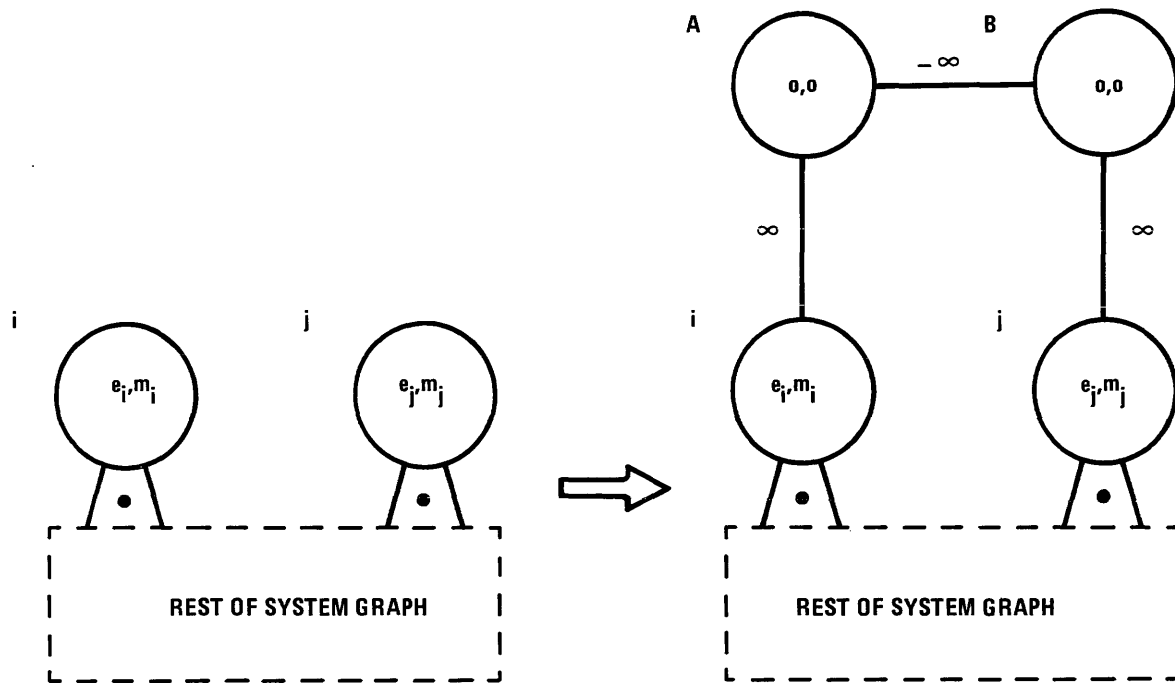

Figure 16—Assigning process  $i$  to processor  $A$ , and process  $j$  to processor  $B$ .

## CONCLUSIONS

A simple model to represent a wide class of real-time control systems is introduced. The model can be used in the early stages of system planning to represent the system in a gross form while hiding the fine details till later stages. The model can be also used to compute the values of different parameters which are critical to the planning of real-time systems. The required computations are simple and can be constructed and executed in a systematic way. The model is also useful in planning the computer system to host the application.

It is conceivable that for specific applications, more features (or restrictions) can be added to (or imposed on) the model to "tune" it to that particular application. In this presentation, however, we have only discussed those features that seem common to a wide class of applications.

## ACKNOWLEDGMENTS

# Performance and economy of a fault-tolerant multiprocessor\*

by JAYNARAYAN H. LALA and CHARLES J. SMITH

*The Charles Stark Draper Laboratory, Inc.*  
Cambridge, Massachusetts

## INTRODUCTION

The FTMP (Fault-Tolerant Multiprocessor) is one of two central aircraft fault-tolerant architectures now in the prototype phase under NASA Langley Research Center sponsorship.<sup>1,2</sup> The intended application of the computer includes such critical real-time tasks as "fly-by-wire" active control and completely automatic Category III landings (zero visibility and zero ceiling) of commercial aircraft. The life-critical nature of these tasks and the profit-oriented attitude of airlines translate into some very challenging and sometimes contradictory computer requirements. For example, a candidate computer should be able to execute tasks on time, without significant delays, be extremely reliable, and yet be cost-effective. At a first glance these requirements seem to be in conflict with each other. After all, to meet the performance criteria some sort of parallelism such as multiprocessing capability would be in order. Second, to meet the reliability and safety requirements it would be necessary to use redundancy since no simplex computer could possibly meet the "extremely improbable" failure criterion of the Federal Aviation Administration. The result is a computer that could be very expensive. Yet it may still be cost-effective. The reason is that it is the balance between the benefits and costs that determines the cost-effectiveness of a product; cost alone is not a pertinent criterion. In this paper we intend to show that the FTMP architecture is a viable solution to the multi-faceted problems of safety, speed, and cost.

The next section briefly describes the FTMP architecture. The third section is devoted to the performance analysis. Three job dispatch strategies are described, and their results with respect to job-starting delays are presented. The first strategy is a simple First-Come-First-Serve (FCFS) job dispatch executive. The results of FCFS were obtained by running a representative job-mix on a multiprocessor and through Markov modeling techniques. The other two schedulers are an adaptive FCFS and an interrupt driven scheduler. The results of these schedulers were obtained by a

GPSS simulation of a representative job-mix. The fourth section briefly discusses the impact of FTMP involvement on aircraft safety and its survival probability in the face of random hard failures. The fifth section outlines the benefits to airframe manufacturers and airlines of using a fault-tolerant computer, and estimates the life-cycle-cost to airlines of operating the FTMP. A comparison is also made on a flight-hour basis to the life-cycle-cost of operating a civil transport aircraft.

The emphasis in this paper is on results rather than means of getting those results. Simulation, analytical techniques, and empirical formulas are some of the methods and techniques used to arrive at these results. However, the methods have not been dealt with here so that more attention can be devoted to the results and their implications.

## FAULT-TOLERANT MULTIPROCESSOR DESCRIPTION

The FTMP is to be constructed of ten identical line replaceable units (LRUs). Each LRU contains one processor/cache module, one mass memory module, one I/O port, one clock generator, and related peripheral support and control circuitry. Each LRU will be packaged in one one-half-ATR-long box (approximately 19.6"×4.9"×7.6"). The processor/cache modules operate in groups of three called triads. Processor triads are formed by assigning any three modules to work together in tight synchronism. A triad functions as if it were a single processor. The failure of a module within a triad does not impact the correct execution of its instruction stream because voting is used to mask the effects of the failed module. A spare module, if available, can be used to replace the failed element. Otherwise, the damaged triad is retired from service with the surviving elements being turned into spares. Memory triads are formed in much the same way as processor triads, with the three memory modules of a triad assigned to work together in tight synchronism. All elements of the multiprocessor operate using a common time reference. This time base is provided by four clock generator modules operating together and phase-locked to each other. Figure 1 illustrates the functioning of this system from a software viewpoint. Three processor triads function as the

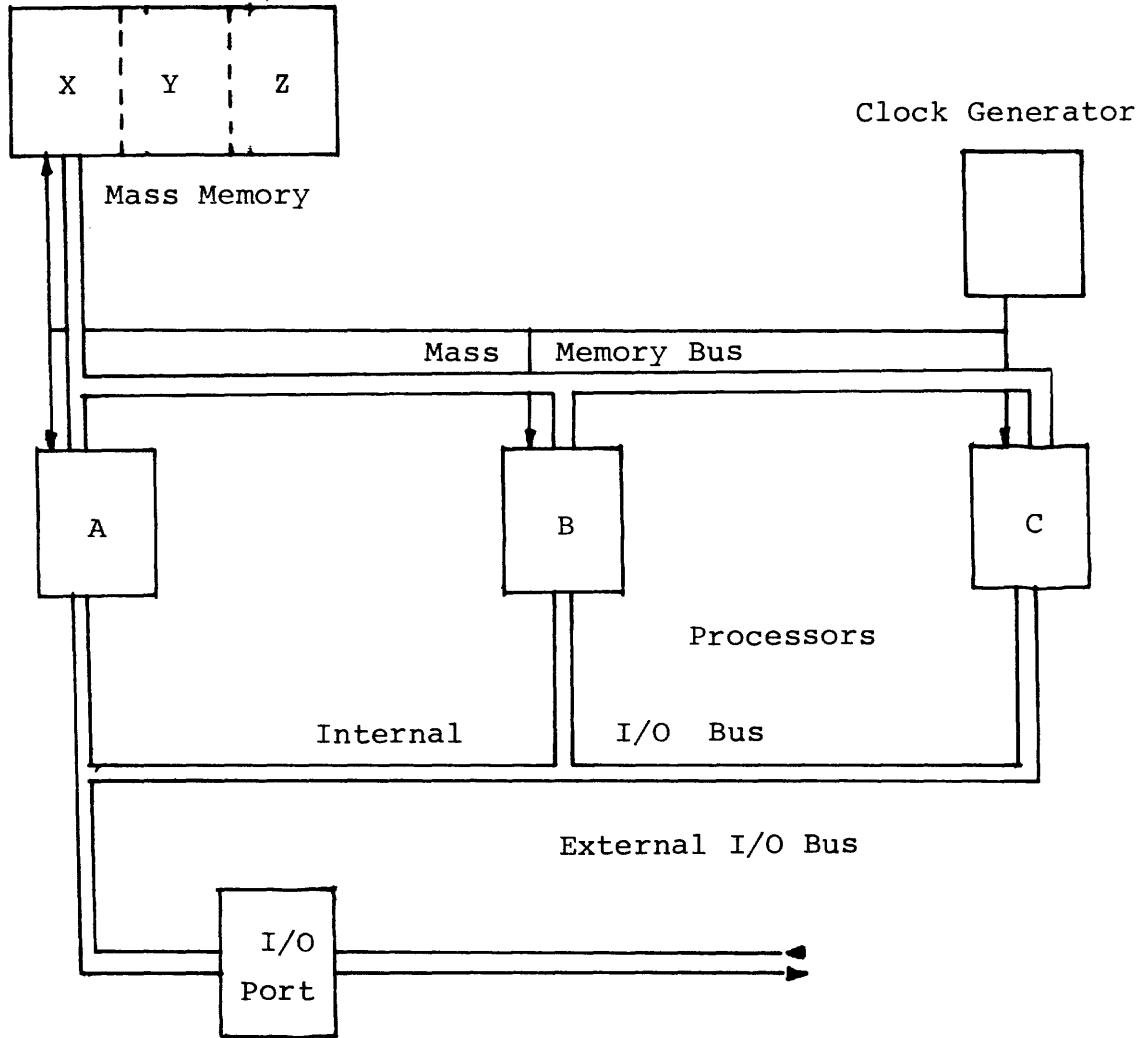

Figure 1—System architecture—Programmer's view.

logical equivalent of three simple processors with shared access to a single mass memory and a common logical I/O bus. The actual redundancy underlying the system is invisible to the programmer. The system is completely symmetric and non-discriminatory in that all processor triads operate at the same level. There are no master or slave processors or triads. Each triad is capable of performing every task in the system, be it the executive programs or applications programs, and does indeed perform every task in turn. The system executive whose performance is to be analyzed in the next section may thus be called a floating executive.

#### MULTIPROCESSOR PERFORMANCE IN AN AIRCRAFT ENVIRONMENT

The mission of a central computer in an aircraft can be described as the compensation and closure of a number of simultaneous sampled data control loops. Typical examples include navigation, guidance and control, load alleviation

and flutter control. The loop control jobs must be invoked at specified times or by specified events. Several studies of workload expected in an aircraft environment<sup>3,4</sup> show that such a job-mix can be closely approximated by a number of purely periodic jobs, with execution frequencies ranging from several times per second to as much as a hundred times per second. In addition to the workload imposed by the applications programs there are a number of housekeeping tasks that must be carried out in a fault-tolerant multiprocessor, specifically in the FTMP. These tasks range from routine diagnostic programs to system configuration control and other internal redundancy management and system management programs. All of these jobs are also periodic in nature, and can be handled in a fashion identical to the handling of the applications programs. Such a treatment of system and applications tasks removes most of the burden and complexity from the central or the core executive. The only important function left to the executive is to dispatch jobs at appropriate times and monitor their progress to completion. In essence, the core executive is just a job sched-

uler. In conventional data processing applications, it is common to find complex operating systems in which the objective is to support a variety of simultaneous demands for resources. In this application, by contrast, we desire to have a simple, straightforward job dispatch process that is reliable, error free and easily verifiable, so that the resultant software is of a quality commensurate with the hardware reliability.

Several philosophies exist for implementing such a job scheduler. For example, the periodic jobs may be completely prescheduled with each job occupying a certain time slot in the schedule. This is the synchronous job scheduler. Its advantages include the on-time execution of jobs with practically no delays, while at the same time keeping a rather high load factor. However the overwhelming disadvantage of such an algorithm is the total inflexibility and the complexity of preassigning jobs to processors in a three-unit multiprocessor. In addition, a degradation in system capacity, to two processors, for example, or changes in job parameters such as iteration rates, may require a totally new schedule. The synchronous scheduler is therefore not considered here.

Another scheduling strategy is the First-Come-First-Serve (FCFS) executive. All jobs are simply arranged in a waitlist ordered by their starting times. Each processor triad that is idle examines this list and picks up a job that is due next. Such an executive is simple, straightforward, and easy to implement. However, it is not obvious what the impact of this job dispatch strategy on system performance would be. One of the important performance criteria in our application is the job-starting delay. The next section details the results of a simulation of the FCFS executive carried out on a breadboard multiprocessor.<sup>5</sup> As shall be seen in that section, although the multiprocessor's performance may be quite satisfactory using the FCFS executive and its minor variations for most real-time applications, no guarantees can be made regarding maximum job-start delays. Therefore an interrupt-driven job scheduler was also evaluated. A major advantage of this scheduler is that the more important jobs can be given higher priority by interrupting the execution of the less important jobs. A later section describes this scheduler and the simulation results.

#### FCFS scheduler results

The results of the FCFS scheduler were obtained by running a representative workload of 25 periodic jobs under a FCFS scheduler on a three-processor bus centered multiprocessor which emulated the FTMP architecture from the software viewpoint. To discuss the results it is convenient at this point to define a few parameters for this section. First of all, the percent system load is defined as (100 minus percent idle). In other words, the percent load includes the percent of time a processor is running a job step or the scheduler, waiting for the scheduler or memory access, and fetching instructions/data from the shared memory. At the saturation point there is no idle time, and the load equals 100 percent. Another important parameter for this section

is the ratio,  $R$ , of the mean job step length to the mean executive/scheduler run time. This is a normalized measure of job starting delay. We define normalized delay as the delay measured in units of mean job step length.

The importance of job-starting delay as a performance criterion in a real-time system cannot be overemphasized. Extensive measurements regarding the probability distribution of the delay were made in the simulation experiments. Figure 2 shows the normalized mean job starting delay as a function of the load. The normalized delay decreases as the ratio of the mean job step-length to executive running time is increased. This is due to the fact that the higher the ratio  $R$ , the lower is the probability of executive access conflict between processors. For each value of  $R$  the mean delay function increases without bound as the load approaches saturation. In some real-time applications the important performance criterion may be the absolute rather than the normalized measure of mean starting delay. Figure 3 shows the mean delay, measured in milliseconds, as a function of the mean job step length for three values of the system load. It is seen that a linear relationship exists between these two parameters, with the slope of the function increasing rapidly with the system load.

Figures 4 and 5 show the probability distribution function (PDF) of the delay for  $R=1$  and 50 respectively. For low system loads the delay distribution can be described as a monotonically-decreasing function with a very sharp initial

Figure 2

Figure 3

decline, indicating that a large percentage of jobs start without an appreciable delay. These characteristics are mostly retained for loads approaching 90 percent. Beyond that, however, the function shape changes considerably and for 99 percent load the probability function, in fact, increases slightly before gradually decreasing with a long tail. A monotonically-decreasing function implies that the probability of a job starting without a delay is higher than with any other value of delay. The distribution function for  $R=50$  is slightly more complex as shown in Figure 5. The high load curves have three distinct phases; a rapid initial decline followed by a plateau and then a final asymptotic descent.

Let us turn our attention now to results regarding maximum job-starting delay. In principle, the probability of any delay, no matter how large, occurring in practice is non-zero. That is, maximum delay is always infinite. However, it is instructive to take a look at various percentiles of delay. Figure 6, for example, shows for  $R=1$  the 80 percentile delay as a function of the system load. That is, 80 percent of all delays fall below this function. This function has the same characteristics as the mean delay of Figure 2. The 80 percentile delay doubles, for example, as the load is increased from 50 to 75 percent. The 99 percentile curve, however, has a slightly different nature. It is seen that the same increase in the load factor results only in a 50 percent

increase in the 99 percentile delay. This has some important consequences. For example, the penalty to be paid in going from a low to a high load factor operating point is not as great as the mean delay function implies. Figure 6 also shows points corresponding to the 99.99 percentile curve. The scattering of points is due to the small number of samples obtained. At any rate, the function tends to show a linear behavior in the 5 to 95% load range. In other words, cost incurred in terms of worst case delays increases only linearly with the system load. This has also been found to be true for the higher values of  $R$ .

Figure 7 shows the probability of the job-starting delay exceeding a given value as a function of the system load for  $R=1$ . It is seen that this probability approaches a linear function for zero delay. That is, the percent of jobs that start right on time decreases linearly with the load. This figure indicates that large system loads may be quite acceptable in real-time systems if moderate delays are permitted. Notice, for example, that if a 51 msec starting delay is permissible, then a system load of 85 percent will produce delays in excess of 51 msec only one percent of the time.

The results discussed so far have been obtained with the First-Come-First-Serve job dispatch strategy. It can be shown with the help of an example that by using the shortest-job-first strategy the mean delay can be reduced, while the spread of the delay is widened.<sup>5</sup> Simulation results shown

Figure 4

Figure 5

in Figures 8 and 9 confirm this. Figure 8 compares the normalized mean job starting delay for  $R=1$  for the two strategies as a function of the system load while Figure 9 shows the PDF for 50 percent load for the same value of  $R$ . It is seen that the delay for some jobs is reduced, thereby increasing the probability of short delays. However, this is done at the expense of the longer jobs, thereby increasing the probability of longer delays. The range of delays is increased considerably while the mean delay is reduced only slightly. Also for  $R=1$  the processor time devoted to the executive is up to two percent more for SJF than for FCFS.

One other variation of the FCFS strategy is the adaptive FCFS algorithm. In this case the starting times of jobs are adjusted dynamically based on past performance measured in terms of job start delay. The idea is to find a time slot that best suits each job and creates the least amount of interference with the other jobs. This strategy shows some improvement over the FCFS strategy. However, in applications such as ours where it may be necessary to certify that a certain subgroup of jobs will never be delayed more than a given amount, neither the FCFS nor the adaptive FCFS scheduler are particularly good candidates. Therefore an interrupt driven scheduler was also simulated. The next section describes the results of adaptive and interrupt driven schedulers which were evaluated using simulation.

Figure 6

**FCFS scheduler ("B" scheduler)**

The *B* scheduler algorithm is an implementation of a FCFS within-priority-class method for determining which task a triad is to select. The set of all eligible tasks is divided into four priority classes, according to the criticality of the func-

Figure 7

Figure 8

tion to be performed by the task. The criticality of the task determines its dispatching priority. The adaptive model uses delay information feedback in order to minimize job-starting delays. The result of this feedback is a modification of the next scheduled arrival time of the previously delayed task. If the starting delay for the previous iteration of a task exceeds a certain minimum value, the next iteration is delayed by a fraction of the inter-arrival time. The adaptive technique as implemented was stable, and led to significant reductions in mean starting delays for all tasks. However, because of the lack of pre-emptability, all tasks must execute for only a short period of time, or high iteration rate jobs will not be executed often enough. This and other weaknesses of the algorithm would preclude its use, even if the delay and jitter could be controlled.

**Preemptive scheduler ("X" scheduler)**

This model incorporates a preemptive interrupt-driven scheduling algorithm. Interrupts are periodically generated to cause activation of high-priority tasks and suspension of low-priority tasks. All tasks are assumed to be periodic, executing at rates of 5, 20, or 40 iterations per second. The

high iteration rate tasks are of higher priority than the lower-rate tasks, and intra-group dispatching constraints can be specified.

**Results**

In this section, results of three experiments are presented. In each experiment, the architectural parameters were held constant and the job mix used in each experiment was also identical. The experiments consisted of executing 1000 tasks, using the following test configurations:

1. The basic *B* model, not adaptive.
2. The adaptive *B* model.
3. The preemptive (*X*) model.

The 1000 job simulation corresponded to approximately 3.25 seconds of FTMP execution time. Based on an analysis of the time history output it appears that the system reached a steady-state condition within this time period.

The statistics of primary interest in this simulation are related to the job-starting delays. Because the jobs are used to implement a sampled data control system, the jitter is a

Figure 9

Figure 10—Adaptive FCFS scheduler, autopilot task.

critical parameter with respect to the overall system performance. The measurement of jitter in these models is the standard deviation of the job-starting delay. A relatively long delay which is constant between iterations is preferable to a large deviation between iterations. The absolute delay will not affect the performance of the control system as long as it is constant between update loops.

A time history of delay for sample jobs is presented in Figures 10-13. The delay, normalized by interarrival time, is plotted versus time. These plots represent the envelope of the set of discrete delay data points, and illustrate the changes in delay from one iteration to the next for a particular job.

Figure 10 is the delay plot for an example job, dispatched

Figure 11—Preemptive scheduler, autopilot task.

Figure 12—Adaptive FCFS scheduler, NAV and guidance task

by the adaptive FCFS scheduler. Up until approximately 1.25 seconds, there is a relatively large variance in the delay between iterations. This phase corresponds to the time period in which the delay feedback mechanism is active. After this initial phase, the feedback cannot provide any further improvements, and the delay reaches a steady-state value. For this task, the jitter is reduced to near zero. For other

tasks, however, a periodic change in delay is observed, because there is no interference-free time slot that can be found for each and every task.

Figure 11 is the delay plot for the same sample job, but dispatched by the preemptive scheduler. The delay is relatively constant throughout the simulation, but at a higher level than the FCFS delay. For this particular task, the

Figure 13—Preemptive Scheduler, NAV and guidance task.

adaptive FCFS model yields better performance than the preemptive model.

Figures 12 and 13 are the delay plots for another job, using the adaptive FCFS and preemptive schedulers. In this case, the preemptive model yields less jitter, both in the initial phase and in the steady-state phase of the simulation.

The three strategies have been compared with respect to performance of individual jobs. Table I lists the mean delay and jitter for each task for each of the three strategies. The following results were obtained with respect to aggregate performance.

The non-adaptive *B* model had a mean delay of 6.2 milliseconds, and the adaptive *B* model had a mean delay of only 1.5 milliseconds. However, the mean jitter was approximately 6.9 milliseconds in the adaptive model and was only 2.4 milliseconds in the non-adaptive model. Thus, the delay information feedback scheme used in the adaptive scheduler reduced the mean delay, but at the expense of the jitter.

In the adaptive experiment, the average jitter is approximately 6.9 milliseconds; in the preemptive experiment, it was approximately 1.2 milliseconds. Therefore, with respect to jitter, the preemptive model yields better performance on an aggregate basis.

#### Performance conclusions

Three major scheduling strategies *viz.*, FCFS, adaptive FCFS and preemptive schedulers have been evaluated. Each has certain advantages, and a selection must be made depending on the applicable performance criteria for the intended application. The FCFS strategy is a simple, straightforward algorithm that is suitable for most real-time applications. With this scheduler, high load factors can be maintained without making maximum jobstart delays inordinately high. The adaptive version of this algorithm can decrease the average delays, at the expense of being slightly more complex to implement. FCFS and adaptive FCFS schedulers can be used in those applications where the maximum delay can be allowed to exceed a certain value, say, only 10 percent of the time. Neither algorithm, however,

guarantees that the maximum start delay for a job will never exceed a given value. In those applications, such as ours, where this performance guarantee is of paramount importance, one must give up the simplicity and ease of verifiability in favor of guaranteed performance. In light of these requirements, the interrupt driven preemptive scheduling philosophy has been selected for the FTMP.

#### MULTIPROCESSOR RELIABILITY

The likelihood of a catastrophic failure of a central computer in a civil transport aircraft is required by the Federal Aviation Administration to be "extremely improbable." This requirement has been interpreted to mean a failure probability of the order of magnitude of  $10^{-9}$  per hour. There are a number of ways in which random failures can result in a catastrophic failure of the FTMP. For the sake of analysis, these have been grouped under three categories as follows.

##### *Lack of perfect coverage*

In the FTMP some time is required to detect, isolate and recover from any failure. Depending upon the subtlety of the failure this time may range upward from several milliseconds. During this time the system is exposed to a second failure which may arrive in such a place as to be catastrophic. It may be mentioned here that by design there is no single point failure mechanism in the system. It takes two or more failures to bring the system down. Given that there is one fault in the system, the probability of successfully recovering from the failure is not 100 percent. This lack of unity coverage is the first failure mode.

##### *Exhaustion of Spares*

When a failure is detected in a module, that unit is replaced by a spare, if one is available. A succession of failures

TABLE I—Job Starting Delay Statistics

JOB NO.	PRIORITY (GROUP)	FCFS		FCFS ADAPTIVE		PREEMPTIVE	
		MEAN ( $\mu$ sec)	STD DEV ( $\mu$ sec)	MEAN ( $\mu$ sec)	STD DEV ( $\mu$ sec)	MEAN ( $\mu$ sec)	STD DEV ( $\mu$ sec)
01	005	17,160	401	8,963	2,478	36,844	771
02	005	26,371	3,476	4,308	8,448	35,633	809
03	005	31,777	460	9,102	7,040	32,617	1,108
04	005	33,271	1,318	10,940	7,628	22,236	553
05	005	36,382	803	8,154	10,265	20,115	397
06	020	4,904	212	675	803	18,087	568
07	020	6,355	337	1,143	1,019	8,519	307
08	020	9,250	194	1,948	1,382	7,244	499
09	020	15,029	616	1,715	2,440	5,390	226
10	040	375	250	480	588	4,908	297
11	040	758	491	647	892	3,188	201
12	040	1,133	689	692	716	1,227	69
13	040	4,030	342	757	697	889	56
14	040	4,577	534	698	760	601	42

can cause the system to degrade to a point where it cannot keep up with the minimum workload critical to the safety of the flight. This second failure mode is the result of a lack of throughput and/or memory capacity.

*BGU enable mode failures*

In the FTMP, there are two Bus Guardian Units (BGU) in each LRU that allow each processor, memory, and oscillator within that LRU to transmit on the memory and I/O buses. Both BGUs must be in agreement before any module may transmit on a bus. When a module fails, the BGUs can be commanded to disable the failed module from transmitting on the bus. It is evident that if the two BGUs fail to perform their duty when a module in their LRU fails, a number of buses may be rendered useless, thereby causing a system catastrophe. This is the third failure mode.

Figure 14 shows the system failure probability as a function of time due to each of the three failure modes described above.<sup>1,4</sup> Figure 15 shows the composite failure probability of the FTMP due to all random failures. The following conclusions can be drawn from these two figures:

1. During a typical commercial flight of one-to-ten hours, the most likely threat of the FTMP failure is due to an arrival of two failures so close that system reconfiguration is not possible. The probability of this event, however, is acceptably low (about  $3 \times 10^{-10}$  per hour) because of high component MTBFs and fast reconfiguration times.
2. There is very little chance that the FTMP computer will run out of spares during a ten-hour flight, assuming that the system initially has all ten LRUs fully operational. In longer flights, however, failure would be quite possible, as evidenced by the sharply rising failure probability curve after 50 hours.
3. Finally, the system failure rate due to BGU enable mode failures is substantially lower than other system failure modes. Therefore, it does not contribute significantly to the overall system failure probability.

Figure 14

Figure 15

**FTMP ECONOMICS**

The viability of the FTMP depends not only on its technical merits but also on its cost effectiveness. For the FTMP to be economically attractive to the airframe builders and airlines, the direct and indirect benefits such as fuel savings and improved safety should be shown to be commensurate with its cost of ownership. The next two subsections explore these two facets of the FTMP economics.

*Life-cycle-costs*

The cost of ownership of the FTMP can be measured effectively in terms of its life-cycle-cost (LCC). The LCC includes all the cost items associated with the computer over its total life time. It can be broken down into the following four major categories: (1) acquisition cost, (2) maintenance cost, (3) spares inventory cost and (4) added fuel cost.

Each of these is self-explanatory except for the last item. The added fuel cost is the cost of extra fuel that must be burned to carry the computer on-board. Each of these cost items is determined by a number of different variables. For example, one of the variables that affects the acquisition cost is the initial purchase price, which in turn is determined by hardware cost, software development cost, certification cost, company profit, etc. The number of variables determining LCC is increased even further when normalized costs such as per flight-hour cost or per passenger-mile cost are considered. The normalized costs can be directly compared to airlines' present operating costs since all the data reported to the Civil Aeronautics Board by the airlines is normalized by flight-hours, block-hours or passenger-miles. Using the empirical formulas developed by the Boeing Commercial Airplane Company<sup>6</sup> for cost estimation, and with a reasonable estimate of input variables, the FTMP absolute and normalized costs were computed. These costs are summarized in Tables II and III, respectively. According to these figures, it would cost \$138,500 to acquire one FTMP unit and each spare LRU would cost about \$13,000. An airline with a fleet of 100 airplanes, each equipped with two FTMPs, would need to maintain a spare inventory of 112

TABLE II—FTMP Absolute Cost Summary  
(\$)

LRU Cost	12,960
Unit Hardware Cost	135,861
Software Development Cost	1,340,000
Unit Software Cost	2,680
FTMP Cost	138,541
Spare Inventory	112

LRUs. The reason for having two FTMPs (connected through an I/O node network) per aircraft is to be able to survive localized physical damage to either computer.<sup>7</sup> The normalized cost of operating two FTMPs is found to be \$37 per flight-hour. Most of this is about evenly split between acquisition (\$17) and maintenance (\$16) costs. The normalized costs of carrying the added weight and maintaining the spare LRU inventory are found to be negligible in comparison to the other two components.

To put these numbers into proper perspective, the cost of operating a jetliner as reported to the Civil Aeronautics Board is itemized in Table IV. The numbers shown are the flight-hour costs (1974 dollars) of operating a Boeing 747, averaged over all the U.S. carriers operating such an aircraft. The total cost is \$2708 per flight-hour or \$2415 per block-hour. The largest single component of this is the fuel and oil at \$795. By comparison, the additional cost of operating two FTMPs would be \$37 per hour. This is about five percent of fuel expense or 1.5 percent of the overall 747 cost. Thus, if the FTMP can help make the aircraft just five percent more fuel efficient it can pay for itself. This and other FTMP benefits are discussed in the next section.

As stated earlier, a large number of variables are involved in this study. Uncertainties in the estimation of values of these variables can lead to erroneous cost figures. However, not all the variables are equally important in that the FTMP cost is not equally sensitive to all the parameters. Variations in some parameter values have direct impact on daily operating costs of the FTMP, while others have none. A sensitivity analysis found that only four items have important bearing on the FTMP cost. Table V lists the percent change in the hourly operating cost of the FTMP due to a 100-percent change in each of the four variables. Not surprisingly, the LRU reliability and repair time have a direct impact on the maintenance cost, which is one of the recurring cost items. The parts and labor cost to build the FTMP are the major factors in determining the FTMP acquisition cost. Lastly, the FTMP life-time is important because it is used to normalize all the fixed costs to obtain the hourly operating cost. The effect of all other factors is five percent

TABLE III—FTMP Flight-hour Cost  
Summary (\$/hr)

Total Cost	37
Acquisition Cost	17
Spare Inventory Cost	1
Added Weight Cost	3
Maintenance Cost	16

TABLE IV—Boeing 747 Operating Cost  
(1974)  
(\$/Block-Hour)

Flying Operations	1183
Crew	363
Fuel and Oil	795
Insurance	25
Maintenance	570
Depreciation and Rental	662
Total/Block-hour	2415
Total/Flight-hour	2708

or less. As an example of this, if the software development cost \$2.7 million rather than the \$1.35 million assumed, the hourly operating cost of the FTMP would be increased from \$37 to only \$39. On the other hand, if the LRU mean time between failure (MTBF) turned out to be only 925 hours rather than 1850 hours assumed, the hourly cost would increase from \$37 to \$46.

#### FTMP benefits

As pointed out in the previous section, the hourly operating cost of two FTMPs is less than five percent of just the cost of fuel burned per hour by a Boeing 747. The potential of the FTMP to make future aircraft fuel efficient is enormous. The performance advantages of statically-unstable aircraft where the tail shares the wing load, rather than opposing it, are well known. Similarly, load alleviation can be used to build a lighter wing structure. All of these applications, however, require some form of active controls, the failure of which can have financial and/or fatal consequences. Lockheed is already flight testing an advanced version of the L-1011 Tristar with increased wingspan supported by active wing tip ailerons. The wing fatigue life in the absence of active controls would be only 40 hours, compared to 30,000 hours or more for a conventional wing. The economic penalty of the control system failure would be catastrophic in this case. These are some of the areas where airframe builders can use a central fault-tolerant computer to advantage.

The next generation of jet aircraft will be making extensive use of digital computer technology. The Boeing 767, for example, will employ more than six different digital computers, ranging in functions from air data to flight control.<sup>8</sup> By consolidating guidance, navigation, control and other functions into one single computer, there are obvious savings to be obtained in terms of commonality of design, implementation, spares, and maintenance overheads.

TABLE V—Effect on Flight-hour Cost

FTMP Life-time	24%
LRU and FTMP	
Parts Cost & Assembly/Test Time	43%
LRU MTBF	24%
LRU Repair Time	33%
All Others	≤5%

There are other recurring benefits of the FTMP to the airlines, such as fewer false removals of LRUs, which presently run at about 50 percent. A fault in the FTMP can be traced to the LRU level quickly and with almost 100 percent certainty. The FTMP can also extend the aircraft flight envelope by giving the airlines an all weather operational capability, such as Category III operations. There also are some intangible benefits such as increased safety. The general increase in automation can reduce the crew workload, which indirectly contributes to safety.

## CONCLUSIONS

From the results presented in this paper, it can be predicted that the FTMP can do the job for which it is designed, and do it reliably and economically. Using the interrupt driven job scheduling strategy, it can respond to critical job requests promptly. It has a very low failure probability, and at the same time the hourly cost of operating two FTMPs in a transport aircraft can be as little as one-to-two percent of the total flight-hour cost of the aircraft. The benefits of the FTMP, in any case, far outweigh its costs. It is our conten-

tion, therefore, that the FTMP will be a viable and competitive option for the future generation of transport aircraft.

# Serviceability features of the HP 300 small business computer

by CURTIS R. GOWAN

*Hewlett-Packard*  
Santa Clara, California

## INTRODUCTION

As computing system prices go down due to technological advances in hardware, more emphasis is being placed on the overall cost of ownership. To meet this challenge, serviceability features are designed into the HP 300—intertwined throughout the system hardware and software.

## THE HP 300

The HP 300 is a broad-capability system for dedicated business data processing applications. It includes general-purpose features found on much larger systems, yet it is designed for direct use in daily business activity.

A typical HP 300 configuration consists of the System Unit (Figure 1), a printer and several application terminals.

### *The System Unit*

The central element in every HP 300 system is the HP 300 Mainframe, or "System Unit." The System Unit combines the HP 300's processing, storage and control functions into a single compact package:

**Integrated Display System**—A keyboard and display screen form the Integrated Display System, or IDS. The display can be broken into multiple windows, each of which is directly attached to a data file. Eight "softkeys" bordering the right side of the IDS screen provide a push-button choice capability.

**Processor**—The HP 300 is based on a Silicon-on-Sapphire (CMOS/SOS) LSI processor. The processor has a stack architecture and provides hardware support for virtual memory operation.

**Main storage**—A standard HP 300 system includes 256 KBytes of semiconductor memory expandable to 1024 KBytes in 128 KByte increments.

**Flexible disc drive**—The HP 300 System Unit includes a flexible disc drive for offline storage and data exchange with other HP 300 systems.

**Online disc storage**—A fixed disc provides 12 million bytes of storage for system and user programs and data. It is

also used as secondary storage for virtual memory operation. In larger configurations, the fixed disc can be replaced by a stand-alone disc drive.

The 25-slot card cage in the System Unit contains not only the CPU, memory and I/O boards but also circuit boards for the console (IDS), flexible disc and 12 MByte integrated system disc. Except for the circuitry which must be near either the display tube, the disc mechanisms, or the power supply, every mainframe PC board is in the System Unit card cage—with all configuration switches accessible on the board edges. This simplifies diagnosis by making it very easy to check the mainframe's hardware configuration for human error.

### *Amigo/300 operating system*

The HP 300's operating system, Amigo/300, is an advanced virtual memory operating system, with extensive data management and online processing facilities. In dedicated, terminal-oriented applications, Amigo/300 supports terminal response and interactive processing in addition to concurrent non-interactive jobs.

Some of the key features include:

- Multiprogramming
- Multitasking
- Large addressing space—A potential addressing space of over 260 million bytes for each program.

## CLASSES OF SERVICEABILITY FEATURES

Serviceability features exist either to contain faults or to diagnose them.

- Fault containment features correct or detect faults to minimize their effect on the system. The next section covers these features in detail.

The diagnosis features can be split into two sets—Monitoring tools and stimulus-response tools.

- Monitoring tools (fourth Section) allow you to see what

Figure 1—HP 300 system unit.

is happening or what has just happened leading up to an error. The tools must disturb the system as little as possible.

- Stimulus-response tools, on the other hand, by their nature perturb the system under test by providing simple, controlled, repeatable stimuli instead of the complex stimuli provided by normal operation. These are covered in the fifth section.

## FAULT CONTAINMENT FEATURES

The HP 300 hardware and software have built-in provisions which correct or detect certain faults when they occur. Whether the result of hardware failure or human error, these faults are of the type that cause multiple, obscure (and often delayed) system faults.

### *Error-correcting memory*

The memory subsystem corrects all single-bit memory errors; plus, it detects all double-bit and the vast majority of multi-bit errors. Each memory word consists of 16 data bits plus five Hamming-encoded correction/detection bits and a parity bit.

### *Privileged mode instructions*

Programs may execute in one of two modes—privileged or user. In user mode, a program is confined to its own code and data areas and is prevented from destroying the operating system or directly performing I/O.

### *Instruction bounds checking*

The CMOS/SOS LSI processor performs bounds checking on memory reference instructions, in both user and privileged code, via hardware limit registers. The executing user code segment is kept separate and distinct from the data segments.

### *Error-detecting disc subsystems*

The disc subsystems record cyclic-redundancy error-detecting codes with the data; the controller and driver automatically retry if the data read fails the CRC check.

## MONITORING TOOLS

Monitoring tools show what is happening—the current state—or what just happened—a state history. The key to the design of monitoring tools for diagnosis is that they be as non-invasive as possible, i.e., the tool should not affect the circuit under test.

The first group of monitoring tools are intrinsic to the HP 300—they are always present, monitoring the system during normal operation. The last two monitoring tools are extrinsic—they are external instruments connected to the system when a fault is suspected.

*Trace-LEDs*—HP-manufactured light-emitting diode arrays (with integrated current-limiting resistors) are built into most boards. All of these LEDs are observable by opening the rear door. They provide non-invasive monitoring of normal activity—to check certain key nodes without tools. The Trace-LEDs are, in effect, a low-cost built-in maintenance panel. For example, one LED is connected to the last stage of the CRT timing chain; its once-per-second blink shows that the chain is working. Another LED is connected to the system power-fail-warning line; this circuit is checked by turning the system on and off while watching the LED.

*System Error Log*—The error logging facility records errors, both user-transparent and fatal, as time-stamped entries in a disc file. The number of I/O requests and errors are tallied for each device, then regularly recorded on the disc. Fault trends may be detected by analyzing this data.

*System Trace Table*—The operating system keeps a list of the most recent events in a circular table in memory. The data can be dumped via the System Debug facility.

*Console Log*—A list of the most recent console commands is kept in a disc file so that one can check the sequence of commands which led up to some event.

*System Debug*—Running under the operating system, System Debug provides to Specialist CEs interactive control, examination and modification of both code and data.

There are two key external tools which Customer Engineers use in monitoring—the Processor Maintenance Panel and state analysis instrumentation.

*Processor Maintenance Panel*—The Processor Maintenance Panel (PMP) is used by Specialist CEs for detailed tracing of HP 300 microcode and macrocode. The PMP consists of a printed circuit board which plugs into a reserved slot in the system card cage and an HP 9825 Calculator which provides a user interface independent of the system under test. The PMP provides non-invasive breakpoints plus micro-level and macro-level manipulation of the system hardware.

*State Analysis Instruments*—HP 300 Customer Engineers are trained in the use of the HP 1602A Logic State Analyzer and the HP 1640A Serial Data Analyzer—both standard portable instruments—to trace I/O transactions on the system busses and data communication ports.

**STIMULUS-RESPONSE TOOLS**

The key to the design of stimulus-response diagnosis tools is that they not only identify that a problem exists but also

isolate it to a replaceable module. To do this, tools must:

- Depend as little as possible on portions of the system other than the portion under test.
- Build outward from a small kernel, layer by layer, using already-tested circuit blocks to test additional circuitry.

Figure 2 gives a block diagram of the system hardware. This diagram is then annotated to show the outward progression of the stimulus-response tools. The layer-by-layer sequence of tests starts at the processor, directly attacking the diagnostics-won't-load problem.

*CPU Self-Test*

The CPU Self-Test is a ROM-resident microdiagnostic which is invoked on power-on or by depressing a switch on the edge of the CPU Bus Interface board. Its purpose is to check the hardware required to cold-load the system. CPU Self-Test results are displayed on two five-LED arrays next to the CPU TEST switch. The test may be set up to loop continuously, either halting on the first failure or continuing regardless of failure.

The CPU Self-Test first performs a thorough test of the processor, including checksum tests on each of the micro-code ROMs. It then tests the Inter-Module Bus handshake lines, checks communication with the Memory Controller

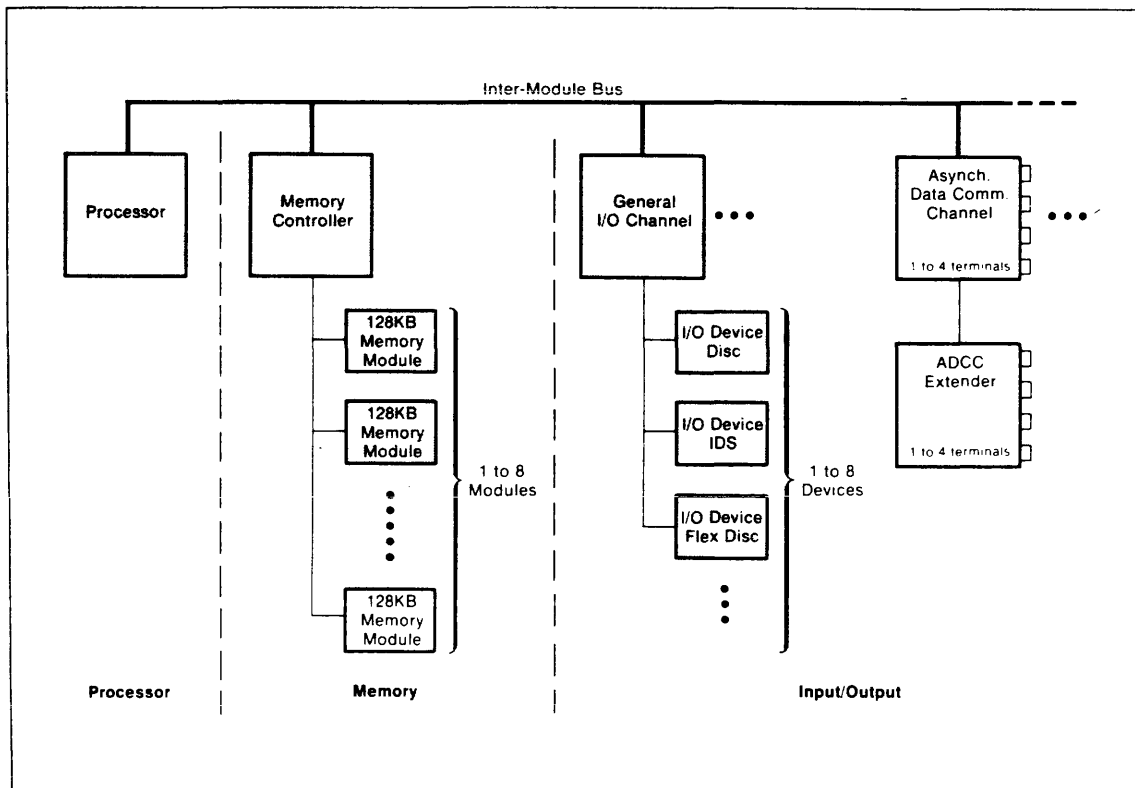

Figure 2—HP 300 logical hardware organization.

and tests the lowest memory module for stuck bits. The General I/O Channel (GIC) is tested—first proving that the CPU can communicate with the GIC, then looping data completely through the board to the output of the LSI device-bus interface chip and back to the memory via DMA.

The device to test is selected by the Control Panel switch used to select the load/dump device. The CPU Self-Test sends a data pattern through the channel to the device controller's memory, commands the device to return the data, and then checks for correctness.

When the Control Panel is set up for a cold-load, the CPU Self-Test checks and diagnoses the entire data path from disc to CPU. By changing the Control Panel switches, the loopback process is also used to check out the links to the Interactive Display System, printers and other peripherals. See Figure 3.

*Fixed Disc Self-Test*

The built-in 12 MByte fixed disc has its own independent Self-Test. Actuated by a switch on the disc Controller board, it loops and displays errors in the same manner as the CPU Self-Test.

Key steps include a processor test, ROM checksums, device-bus interface chip loopback, actuator arm motion tests and extensive writing/reading on a reserved track.

*Interactive Display System Self-Test*

An independent self-test is also provided in the Interactive Display System (IDS). It checks for ROM checksums, device-bus interface chip loopback, keyboard scanning and stuck keys, character ROMs in wrong sockets, horizontal oscillator, and correct dot emission to the sweep circuitry. The operator checks the displayed fonts on the display screen.

*Flexible Disc Unit Self-Test*

A similar Self-Test is provided for the flexible disc unit (FDU). If a flexible disc is present, reading will be tested; if an additional switch is depressed at the start of FDU Self-Test, write/read testing is performed.

At this point in the stimulus-response test sequence, the kernel of the system has been tested by microcode (Figure 4). One can now load and run macrocode test programs.

*Diagnostic/Utility System*

A memory-based operating system, the Diagnostic/Utility System (DUS), provides file management of test and utility programs on a flexible disc. DUS provides a simple and deterministic base for software testing of the hardware.

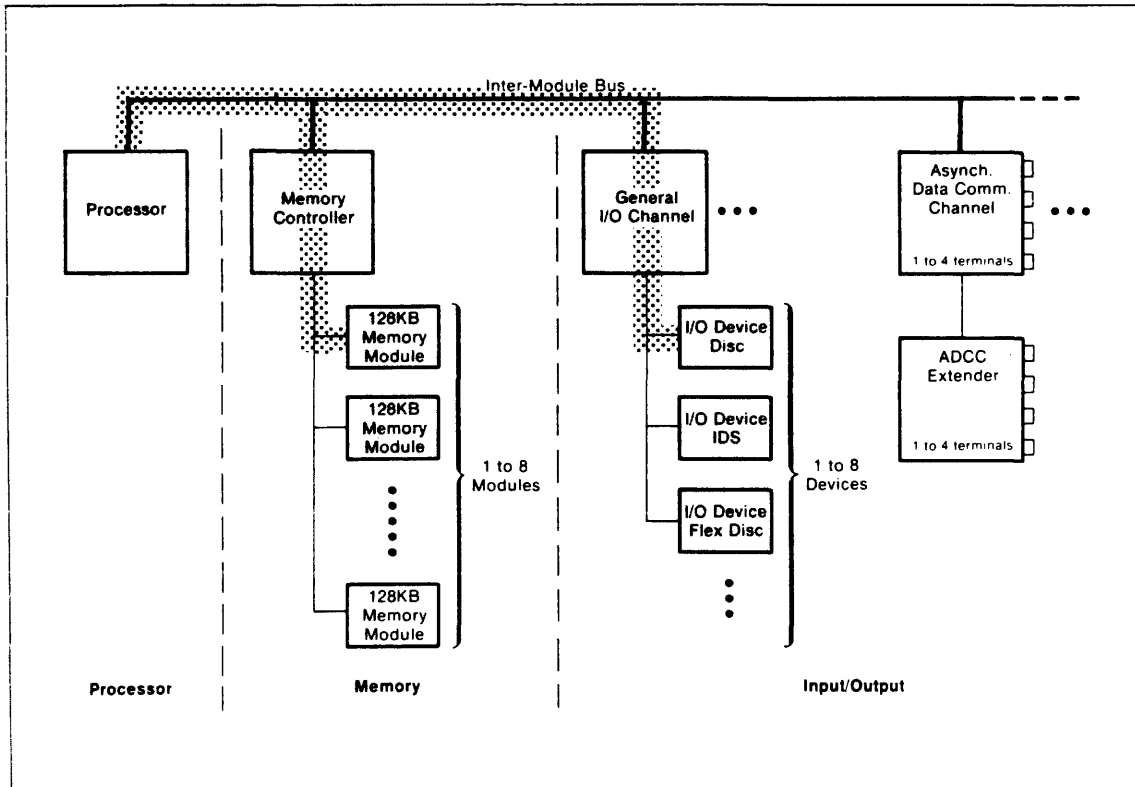

Figure 3—CPU Self-Test data paths.

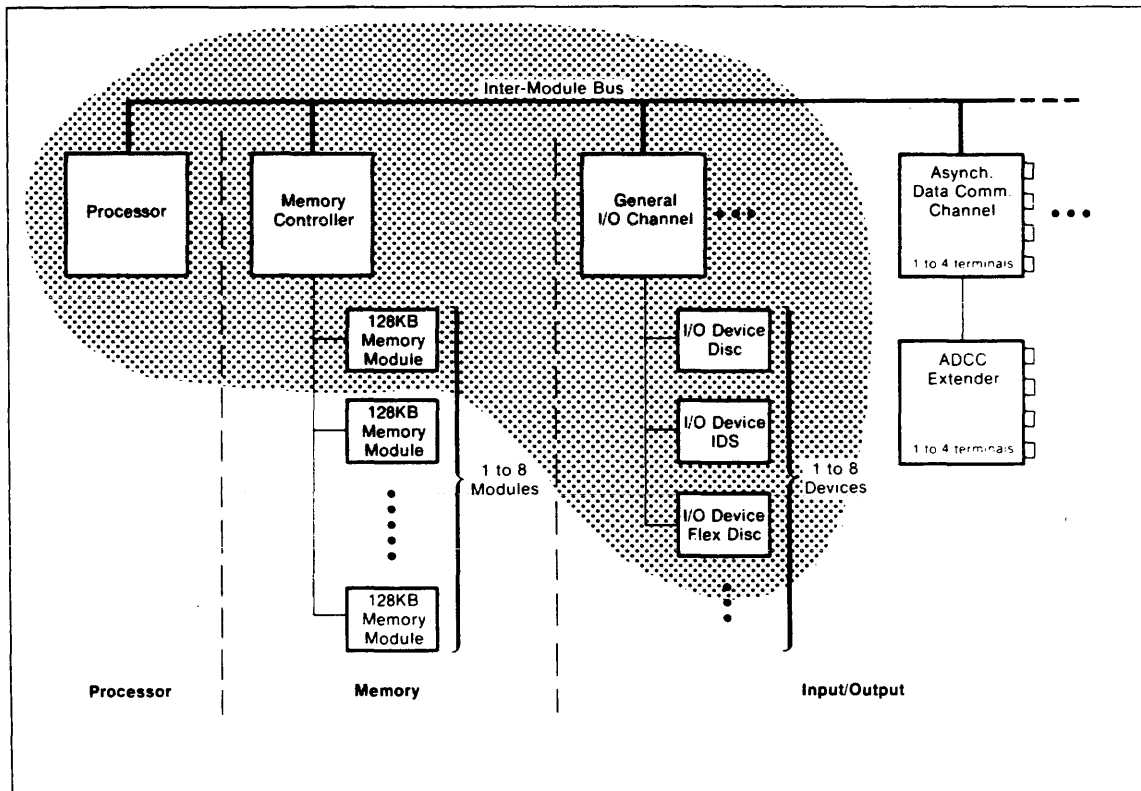

Figure 4—System kernel.

DUS is easily used by a CE or trained user to check system hardware. There is a HELP capability which lists the directory and commands; a program is invoked by simply typing its name.

#### *Processor test program*

This program checks certain software-related CPU functions not tested in the CPU Self-Test.

#### *I/O map program*

The IOMAP program uses hardware self-identification features to display the type and address of each channel and device in the system. Any number of Identify, Loopback, or Self-Test commands may be sent to any device—for example, a printer's self-test can be invoked to check out both the I/O path and the device.

#### *Device diagnostic and test programs*

There is a diagnostic or test program for each device. These are easily used by a CE or trained user—each has step-by-step prompt messages and a default mode which consists of a fast, non-destructive subset of the overall test sequence. If the user suspects a disc problem, for example,

the default mode of the disc diagnostic program runs a subset of the test menu which will give a good confidence check of the disc drive without damage to the user's data base.

Users with more time and knowledge can run these tools at the CE level—this is particularly valuable to OEMs and software houses incorporating the HP 300 into their own products.

#### SUMMARY

The HP 300 has been described in an overview. The product's serviceability features are broken into three groups—fault containment features, monitoring tools and stimulus-response tools. Each specific feature has been described in detail sufficient to show its role in reaching the overall goal—low cost of ownership for a small commercial system.

\* \* \*

#### ACKNOWLEDGMENT

Like quality, serviceability cannot be added to a product by an outside group. The design of serviceability into the HP 300 was intertwined with the system design process—thus, the features described are the result of contributions by every member of the project.

# Automatic tuning of computer architectures

by KEN SAKAMURA, TATSUSHI MOROKUMA and HIDEO AISO

## INTRODUCTION

One of the most important unsolved problems in the design of a computer system is the automatic optimization or tuning of the computer architecture to better suit the problem under consideration. In particular, it is very important to make an effective mapping of the structure of the problem to be solved to the structure of the computer being used.

The best approach to this problem is to automate the tuning procedure of the computer architecture by the computer itself, in which the computer evaluates its performance and thereby achieves better performance. This seems to be the best approach because the existing computer systems have become too large and too complicated to be handled by manual tuning techniques. It should be noted that tuning iteration is carried out automatically at the Instruction Set Processor (ISP) level utilizing the inherent characteristics of dynamic microprogramming.

The purpose of this paper is to present a detailed algorithm for an automatic tuning of computer architectures using dynamic microprogramming techniques and to show the effectiveness of the proposed ideas by describing the results of some experiments. We have been doing research on this problem since the late 1960s.<sup>1</sup> Very little research has been conducted with regard to the automatic tuning of computer architectures.<sup>2-5</sup>

## PRINCIPLES AND IMPLEMENTATION MECHANISMS

### *Basic principles*

A simplified model of a mechanism for automatic tuning of a computer architecture at the ISP level is shown in Figure 1. The basic functions required for the optimization of the architecture or tuning are as follows:

### **Monitoring of programs**

Detailed information regarding the dynamic characteristics of both the computer and the program to be solved is necessary to perform the optimization processes. This information must include the relative frequencies of machine instructions, the relative frequencies of sequences of instructions, that is serial dependencies, and the relative frequencies of address and data values. A monitor implemented in hardware, software or firmware collects this information.

### **Analysis of data**

The information obtained from the monitor is processed by an analyzer which may be an independent computer. The function of the analyzer is to identify all possible candidates for instruction patterns that can be tuned up in order to create new instructions to save execution time and storage space. This is performed by a thorough analysis of the application program and its execution profile.

### **Feedback to computer**

New instructions, that were synthesized by the analyzer, are converted into new microprograms which occupy less storage space and have faster execution time than the original instructions. The synthesized microprograms are loaded into the writable control storage (WCS) in the computer through the feedback path during the program execution to form a new enhanced architecture. This results in dynamic modification of the computer architecture and in better performance. It should be noticed that dynamic microprogramming techniques are very effective to realize this dynamic modification.

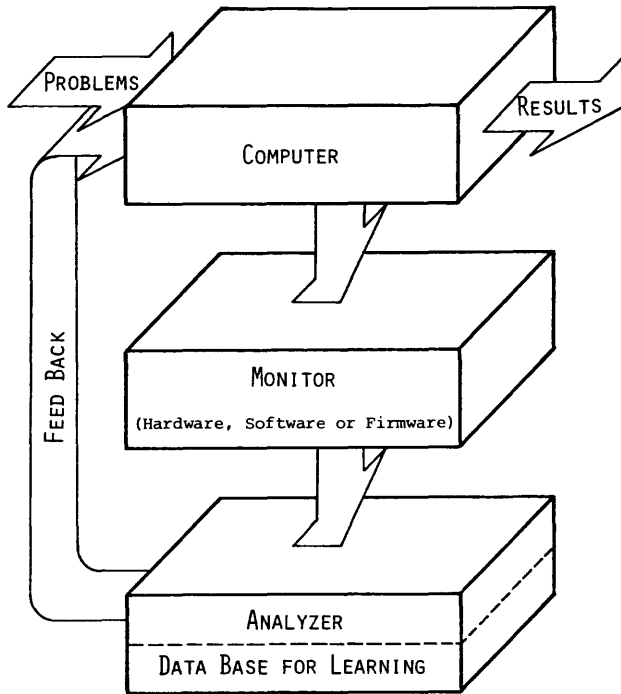

Figure 1—Model of an automatic tuning mechanism.

### Learning of tuning behavior

A special feature of our method is the fact that a data base is provided in the analyzer. The above-mentioned tuning processes are usually repeated until the desired performance improvement has been achieved. Therefore, the analyzer keeps track of the tuning behavior in the data base whenever tuning occurs. The analyzer can refer to the contents of the data base so that the number of tuning iterations will be minimized.

### Definition of terms

The terms used in the next two sections are defined as follows:

#### Machine

Each intermediate language (IML) instruction set defines a corresponding *machine*,  $M_i$ , which has an IML instruction set  $IML_i$ .  $IML_i$  is a set of instructions represented as follows:

$$IML_i = (I_1, I_2, \dots, I_k, \dots, I_n)$$

where  $I_k$  is an instruction which is a microroutine consisting of a sequence of microinstructions.

#### Program

A *program* is a sequence of IML instructions.

#### Block

In order to define a block, IML instructions have to be divided into the following two types:

1. Branch type—Instructions whose next instruction to be executed is not necessarily next one in sequence.
2. Sequential type—Instructions whose next instruction to be executed is always the next one in sequence.

A *block* is a static sequence of instructions which satisfies the following conditions:

1. Its entry point is restricted only to the top instruction.
2. The last instruction is of branch type.

#### Length of block

The length  $\gamma(B)$  of a block  $B$  is the number of instructions contained in that block.

#### Instruction pattern

An instruction pattern ( $P$ ) is a continuous sequence of instructions in a block. The number of different instruction patterns in a block is not greater than  $\frac{1}{2}\gamma(B) \cdot (\gamma(B) - 1)$ .

#### Length of pattern

Let the bit length of pattern  $p$  consisting of  $\gamma$  be  $\gamma(p)$ .

#### Weight of a pattern

The weight of a pattern  $p$ ,  $\xi(p)$  is defined as follows:

$$\begin{aligned} \xi(p) &= \sum_i^B \frac{\tau(p) \times f(p, i)}{T_0 \times \gamma(p)} \\ &= \frac{\tau(p)}{T_0 \times \gamma(p)} \sum_i^B f(p, i) = \frac{\tau(p) \times f(p)}{T_0 \times \gamma(p)} \end{aligned}$$

where

- $\tau(p)$ : Execution time of pattern  $p$
- $f(p, i)$ : Number of times that pattern  $p$  is executed in the block  $i$ .
- $f(p)$ : Number of times that pattern  $p$  is executed in all blocks.
- $T_0$ : Total program execution time
- $\gamma(p)$ : Length of pattern  $p$ .

#### Improvement ratio

The capacity of writable control storage required to convert a pattern  $p$  into a microprogram may be thought of as the overhead of the tuning. It is represented by  $\theta(p)$ . Fur-

thermore, the improvement ratio ( $\mu(p)$ ), indicating how much improvement of the execution speed has been achieved by tuning, is defined by the following equation:

$$\begin{aligned}\mu(p) &= \frac{T(p) - t(p)}{T_0} \\ &= \frac{\tau(p) \times f(p)}{T_0} - \frac{\tau'(p) \times f(p)}{T_0} = \frac{\tau(p) - \tau'(p)}{T_0} f(p)\end{aligned}$$

where

- $T(p)$ : Total execution time of pattern  $p$
- $t(p)$ : Total execution time of pattern  $p$  after tuning
- $\tau(p)$ : One execution time of pattern  $p$
- $\tau'(p)$ : One execution time of pattern  $p$  after tuning
- $T_0$ : Total program execution time
- $f(p)$ : Execution frequency of pattern  $p$  in all blocks

#### *Optimum design of an intermediate language based on dynamic computer behavior*

It is well known that better execution efficiency may be achieved through description of the problem in a lower-level language. For instance, better performance can be expected when the problem is written in machine instructions rather than in high-level languages, and much better performance can be expected when the problem is written in microinstructions rather than in machine instructions.

The direct description of a problem in microinstructions is called "Firmware," and this results in the creation of new instructions suitable for the problem to be solved. The improvement of the execution efficiency is carried out at the ISP level, and this procedure is called "Architecture Tuning."

To achieve optimal efficiency, it is clearly desirable to implement all the programs in firmware. However, more than 80 percent of the execution weight is concentrated on at most four to five percent of the total number of program steps.<sup>6</sup> Therefore, the best performance cost ratio is not achieved by making all the programs into firmware. Parts of the program should be implemented in firmware considering the dynamic behavior of the program execution. In this case, the best strategy is to apply microprogramming to those parts of the program, which are most frequently executed. In order to automatically detect the parts to be tuned up, the program is divided into blocks based on the proposed algorithm described in the next section. Next, the execution weight is measured to decide the blocks that have to be implemented in firmware starting from the block with the highest execution weight.

#### *An algorithm for tuning of IML instruction patterns*

An important consideration is that detailed information about the characteristics of programs is necessary to perform the tuning processes. Since the use of each IML instruction is not always uniform at the moment of program

execution, the relative frequencies of both machine instructions and sequences of instructions, that is, serial dependencies, must be included in this information. The sequences of pairs or multiplets of instructions, that create new instructions are called "Instruction Patterns." Thus, the programs can be expressed in terms of a finite number of instruction patterns by static analysis described below.

#### **Weighting of the instruction patterns**

In order to give a weight to each of the instruction patterns, the frequencies of sequences of instructions should be measured. In this case, no branch instruction should be contained in the instruction patterns. The program is divided into blocks separated from each other by branch instructions. The frequencies of the blocks are measured by a hardware or firmware monitor. The weight of the corresponding instruction patterns can be calculated from the measured frequencies of the blocks.

#### **Selection of the instruction patterns to be tuned up**

Many strategies have been considered to select the instruction patterns to be tuned up. We propose the following two methods:

##### 1. Method to achieve maximum execution efficiency.

Using the equation for estimating the tuning effect, which will be described in the next section, we can estimate the performance improvement ( $\hat{\mu}$ ) by means of the previously found instruction patterns.

First, we select the instruction patterns with the maximum value of  $\hat{\mu}$ . It turns out that the weight of the other instruction patterns may be changed, since some of the instruction patterns may be overlapping each other and some instruction patterns contain other instruction patterns.

Next, we carry out the static analysis again to weigh the instruction patterns. The value of  $\hat{\mu}$  is recomputed to select new instruction patterns. The above steps are repeated until the sum of all the  $\hat{\mu}$ 's exceeds a certain percentage which has been determined through some experiments.

##### 2. Method to achieve maximum economical effect.

This method is similar to the method described above, but now we use  $\hat{\mu}/\hat{\theta}$  instead of  $\hat{\mu}$ . Here,  $\hat{\theta}$  represents the estimated value of the capacity needed for the WCS, which is necessary for the translation into firmware of the instruction patterns. It is also derived from the equations for estimating the tuning effect. Tuning is executed until the following condition is satisfied:

$$\hat{\mu} > \delta \quad \text{or} \quad \hat{\theta} > \delta'.$$

### Synthesis of new instructions

We make a selected instruction pattern into a new instruction. Each sequence of instructions is implemented in a single microprogram, which occupies less space and has a faster execution time than the original instructions. The tuning is based on the existing microprogram optimization techniques<sup>7</sup> which bring about reduction in the number of memory references, efficient use of internal resources and the possibility of parallel processing.

### Feedback

The synthesized instructions are stored into the WCS and also registered in the code generation part of the compiler. The codes being compiled are translated into corresponding new codes by applying an editing operation at the machine code level.

### Estimation of tuning effects

If no limitation is imposed on the capacity of the WCS, then optimal tuning may be achieved by synthesizing new instructions corresponding to the instruction patterns detected during the program execution. However, the capacity of the WCS is directly related to the cost of the system. It is also necessary to save time and effort in writing the microprograms.

It is difficult to give a quantitative evaluation of this effort. However, if we assume that the amount of work spent on microprogramming is proportional to the number of the microprogrammed steps, then the amount of labor will be proportional to the capacity of the WCS. Therefore, it is desirable to select instruction patterns which may combine maximal efficiency with minimal capacity of the WCS. To accomplish this, a simple method to estimate the firmware effect, that is the ratio of the execution efficiency improvement to the increase of the capacity of the WCS, when instruction patterns are implemented in firmware, must be developed. If such an estimation is possible, the selection of instruction patterns can be done based on the overhead of the tuning.

Here, we assume that the efficiency improvement resulting from the implementation of a microprogrammed new instruction ( $\mu$ ) is a function of the weight of the instruction pattern implemented in firmware ( $\xi$ ) and the increase of the capacity of the WCS ( $\theta$ ), that is,

$$\mu = f(\xi, \theta). \quad (1)$$

Further, we assume that  $\theta$  is a function of the length of the instruction pattern ( $\gamma$ ), i.e.

$$\theta = g(\gamma). \quad (2)$$

We determined the function  $f$  and  $g$ , experimentally.

In order to determine  $f$ , we determined  $\log(\mu/\theta^m)$  as a function of  $\log \xi$ . The result is shown in Figure 2, indicating an approximately linear relation. From Figure 2, we ob-

Figure 2—Relationship between  $\log \xi$  and  $\log(\mu/\theta^m)$ .

tained

$$\log(\mu/\theta^m) = n \log \xi + a, \quad (3)$$

hence;

$$\mu = A \theta^m \xi^n, \quad (4)$$

where  $a$ ,  $A$ ,  $m$  and  $n$  are constants determined by the IML instruction set under consideration.

Similarly, we obtained the relationship between  $\theta$  and  $\gamma$ , which is indicated in Figure 3. The relation is given by a linear expression:

$$\theta = b\gamma + c, \quad (5)$$

where  $b$  and  $c$  are constants determined by the IML instruction set.

Equation 4 includes that firmware effect can be estimated from the weight of an instruction pattern and the total steps

Figure 3—Relationship between  $\gamma$  and  $\theta$ .

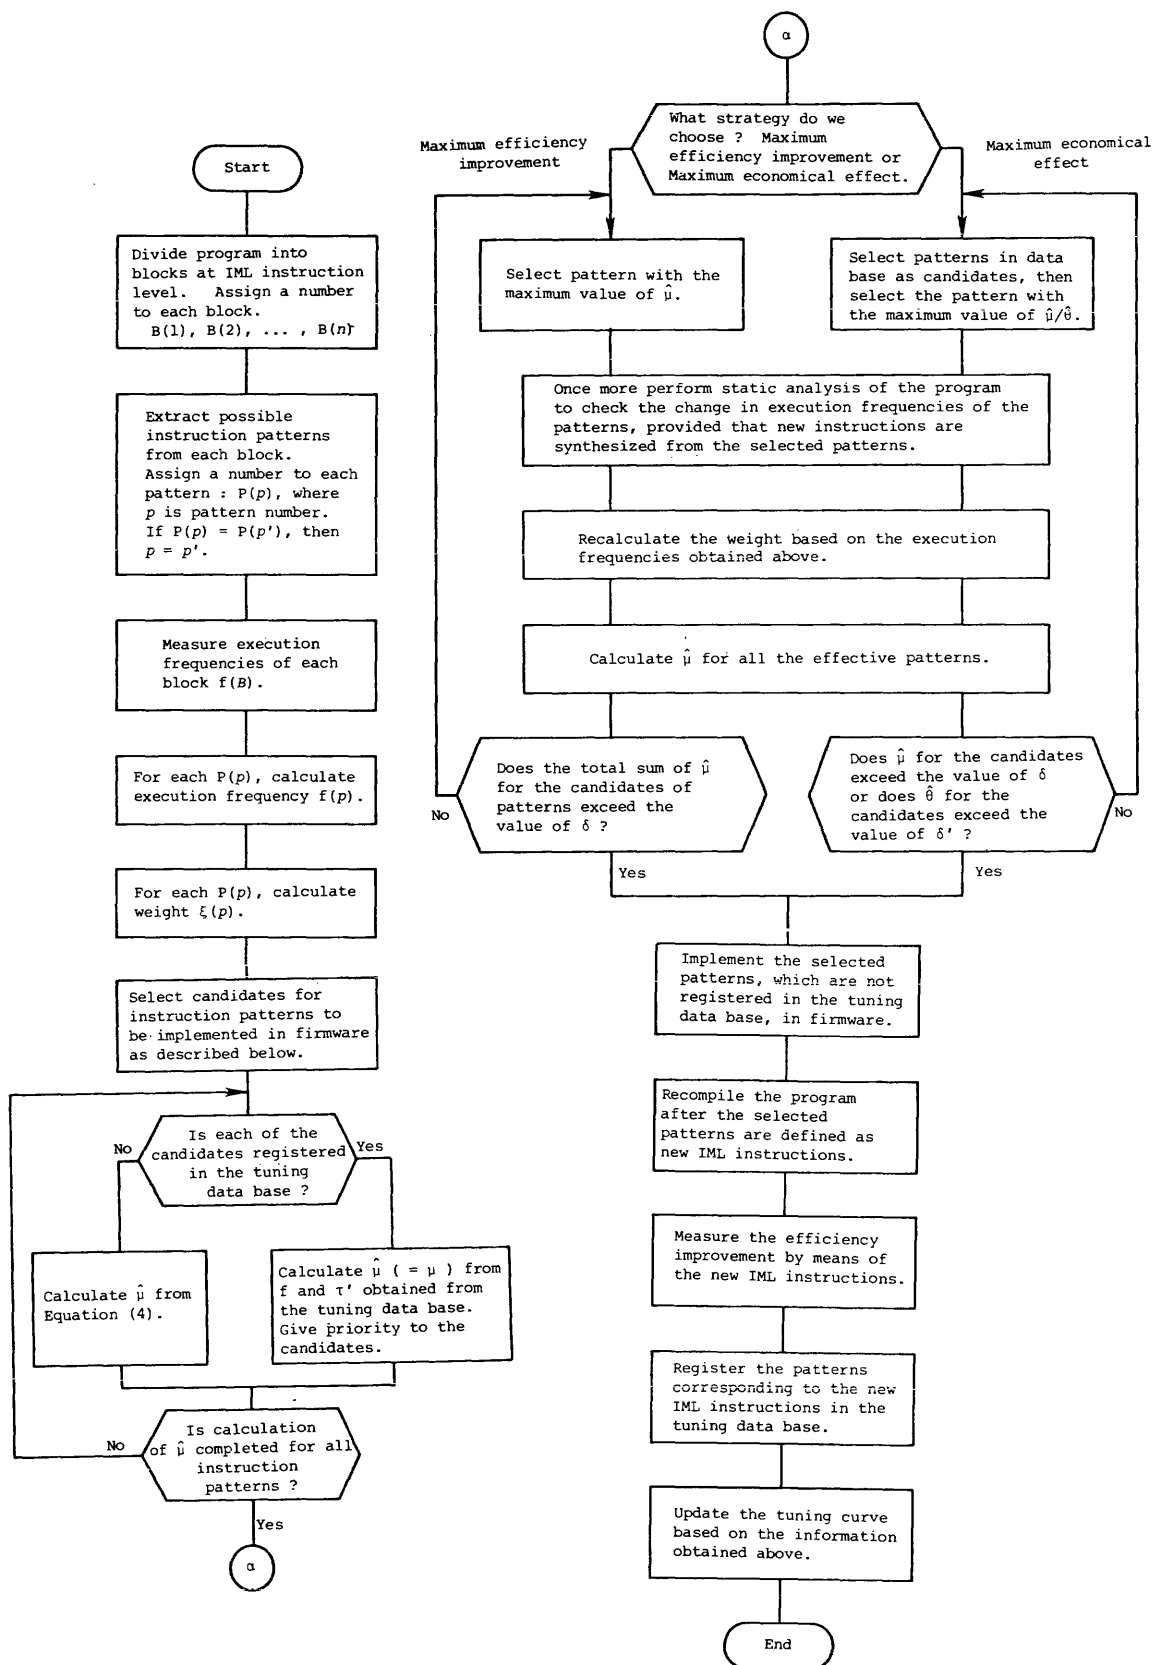

Figure 4—Simplified flowchart of the tuning algorithm.

required for the corresponding microprogram. Therefore, this relationship is called the "tuning curve."

Obviously, the constants  $a$ ,  $A$ ,  $m$  and  $n$  are positive and the larger the weight  $\xi$  and the increase of capacity of the WCS  $\theta$  become, the greater the efficiency improvement will be.

A simplified flowchart of the algorithm just discussed is shown in Figure 4.

*Implementation*

It should be noticed that the tuning procedure just described can be performed automatically. The following implementation mechanisms are required:

1. Either hardware or firmware monitor is used to determine the weight of the instruction blocks.
2. A dynamic microprogramming technique is employed to modify the contents of the WCS.
3. The compilers for high-level languages should be able to expand the IML instruction codes. A technique used for incremental compilers can be adopted for this purpose.
4. The mechanism for the synthesis of new instructions can be implemented on a minicomputer or microcomputer.

EXPERIMENTAL SYSTEMS

We call the tuning mechanism consisting of a Monitor, an Analyzer and a Synthesizer the "Automatic Performance Evaluator (APE)." We developed two simple APE mechanisms to prove the effectiveness of the principles described in the previous chapters.

*Experimental System-1 on a HP-2100 and hardware monitors*

The process flow of tuning and learning in the experimental system is shown in Figure 5. We used a HP-2100 computer as the host computer to be tuned up. The HP-2100 computer is a 16-bit microprogrammable minicomputer.<sup>8</sup> Since the machine instructions are incorporated in HP-2100, we can utilize two accumulators, while six other registers can be used with the micro-instructions.

The control storage consists of a ROM board with a capability of 256 24-bit words in which the microprogram that has to interpret the machine instructions is stored, and three WCS boards for user microprograms. Each WCS board has the same as the ROM.

We employed a DYNAPROBE 7900+8000 hardware monitor of COMPRESS Co. as the APE monitor. We used

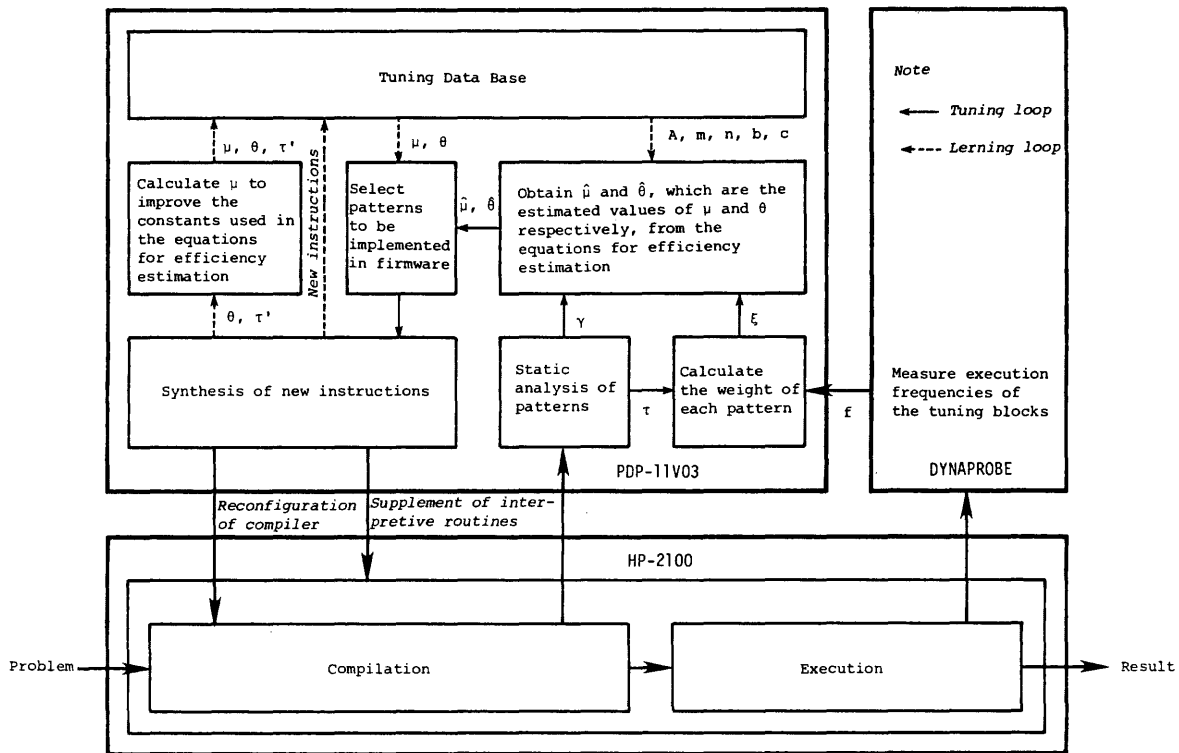

Figure 5—Process flow of tuning and learning in the experimental system.

a PDP-11V03 system to analyze or synthesize the output derived from the hardware monitor and further a D7916 count/time type hardware monitor and a D8028 map/store type hardware monitor to accumulate periods of time during which certain events have happened.

Figure 6 shows the block diagram of the experimental system. The program to be measured is executed on the HP-2100 host computer. The D7916 and D8028 hardware monitors collect signals generated from the host computer through probes in order to measure the weight of the instruction patterns.

The signals collected by the hardware monitors are directly supplied to the PDP-11V03 on which tuning analysis is carried out, the LSI bus of the PDP-11V03 is connected to the I/O bus of the HP-2100 through the I/O interface in order to make a feedback loop.

The LSI-11 is used for the analysis of instruction patterns, the reconfiguration of the IML instruction set and the organization of the data base in the tuning phase. To form a new IML instruction set, the microprograms for the synthesized instructions are stored into the WCS, that is incorporated in the HP-2100 through the I/O interface.

One of the main features of this system lies in the fact that there is no overhead in the monitoring function at all, since high-speed hardware monitors are used, and since the LSI-

11 is exclusively used for tuning analysis. Figure 7 shows several equipments of the experimental system.

#### Experimental System-2 on a Burroughs B-1700

The Burroughs B-1726 is a microprogrammable computer with a data length of 24 bits.<sup>9</sup> It provides many internal resources, such as four general registers and thirty two scratchpad registers. It can perform bit addressing and it has access to any sub-field of the registers. The capacity of the WCS which stores microprograms expressed by 16-bit words is 4K words.

We developed several S-code interpreters in which a firmware monitor was implemented. To measure frequencies of instruction patterns, a firmware monitor was incorporated in the microinstruction fetch routine in the S-code interpreter. Therefore, apart from the B-1700 computer no special hardware is necessary. Hereby, the monitoring overhead becomes larger and the time required for the instruction fetch is approximately twice as long as that in the original computer.

However, the tuning operation does not occur very often, and if it occurs, the microprogram for the monitor is removed and the S-code interpreter is reconstructed so that the total overhead does not become very large.

Figure 6—Functional configuration of the experimental system.

Figure 7—APE experimental system.

### *IMLs used for the experiments*

For the IMLs to be tuned up, we chose the following two languages:

1. The IML for PASCAL<sup>10</sup> which incorporates 60 instructions and is emulated on both the HP-2100 and B-1700 computers.
2. The FORTRAN IML for the HP-2100, i.e. sequences of machine instructions interpreted on the HP-2100 computer.

## RESULTS OF THE EXPERIMENTS

### *Tuning results*

Some tuning results are shown in Figure 8-Figure 11. Figure 8 indicates the tuning results when a sorting program is executed on the PASCAL machine emulated by the HP-2100. For the tuning procedure on the B-1700 PASCAL machine, see the Appendix.

If the strategy selected is maximum execution efficiency, it turns out that the execution efficiency is twice as high as

that of its corresponding non-tuned version, while the required capacity of the WCS is increased by 210 words when seven instruction patterns are selected. Further, the amount of the object code is reduced from 392 bytes to 284 bytes. This indicates that an effective code compaction is carried out during the static analysis of the program.

If the strategy selected is maximum economical effect, the capacity of the WCS is increased by 130 words, while the overall execution time of the program is reduced by 30 percent.

These results prove the effectiveness of the principles that we propose for automatic tuning of the computer architecture.

### *Frequently generated instruction patterns*

Table I is a list of the instructions frequently generated in maximum execution efficiency strategy as well as in maximum economical effect strategy. The detected instruction patterns in the former strategy consist of more machine instructions than those in the latter strategy.

The meaning of most of the long instruction patterns is indicated in the table. For instance, the instruction pattern,

(a) Maximum Execution Efficiency Strategy (Select the instruction patterns so that  $\bar{\mu}$  becomes maximal.)

(a) Maximum Execution Efficiency Strategy (Select the instruction patterns so that  $\bar{\mu}$  becomes maximal.)

(b) Maximum Economical Effect Strategy (Select the instruction patterns so that  $\bar{\mu}/\bar{\theta}$  becomes maximal.)

(b) Maximum Economical Effect Strategy (Select the instruction patterns so that  $\bar{\mu}/\bar{\theta}$  becomes maximal.)

(a) Maximum Execution Efficiency Strategy (Select the instruction patterns so that  $\bar{\mu}$  becomes maximal.)

(b) Maximum Economical Effect Strategy (Select the instruction patterns so that  $\mu/\bar{s}$  becomes maximal.)

Figure 10—Tuning results (matrix multiplication problem on the B-1700 PASCAL machine).

e.g. the loading of the contents of array elements into a register, is reflected in the environment of the problem to be solved. The characteristics of these instruction patterns will play a very important role in the design of ISP architecture for high-level language oriented computers in the future. On the other hand, the short instruction patterns detected in maximum economical effect strategy do not have any significance.

*IML structures and computer organization*

The best way to emulate an IML instruction set depends on the structure of the computer, which has a subtle influence on the tuning effect. For instance, the tuning results on the HP-2100 machine instruction is shown in Figure 11, indicating that the tuning effect is not great if we do not take the address patterns as well as the instruction patterns into consideration. This is because the machine instruction and its corresponding operand are simultaneously fetched by a hardware mechanism on the HP-2100, while it is impossible to fetch the microinstruction and its operand simultaneously in user microprogramming.

There are two methods to solve this problem:

1. If the tuning is performed using only instruction patterns, the structure of the HP-2100 has some disadvan-

tages, since the possibility of handling multiple operands is not taken into account. It is desirable to make it possible to expand the operand field at the microprogramming level. The microprogrammable bit addressing function incorporated in the B-1700 and the machine instructions concerning the manipulation of multiple operands provided in the PDP VAX-11/780<sup>11</sup> make this problem easier to handle.

2. If the tuning is performed using both instruction patterns and their corresponding address patterns, a better tuning effect is achieved. For instance, the broken line in Figure 11 indicates the tuning results using both the instruction patterns and the address patterns. This result was obtained by a manual procedure. However, it is possible to automate the tuning procedure using address patterns by modifying the proposed algorithm.

*IMLs and host computers*

We arbitrarily selected two IMLs, namely the PASCAL and HP-2100 machine instructions. Nevertheless, significant performance improvement is achieved. Therefore, if we would use an IML instruction set which is more suitable for tuning procedure, an even better performance achievement is to be expected.

The HP-2100 is intentionally designed for the machine instructions. Therefore, it does not have effective features for tuning. Although the B-1700 is an emulation-oriented computer, it seems to us that its microprogram capability is designed to integrate the hardware and software on the Master Control Program. Therefore, some of the well organized mechanisms were not utilized in the automatic tuning procedure.

We think an automatic tuning oriented computer should be developed in the future.

*Tuning curve and learning*

The tuning curve is shown in Figures 12 and 13. The experimental results confirm that the methods to estimate the tuning effect are useful for the proposed algorithm.

Maximum Execution Efficiency Strategy (Select the instruction patterns so that  $\bar{\mu}$  becomes maximal.)

Figure 11—Tuning results (bubble sort problem on the HP-2100 machine instructions).

Figure 12—Tuning curves (HP-2100 PASCAL machine).

As shown in Table I, the frequently generated instruction patterns are significant. These patterns may often be generated in other application programs. This proves that the proposed method is very effective to improve IMLs for a wide variety of applications.

## CONCLUSION

Development of a computer architecture that is adaptable to the problems to be solved is an important area of research. In this paper, we consider an automatic tuning of computer architectures at the ISP level using dynamic microprogramming techniques. After a brief explanation of the principles of the automatic tuning mechanisms, a detailed algorithm for the tuning procedure is described.

The basic processes of the proposed automatic tuning algorithm are:

1. Monitoring of the dynamic characteristics of the program to be solved.
2. Analysis of the monitored information to create new instructions.
3. Feedback of corresponding microprogrammed instructions to the WCS in the computer to form a new enriched architecture.

Figure 13—Tuning curves (B-1700 PASCAL machine).

4. A learning process with regard to the tuning behavior to guarantee faster achievement of performance improvement.

The first three processes are automatically carried out until the desired performance improvement is achieved.

In order to prove the effectiveness of the proposal algorithm, we carried out some experiments on a HP-2100 and a Burroughs B-1700 computer. Our experiments show that tuned programs are executed in 30-60 percent less time than the original programs.

It should be noted that dynamic microprogramming techniques are very effective to dynamically modify the computer architectures during the program execution. Our experiments proved that a computer can change dynamically so as to function optimally depending on the status of the problems to be solved, and that the learning effect is significant. We hope that the results of this research will contribute to the future development of adaptive computer systems and learning machines.

## ACKNOWLEDGMENT

We wish to thank Mr. Yamaishi, Mr. Kato and our colleagues of Keio University and the Electrotechnical Laboratory for their kind suggestions and assistance. We would like to gratefully acknowledge the support and counsel of many people of Burroughs Co., Ltd. in Japan.

## APPROACHES TO GROWTH IN COMPUTER USAGE

With the price of computer hardware decreasing steadily and the scope of data processing applications ever rising, the problem of upgrading a computer system is omnipresent. The myriad of potential pitfalls includes losing an investment in purchased hardware and software, reprogramming applications, reformatting data files, retraining personnel, operating two different systems in parallel during the conversion period and reoptimizing finely tuned applications.

### *Computer series*

Most computer vendors attempt to ease the pain of upgrades by offering an entire series of similar computers spanning a wide range of price and performance. Such series (e.g., IBM 360<sup>1,10,28</sup> and its successors, and PDP-11<sup>8,6</sup>) usually consist of a relatively constant machine architecture with different underlying implementations which yield faster and faster central processing units (cpus) and memories (see Reference 7, Part 6, "Computer Families").

Unfortunately, re-implementation of an architecture may result in forced changes at the user level; for example, a program or even the operating system may run on one implementation and not another. At the least, re-implementation is costly in terms of the additional design and manufacturing efforts required.

In addition, minimal configurations of cpus, memories, and peripherals are designed with the typical user in mind. Thus, it is common for a user requiring much central processing power but little I/O to be forced into a configuration sporting many unneeded data channels in order to get a powerful enough cpu.

### *Modular multiprocessor*

An alternative to the typical computer series with multiple implementations is a multiprocessor architecture which offers systems of one to many identical cpus, memories and data channels, thereby spanning the desired price and performance range. Cpus, memories and channels can be added independently to meet a particular processing need and without changes to user programs.

It costs less to design a simple cpu once and replicate it within an elegant multiprocessor architecture than to design many different, possibly very complicated cpus. Increased reliability because of redundant resources is an additional benefit of such a modular approach. Indeed, we feel that computer systems of the future should not have to depend upon the availability of a single cpu.

## BACKGROUND ON MULTIPROCESSING

There has been much interest in multiprocessing computer systems since the first, the Burroughs D 825,<sup>3</sup> appeared in 1962. A *multiprocessor* system has more than one cpu, each with its own stream of instructions operating on its own data stream. Such an architecture is often termed "MIMD" for these "multiple instruction, multiple data" streams.<sup>19</sup>

### *Homogeneity of resources*

There are many possible ways to classify MIMD architectures (Figure 1, after Reference 16). Perhaps the most useful is by their degree of *homogeneity*, or the degree to which resources of the system (processors, main memory, and peripheral units) can be shared indistinguishably (Reference 18, pages 104-105). This has also been defined as the quality that all resources of a particular type appear *symmetric* to the rest of the system.<sup>17</sup>

\* Currently at Systems Control, Inc., Palo Alto, California.

Figure 1—Multiprocessing aspects of some computers.

Adding capabilities to an existing system is straightforward when it is composed of homogeneous modules. The more homogeneous a system is, the more robust (i.e., less prone to catastrophic failure), because other equivalent resources are still available when one fails. Using only one basic design in each part of a multiprocessor also keeps design, manufacturing and programming costs to a minimum. And homogeneity allows more efficient utilization of resources, since each member of a particular resource pool is unrestricted as to what tasks it can do.

Most multiprocessors of the past have lacked homogeneity in at least one respect. The concept of homogeneous cpus, for instance, breaks down if a system has one general purpose processor and one or more special purpose processors, e.g., the fast floating point AP-120B array processor by Floating Point Systems.<sup>30</sup> In this case, programming for each type of cpu is obviously different and must be done explicitly. (Not to be considered a multiprocessor at all in this discussion is the typical computer with one general-purpose cpu and one or more special-purpose I/O processors, Reference 7, Part 5, Section 2, "Computers with One Central Processor and Multiple Input/Output Processors.")

Ideally, all cpus would have access to all of memory to make the sharing of programs and data simpler and more efficient, and thus cpus would not have local private memories (other than perhaps a small transparent cache for performance improvement). This type of cpu is often termed "closely coupled." The Tandem Computers T 16 NonStop computer,<sup>21</sup> which has nonshared memory for each cpu, must be regarded as a network of computers (each consisting of a cpu, I/O processor and memory) with partial sharing of peripherals. Similarly, the Datapoint Attached Resource Computer (ARC) and IBM's loosely coupled attached support processor (ASP) (Reference 7, page 506) are networks (Figure 2). The Carnegie-Mellon University C.mmp (based on Digital Equipment PDP-11 cpus)<sup>31,24</sup> and the Bolt Beranek and Newman PLURIBUS (based on Lockheed SUEs)<sup>20,26,4</sup> are hybrids, having both shared memory and memory private to each cpu.

The sharing of all I/O capabilities is the next aspect of homogeneity, one which is lacking in C.mmp, for example, because an I/O device must be attached to the Unibus of

one of its PDP-11s and is restricted to communicating with a local memory there. This is undesirable because the loss of either the cpu or its local memory isolates the I/O device from the rest of the system.

A final aspect of homogeneity concerns software, including both the operating system and user programs. Ideally, for efficient use of processor and memory resources there should be only one copy of one operating system which can be run on any of the cpus; this is the case with C.mmp. In practice, however, the typical multiprocessor system has resorted to having either separate copies of the same operating system running on each cpu or one copy restricted to always running on the same cpu (the common master-slave mode of many dual processor systems).

For reliability and efficiency it should be possible for any user program to run on any processor. Too often, applications are segregated to run on dedicated cpus. When segregation is done by entire classes of programs (e.g., interactive, batch, data base management), it may be a consequence of the lack of homogeneity in I/O. A common example of this is the restriction of interactive terminals to one cpu.

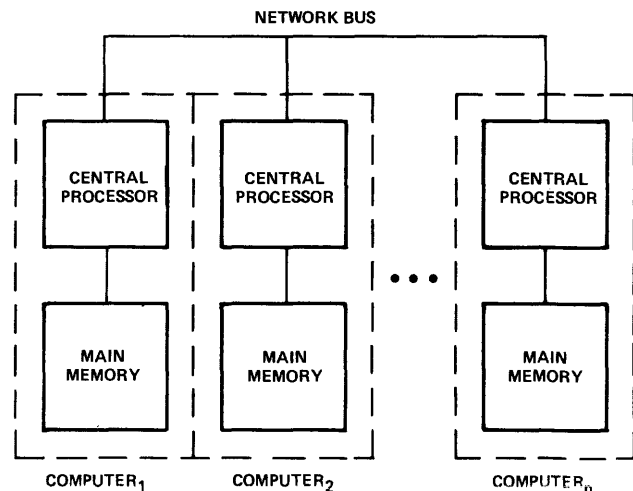

Figure 2—Architecture of a computer network.

### Purpose

Another dimension of multiprocessors is their purpose. Most successful multiprocessors have not been designed for the general purpose commercial computing environment. The D 825 and the Bell Telephone Laboratories CLC (part of the SAFEGUARD ABM system)<sup>25</sup> were designed for real-time military command and control applications in which maximizing both overall throughput and reliability was paramount. The T 16 was designed for transaction processing applications in industries, such as banking and airlines, in which continuous system availability is required. PLURIBUS was designed as a packet-switching node for the ARPAnet. One-of-a-kind research prototypes have included C.mmp and the University of California at Berkeley PRIME,<sup>5</sup> designed for real-time artificial intelligence applications and timesharing, respectively.

Many computer manufacturers have introduced multiprocessing to extend the high-end capabilities of a computer line. Examples are the Sperry Rand Univac 1108,<sup>27</sup> IBM 370 MP,<sup>23,15</sup> and DECsystem-10<sup>9</sup> dual processors. These architectures were not designed from the start with a multiprocessor in mind. So we often observe systems which could theoretically support a number of processors, but in practice never have more than two.

Closely related to the purpose of a multiprocessor is the way in which user programs are expected to take advantage of its multiprocessing capability. There are two basic philosophies.

The first is most useful for special-purpose multiprocessors (e.g., C.mmp, PLURIBUS, CLC) dedicated to running a small number of large, known programs. In this case the user must explicitly segment an application into a number of independent programs. These programs, called *processes*, are designed so that they may run concurrently, thus taking advantage of the multiple cpus available. Segmenting a program currently must be done by hand by the programmer or analyst and is not a simple task.

The alternative used in general purpose multiprocessors, especially in time-sharing, is to rely upon the job mix of a multiprogramming environment to provide enough processes (one per job) to keep all cpus busy. This avoids the programmer headaches of program segmentation and also avoids the system overhead resulting from the interprocess communication needed to coordinate processes. Of course, it is desirable to allow such coordination, while not requiring it.

### Processor-memory interconnection schemes

Probably the most critical design decision in a multiprocessor architecture is selection of the method by which main memory is interconnected to the cpus and peripheral processors (channels). The bandwidth of this interconnection switch provides an upper bound on the number of processors which can be handled, and thus on the throughput of the entire system.

Four basic schemes have been used. In decreasing order

of complexity and potential throughput, they are

1. A crossbar switch or matrix connecting each memory unit with each processor.
2. Multiported memory, in which each memory provides a port for a connection from each processor.
3. Multiple buses, each of which connects some cpus, memories and other buses (which may in turn connect to other cpus, memories and buses).
4. One common time-shared bus, over which all data traffic must pass.

Although the first three alternatives provide concurrent transfers between more than one processor-memory pair (Figure 3), analogous to a telephone switching exchange in which more than one conversation can occur simultaneously, they are also relatively expensive and typically only used in large systems. The D 825 and C.mmp used crossbar schemes, while the dual processor IBM 370 MP systems, Univac 1108, and DECsystem-10 (along with most other multiprocessors) rely on multiported memory.

The complexity (and hence cost) of a switch is proportional to the number of hardware switching elements it has, which in turn depends on the number of unique interconnections allowed between processors and memories. If each of  $p$  processors is to be capable of "talking" to each of  $m$  memories in parallel, then there must be  $p \times m$  unique interconnections. If, on the other hand, each processor and memory need only be able to talk to a single common bus, then the number of interconnections is reduced to just  $p+m$ . For systems with more than two cpus and two independent memories, the difference in the complexity of the two schemes becomes immense.

Until now, no one has developed a bus fast enough to make a multiprocessor using a single timeshared bus feasible (Figure 4), analogous to a telephone exchange in which all subscribers are on a single party line. For example, limited by buses with 200-nanosecond data transfer rates, a PLURIBUS system requires multiple buses, each bus connecting up to two processors and two memories. Up to seven of these buses may then be connected to shared memory and peripherals by still other buses.

ARCHITECTURE OF THE BTI 8000

The BTI 8000 computer system was designed to be a general-purpose system featuring inexpensive, modular resources for easy upgrading and high reliability, interactive time-sharing, an easy-to-use and constant virtual machine for the user and high-level programming languages.<sup>11</sup>

In light of these goals, the BTI 8000 was designed from the beginning with fully homogeneous, general-purpose multiprocessing as an objective. To our knowledge it is the first system to meet this goal, while also being the first general purpose multiprocessing minicomputer. The BTI 8000 is homogeneous with respect to cpus, memory, peripherals, operating system and user programs.

A BTI 8000 system (Figure 5) is based on 32-bit words and consists of a number of modular *resource units*.

1. Computational processing units (CPUs). (This paper denotes a computational processing unit of a BTI 8000 by "CPU" and an arbitrary central processor by "cpu.")
2. Memory control units (MCUs) and associated memory.
3. Peripheral processing units (PPUs) and associated I/O peripherals.
4. System services unit (SSU).

Up to 16 of these resource units (each of which is actually a microprogrammed processor) communicate via a single

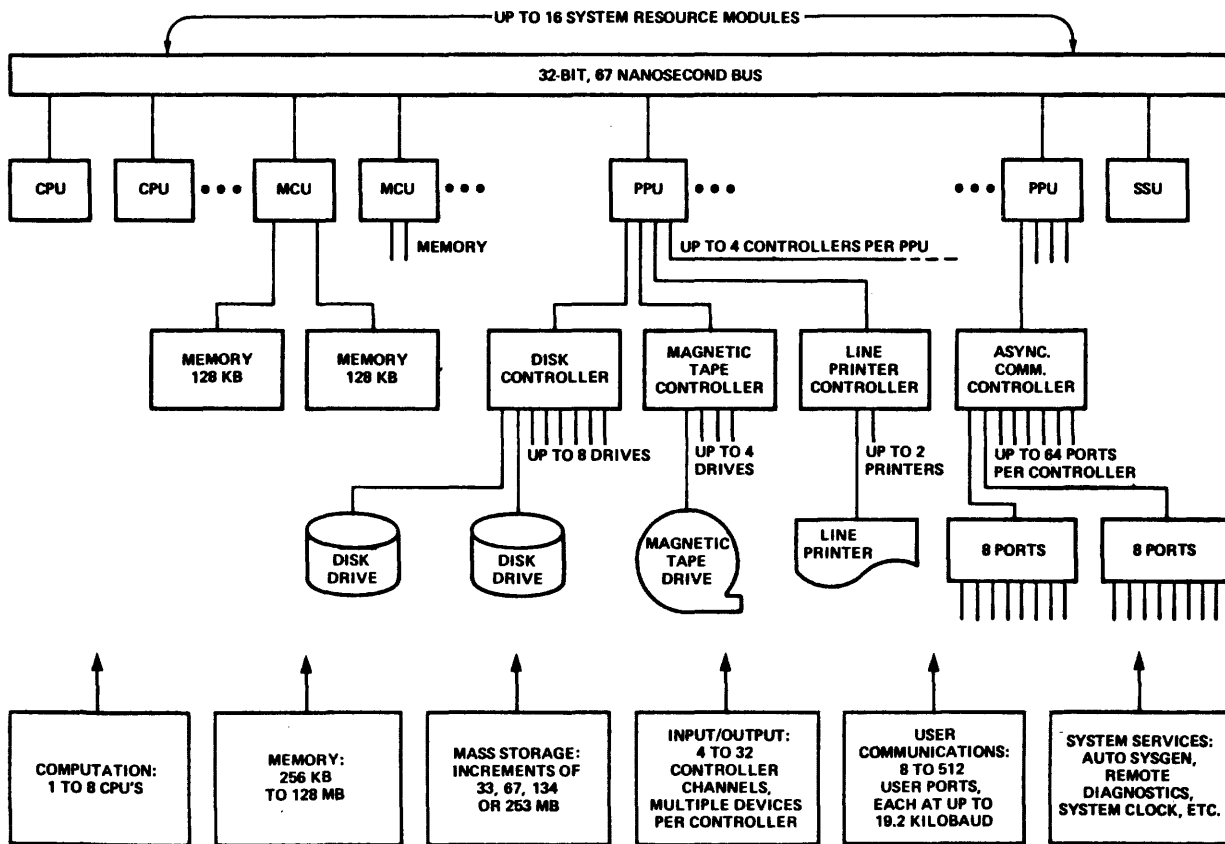

Figure 5—Block diagram of the BTI 8000 architecture.

32-bit-wide directly connected common (or "global"<sup>29</sup>) time-shared (or functionally and physically "non-dedicated"<sup>29</sup>) bus. Its speed is the key to the success of the 8000 as a multiprocessor. The bus can transfer one 32-bit word every 66.7 nanoseconds, or 15 million words (60 million bytes) per second. This speed is possible because the passive, synchronous bus relies upon distributed (or "decentralized"<sup>29</sup>) control logic for fast resolution of the bus contention arising from simultaneous, independent bus requests from two or more resource units.

The hardware modularity (along with an operating system which requires no reprogramming to handle hardware re-configuration) makes possible both easy system enhancement and graceful degradation. A small user may start out with the minimum system configuration, comprising one each CPU, MCU, PPU, and SSU and corresponding to a medium speed minicomputer. As system requirements increase, additional resource units can be added, resulting in a system which has a throughput rivaling that of many mainframes, but which is much more cost effective. For example, an additional CPU costs a fraction of the price of a complete system and consists of one 20-inch-by-23-inch printed circuit board ready to be plugged into the bus (Photograph 1). A typical large 8000 configuration might consist of six CPUs, six MCUs, three PPUs, and one SSU.

Because all CPUs must communicate via the same bus to the same homogeneous memory, the question arises, how badly will bus and memory contention degrade performance in a system with more than one CPU? In many multiported memory multiprocessors, for example, more than two cpus are impractical because the cpus are faster than memory and not enough memory ports are provided. In contrast, the number of CPUs and MCUs in a BTI 8000 can be flexibly chosen based upon the relative speeds of each type of resource. And the bus is fast enough so that contention for it is minor.

Simulation studies of various configurations of CPUs, MCUs and PPUs have been run assuming typical memory accesses for each type of processing unit. An 8000 system with six CPUs, six MCUs, and two PPUs should have the throughput of approximately five separate 8000 systems, each having one CPU, one MCU and one PPU (Figures 6, 7). Each of these five systems would, of course, require its own SSU, bus, and peripherals. So for equivalent throughput, the multiprocessor configuration requires one additional CPU and MCU, but eliminates the redundant three PPUs, four SSUs, four buses, four sets of peripherals, four sets of power supplies, four system cabinets, etc. The multiprocessor will become even more attractive as the cost of CPUs and MCUs continues to drop with respect to the cost of other system components.

#### Bus protocols

The common bus is a number of parallel lines which may be grouped into

1. Four lines identifying the bus slot to which the current message on the bus is being routed.

Typical Multiported Memory Multiprocessor		
Cpus	Throughput (cpu equivalents)	Additional Throughput from Additional Cpu
1	1.0	
2	1.7	.7
3	2.1	.4
4	*	*
5	*	*

CPUs,MCUs,PPUs	Throughput (CPU Equivalents)	Additional Throughput from Additional CPU
1,1,1	1.0	
2,2,2	1.9	.9
3,3,2	2.7	.8
4,4,2	3.5	.8
5,5,2	4.3	.8
6,6,2	4.9	.6
7,7,2	5.5	.6

Figure 6—Throughput of multiprocessors.

2. Two lines identifying the type of message currently on the bus.
3. 32 data lines containing the message.
4. A number of control lines which allow the resource units to resolve bus contention.

All traffic on the bus takes place in terms of messages between a source and a destination resource unit. Furthermore, all resource units use the same types of messages.

There are three message types—command, data and abnormal data. A command message is a request from one resource unit to another to carry out a specified function. A data message has 32 bits of data on the data lines (e.g., a word read out of memory by an MCU and being sent to a CPU). An abnormal data message is sent instead of a data message if an error occurs in trying to provide data. In this case the data lines contain error information.

A command message has a type code on the four high-order data lines, has an address or request code on the lower 22 lines, and leaves the other six lines unused. There are five command types—information request (known as "who are you"), read, write, read/modify/write, and self test (which starts microcode diagnostics).

Depending upon the request code, an information request can ask a resource unit to return a data message identifying its resource unit type, interrupt status, bus error status, error count, etc. This could then be used, for instance, by the SSU to determine the system configuration upon reload (e.g., how many CPUs are now on-line and occupying which bus slots).

A read command specifies the 22-bit address of the requested word to the destination resource unit. The destination responds with either a data message containing the

Photograph 1—BTI 8000 CPU board and chassis for up to 16 resource units.

Figure 7—Throughput graph for multiprocessors.

contents of the requested word or an abnormal data message containing error information.

A write command specifies the 22-bit address to be stored into the destination unit. This is followed by a data message containing the word to be stored.

A read/modify/write command is only sent to an MCU. The MCU returns the contents of the addressed word in memory in a data message and then waits for the source resource unit to send another word to be written back into the same location. In the interim the MCU denies other access to that memory location. This is the hardware feature which makes process interlock mechanisms possible on the 8000.

#### *Computational processing unit*

Because the system relies upon multiple CPUs working concurrently to achieve high throughput, the CPU design was purposefully kept straightforward and inexpensive. Each CPU is an identical microprogrammed processor with

a program state described by eight 32-bit general-purpose registers, a 17-bit program counter, a 17-bit current console area register, a 15-bit process status register, a 32-bit monitor status register and a page map of 256 20-bit words.

The current console area register points to the 10-word block of memory which stores the user's program state during an interrupt. This register, instructions which load and store the entire console area, and interrupt firmware which stores the area automatically all enhance the speed of context switching.

The process status register contains flags for arithmetic faults and condition bits set by compare operations.

The monitor status register contains information accessible only to the monitor, such as the processor number (i.e., the bus slot the processor is plugged into), interrupt enabling flags and paging control flags.

Every virtual memory address is transformed into a physical address by a calculation involving the page map. The page map is divided into two 128-word halves, one for the monitor and the other for the current user. Which half is used is controlled by bits in the monitor status register.

Memory is divided into pages of 1024 words. Of a 17-bit virtual address, the upper seven bits select a word in the page map and the lower 10 bits a word within the physical page. The physical page is determined by the selected word of the page map. Of this 20-bit word, 12 bits determine the physical page and four bits the bus slot. This scheme allows for many MCUs, each containing  $2^{22}$  ( $22=12+10$ ) words of memory, and means that PPU and MCU are addressed identically. The remaining four bits in the page map word determine the legal types of access to this page (e.g., execute only, read only, read/write) and note whether the page has been read or written.

#### *Memory control unit*

An MCU is a "slave" resource unit in that it operates only in response to commands from other units, i.e., it does not originate commands itself. Its microprocessor selects one of two memory devices, handles error conditions occurring in memory and locks out other references to the MCU during a read/modify/write cycle (discussed under "Bus Protocols"). The data paths within an MCU are 32 bits wide.

#### *Peripheral processing unit*

A PPU handles up to four I/O controllers, two for high-speed devices (disk or high-speed tape drives) and two for slow devices (e.g., low-speed tape drives, line printers, and interactive terminals). Data transfers between a PPU and its controllers occur in eight-bit bytes and are buffered by FIFO queues.

A CPU initiates I/O by writing control information into the appropriate PPU. Some of this information is passed on to the controller being addressed. Other information (e.g., the MCU memory starting address for a block transfer) is stored in the local RAM of the PPU's microprocessor. Once a DMA (direct memory access) transfer is begun between the MCU and PPU, the originating CPU is free to do other tasks until completion of the transfer.

The disk and communications controllers are also microprocessor-based.

#### *System services unit*

The SSU performs a number of functions which need only be done in one place in the 8000. Among these are (1) providing the system-wide clock for synchronizing bus operations, (2) providing a real-time clock readable by other resource units, (3) sensing abnormal environmental conditions (e.g., temperature, humidity), (4) providing a local system status and reload capability via an extremely simple front panel and (5) providing remote diagnostic and preventive maintenance capabilities for BTI personnel via a dial-up communications port.

## INSTRUCTION SET ARCHITECTURE

The instruction set processor of the CPU was designed to (1) keep bus traffic due to instruction fetches to a minimum and (2) to enhance the efficiency of the operating system, system utilities, compilers and compiler-generated code. These two goals have led to a rather high-powered instruction repertoire—there are 10 data types, approximately 200 different operation codes, and about 50 addressing modes.<sup>12</sup>

#### *Data types*

Data types supported include 32- and 64-bit fixed point numbers, 64-bit floating point numbers, eight-bit ASCII characters, one-bit Boolean values, 32-bit pointers, one- to 32-bit bytes, arrays of all of the preceding types, linked lists and pushdown stacks. Arithmetic is two's complement. There is a special "undefined number" value (a leftmost one bit followed by 31 or 63 zero bits) which may cause an error trap when used. A byte may cross the boundary between two words.

#### *Instruction set*

All instructions comprise one 32-bit word in which the leftmost 10 bits define the operation code, sometimes specifying a general register to be used, and the rightmost 22 bits specify the operand. The instruction set is fairly complete, providing most useful variants of each instruction, e.g., reverse subtract and reverse divide.

As a precautionary measure to prevent runaway programs, operation codes which arise in common data words are illegal. These include words containing all zeros or all ones, containing the undefined number, or starting with an ASCII space.

Arithmetic, Boolean, and compare instructions all have both register-to-register and register-to-memory modes. Also, certain arithmetic operations store the result into both a register and memory. Arithmetic reverse subtraction and division, as well as Boolean subtraction and reverse subtraction, are provided.

To support process synchronization, a number of instructions can read and write a word of memory in one indivisible step. In this class of instructions are the four Boolean operations to memory, the set and test operation, an operation which exchanges a register with a word in memory, and the seven single-word fixed point add and subtract to memory instructions.

#### **Instructions to enhance systems software**

A number of instructions simplify common tasks done by systems software. Two instructions jump based on the value of a particular bit of a register. Other instructions store in memory useful constants such as 0, 1, -1, and the "unde-

defined" value. One instruction jumps to itself without requiring any subsequent instruction fetches from memory, effectively causing the CPU to do nothing until interrupted.

The permutation operation computes the exclusive OR of those words in a contiguous 32-word block of memory which are indicated by a one in the corresponding bit position of a register. Thus, the bits in a register may be permuted according to a pattern defined in the 32-word block of memory. A checksum of a block of memory is computed by initializing the controlling register to all ones. By loading the register with a data word and memory with 32 words containing the integer 1, the parity of the register is computed.

### Operations on linked lists

Linked lists are supported by instructions which advance to the next element of a list, testing for the end of the list. Both one-way and two-way lists may be used.

A one-way list consists of a number of list *elements*, or blocks of memory of arbitrary size. The address field (rightmost 17 bits) of the first word of each element contains the address of the successor element in the list, or zero if there is none. A pointer to the current place in the list is kept in a register. If a list is to be left unmodified, this is all the information necessary to traverse it. If, however, elements are to be inserted or deleted, an optional pointer to the predecessor of the current element is maintained in an adjacent register.

In place of the address of its successor, an element of a two-way list has the exclusive OR of the addresses of its left and right neighbors.<sup>22</sup> Call this  $l \oplus r$ . An important property of exclusive OR is that  $(l \oplus r) \oplus l = r$  and  $(l \oplus r) \oplus r = l$ . Thus, given the addresses of an element and one neighbor, the address of the other neighbor can be calculated. So the instruction to move ahead in a two-way linked list *requires* that pointers to both the current and previous elements be in adjacent registers. An example Exclusive OR Link and Jump on Non-Zero Address instruction is

```
HERE: XLJNA i THERE
```

The effect of executing this instruction is defined by the following program, and is shown graphically in Figure 8.

```
temp ← registeri+1;
registeri+1 ← registeri;
registeri ← temp ⊕ contents (registeri+1);
if registeri ≠ 0 then pc ← THERE;
```

Also, an instruction is available which searches a one-way linked list for an element containing a specified key. The key may be a word, character, or byte which is offset a fixed amount from the first word of the list element, as specified in the instruction. One register is loaded with a pointer to the first element to be examined. After a successful search, it points to the desired element. Another register holds the key being searched for.

### Subroutine linkage instructions

A group of 27 instructions is provided for subroutine linkage, including parameter passing and type checking and ensuring that a legitimate subroutine is called. The following example shows a typical pair of calling and entering sequences:

```

:
C: CALL S      S: ENTR REG7
   PAR  A1     STP  F1
   PAR  A2     STPV F2
   PAR2 A3     STP2 F3
   PARV A4     STPV F4
   PARL A5     STPL F5
C+6: :         : [subroutine body]
                        LEAVE REG7
```

Here the main program on the left calls subroutine S, passing it five actual parameters, A1 through A5. After type checking and storing the parameters into local locations F1 through F5, the body of the subroutine is executed, and then control is returned to the main program at C+6.

These instructions use general registers R0 for passing single-word parameters, R0 and R1 for double-word parameters and R7 for holding the next address and parameter specifications.
