The CALL Subroutine instruction ensures that the instruction located at S is some type of Enter Subroutine (ENTR being the simplest of these), saves the contents of R7 in memory location REG7 and puts S+1 in R7.

The PARAMeter instruction at C+1 stores its type (in this case, single-word call by reference) along with C+2 in R7, loads R0 with the address A1, and jumps to the address previously in R7 (S+1).

The STP Store Parameter instruction at S+1 ensures that its desired type is the same as that of the actual parameter, as defined in R7 (it is). Then the contents of R0 (A1) are stored in F1, S+2 put in R7, and control returned to C+2.

The rest of the corresponding Parameter and Store Parameter instructions are executed in interleaved order until a Store Parameter Last (STPL) is encountered. This instruction marks the last parameter, so control passes into the body of the subroutine instead of returning to C+6 for more parameters.

At the end of subroutine execution, the LEAVE Subroutine instruction returns to C+6 (assumed to still be in R7) after restoring R7 from REG7.

Suffixes "2" and "V," singly or together, on PAR and STP operation codes define double word and call by value types. For example, PARV2 A6 will load the 64-bit value located at A6 and A6+1 into R0 and R1. There are three other type bits available to distinguish, e.g., fixed and floating point operands.

Some type coercion is possible. The PAR at C+2 is call by reference, while the corresponding STPV at S+2 specifies call by value. The STPV is smart enough to load indirect through R0 to get the value stored at A2.

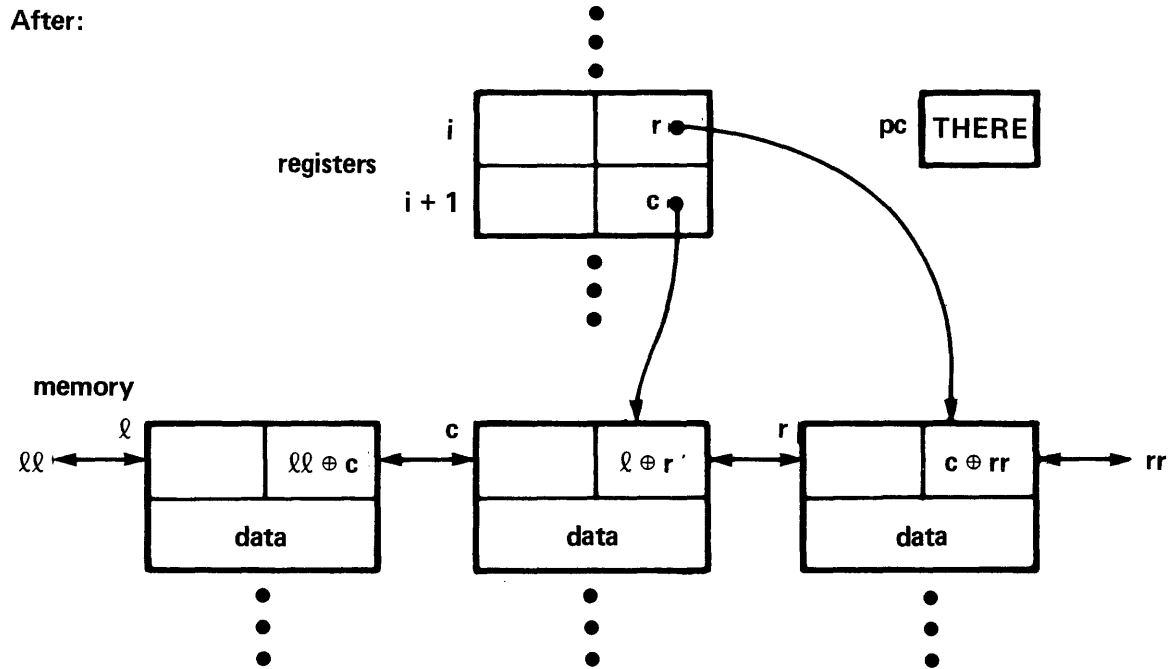

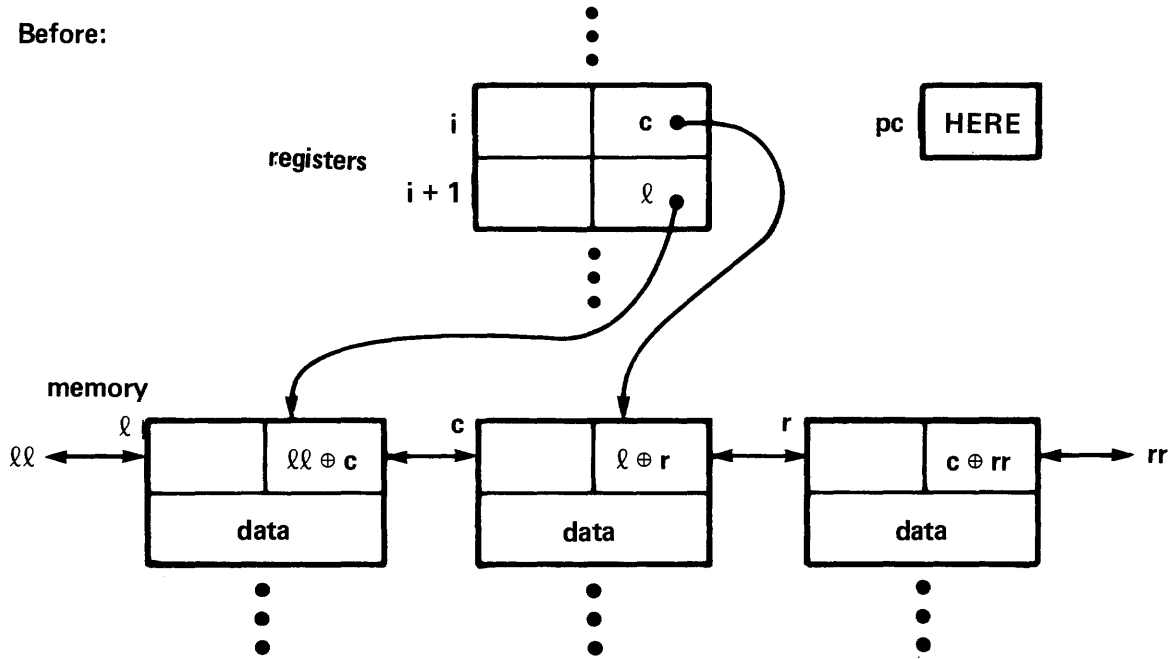

Figure 8—Registers and memory snapshots of "Exclusive OR Link and Jump on Non-Zero Address" instruction.

**Instructions for compiled code**

To improve compiler efficiency, an instruction exists to load an effective address. It performs the address calculation done for a load, but loads a register with this computed address instead of the value contained there.

Four instructions trap if an array index is out of prescribed

bounds. The instructions handle single word integer, double word integer and floating point indices.

*Addressing modes*

Much of the power of the BTI 8000 instruction set arises from its wealth of ways to address data. As discussed in the

previous section, each 32-bit instruction has its operation code in the upper 10 bits. This leaves 22 bits to define the way in which the operand, operands and/or the location to store the result will be determined. Two instruction classes don't use the addressing modes. Jump instructions use the lower 22 bits as a five-bit number defining which bit to test and a 17-bit jump address. Character instructions have a five-bit extended operation code, and the Character Fill instruction also has an eight-bit immediate operand.

Completely separating designation of the operation codes from the address modes implies that any operation may utilize any address mode which is well defined for that operation. For example, in a single instruction one could

add to a register an integer which is stored as a three-bit byte, split across the boundary of two words of memory. For a 32-bit add, the three-bit byte would be right justified and padded with 29 zero bits; for a 64-bit add, an additional word of padding would be provided. Conversely, storing a register into such a three-bit byte location in memory would only use the rightmost three bits of the register.

**Addressing mode formats**

There are six different formats for addressing modes (Figure 9). The format, as well as the specific address calculation

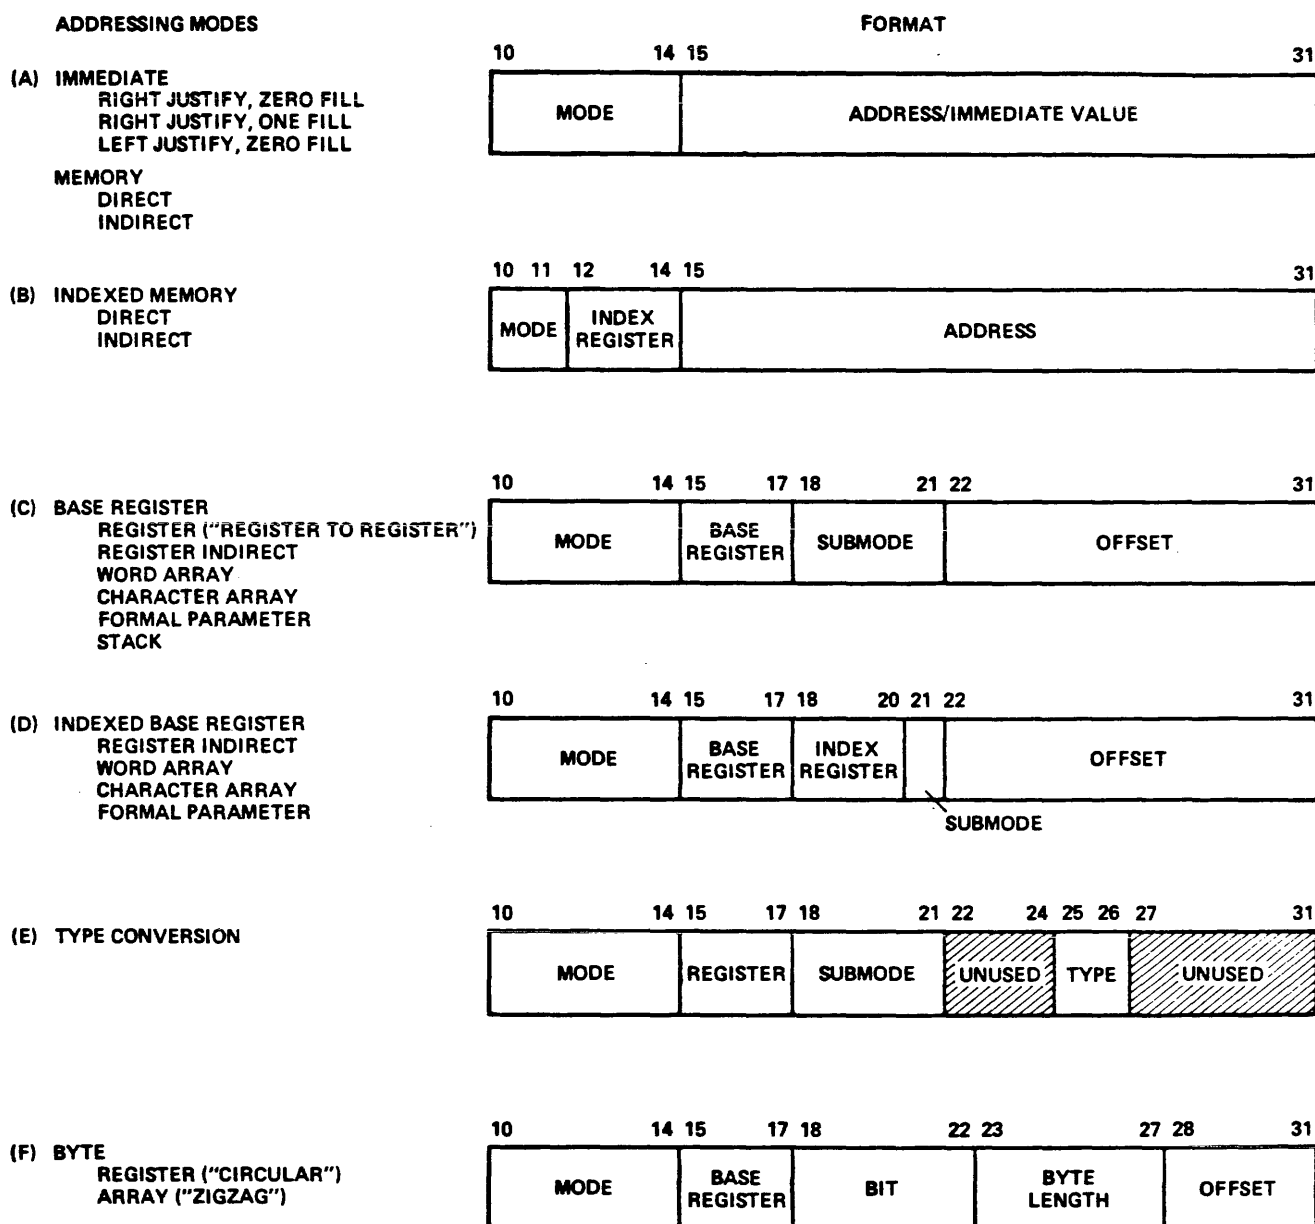

Figure 9—Instruction addressing modes and formats.

to be done, is determined by the mode field of the instruction.

Address mode format A is the simplest one. It is used for direct and indirect access of the memory word specified in the address field. In addition, the address field may be used as an immediate operand in three ways—right-justified with zero fill, right-justified with one fill, and left-justified with zero fill.

Format B specifies a register to be used to index the result of a direct or indirect address calculation. For instructions dealing with 64-bit operands and results, the index register is added twice.

Format C specifies a base register and a constant index or offset. Depending on the submode, six calculations are possible. The simplest of these uses the specified register directly, adding the offset to the contents of the register to form an operand. When addressing a result, the offset is subtracted from the result before the result is stored in the register. The second submode uses the register as an indirect pointer. The next three submodes use the register to point to the base of an array and the offset to specify the desired array element. The array can be of words, characters, or formal parameters, which are indirect pointers to the actual parameters of a procedure. The sixth submode uses the register as a pointer to the top of a stack (pushdown list) growing downward from high memory addresses to low. The register is decremented by the offset prior to storing a result, thus pushing the stack. After fetching an operand from the top of the stack, the register is incremented by the offset to pop the stack. For an instruction which loads an operand and stores a result, the stack is both popped and pushed.

Format D has four calculations analogous to format C, but with the added capability of indexing with a register the final address calculated. An extra mode is used because the submode field is limited to one bit to accommodate the index register field.

Format E specifies type conversion to be done upon loading or storing one or two consecutive registers. For loading an operand from the register(s), three submodes specify converting either a 32- or 64-bit integer into either a 64-bit integer or floating point quantity. The register(s) are unchanged. When storing a result into the register(s), the inverse conversion is done. The type field has bits specifying whether integers are considered signed or unsigned and whether to round or truncate upon conversion.

Format F is used for two byte-accessing modes which allow the 8000 to omit shift instructions. In the first the

register is considered to be a circular list of bits, and a byte is referenced starting at the specified bit and extending for the specified length. The offset is unused in this mode. The second mode uses the register as the bit address of a bit array. The desired byte in this array starts with the bit indexed by 32 times the offset plus the bit field. The size of the byte is specified by the byte length field. The byte may cross a word boundary, hence the name "zigzag byte" for this addressing mode.

#### Format of pointer words

Words used as pointers to fields in memory use the format shown in Figure 10. A base or index register for a word array uses only the address field. A base or index register for a character array in addition uses the character field to select a particular character of the word addressed. The base register for a bit array also uses the bit field to specify a bit within the character.

The mode field is used in pointer words in a register or memory which are specified by instructions in an indirect addressing mode. Four of the pointer's own modes specify direct addressing and three forms of immediate operands, as discussed earlier under address mode format A. In these modes the character, bit and byte length fields are unused. The fifth pointer mode uses the character field to select a character in the word addressed. The sixth pointer mode references a word of memory and a zigzag byte within that word. The byte starts at the bit specified by the bit field within the character specified by the character field. Indexing a pointer in zigzag byte mode causes the index register to be multiplied by the length field before being added in, thus allowing indexing of an array with elements of arbitrary byte size (not greater than 32 bits).

#### IMPLEMENTATION

Little has been said about the implementation of the 8000. This has been deliberate. Because memory and logic circuits are continuing their well established trend toward smaller size, lower cost and higher performance, the design philosophy has been to separate specific implementation decisions from the system architecture as much as possible. Thus, a future implementation of a system component should be able to take advantage of advances in integrated circuit technology.

Figure 10—Format of pointer words.

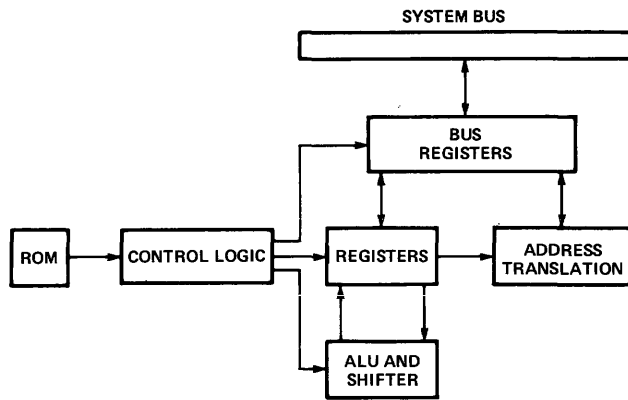

Figure 11—Computational processing unit.

Especially important in this regard was the decision to make every resource unit be a microprogrammable computer with its own internal microprocessor, memories, data paths and I/O connections (current architecture shown in Figures 11-14). From the viewpoint of the resource unit, these I/O connections include the common system bus plus main memory (in the case of an MCU), standard I/O controllers (in the case of a PPU) and special devices such as a thermometer (in the case of the SSU). Each of these computers may now be treated as possessing a flexible ar-

chitecture, easily changed when desirable, as long as the I/O characteristics of each computer do not change.

SYSTEMS SOFTWARE

A user of the BTI 8000 is presented with a virtual machine which is independent of a particular physical configuration.<sup>13,14</sup> For example, if an additional CPU is required to meet increasing system load, it is merely plugged into the bus and the operating system is reloaded at the push of a single button. The system automatically recognizes the hardware reconfiguration; no user reprogramming is required. In fact, a user never knows—and need not care—on which CPU his program was run. Similarly, a failing CPU in a multiprocessor configuration is merely unplugged from the bus, followed by the same reload. The only difference noticed by a user may be a degradation of response time. Because of virtual memory mapping, physical memory can be similarly reconfigured without affecting the user's access to 131,072 (128K) words (512K bytes) per user process.

The 8000 is designed to facilitate the use of high-level languages, including PASCAL, FORTRAN, BASIC, COBOL and RPG. The use of vendor-supported PASCAL is promoted because of its applicability to structured programming and the specification of concurrent processes. Unlike uniprocessor systems, a software process on the BTI

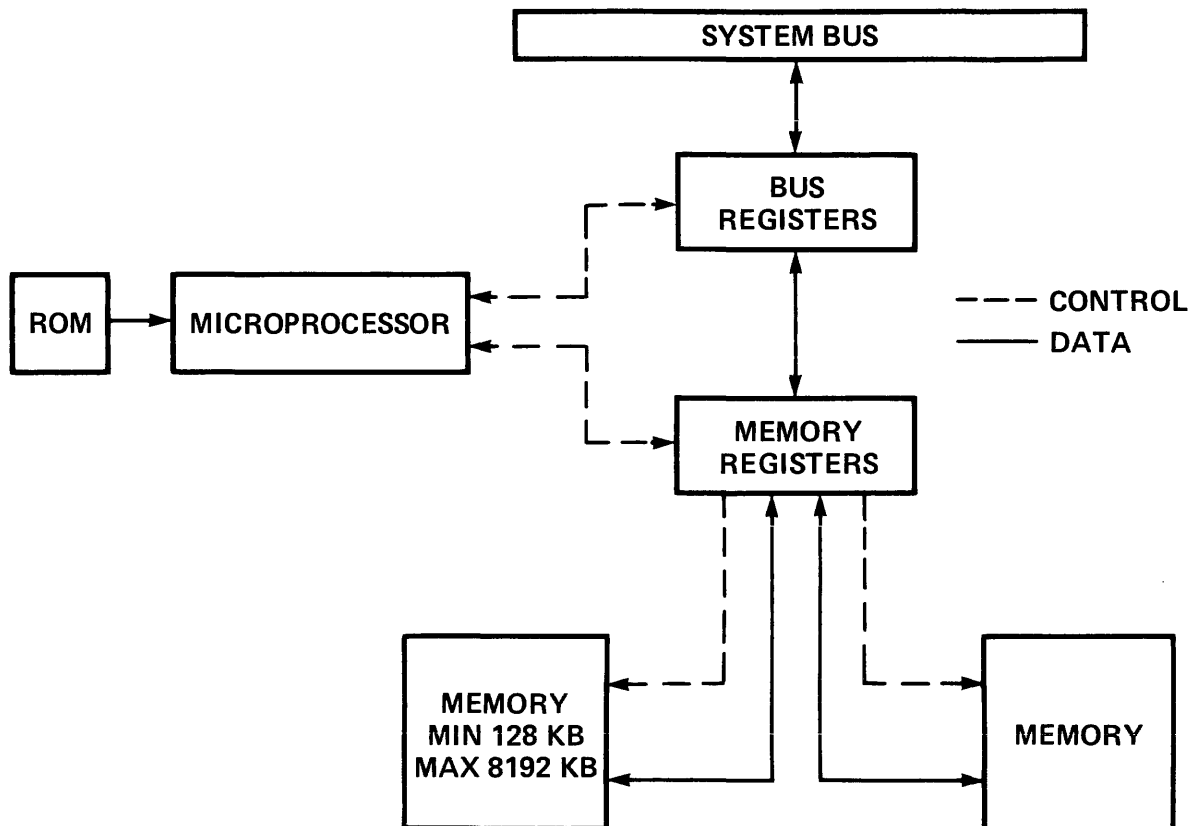

Figure 12—Memory control unit.

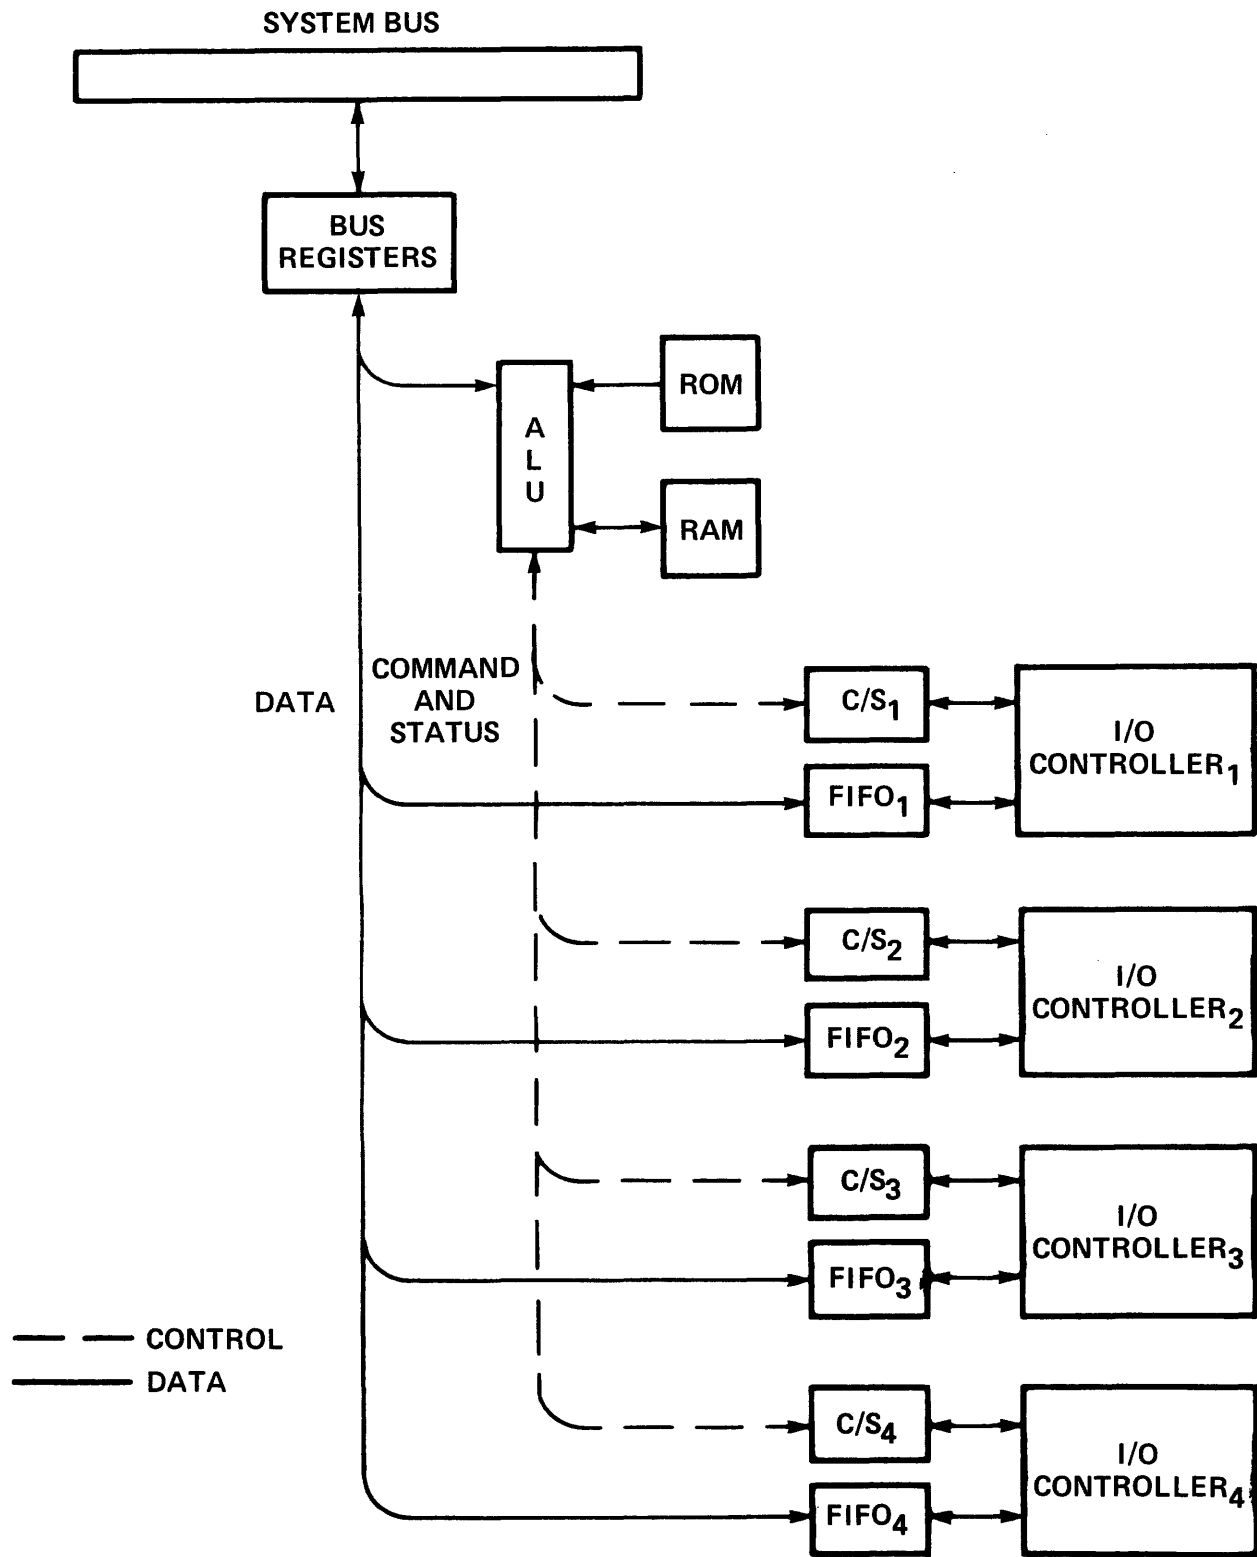

Figure 13—Peripheral processing unit.

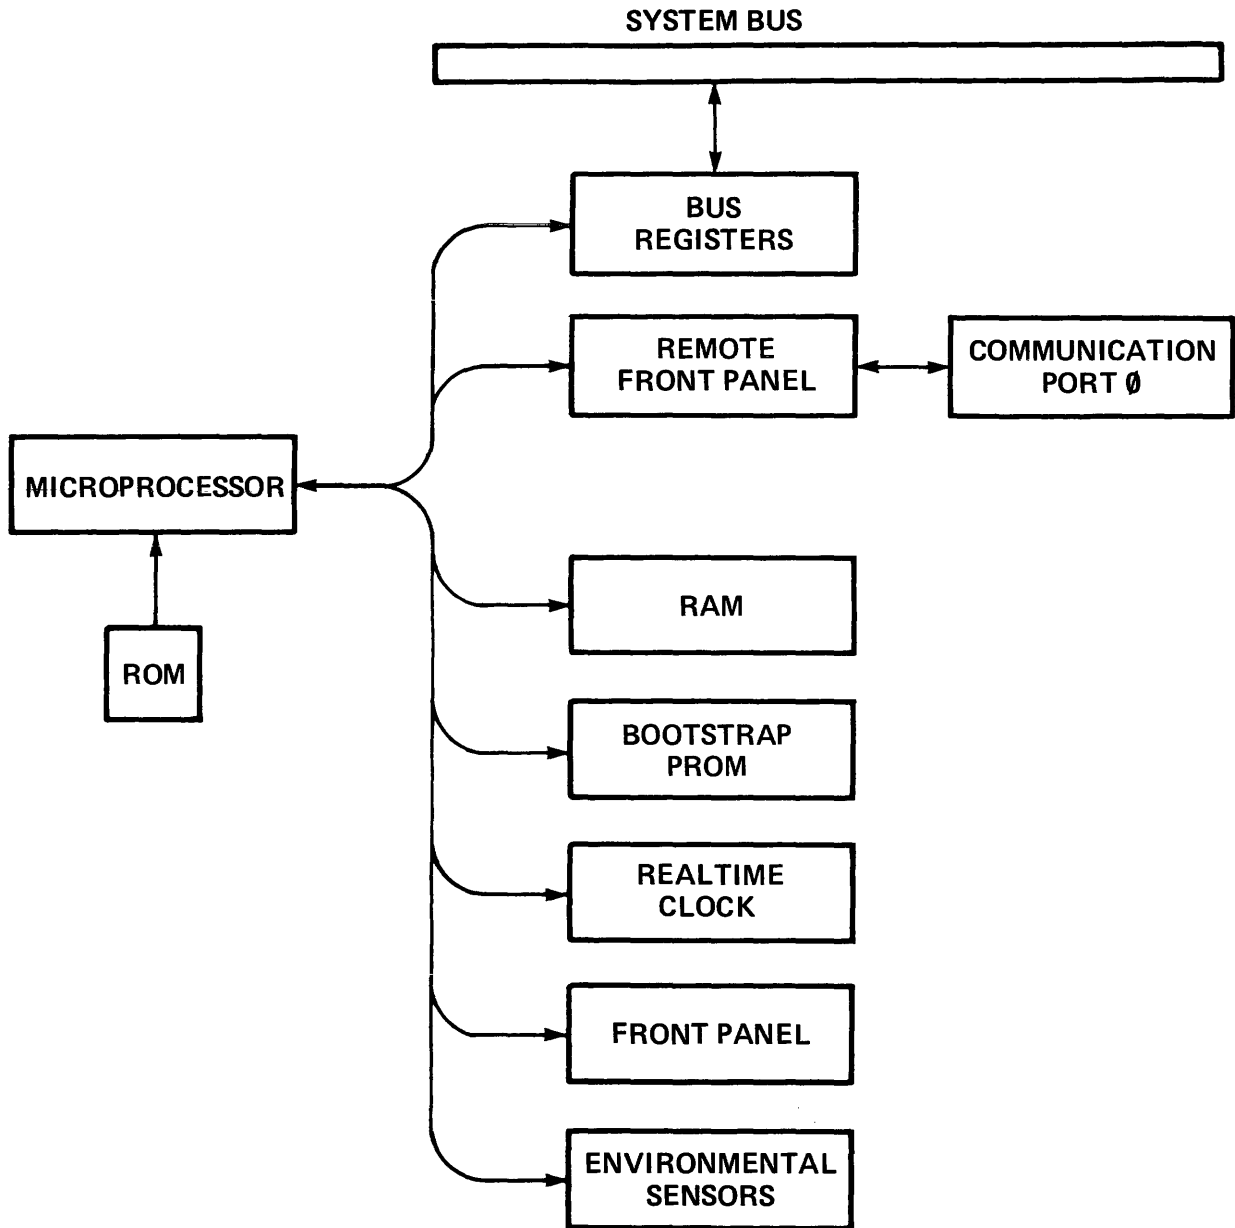

Figure 14—System services unit.

8000 may actually be run concurrently, communicating via shared synchronization regions which are kept in main memory. To promote the use of advanced high-level languages, the PASCAL compiler is the only one bundled with the hardware. By contrast, the assembler is available only to educational institutions for instructional purposes.

#### POTENTIAL PROBLEMS

The high reliability and availability of the BTI 8000 depend strongly on the unique elements of the system. For example, each system has only one active SSU, which includes the

system clock. However, a spare SSU can be kept ready to go online if the primary SSU fails.

There is only one bus, the failure of which would be catastrophic. By distributing all of its active logic to each of the connected resource units, most of the potential for such a failure is alleviated. However, distributing the bus logic to resource units means that each such device is more complicated.

Software complexity is usually higher on multiprocessors than uniprocessors. Most of the added complexity has been handled in the 8000 instruction set and operating system. The issue will be further ameliorated by the availability within high-level languages of a capability for writing concurrent processes.

A final problem is the continual desire for larger and larger contiguous addressing spaces for user programs. Because each machine instruction takes one 32-bit word and many bits were allocated to the operation codes and addressing modes of the 8000, virtual addresses are 17 bits. Thus, 128K words (512K bytes) are directly addressable by each user process. While this is actually a rather large address space for a minicomputer, it may be extended even further in the future. In addition, user tasks can be divided into a large number of communicating concurrent processes, each of 128K.

#### ACKNOWLEDGMENTS

We acknowledge the inspiration and hard work that the BTI Research and Development group has contributed to the 8000 project. We are especially grateful to the management of BTI Computer Systems for its continuing faith in a project of such high risk. Robert Adams, Ron Crandall, Bill Quackenbush, and Don Quaintance provided important details of the 8000 and advice on their presentation during the writing of this paper. Finally, special thanks are due Carol Hjerpe for countless hours spent preparing this document.

# A survey of interconnection methods for reconfigurable parallel processing systems\*

by HOWARD JAY SIEGEL, ROBERT J. MCMILLEN and PHILIP T. MUELLER, JR.

Purdue University  
West Lafayette, Indiana

## INTRODUCTION

This is a survey of a variety of interconnection networks for reconfigurable parallel processing systems that have appeared in the literature. A system is *reconfigurable* if it may assume several architectural configurations, each of which is characterized by its own topology of activated interconnections between modules.<sup>18</sup> The systems whose networks will be examined include multiple-SIMD and MIMD systems, as well as both fixed and dynamic word size systems. This paper is restricted to networks for geographically-localized parallel processing systems using 12 or more processors in a reconfigurable manner. Related survey papers include References 1, 3, 10, 19, 20, 45-47.

The next section defines parameters that will be used to describe and evaluate networks. The later sections will discuss the interconnection networks, grouped by their overall structure—multistage switching networks, dedicated path networks, and shared path networks.

## PARAMETERS

A variety of parameters which can be used to describe interconnection networks are briefly presented. Their purpose is to provide a common set of terms to use as a basis for the examination of the different networks; however, all parameters will not be applicable to all networks. It is assumed that a system has  $N$  processors and, if  $N$  is a power of two,  $n = \log_2 N$ .

Anderson and Jensen<sup>1</sup> define a *path* as "the medium by which a message is transferred between the other system elements" (e.g., wires or buses), and a *switching element* as "an entity which may be thought of as an 'intervening intelligence' between the sender and receiver of a message." Networks may be described by the type of switching elements used and the paths between switching elements. One classification is by the way the switching elements are

physically located with respect to the system processors. Two types are *distributed* and *centralized*. Networks may be used to connect processors and memories (*processor-to-memory*) or to connect processing elements (*PE*s) to other processing elements (*PE-to-PE*), where a *PE* is a processor-memory pair.

*Reconfiguration method* is the method used to reconfigure the network, i.e., to change the way in which submachines are organized. The *communications setup method* is the method used to establish an interprocessor communications path within an already existing submachine. *Delay* is the time it takes a network to transfer one data item from a source to the desired destination. The *ease of use* of a network is the degree to which connections are automatically established. The *cost* of a network is the asymptotic complexity of its implementation.

The *partitionability* of a network is its ability to divide the system into independent subsystems of different sizes. Partitionable systems may be characterized by any limitation on the subset of processors which may belong to a partition. Furthermore, a system may be *logically partitioned* using software techniques or *physically partitioned* using hardware switches within the network control structure. A network is *homogeneous* if it treats all processors similarly. *Modularity* is the ability of a network to be constructed from a small set of basic modules. *LSI compatibility* is the suitability of a module to be implemented as an LSI chip, i.e., high-circuit complexity and low external connection requirements. The *extensibility* of a network is its ability to be extended to a larger size, i.e., the amount of modification needed to make the network function for a larger number of inputs/outputs. *Fault tolerance* will be discussed in terms of a system's features which would allow the system to remain operational with faulty components (with possible degradation).

Let  $m$  be the number of processors which can transfer data simultaneously using the interconnection network. Then the degree of *simultaneity* supported by the interconnection network is  $S = m/N$ ,  $1 \leq m \leq N$ . Permutations are one-to-one connections in which all processors participate. For networks with  $N$  inputs,  $N$  outputs, and  $S=1$ , let  $r$  be the number of permutations possible in a single pass through an interconnection network. Then the *connectivity*

\* This work was supported in part by the Air Force Office of Scientific Research, Air Force Systems Command, USAF, under Grant No. AFOSR-78-3581. The United States Government is authorized to reproduce and distribute reprints for Government purposes notwithstanding any copyright notation hereon.

of the network is  $C=r/(N!)$ ,  $1 \leq r \leq N!$ . The ability of a processor attached to the network to broadcast a single data item to all other processors can be measured by the *broadcast scope*. Let  $b$  be the maximum number of other processors which can receive data simultaneously from a given processor after one pass through the interconnection network. Then the broadcast scope is  $B=b/(N-1)$ . The *broadcast delay* is the number of transfers required for a complete broadcast. The *range* of a network can be measured by  $R=x/(N-1)$ , where  $x$  is the order of the set of processors (i.e., the number of processors) from which a single processor can choose to send data to in one pass through the network. The range can be further characterized by specifying the set of processors which can be sent data. Similarly the *domain* of a network can be measured by  $D=x/(N-1)$ , where  $x$  is the order of the set of processors a single processor can receive data from in one pass through the network, and can be further characterized by specifying the set of processors which can send the data. The networks discussed support SIMD, MSIMD, MIMD, or PSM parallelism. Furthermore, some support dynamic word sizes.

An *SIMD (single instruction stream—multiple data stream) machine*<sup>14</sup> typically consists of a set of  $N$  processors,  $N$  memories, an interconnection network, and a control unit (e.g., Illiac IV<sup>8</sup>). The control unit broadcasts instructions to the processors and all active ("turned on") processors execute the same instruction at the same time. Each processor executes instructions using data taken from a memory to which only it is connected. The interconnection network allows interprocessor communication. An *MSIMD (multiple-SIMD) system* is a parallel processing system which can be structured as two or more independent SIMD machines (e.g. MAP<sup>23</sup>). An *MIMD (multiple instruction stream—multiple data stream) machine*<sup>14</sup> typically consists of  $N$  processors and  $N$  memories, where each processor may follow an independent instruction stream (e.g. C.mmp<sup>50</sup>). As with SIMD architectures, there is a multiple data stream and an interconnection network. A *PSM (partitionable SIMD/MIMD) system*<sup>32</sup> is a parallel processing system which can be structured as two or more independent SIMD and/or MIMD machines (e.g., PASM<sup>35-38</sup>).

There are two methods of achieving variable word sizes. The first method, *intraprocessor dynamic word size*, uses processors with long data words which can be split up to form several independent smaller data words (e.g. Illiac IV<sup>8</sup>). The second method, *interprocessor dynamic word size*, combines two or more processors with small data words to form a single processor with a long data word (e.g. Dynamic Computer<sup>18</sup>).

## MULTISTAGE SWITCHING NETWORKS

### Introduction

A *Multistage Switching Network (MSN)* is an interconnection network consisting of many (usually  $n$ ) stages of

switches. Each stage is connected to the next by at least  $N$  paths. Each switch can choose from two or more input paths to connect to an output path. The multistage networks discussed in this section are all physically centralized and have simultaneity, range and domain  $S=R=D=1$ . All have a cost of  $O(nN)$  and a transfer delay proportional to their number of stages. The switch elements are modular, but not complex enough for LSI. These MSNs are capable of exploiting pipelining to pass data through the network. For example, stage  $i$  could contain  $N$   $w$ -bit registers, where  $w$  is the width of the network, and act as the  $i$ -th stage of the pipe<sup>38,39</sup>. If a switch element fails, the network cannot perform completely without significant revision of data routing strategies and algorithms. Three parameters which are used to describe different multistage switching networks are topology, switch and control structure.<sup>34</sup>

The *topology* of a multistage network is the actual interconnection patterns that are used to connect the stages of the network.<sup>34</sup> Interconnection functions specify these patterns. An *interconnection function*<sup>30</sup> is a bijection (permutation) on the set of input/output addresses, which consists of the integers from 0 to  $N-1$ . The interconnection function  $f$  connects input  $i$  to output  $f(i)$ ,  $0 \leq i < N$ . There are  $n$  *Cube*-type interconnection functions:

$$\text{Cube}_i(p_{n-1} \dots p_1 p_0) = p_{n-1} \dots p_{i+1} \bar{p}_i p_{i-1} \dots p_0$$

where  $p_{n-1} \dots p_1 p_0$  is the binary representation of  $P$ ,  $0 \leq P < N$ , and  $0 \leq i < n$ .<sup>28</sup> There are  $2n$  *PM2I (Plus-Minus 2)*-type interconnection functions:

$$\text{PM2}_{+i}(x) = x + 2^i \text{ modulo } N, \text{PM2}_{-i}(x) = x - 2^i \text{ modulo } N,$$

where  $0 \leq x < N$  and  $0 \leq i < n$ .<sup>28</sup> The *Shuffle* interconnection function is:

$$\text{Shuffle}(p_{n-1} \dots p_1 p_0) = p_{n-2} \dots p_1 p_0 p_{n-1}$$

where  $0 \leq P < N$ .<sup>40</sup> The *Shuffle* is usually used with  $\text{Cube}_0$ , also called the *Exchange*. Various properties of these interconnections are discussed in References 28-31, 33, 39, 40.

### Cube-type networks

Cube-type multistage networks are composed of stages of  $N/2$  switch elements, where each switch element may be viewed as an *interchange box*, a two-input, two-output device. Let the upper input and output lines be labeled  $i$  and the lower input and output lines be labeled  $j$ . The four legitimate states of an interchange box are: (1) *straight*—input  $i$  to output  $i$ , input  $j$  to output  $j$ ; (2) *exchange*—input  $i$  to output  $j$ , input  $j$  to output  $i$ ; (3) *lower broadcast*—input  $j$  to outputs  $i$  and  $j$ ; and (4) *upper broadcast*—input  $i$  to outputs  $i$  and  $j$ .<sup>21</sup>

The *control structure* of a network sets the states of the interchange boxes. *Individual stage control* uses the same control signal to set the state of all the interchange boxes in a stage, i.e., all the boxes in a given stage must be in the same state. *Individual box control* uses a separate control signal to set the state of each interchange box. *Partial stage control* uses  $i+1$  control signals to control stage  $i$ ,  $0 \leq i < n$ .<sup>34</sup>

The STARAN flip network<sup>6</sup> with flip control, shown in Figures 1a and 1b, consist of n stages and employs individual stage control. It is used in the STARAN SIMD machine<sup>5,9,12</sup> for processor-to-memory and processor-to-processor connections. This network may also be operated using shift control, a partial stage control scheme as shown in Figure 1c. The interchange boxes may be set to either exchange or straight. In stage i, boxes set to exchange are

performing the  $Cube_i$  interconnection function on their inputs,  $0 \leq i < n$ . With flip control, the network has connectivity  $C=2^{n/2}N!$  (each stage is either "straight" or "exchange") and, with shift control  $C=2^n N!$ , where  $s=1+2+\dots+n=n(n+1)/2$  (each control signal is either "straight" or "exchange"). The network is homogeneous under flip control, where all inputs are treated equally. Under shift control, it is not homogeneous. The network broadcast scope  $B=1/(N-1)$ , and a broadcast requires n passes. Due to the limited control schemes, it is not capable of being partitioned. The network can be expanded by factors of two. To double the size, from N to 2N, connect two size N networks with a "Cube<sub>n</sub>" n-th stage.

This network, using only flip control, supports STARAN's multidimensional access (MDA) memory,<sup>7</sup> which makes STARAN an interprocessor dynamic word size system. The MDA memory consists of 256 physical words, each of which is 256 bits long. Each of the system's 256 processing elements operates on one bit. This allows the system to operate on  $2^i$  consecutive bit logical words, where the logical words are from physical words  $2^i$  apart,  $0 \leq i \leq n$ . The two extremes are a word-slice (an entire physical word) and a bit-slice (the jth bit of all physical words). A total of  $N^2$  different formations are possible.

The indirect binary n-cube network<sup>26</sup> is basically identical to the flip network (Figure 1b), except that individual box control is used. It is a PE-to-PE SIMD network. The connectivity  $C=2^{n/2}N!$ , since each box may be either "straight" or "exchange." As with the flip network,  $B=1/(N-1)$ , broadcast delay is n passes, and the network can be expanded. Due to the individual box control, all inputs may be treated in the same way, so the network is homogeneous.

It was proposed<sup>26</sup> that the individual box control be implemented by a single microprocessor for each stage. If this implementation is employed, the use of this network in MSIMD mode is limited. However, the network topology, interchange box and control structure do support partitioning for MSIMD mode, where the only restrictions are that the number of processors in each submachine is a power of two and the addresses of the processors agree in certain bit positions, as specified in References 34 and 39. For example, the system may be divided into independent partitions, the odd numbered PEs and the even, by physically setting all of stage 0 to straight.

The Omega network<sup>21</sup> shown in Figure 2a, is a processor-to-memory network for SIMD machines, which can be adapted for MSIMD systems. The interchange boxes may assume any of the four legitimate states. Without the broadcast states, each stage of the network is a Shuffle interconnection function, followed by possible Exchange function. The network may be redrawn, as in Figure 2b, where the i-th stage corresponds to a possible  $Cube_i$  interconnection function. Thus, the Omega is identical to indirect binary n-cube and has the same parameter values, except the stages are in reversed order and the Omega has the capability to broadcast from any input to all outputs in one pass ( $B=1$ ).<sup>34</sup> Its use of n-bit destination tags to control the straight/exchange states make it easy to use and well suited to

Figure 1—STARAN network for N=8. (a) with flip control, (b) "a" redrawn, and (c) with shift control (0A, 1A, etc. are the control signals).<sup>34</sup>

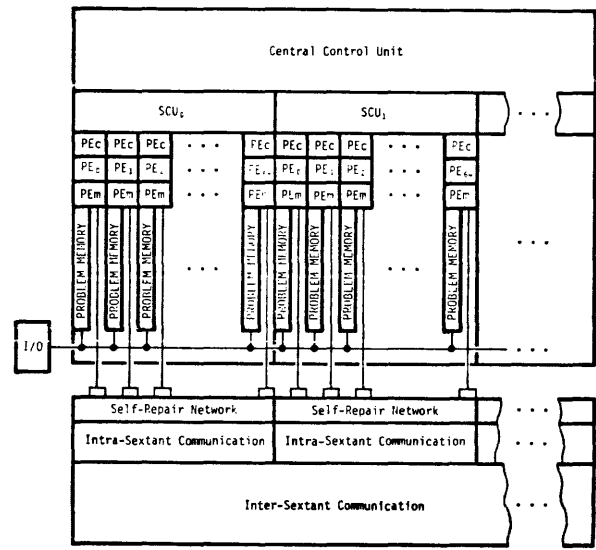

(a)

(b)

Figure 2—(a) Omega network for N=8 and (b) "a" redrawn.<sup>39</sup>

stream which is broadcast by the central control unit. Thus, the system is not MSIMD, since the SIMD submachines are not independent. The network size is halved by setting the middle stage and the one before it (or after it) to all straight. The network can perform any permutation in one pass ( $C=1$ ) and any processor can broadcast data to all other processors in one pass ( $B=1$ ). The network can only be extended by doubling the number of processors (from  $N$  to  $2N$ ) and adding two stages (a new  $Cube_{n-1}$  and a  $Cube_n$ ) immediately prior to the old  $Cube_{n-1}$  stage. Each sextant of the Phoenix has a spare processor. This spare processor can be swapped in by the "self-repair network" when a faulty processor is detected. This allows the Phoenix to run unaffected even after a processor has failed. Sextants which have failed can be ignored.

(a)

(b)

Figure 3—Phoenix. (a) Block diagram overview. (b) Programmable switching network.<sup>11</sup>

MSIMD mode, with the same restrictions as the n-cube.<sup>34,39</sup>

The *Phoenix Project*<sup>11</sup> is an SIMD system consisting of 1024 PEs with hierarchical control. The PEs are divided up into 16 sextants of 64 PEs each. Each sextant has a control unit, and there is a central control unit which broadcasts instructions to the sextant control units. A block diagram is shown in Figure 3a. Communication between PEs is handled by a  $2n-1=19$  stage network, where stage  $i$  performs the  $Cube_i$  function for  $0 \leq i \leq 9$  and stage  $i$  performs the  $Cube_{18-i}$  function for  $10 \leq i \leq 18$ . The network, whose interchange boxes can assume any of the four legitimate states under individual box control, is shown in Figure 3b. The algorithms used to calculate the switch settings are inherently serial and require  $O(nN)$  time. Switch settings can be precomputed for commonly used connections.

The network is homogeneous and may be partitioned. The array can only be partitioned into subarrays of equal size (powers of two) all following the same instruction

### Banyan networks

The class of banyan networks is formally defined in 16. In particular, the SW-banyan with "f=s=2" is used in the PSM *Reconfigurable Varistructured Array Processor (RVAP)*,<sup>22</sup> as shown in Figure 4. This SW-banyan is topologically equivalent to the Omega, STARAN, and n-cube networks. It differs from these Cube networks in its switch elements and the way in which it is used.

The RVAP network is homogeneous and connects processors with memories or processors. The network includes lines for carry propagate and generate signals to support

(a)

(b)

Figure 4—SW-banyan network, (a) data trees and (b) instruction tree.<sup>22</sup>

interprocessor dynamic word size. Figure 4a shows how processors can be linked to separate memories and I/O devices for data transfers and Figure 4b shows how processors can be linked to a single memory to receive instructions in SIMD mode. A data or instruction tree can be established by having each leaf send a signal to all potential roots. Exactly one of the potential roots which receives a signal from all of the leaves is selected to be the root by a priority circuit. The root broadcasts a signal downward and each leaf broadcasts a signal upwards. All paths receiving both upward and downward signals are connected to form the tree. Thus, it takes  $p+2$  steps to, for example, connect  $p$  processors to a single memory. It is stated that this method may be converted into a one step algorithm.<sup>22</sup>

Measurements in 15 indicate that on the order of 10 percent of the possible interconnection structures are not connectable, therefore there are many ways to partition the system. In the area of fault tolerance, this system differs from the other networks in this section in that a faulty switch is treated as a busy switch and is not a special case. Thus, depending on how many and which switches are "busy" the network may be successively reconfigured, interrupting, but not modifying, the algorithms being executed. It is possible to broadcast data by using a dummy memory node, thus the broadcast scope is  $B=1$ . The broadcast delay is two passes through the network. This network can be extended as in the STARAN network. A prototype system using a more complex SW-banyan ("f=3, s=2") is currently being constructed.

### PM2I-type networks

The *Augmented Data Manipulator (ADM)* network<sup>34,39</sup> is used in the PSM machine called *PASM (PARTitionable SIMD/MIMD)*.<sup>32,35-38</sup> Figure 5a is a block diagram of PASM, a system being designed for image processing and pattern recognition at Purdue University. The heart of PASM is the *Parallel Computation Unit (PCU)*, which contains  $N$  processors,  $N$  memory modules, and the interconnection network. The *PCU processors* are microprocessors that perform the actual SIMD and MIMD computations. The *PCU memory modules* are used by the PCU processors for data storage in SIMD mode and both data and instruction storage in MIMD mode. The PE-to-PE ADM network, shown in Figure 5b, is composed of  $n$  stages, where each stage consists of  $N$  independently-controlled switch elements (cells). It is based on Feng's data manipulator, which uses a less flexible control scheme.<sup>13</sup> At stage  $x$ , cell  $j$  can be connected to any or all of the following cells at stage  $x-1$ :  $j$ ,  $j+2^x$  modulo  $N$ , and  $j-2^x$  modulo  $N$ , where  $0 \leq x < n$ . Thus, stage  $x$  is analogous to  $PM2_{+x}$  and  $PM2_{-x}$ . Various schemes for controlling the network, including destination tags, are being studied.

The network may be partitioned into independent subnetworks of varying sizes, with the constraints that the size (number of inputs/outputs) is a power of two and that the input addresses of a subnetwork all agree in their low order bit positions. For example, the system may be partitioned

(a)

(b)

Figure 5—PASM. (a) Block diagram overview. (b) Augmented data manipulator, for  $N=8$ .<sup>38</sup>

into two independent groups, the odd numbered PEs and the even, by setting all of stage 0 to straight ( $j$  to  $j$ ,  $0 \leq j < N$ ). The network can be expanded by factors of two. A size  $2N$  network may be constructed by "interleaving" the cells of two size  $N$  networks, combining the two old stage  $x$ s into the new stage  $x+1$ , and adding a new  $2N$  size stage 0 (the  $PM2_{+0}$ ,  $PM2_{-0}$ , and straight connections). This is the "inverse" of the partitioning method.

The *Micro Controllers (MCs)* are a set of microprocessors which act as the control unit for the PCU processors in a virtual SIMD machine and orchestrate the activities of the PCU processors in a virtual MIMD machine. There are  $Q=2^q$  MCs, *physically addressed (numbered)* from 0 to  $Q-1$ . Each MC controls  $N/Q$  PCU processors, in particular, MC  $i$  controls the  $N/Q$  processors whose low-order  $q$  address bits equal  $i$ . There is an MC memory module for each MC. A virtual SIMD machine of size  $MN/Q$ , where  $M=2^m$  and  $0 \leq m \leq q$ , is obtained by loading  $M$  MC memory modules with the same instructions simultaneously. Similarly, a virtual MIMD machine of size  $MN/Q$  is obtained by combining the effort of the PCU processors of  $M$  MCs. In both cases, the physical addresses of these  $M$  MCs must

have the same low-order  $q-m$  bits since the physical addresses of all PCU processors in a partition must agree in their low-order bits. Thus, each partition contains at least  $N/Q$  PEs and the number of partitions is at most  $Q$ .

It can be shown that the interconnection capabilities of the ADM are a superset of those of the Omega network,<sup>34</sup> i.e., it can do all the connections the Omega can and some the Omega can not (e.g. Shuffle). Thus, the ADM can perform more than the Omega's  $2^{N/2}$  distinct permutations, however, it can not perform all  $N!$  permutations (e.g. inverse Shuffle). It can broadcast data from any PE in one pass through the network ( $B=1$ ). The cost of the ADM network is  $O(nN)$  and it treats all PEs equally so it is homogeneous.

## DEDICATED PATH NETWORKS

### Introduction

*Dedicated Path Networks (DPNs)* are characterized by communication links (usually bidirectional) which connect exactly two processors. All of the DPNs in the following two subsections are physically distributed. DPNs are divided into two classes by their control structures: centralized or distributed.

### DPNs with centralized control

The Illiac IV discussed here is the original design rather than the machine which was actually built. The *Illiack IV*<sup>4</sup> is an MSIMD system composed of four quadrants, each of which has 64 PEs and a control unit. Each PE consists of a 64-bit processor and a memory. Each quadrant can operate independently, or in conjunction with other quadrants by having either two or four control units broadcast the same instruction stream. Thus, the partitioning of Illiac is limited to three states: four partitions each with 64 processors, two partitions each with 128 processors, or one partition with 256 processors. The PEs in a partition are numbered (addressed) from 0 to  $M-1$ . The network connects PE  $i$  with PE  $i+1$ ,  $i-1$ ,  $i+8$ , and  $i-8$ , modulo  $M$ . The processor to network interface is part of each PE and the cost of the network is  $O(N)$ .

Each Illiac processor supports intraprocessor dynamic word size and can be partitioned to operate on one 64-bit word, two 32-bit words, or eight 8-bit words. The system is restricted such that each processor must perform the same operation on all the fields of its partitioned word. If a PE fails, its quadrant can be ignored.

The degree of simultaneity of the Illiac network is  $S=1$ . The Illiac network has no special provisions for broadcasting a data item from one PE to the other PEs ( $B=1/(N-1)$ ). However, the Control Unit may broadcast a data item from one PE to all PEs.<sup>41</sup> The range and domain are  $R=D=4/M$ , where  $M$  is the number of processors in the partition. The worst delay using 256 PEs is 19 transfers (e.g. PE 0 to PE 124). The network is homogeneous and its control is cen-

tralized. The network can be extended, but the worst case delay would make significant increases in the number of PEs undesirable.

Using permutation group theory,<sup>30</sup> it can be shown that for an  $M$  PE system the number of permutations possible in one pass is  $3+2*2^8=3+2^9$ . There are eight cycles which can be in either the +8 state or the inactive state (the  $2^8$  factor). The same eight cycles could also be in either the -8 state or the inactive state (the  $2^*$  factor). In addition there is one cycle which can be in either the +1 state, the -1 state, or the inactive state (the  $3+$  term). Hence the connectivity is  $C=(3+2^9)/M!$ .

The overall architecture of *A Novel Multiprocessor Array (ANMA)*<sup>24</sup> is SIMD. ANMA has a host computer, a control unit, and 16 eight-bit processors. The PE-to-PE DPN of ANMA is made up of two parts: the *Variable Word Length (VWL)* structure and the *Logarithmically Structured Transfer (LST)*.

The VWL is used to connect a processor with its left or right neighbor to form longer data words, i.e., the VWL supports interprocessor dynamic word size. The VWL is controlled by an  $N-1$  bit register where  $N$  is the number of processors in the system. Bit number  $i$  determines whether or not processor  $i$  is connected to processor  $i+1$ ,  $0 \leq i \leq N-2$ . The VWL structure is made up of the carry, shift, VWL shift rotate and Partially Selectable Microinstruction control lines. These lines allow the communication necessary to link processors together to form longer data words. The cost is  $O(N)$ .

The LST is a set of bidirectional serial links between processors, as shown in Figure 6. If the processors are numbered (addressed) from 0 to 15, then the links are between processor  $i$  and processor  $i+2^j$ , for non-negative integers  $i$  and  $j$ , such that  $i+2^j \leq 15$ . This network is a subset of the PM2I containing connections  $i$  to  $i+2^j$ , where  $i+2^j \leq 15$ , and  $i$  to  $i-2^j$ , where  $i-2^j \geq 0$ ,  $0 \leq i \leq 15$ ,  $0 \leq j \leq 3$ . Thus, the network may be easily extended by factors of two. The cost is  $O(nN)$ .

The degree of simultaneity for the VWL structure is  $S=1$ . Assuming the LST can be used in only one direction at a time, then  $S=1/2$ . Note that the VWL structure only supports combining left or right neighbors to form longer data words. Faulty processors would create word partitions.

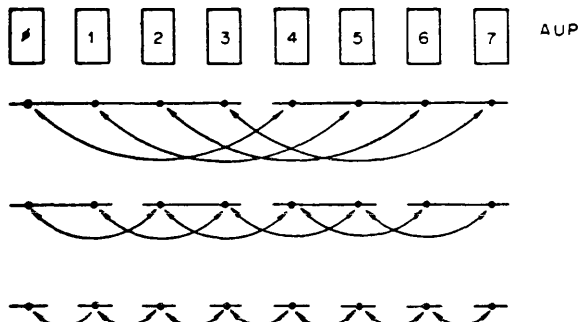

Figure 6—The LST network for ANMA,  $N=8$ .<sup>24</sup>

For the LST, the broadcast scope  $B=1/(N-1)$ , but a processor can broadcast a value to all processors through the Control Unit. The delay of the LST is  $n$  transfers. The range and domain of the LST for "middle" processors (i.e., processors 7 and 8) is  $R=D=(2n-1)/(N-1)=7/15$ . For "end" processors (i.e., processors 0 and 15),  $R=D=n/(N-1)=4/15$ . However, for the VWL structure the range and domain for middle processors are  $R=D=2/15$ , and for end processors  $R=D=1/15$ . For both networks,  $R$  and  $D$  vary for different processors, so neither is homogeneous. Furthermore, the network interfaces can not be made of identical modules, unless some outputs are not used.

#### DPNs with distributed control

The *Columbia Homogeneous Parallel Processor (CHoPP)* MIMD system<sup>42</sup> is made up of modular nodes, each of which consists of an application processor, a communications processor, and a memory. The CHoPP processor-to-memory network is based on the Cube interconnection functions described earlier. Assuming the nodes are numbered (addressed) from 0 to  $N-1$ , each node can communicate directly with any node whose address differs with its address in only one bit position. To communicate with a node which has an address which differs in more than one bit, the information must travel through intermediate nodes. Thus, there may be a delay of  $n$  transfers. As with the indirect binary  $n$ -cube, CHoPP may logically be partitioned into subsystems. Arbitrary subsystems may be constructed, but this may involve the use of communications processors not in the subsystem. Faulty nodes may be ignored.

The network control is distributed, based on destination tags. Each communication processor examines the tag and determines where to send the message. The network is homogeneous and the degree of simultaneity of CHoPP is  $S=1$ . The range and domain are  $R=D=n/(N-1)$ . The broadcast scope is  $B=n/(N-1)$ , and a complete broadcast requires  $n$  transfers, i.e., the broadcast delay is  $n$ . The cost of the network is  $O(nN)$ . The system can be extended by factors of two.

The *variable topology multicomputer (VTM)*<sup>25</sup> is an MIMD system composed of nodes similar to those of the CHoPP system. Each node of the VTM contains a processor, an inter-computer message handler, and a memory. The VTM network is made up of unidirectional serial communication lines. The topology of the network may be changed by adding or deleting lines by physically rewiring the network, e.g., via a patch panel. However, once a topology is chosen, communication links are formed under software control.

The message routing is done by two methods: message switching and circuit switching. When operating in the message switching mode, the inter-computer message handler examines the message to determine its destination and sends the message out on the proper link. In the circuit switching mode of operation, the inter-computer message

handler effectively shorts an input link to an output link, i.e., the node is bypassed. When a link is used for circuit switching, it can no longer be used by the node being bypassed.

Because this system allows rewiring, it is difficult to apply the parameters that depend on the topology. The degree of simultaneity is  $S=1$ , provided every node has at least one output link. By using the circuit switching capabilities a direct link between any pair of processors can be set up for partitioning the system, provided there are a sufficient number of links. The network is physically distributed and new nodes may be added to increase the system size.

## SHARED PATH NETWORKS

### Introduction

A *shared path network* is defined recursively as a communications path which may be used by more than two processors, or a set of shared path networks which may be interconnected by switch elements that can either make or break a connection between these paths. A shared path network can be distinguished from the multistage switching networks discussed previously based on the complexity of the switch element and the number of path segments. In a multistage switching network, there are at least  $N$  paths connecting one stage to the next, and there are at least  $n$  stages. Furthermore, each stage contains switch elements with the capability of choosing which of two or more input and output lines to connect, if any. A shared path network connects paths using simple connect/disconnect nodes or processors. In addition, there are typically fewer than  $O(nN)$  bus segments.

Two buses are said to be *similar* if they (1) have the same width; (2) have the same delay (on the average), including that incurred by passing through controllers or arbiters; (3) are connected to the same class of sender/receivers; and (4) the priority of the data they carry, as assigned by the respective sender/receivers, is independent of the bus on which they arrive. If a shared path network contains only one bus, or contains several buses which are similar, it can be classified as *linear*. If there are multiple buses which are dissimilar, it is classified as *hierarchical*.

### Linear shared path networks

The *Minerva Multi-Microprocessor*<sup>48</sup> is an MIMD system which connects eight 8080 and four 3000 Intel processors to a single demand-multiplexed bus called *IDBUS* (Inter-Device Bus) and to the *IDBUS ARBITER*. Use of the bus is controlled by the *IDBUS ARBITER*. The bus is used to gain access to public memory which is the means processors use to communicate with each other. Thus the *IDBUS* is used as a processor-to-memory structure. Processors use the *IDBUS* one at a time, so  $S=1/N$ . Any arbitrary group of processors can communicate with each other, and the

subset of processors that constitute a group can vary arbitrarily with time. Thus, the *IDBUS* fully supports system reconfiguration and submachines containing up to eight 8080 and four 3000 microprocessors may be formed to work toward a common goal.

The single shared bus does not permit one-to-many communication, so the broadcast scope  $B=1/(N-1)$ . To send the same data item to all other processors takes  $O(N)$  time. The *IDBUS* interfaces are physically distributed and the *ARBITER* is physically centralized. Each *IDBUS* interface is part of a processor module and is LSI compatible.

The *IDBUS* is readily expandable at the cost of a slight increase in arbitration time, however, expansion is limited by contention problems that grow worse with each additional processor, since there is only one bus. While the *IDBUS* and *ARBITER* are not fault tolerant, it is possible for them to support the fault tolerance of the system as a whole, i.e., a defective processor may be ignored. Since the *ARBITER* handles all bus use automatically, control of the network from the user's point of view is simple. The number of elements used to construct the network is  $O(N)$ , which leads to a low cost, but the delay incurred while waiting for use of the bus is significant. The range and domain of each processor are  $R=D=1$ , since processor communications are through memory and any processor can read from memory. Finally, all processors view the bus in the same way, so it is homogeneous.

The *Dynamic Computer (DC)* described by Reference 18 is a multicomputer system which contains a reconfigurable bus and "carry" links, as shown in Figure 7. Software controllable switches (*MSs*) placed between each adjacent pair of processors allow  $2^{N-1}$  different system configurations to be formed, via the reconfigurable bus, by linking subsets of the *computer elements (CEs)* together. This bus is 16 bits wide and is used only for broadcasting instructions to other CEs within a given group. The bus is used in the PE-to-PE interconnection mode. The "carry" links between adjacent CEs allow "carry" information to be passed along efficiently, with  $S=1$ .

The *V monitor* is responsible for initiating changes in the bus configuration and arbitrating conflicting requests for a change (made by concurrent programs). Changing any configuration includes writing new control words to each processor and sending new switch settings to the *MS* units. The reconfigurability of the bus and the interprocessor

Figure 7—Dynamic computer group of size four.<sup>18</sup>

carry connections allow the system to be partitioned into independent computers whose word size may vary. The processors in a partition are called a DC group. The only constraint that determines which CEs may be in a group is that they must be adjacent. Because the bus structure each CE 'sees' is dependent upon where that CE is physically located (i.e., each CE has a different number of CEs on its left and right than the others), the network is not homogeneous.

The MS units are physically distributed, modular and complex (the latter being the result of their construction from microprocessors). These characteristics allow the network to exploit LSI technology. The cost of this network and the carry links is  $O(N)$ . Expansion is incremental and is limited only by the V monitor. The bus is fault tolerant, however, for each MS unit that becomes defective, the number of possible bus configurations is halved. The bus supports the fault tolerance of the system as a whole, permitting continued operation with reduced overall performance. Control of the bus configuration is completely automatic and thus presents no hindrance to the user. Data words may be passed between processors by shifting them serially through the carry links. All processors have a range and domain of  $2/(N-1)$  except those on the ends, whose range and domain are  $1/(N-1)$ .

The DC may be viewed as an MIMD multicomputer system, where carry links are used for intercomputer data transfers instead of "carry" information. Thus, the broadcast scope  $B=1/(N-1)$ . Since data transfers are serial, the broadcast delay is  $O(Pw)$ , where  $P$  is the number of DC groups and  $w$  is the number of bits in the word to be broadcast. It may also be viewed as an MSIMD system, where each DC group operating as an SIMD machine establishes a multi-array mode in which a number of computers execute the same instruction stream broadcast by a computer supervisor. One way this may be accomplished is to enable all MSs between the processors that form the array for instruction broadcasting, but disable the carries at word boundaries. Since different parts of the system may operate in MIMD and MSIMD mode simultaneously, the Dynamic Computer may be categorized as a PSM computer with the ability to vary the word width at each "processing element."

The *Restructurable Computer System (RCS)*<sup>27</sup> is composed of 64 *Functional Units (FUs)*, and 24 *Bus Units (BUs)*, as shown in Figure 8. Sixteen BUs are responsible for processing the communications needs of at most four functional units each, while six are reserved for operand streams from memory and two for streams into memory. Thus, the buses are used both as a processor-to-memory and a processor-to-processor connection structure. The data words are 48 bits wide and each bus is ten words wide.

By properly loading registers in the BUs, any of the BUs can be assigned to any of the FUs, making the system restructurable. Arbitrary pipelined structures as well as SIMD array structures may be formed. Thus, the RCS is partitionable with each partition consisting of the FUs that form a single pipe or array. There are no restrictions on the

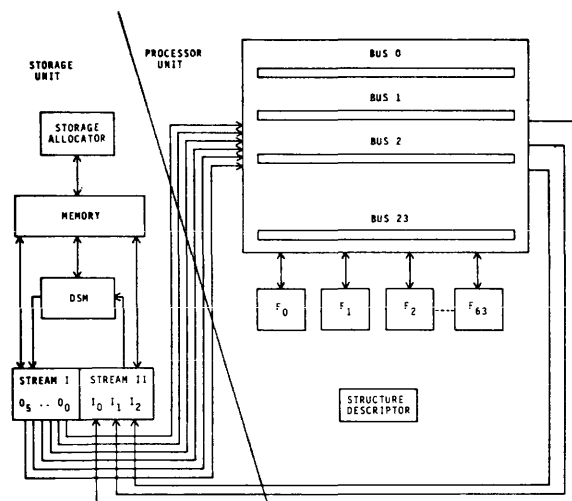

Figure 8—Restructurable computer system.<sup>27</sup>

subset of FUs that may belong to a partition. Software associated with the system provides for conversion from a logical description of a desired configuration to the specific register values to be loaded.

The BUs are physically distributed, identical and thus modular units. In spite of their modularity and high complexity, the pin requirements prohibit implementation as LSI chips using current technology. The cost of the network is  $O(N)$ , but the coefficient of  $N$  may be large due to the very high bandwidth of the buses and the high complexity of the BUs. The worst case delay for an interprocessor data transfer is four bus cycles, however, in time, critical applications more than one BU can be assigned to a FU.

Each FU contains a bus unit scanning station (*BUSS*) that can look for input from any of four BUs, thus the domain is  $D=4/(N-1)$ . Similarly the BUs can send data to only four other BUs so the range is  $R=4/(N-1)$ . Structurally, the network of BUs looks the same to all FUs so the network is homogeneous. Since there are 16 independent buses which may be transferring data simultaneously, the degree of simultaneity  $S=16/64$ . One FU can send data to only four other FUs at the same time, so the broadcast scope  $B=4/63$ .

Reddi and Feustel point out that fault tolerance may be acquired by forming three identical pipes and routing their output to a FU that performs a voting function. Any bad units could be tagged and avoided by the operating system. The network itself is fault tolerant in the sense that multiple, identical units are used for communications, and the system can operate without all BUs functioning. To expand the RCS it would be necessary to increase the size of several registers in each BU that identify the FUs assigned to it. As the number of FUs increases, the ratio of BUs to FUs decreases, degrading the total throughput of the system. Thus, it is desirable to add BUs to maintain system performance, which would require increasing the size of certain identification registers in each *BUSS*.

*Hierarchical shared path networks*

The  $Cm^*$ <sup>17,43,44</sup> shown in Figure 9, is an MIMD system composed of a large number of computer modules that are grouped into clusters and connected by a hierarchy of buses. Communications are processor-to-memory. All buses are physically 16 bits wide, however local buses use an address space of 16 bits, *Map Buses* (intra-cluster buses) use an address space of 22 bits, and *Inter-cluster (IC) Buses* use an address space of 28 bits. Address translation and data routing are performed by local switches called *S.locals* and mapping controllers called *K.maps*, both considered switching elements. At most 14 computer modules may belong to the same cluster. If all clusters are filled, in the best case the degree of simultaneity  $S=1/14$ , where it is assumed all communications are intra-cluster, i.e., they take place on *Map Buses*. If all communication requires use of IC buses, neither  $S$  nor the delay can be determined since the topology of IC buses is not specified. There are no facilities for broadcasting data, so  $B=1/(N-1)$ . The broadcast delay is  $O(n)$ , since a recursive doubling algorithm could be used to transfer a given data item to all processors.

There is no hardware in  $Cm^*$  that is designed to partition the computer modules. There is, however, firmware (i.e. microcode) built into the address translation units that supports logical partitioning. Capability lists are associated with each computer module that specify those areas of memory to which it may have access. The network is homogeneous, since it treats all processors equally. The switching elements (*S.locals* and *K.maps*) are physically distributed and modular. It appears that they could be implemented by a small set of LSI chips, due to their complexity and reasonable pin requirements. The cost of the network is  $O(N+N/14)=O(N)$ .

$Cm^*$  is readily expanded by attaching more switching elements to the appropriate buses, with the limiting factor being the maximum amount of memory that can be addressed ( $2^{28}$  words). Each computer module can access any word in memory and so can communicate directly with any other computer module in its cluster, making the range and domain  $R=D=13/(N-1)$ . Intercluster communications can

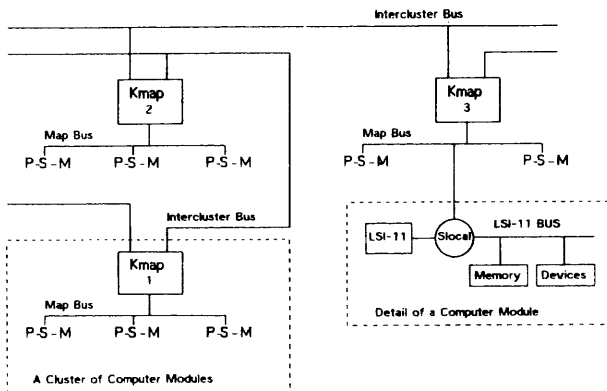

Figure 9—A simple three cluster  $Cm^*$  system.<sup>43</sup>

expand the range and domain, but this is dependent on the unspecified IC bus system topology. All address translation is transparent to the user, so the network is very easy to use. Two-way communication is employed and status of the progress of a message is kept, making it possible to identify a bad computer module and avoid using it. There is, however, no specific fault tolerance built into the network.

A network for message routing in a *Mega-Micro-Computer (MMC)*<sup>49</sup> is shown in Figure 10. Buses connecting computers logically subdivide the toroidally continuous physical space into nested square groups of  $16, 16^2, 16^3, \dots, 16^{(j+1)}$  computers. Spanning, but not leaving, each  $16^{(k+1)}$  group are level- $i$  buses (*i-buses*), each connected once in each inner  $16^i$  group,  $0 \leq i \leq k$ . Each computer is connected to one 0-bus and one higher-level bus, thus, the network is not homogeneous since all computers are not connected to buses of equal "distance" capability. The computers in Figure 10 are signified by numbers indicating the higher-level bus to which they are attached. The "X" is for buses of level  $> 4$ . The computers shown are connected to 24 different 0-buses, 16 1-buses, 64 2-buses, 48 3-buses, and 34 4-buses. However, only one 1-bus, one 0-bus and parts of a 2-bus and another 1-bus are explicitly shown. Each bus is connected to only 16 computers and is used in the PE-to-PE configuration.

Since each processor is connected to two buses and there are 16 processors per bus, in one bus cycle a given processor can communicate with any of 30 other processors, thus  $R=D=30/(N-1)$ . No particular hardware features are described that could be used to partition the system. It is also not designed to broadcast data, so  $B=1/(N-1)$ . Using a recursive doubling algorithm, data can be passed to all processors with broadcast delay  $O(n)$ .

The mechanisms that move data from bus to bus are built into the computers, thus the network is physically distributed as well as modular. If bus widths are kept reasonable, it appears the system is LSI compatible. The cost is  $O(N)$ . Routing in the network is automatically performed by com-

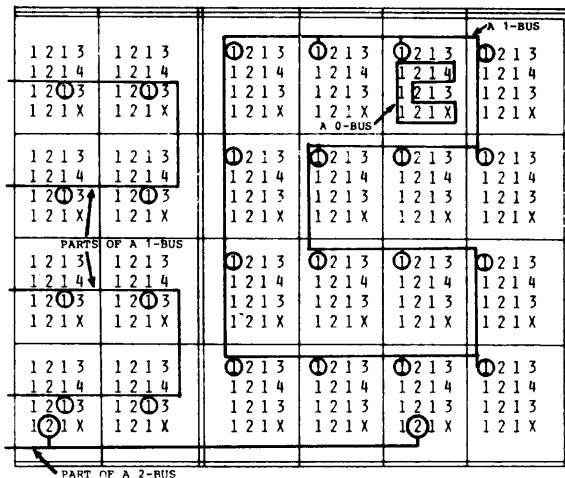

Figure 10—Logical groups of computers showing bus sharing in a Mega-Micro-Computer network.<sup>49</sup>

paring a destination tag to a local address, making it necessary only for a user to specify the desired destination. Since there are a large number of routing choices, it is a simple matter to bypass faulty computers. If  $A$  is the absolute difference between the addresses of the sender and receiver, the delay is  $O(\log_2 A)$ . If the maximum level is  $i$  and there are  $16^{i+1}$  computers, then the number of buses in the system is  $b = \sum_{j=0}^i 16^j/2^j$ . Since all buses may be in use simultaneously,  $S = b/16^{i+1}$ . For example, for  $i=4$ ,  $S=0.12$ .

The *Hierarchical Restructurable Multi-Microprocessor (HRMM)*<sup>2</sup> architecture employs multiple control buses called *Control Groups (CGs)* and a circulating data bus. Switching elements, called *Block Short Modules (BSMs)*, segment the control group buses between adjacent pairs of processors, as shown in Figure 11. A CG consists of three buses—(1) the CMD bus that carries commands to processors; (2) the ACK/NAK bus with which a processor recognizing a command can acknowledge its acceptance or rejection (due to a full queue); and (3) the DONE bus where a command processor can acknowledge the completion of a required task. When a command is received by a processor, it is placed into a queue and cannot be executed until the data associated with it arrives on the data bus, consequently all processors execute instructions independently as an MIMD machine. Each CG is given a fixed priority, thus enabling establishment of a hierarchy for communication.

While the buses that form a CG are of the conventional type, the data bus is of the circulating loop (or Pierce Loop) type where data packets are moved a fixed distance and direction in each unit of time. Both buses are used in the PE-to-PE configuration. The simultaneity of the data bus is  $S=1$ , since the bus may be viewed as a parallel shift register and each processor may place one data packet on the bus at one time. "Carries" and synchronization information are provided between processors by the sync/carry loop (see Figure 11). Thus, there is interprocessor dynamic word size. Changing the settings of the BSMs changes the structure of HRMM and is accomplished by issuing commands on the Master CG CMD bus. The structure of the system may be viewed as a tree. The broadcast scope  $B=1/$

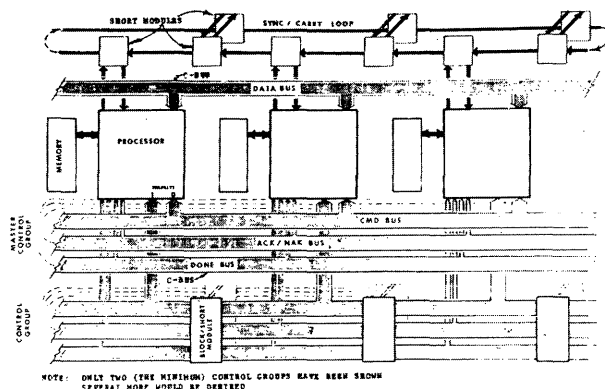

Figure 11—Hierarchical, restructurable multi-microprocessor architecture.<sup>2</sup>

$(N-1)$ , but broadcasting is possible on the data bus in  $N-1$  bus cycles by placing a "don't care" in the destination address.

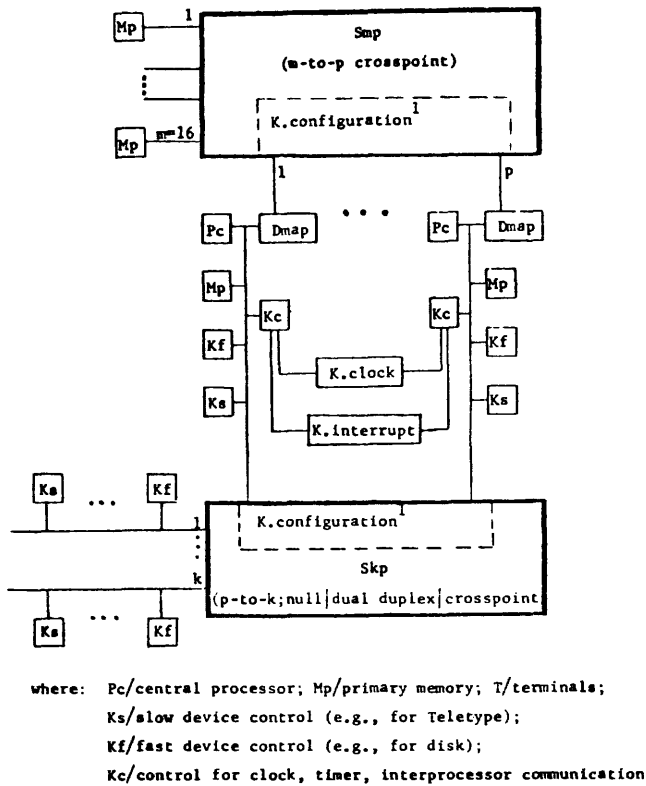

The data bus and CG buses are physically distributed and modular. CG and data bus widths and complexity are not completely specified so LSI compatibility cannot be established. The cost of the CGs is  $O(mN)$  and the cost of the data bus is  $O(N)$ , where  $m$  is the number of CGs. The delay through the CG buses is one control bus cycle. The worst case delay through the data bus is  $N-1$  data bus cycles, where a bus cycle is on the order of 50 ns.<sup>49</sup> The range and domain of the data bus are  $R=D=1/(N-1)$  because of its unconventional structure. Since data packets move from one processor to the next in a fixed amount of time (i.e., one bus cycle), one processor can only send data to or receive data from one other processor each bus cycle. The range and domain of the CG buses are a function of the BSM settings with a best case of  $R=D=1$ . The HRMM is readily expandable by adding more processors to either end. All processors are treated equally by the data bus, thus it is homogeneous.

The data bus is easy to use, whereas the CG buses are more complex due to their flexibility. The CGs are fault tolerant; however, the flexibility to configure them is reduced by varying degrees, depending on which BSMs fail. The data bus is not fault tolerant since a break in the loop makes it virtually unusable.

#### Crossbar switches

*Crossbar switch (CBS)* networks are shared bus networks in which  $p$  nodes can be connected to  $q$  nodes. Such a CBS is called a  $p \times q$  CBS. The cost of a  $p \times q$  CBS is  $O(pq)$ , and the delay of a CBS is constant. CBSs can be extended incrementally, the difficulty of which is implementation dependent. CBSs are modular in design, and may be appropriate for LSI, depending on the complexity of the crosspoints (e.g. queues).

*C.mmp*<sup>50</sup> is an MIMD system consisting of  $p$  processors, one large shared memory with  $m$  memory modules, and  $k$  I/O buses, as shown in Figure 12. The system contains two CBSs. One, the *Skp*, is a  $k \times p$  CBS which connects the  $k$  I/O buses with the  $p$  processors. The other, the *Smp*, connects the  $m$  memory modules with the  $p$  processors and is a  $m \times p$  CBS. Each processor is a self-contained PDP-11. The simultaneity is  $S = \min(k,p)/p$  for the *Skp* and  $S = \min(m,p)/p$  for the *Smp*. Both the CBSs are homogeneous and physically centralized. However, the (software) control is distributed. A memory address is translated by hardware into a setting for the CBS. This makes the CBS transparent to the user. There are hardware switches which can force the CBSs into a given state. The connectivity, range and domain are  $C=R=D=1$ , since any processor can be connected directly to any memory; however, processor-to-processor communications are limited to using a memory as an intermediate node. The broadcast scope is  $B=1/(N-1)$  and the broadcast delay is  $O(n)$ , using a recursive doubling scheme.

where: Pc/central processor; Mp/primary memory; T/terminals;  
 Ks/slow device control (e.g., for Teletype);  
 Kf/fast device control (e.g., for disk);  
 Kc/control for clock, timer, interprocessor communication

<sup>1</sup> Both switches have static configuration control by manual and program control

Figure 12—Block diagram of C.mmp which shows both CBSs.<sup>50</sup>

The C.mmp is completely partitionable, i.e., it can be reconfigured so that any set of processors can work together by sharing a memory. However, there may be some interference. As for fault tolerance, if a memory module or I/O bus fails, the hardware switches can be set to isolate the bad hardware from the rest of the system. Similarly, if a processor fails the switches can be set so that it cannot access any memory modules or I/O buses. However, a failure in either of the CBSs could force the entire system to stop.

The *Multi Associative Processor (MAP)*<sup>23</sup> is an MSIMD system consisting of eight control units and 1024 PEs. The PEs are grouped together into 16 sectors of 64 PEs each. All of the PEs in a sector are connected via a bus. The bus of each sector can be connected to any one of the eight control units via a 16x8 CBS, as shown in Figure 13. Having eight control units allows up to eight independent SIMD programs to be executed simultaneously. Any number of processors can be dynamically allocated to any one of the eight control units; however, the most efficient partitions will be those which put all of the processors of a given sector into the same partition.

The CBS of MAP is physically centralized. Each control unit makes its own requests, and there is a control unit supervisor which arbitrates conflicts.

The simultaneity is  $S=16/1024$  for intra-sector PE-to-PE communications and  $8/1024$  for inter-sector communica-

tions. Since each processor is treated equally, the network is homogeneous. Any processor can broadcast a data item to all of the processors via the CBS, and can send data to, or receive data from, any other processor, so  $B=R=D=1$ .

If a processor fails, it can be removed from the list of available processors. This means it can never be assigned to a program. If a sector fails, all of the processors in the sector can be removed from the list of available processors. A control unit failure means one less SIMD program can be run simultaneously; however the rest of the system can run unaffected.

CONCLUSIONS

Summaries of a wide variety of methods for providing interprocessor communications in reconfigurable large-scale parallel processing systems have been presented. A set of parameters for describing the features of these networks were defined. These parameters were used in the descriptions of the networks to provide a common basis for comparison. The rest of this section discusses future research directions in network design for a reconfigurable system.

Reconfigurable large-scale parallel processing systems are becoming more prevalent as hardware costs decrease and the knowledge about exploiting parallelism in tasks increases. The interconnection networks for these systems should be restructurable under software control. In applications where it is possible, parallel programs, including interprocessor communications, should be generated automatically, with the explicit parallelism hidden from the user. In applications where this is not possible, or for those who wish to have direct command over the parallel system

Figure 13—Diagram of the CBS for the MAP system.<sup>23</sup>

for efficiency or research, the network control must be accessible. For ease of use, each programmer dealing with a partition or submachine of size  $M$  should write network commands based on a logical numbering of the processors, from 0 to  $M-1$ . Furthermore, the user should specify communication paths in terms of destination tags, and let the processors or the network hardware itself compute the data paths, such as is done with the Omega network.<sup>21</sup> There should also be machine instructions for specifying particular network connections, e.g., a method to specify "+1 modulo  $M$ " on the Illiac.<sup>4</sup> Since these systems and their networks will have a large number of components, fault tolerance is very important. Networks should have the ability to work around faulty switch elements, as in the SW-banyan network.<sup>22</sup> Efficient methods for detecting faults in a network must be devised.

As the size of systems increases, the interest in SIMD machines will shift to MSIMD architectures, such as MAP.<sup>23</sup> To increase the range of applications these systems can handle, networks should be able to (1) allow all processors to transfer data simultaneously, (2) prevent independent users' submachines from communicating with each other, (3) allow a single user's submachines to communicate when desired, (4) allow submachines to be of different sizes, and (5) allow each submachine to control its network independently (as the ADM network can<sup>34,35</sup>). MSIMD systems with such communication abilities will have some fault tolerance in that a faulty component need only shut-down the smallest size partition (e.g. an MC group in PASM<sup>35</sup>). Furthermore, in SIMD applications that require high reliability, the task may be run simultaneously in several different partitions. Then the partitions can communicate with each other to confirm the validity of their results. (This assumes a suitable backup scheme for operating without or replacing the "master" controller in case of its failure.)

MIMD system networks should be able to support a high degree of simultaneity so that independent subsystems can communicate with minimum interference. Crossbar switches are too costly for large systems. Multiple bus systems such as those in CHO<sup>42</sup> and MMC<sup>49</sup> appear to be a promising approach. Ways to implement these networks, the use of packet switching, and techniques for evaluating MIMD networks need to be examined.

PSM systems have all of the advantages of MSIMD and MIMD systems. Furthermore, they allow a single system to be built, and then have its processors operate in any combination of either mode (MSIMD or MIMD), depending on the users' needs. Thus, for example, a system may simultaneously behave as four independent SIMD machines and two independent MIMD machines, all of different sizes. In addition, a group of PEs may, for example, do preprocessing for a pattern recognition task in SIMD mode and then the same set of PEs may continue the task in MIMD mode. How well proposed PSM networks such as the ADM and SW-banyan can support such activities must be evaluated, and new approaches must be explored.

Systems capable of varying their word size will also be more prevalent. Machines such as RVAP<sup>22</sup> and DC<sup>18</sup> will

provide flexible systems, capable of functioning as PSM computers, where each "composite processor" operates on a user designated word size. The "carry" lines portion of the network should be easily reconfigured, as with the "carry" network in DC. The inter-"composite processor" network should have the range and domain of a network like the SW-banyan, if operating on tasks which use a large number of "composite processors" that must communicate often. As in the PSM network area, network evaluation techniques and new schemes must be investigated.

Ways in which networks can exploit LSI technology must be studied. Physically distributed networks, such as those in DC<sup>18</sup> and CHO<sup>42</sup>, can be incorporated with other system components and take advantage of LSI. Most proposed and existing physically centralized networks do not take advantage of LSI, due to low complexity/pin count ratio. Future networks may make use of LSI by becoming more "intelligent." For example, architects could design switch elements capable of supporting features such as pipelining, conflict (switch contention) resolution, fault detection, fault tolerance, and destination tag-based routing.

Finally, network designers must not forget the user. Architects must remember that the networks they design must function efficiently for user problems. Therefore, networks should not be designed without considering the intended applications of the system the network is supporting. Work needs to be done in defining descriptive parameters for both networks and the communication needs of users' problems. By establishing a relation between these two sets of parameters, a problem could be analyzed to find its "communication needs parameters," and then the appropriate "network parameters" necessary to solve the problem efficiently could be determined.

## INTRODUCTION

The main characteristic of most powerful parallel systems is that their architecture is oriented towards specific types of problems to be computed. Such an orientation limits the range of tasks that can be effectively solved. As a result, systems are produced in small quantities which must bear all the costs of software and hardware development, and which are, as a result, very expensive. This slows down the computerization of many other complex problems just because they require that new high cost parallel systems be manufactured for their computation.

That is why it is timely to develop parallel systems that can change their architecture via software and thus can be oriented towards whatever problem is currently being computed. Such systems provide a programmer with an essentially new option—during the run-time of a single task he can perform multiple variations in the system architecture, each time selecting those system structures that speed up computation.

In general the architectures which change via software their structure to adapt to that of a program are sometimes called *adaptable* architectures. Now we may distinguish three classes of adaptable architectures—*microprogrammable*, *reconfigurable* and *dynamic*.

Consider historic evolution of adaptable architectures. The first computers had a static architecture which completely precluded any variation in the interconnections between their devices or functional units. With the advent of microprogrammable computers, a programmer was allowed to reconfigure interconnections between different devices such as registers, adders, counters, etc. This resulted in software-controlled variation of an instruction's microprogram. Consequently, computation was speeded up by the expedience of selecting microoperations which were more

task-oriented. Therefore, first adaptable architectures appeared in microprogrammable computers.

The next stage of adaptation had been achieved by introducing reconfigurable interconnections between various functional units, such as processors, memories, I/Os. Such architectures began to be called reconfigurable architectures. One of the first systems of this type was described by Estrin.<sup>1,2</sup> His restructurable system could change into a variety of problem-oriented special purpose configurations which speeded up computations for several classes of applications.

In the beginning of the 60s there appeared reconfigurable array parallel systems in which there was the option to change the number of and interconnections between processors working in the array.<sup>3,4</sup> Further development of array processors proceeded in the direction of establishing new patterns of configurations between various processors and in changing the processors' sizes. Subsequently, reconfiguration was used in other types of systems—pipeline, multiprocessing, multicomputer, etc.

In all, reconfigurable architectures provide the following performance gains:

1. In array systems an augmented vector parallelism is achieved by enlarging the dimension of a data vector processed with a single instruction.<sup>5-11</sup>
2. In pipelined systems the number of dummy-time intervals in the pipeline is minimized, caused by the disparity between program and pipeline structures.<sup>12-17</sup>
3. In multiprocessing systems an additional program parallelism is created by minimizing idle time of processor resource.<sup>18-26</sup>
4. In multicomputer systems computations are speeded up by allowing a closer match between the multicom-

puter network topology and that of a complex computed task.<sup>27-29</sup>

5. System reliability may be improved by deactivating faulty modules which may then be replaced with spares.<sup>30-38</sup>

Further evolution in adaptable architectures was marked by appearance of LSI modules with high throughput. Consequently, it became possible to achieve a higher degree of reconfiguration by activating not only interunit but also intermodule connections. As a result, the available hardware resources could be partitioned via software into a variable number of computers with variable sizes. This allowed one to accomplish the architectural adaptation to the number of available program streams by switching the architecture into the matching number of independent computers.<sup>39-52</sup> Such architectures were named dynamic.<sup>53</sup>

Although the basic feature of dynamic architectures which distinguishes them from other adaptable architectures is the adaptation to the number of parallel program streams, they may accomplish other adaptations, such as:

- a. The instruction set adaptation when the control unit may activate selectively not a single but tens of different instruction sets, each of which is oriented towards a separate class of dedicated applications. For instance, one set is dedicated to handling trigonometrical functions, another one to array processing, a third one handles FFT occurring in signal processing, etc.
- b. Pipeline adaptation means adaptation to parallel program streams when the architecture assumes different states characterized by the number of concurrent pipelines and the number of stages in each pipeline: or adaptation of the number of pipeline stages when the instruction activates the number of consecutive stages in the pipeline which matches the number of operations it realizes; or adaptation to operation time in each stage when each stage of a pipeline changes the time of operation; or adaptation on conditional branch, etc.
- c. Array adaptation means software formation of an architecture suitable for array processing. Furthermore, since different size computers are possible for a single state, array processing may be performed over different sizes of data words. When a dynamic architecture is switched to a state characterized by the array mode of operation, one of the computers assumes the function of a computer supervisor and broadcasts instructions and data addresses to all the other computers of the array, etc.

Finally, dynamic architectures require that each program be preprocessed by a so-called adaptation system in order to find the best architectural states to be assumed by an architecture in execution of a given set of concurrent programs.

In all, modern modular architectures may accomplish all three classes of adaptations mentioned previously—microprogrammable, reconfigurable and dynamic. For instance, the architecture may reconfigure interconnections on a mi-

crolevel (registers, adders, conditional flip-flops) and thus accomplish a microprogrammable adaptation. Or, it may reconfigure on the level of separate functional units and perform a reconfigurable adaptation. Or, it may reconfigure on the level of separate modules and perform a dynamic adaptation. Thus one obtains microprogrammable, reconfigurable and dynamic properties implemented in a single modular architecture.

Given paper is focused on adaptations to executed programs performed by dynamic architectures. Degrees of such adaptations will be characterized by so-called adaptation parameters the paper introduces. These are easily computed objective measures of evaluations expressed either in terms of time and/or in terms of hardware complexities. The paper also outlines general ideas of Dynamic Pipeline organization.

## ADAPTATION PARAMETERS FOR DYNAMIC ARCHITECTURES

Introduction of adaptation parameters is caused by the following reasons:

- a. They allow evaluation of different dynamic architectures from the viewpoint of how well they take into account computational specificities of programs.
- b. They may improve the work of an operating system. Indeed, an operating system must preprocess each program in order to find the best architectural states to be assumed by the dynamic architecture in its execution. Since several alternatives may be obtained, each of them must be evaluated using the adaptation parameters.

Let us show what adaptation parameters may be used to characterize major adaptation properties of dynamic architectures:

### *Bit size adaptation*

Dynamic architecture must be capable of forming variable size computers from the available hardware. Each new partitioning of the resource into a new set of concurrent computers is performed during the architectural switch from one state to another.<sup>41,42</sup> The time of such a switch will be called *the speed of bit size adaptation* (SBA). The SBA may vary depending on the concrete hardware organization. Since during this time execution of some programs may be halted, the SBA should be minimized.

**Example.** As shown in Reference 41, for a DC group, an architectural transition from one state to another is performed by a special architectural switch instruction whose duration is  $2mt_0 + 12t_0$ , where  $m \cdot t_0$  specifies memory speed, and  $t_0$  is the clock period equal to the time of eight-bit addition. For  $t_0 = 200$  nsec and  $m = 1$ ,  $SBA = 400 + 2400 = 2.8 \mu\text{sec}$ . •

The correct selection of computer size is another factor in executional speed-up. Since not only different programs but also different portions of the same program may handle

variable size data words, one program may be computed by a sequence of different size computers so that each task of this program is computed by a minimal size computer. This achieves executional speedup for all processor-dependent operations. This speedup depends on how accurately a computer's size matches that of the data words. Indeed, as an ideal computer, one may consider a computer which for each instruction assumes the maximal size of the data word used in its execution. However, this may lead to a rate of variation in computer sizes which coincides with the instruction rate, i.e., for a program made of  $N$  instructions, the overhead caused by reconfiguration will be  $SBA \times N$ .

Therefore, programs should be partitioned into tasks, so that each task is assigned an individual computer size. Each task may contain hundreds of instructions. For this case there will be some processor operations in each task which handle data words of smaller size than that of the computer selection. Execution of each such operation will be delayed by the time  $\Delta t$ , and the delay in execution of the entire task will be characterized by its *precision of bit size adaptation* (PBA). Clearly,  $PBA = \sum_{i=1}^f \Delta t_i$ , where  $f$  is the number of processor-dependent operations requiring a smaller computer size.

There is another factor which leads toward an increase in the PBA. Since the processor is assembled from  $h$ -bit modules, computer size is obtained in  $h$ -bit increments. Presently  $h=4$  or 8. However, technological advances leading toward a growth in the chip size will also lead toward an increase in  $h$ , but this will increase the PBA and therefore slow down computer processing.

**Example.** Let the program containing 800 instructions be partitioned into four tasks (Figure 1). For the first task, computed by a 48 bit computer, one constructs a diagram of bit sizes required by each processor operation in this task.<sup>54</sup> For the  $i$ th operation, delay in execution is defined as  $\Delta t_i = T(48) - T_i$ , where  $T(48)$  is the time of 48-bit addition. The time  $T(48)$  depends on the organization of carry propagation in the processor. Let the adder be equipped with four-bit group carry propagation, and suppose that the CLA circuit introduces a  $2t_d$  delay, where  $t_d$  is the time to switch

Figure 1—Partitioning of the program into tasks computed respectively by 48-, 32-, 16-, 32-bit computers.

Figure 2—Diagram of bit sizes for processor dependent operations in 48-bit task.

one gate. Since 48-bit addition requires 12 CLA groups,  $T(48) = 12 \cdot 2t_d = 24t_d$ . In this task, the first operation handles 40-bit words (Figure 2) and its time  $T_1 = 2t_d \cdot 10 = 20t_d$ . Therefore  $\Delta t_1 = T(48) - T_1 = 4t_d$ . The second operation handles 32-bit words and  $T_2 = 16t_d$  and  $\Delta t_2 = 8t_d$ , etc. By having found times  $\Delta t_i$  for all processor dependent operations and assuming that  $t_d = 10$  nsec, we find that  $PBA = 827t_d = 8.27 \mu\text{sec}$ . •

#### Adaptation to program streams

Dynamic architectures allow one to achieve a trade-off between computer sizes and parallelism, i.e., by reducing bit sizes one may augment the number of concurrent computers formed from the same equipment. Such an architectural feature allows one to maximize the number of program streams computed by the same equipment. As shown in Reference 54, the assignment of independent programs to computers working in different architectural states is performed by the operating system. The effectiveness of this assignment may be evaluated with a so called *resource utilization factor* (RUF) found for each architectural state,  $N_a$ , as follows. Assume that for a state,  $N_a$ , a complete utilization of the resource is achieved if all its concurrent computers work continuously during the entire time,  $T_a$ , the state  $N_a$  exists. However, for the real case, some of the computers of state  $N_a$  may work only part of the time, so

that if  $N_a$  is characterized by  $d$  computers with sizes  $h \cdot k_1, h \cdot k_2, \dots, h \cdot k_d$ , working during times  $T_1, T_2, \dots, T_d$  respectively, then the RUF for state  $N_a$  is found as follows:

$$\text{RUF}(N_a) = \frac{h \cdot k_1 \cdot T_1 + h \cdot k_2 \cdot T_2 + \dots + h \cdot k_d \cdot T_d}{h \cdot T_a \cdot (k_1 + k_2 + \dots + k_d)} \cdot 100\%$$

Since  $k_1 + k_2 + \dots + k_d = n$ , where  $n$  is the number of computer elements,<sup>53</sup> then

$$\text{RUF}(N_a) = \frac{k_1 \cdot T_1 + k_2 \cdot T_2 + \dots + k_d \cdot T_d}{n \cdot T_a} \cdot 100\%$$

Note, that if an  $h \cdot k_1$ -computer does not work in the state  $N_a$ , then the time  $T_i = 0$ .

**Example.** For state  $N_6$ , let a DC group with  $n=4$  computer elements and  $h=16$  form two 16-bit computers  $C_1(1)$  and  $C_2(1)$  and one 32-bit computer  $C_3(2)$ . Let this state be established for 32 min, but  $C_1(1)$  works during  $T_1=24$  min,  $C_2(1)$  works during  $T_2=27$  min and  $C_3(2)$  works for  $T_3=32$  min. For  $C_1(1)$ ,  $k_1=1$ ; for  $C_2(1)$ ,  $k_2=1$ , for  $C_3(2)$ ,  $k_3=2$ . Thus

$$\text{RUF} = \frac{1 \cdot 24 + 1 \cdot 27 + 2 \cdot 32}{4 \cdot 32} \cdot 100\% = 89.8\% \bullet$$

#### Adaptation to program structures

A significant executional speed-up may be achieved by introducing special instructions which take into account specifics of the computed programs. Such instructions may activate execution of complex sequences of operations, such as  $\frac{A^2 - B^2}{C} \cdot D$  or  $(A + B - C^2) \cdot (A - C)$ , etc. Each such instruction is equivalent to several conventional instructions, so its use results in a minimization of the number of memory access operations. However, introduction into an instruction set of a large number of dedicated instructions narrows the area of application for a parallel system. To offset this problem one has to augment the size of the instruction set. However, such an augmentation is accompanied by an increase in the op-code size. It then follows that the word size,  $h$ , of a memory element,  $ME$ , also increases. However, as was shown above, it is unreasonable to increase  $h$  because it leads to a corresponding increase in the size of each computer element. For instance if one increases  $h$  from 16 to 24 bits, then the dynamic architecture may form computer sizes in 24-bit increments, i.e., it forms 24-, 48-, 72-bit computers, etc. Therefore, architectural adaptation to program streams and bit sizes will decrease, leading to a worsening of the PBA and RUF factors introduced above. As a result, the architecture reduces the number of parallel program streams which may be formed on the existing equipment. It will likewise increase delays in execution of processor dependent operations. That is why the expansion of an instruction set must be accompanied by no consequential increase in the size of the op-code.

Let us introduce one technique named *dynamic adaptation of an instruction set* which accomplishes this objective. The idea of this technique consists of the following. The

control unit may activate selectively not a single but tens of different instruction sets each of which is oriented towards a separate class of dedicated applications. For instance, one set is dedicated to handling trigonometrical functions, another one to array processing, a third one handles FFTs occurring in signal processing, etc. Each set contains for instance 256 instructions partitioned into two categories—dedicated and general-purpose. The difference between sets is in the dedicated instructions. A computed program activates the instruction set which most closely matches its computational algorithm. Such selective activation is made via software by writing a special control code  $\gamma_i$ .

Consider now how one may organize the dynamic adaptation of an instruction set. The control unit contains a special unit which implements the Dynamic Instruction Set, DIS unit. This unit contains  $p$  states,  $IS_1, IS_2, \dots, IS_p$ , each of which is identified with one instruction set. Activation of set  $IS_i$  is performed by the writing of a special code  $\gamma_i$ . Transition of the DIS unit from one instruction set,  $IS_i$ , to the next instruction set,  $IS_j$ , is performed by writing another code  $\gamma_j$  corresponding to  $IS_j$ . When the Dynamic Instruction Set unit establishes state  $IS_i$ , the computer executes instructions from instruction set  $IS_i$ . This is recognized by the op-code  $D$  so that if  $w$  is the bit size of op-code  $D$ , each  $IS_i$  contains  $2^w$  different instructions. Therefore, the same op-code corresponds to  $p$  different instructions belonging to  $IS_1, IS_2, \dots, IS_p$  respectively. It follows that  $D$  and  $\gamma_i$  together recognize a unique instruction from the instruction set  $IS_i$ . Thus this organization allows one to implement a Dynamic Instruction Set without any consequential increase in the size of code  $D$ . Before the computation of a program or task one has to write to the control unit only one code,  $\gamma_i$ , and the computer begins to activate instructions belonging to the instruction set  $IS_i$ .

Selection of the instruction set  $IS_i$  which most closely matches the structure of a given program is performed by the assignment subsystem of the operating system that also defines the computer sizes for consecutive tasks of a computed program.<sup>54</sup> To this end, the same program graph is used for analysis that was constructed for finding computer sizes. For each graph node, the operating system specifies all the sequences of consecutive operations that this node executes. For instance, if node  $b$  executes formula  $[(A^2 - B^2) \times C] / D$ , then the sequence of operations which is found is  $(\times, \times, -, \times, \div)$ . Next, for each sequence of operations constructed in the node, the operating system finds the frequency,  $N$ , of its appearance in the program. The number  $N$  will be used in the future for determining the executional speed-up gained from using this sequence as a dedicated instruction. Consider now how the operating system may select the most appropriate instruction set. This is done by finding, for each instruction set  $IS_i$ , the executional speed-up  $SPA_i$  (speed-up on program adaptation) prompted by the use of  $IS_i$  in the computation of a given program. Indeed, an operation sequence composed of  $d$  consecutive operations is executed by a conventional microprogrammable computer as a subroutine made of  $d$  instructions where each instruction executes one operation. (We exclude from consideration all instructions fetching data for the  $d$  operations,

because it is assumed that the number of such instructions is the same for a complex dedicated instruction and for a subroutine, and thus depends solely on the way storage of the data words required for the operation is organized.) Each instruction in such a subroutine takes time  $t_m$  for instruction fetch and the time  $t_{op}$  for operation execution. It then follows that if one operation sequence containing  $d$  operations is organized as one dedicated instruction, the resulting speed-up,  $SIA_j$ , prompted by instruction adaptation is  $SIA_j = t_m \cdot (d-1)$ .

Therefore, the procedure for finding the speed-up by program adaptation,  $SPA_i$ , for instruction set  $IS_i$ , consists of the following: For each sequence of operations formed in the program, the operating system finds whether or not such a sequence may be implemented as a single dedicated instruction,  $I_j$ , from instruction set,  $IS_i$ . If it does, then the operating sequence finds the overall speed-up  $SIA_j \cdot N_j = t_m(d_j-1) \cdot N_j$  where  $N_j$  is the frequency with which this sequence appears in the program. If it does not, then  $SIA_j \cdot N_j = 0$  and the next sequence is analyzed. Having found all  $SIA_j \cdot N_j$  speed-ups, the operating system finds the total  $SPA_i$  for the instruction set  $IS_i$ :

$$SPA_i = \sum_{j=1}^t SIA_j \cdot N_j$$

where  $t$  is the number of operation sequences constructed for the program. Of the  $p$  times,  $SPA_1, SPA_2, \dots, SPA_p$  found for the  $p$  instruction sets  $IS_1, IS_2, \dots, IS_p$  respectively, the maximum,  $SPA^*$ , is selected. The respective  $IS^*$  provides the best adaptation to the program structure.

**Example.** Let  $t_m$  be 200 nsec and the operation sequence  $A \cdot B - (C + A)$  be repeated in the program 43 times ( $N_1 = 23$ ). Since this sequence has three operations,  $SIA_1 = 200 \cdot (3-1) = 400$  nsec. A second operation sequence  $(A-B) \cdot C$  has  $N_2 = 35$  and  $SIA_2 = 200$  nsec. The third sequence  $(A-B+C)/C-D+C$  has  $N_3 = 72$  and  $SIA_3 = 200 \cdot 4 = 800$  nsec; the fourth sequence

$(A^2 - B^2) \times (C^2 - D^2) / A + B$  has  $N_4 = 46$  and  $SIA_4 = 200 \cdot 8 = 1600$  nsec. Let instruction set  $IS_1$  have dedicated instructions 1, 2, 4 and  $IS_2$  have dedicated instructions 1, 2, 3. Find  $SPA_1$  and  $SPA_2$ :

$$SPA_1 = 400 \cdot 43 + 200 \cdot 35 + 1600 \cdot 46 = 97.8 \mu\text{sec.}$$

$$SPA_2 = 400 \cdot 43 + 200 \cdot 35 + 800 \cdot 72 = 71.8 \mu\text{sec.}$$

Therefore  $IS_1$  achieves a better adaptation to the program structure. •

*Array adaptation*

Dynamic architecture may form an architecture suitable for array computations. Furthermore, since different size computers are possible for a single state, array processing may be performed over different sizes of data words. When dynamic architecture is switched to a state characterized by the array mode of operation, one of the computers assumes the function of a computer supervisor and broadcasts instructions and data addresses to all the other computers of the array. This transfer is done not through the I/O devices but by using the memory-processor interconnection bus which connects memory modules to processor modules. Note that introduction of different size computers requires that the computer supervisor broadcast instructions at the processing rate of the largest computer. Such synchronization in array processing may be accomplished if the largest computer sends a completion signal the moment it completes execution of the present instruction. This signal is sent through a special line of dynamic signals<sup>41</sup> which connects all PEs.

**Example.** Let the hardware resource containing  $n=6$  computer elements (Figure 3) be switched into an array structure containing three computers  $C_1(1), C_2(2), C_4(3)$ . Assume that  $C_1(1)$  is the computer supervisor, so its  $ME_1$  stores all instructions which are broadcasted to all PEs. The same data

Figure 3—Array adaptation of dynamic architectures.

address generated by  $PE_1$  is sent to all six  $MEs$ , causing concurrent fetch of a data vector composed of a 32-bit and a 48-bit operand handled by  $C_2(2)$  and  $C_4(3)$  respectively. The rate of instruction broadcast is limited by the speed of the 48-bit computer. •

Note: The option of forming various size computers for array computations may lead toward an increase in the dimension of a data vector computed with a single instruction, i.e., the number of operands computed in parallel may increase. This may be accomplished by selecting the minimal computer size for each operand.

Therefore, the array mode of operation may be characterized by the *array adaptation of equipment* (AAE) which shows the percentage of redundant equipment left in each computer by selecting a computer size exceeding that of an operand. Namely, in the array made of  $r$  data streams, for an  $i$ th data stream ( $i=1, \dots, r$ ), one finds the maximal data word size,  $WS_i$ . If the  $i$ th stream is computed by a computer of size  $CS_i$ , then for the  $i$ th stream,  $AAE_i = (1 - WS_i/CS_i) \cdot 100\%$  and the overall AAE shows the percent of unused equipment in the entire array:

$$AAE = \left(1 - \frac{WS_1 + WS_2 + \dots + WS_r}{CS_1 + CS_2 + \dots + CS_r}\right) \cdot 100\%$$

**Example.** Let a program requiring array computations have four data streams with  $WS_1=20$  bits,  $WS_2=28$  bits,  $WS_3=22$  bits and  $WS_4=32$  bits. Let this program be computed by two dynamic architectures. The first one forms computer sizes in eight-bit increments, i.e.,  $h=8$ , and the second one has  $h=16$ . Find the AAE for both architectures. The first architecture forms the following computer sizes in the array:  $CS_1=24$  bits,  $CS_2=32$  bits,  $CS_3=24$  bits and  $CS_4=32$  bits. Therefore,

$$AAE(I) = \left(1 - \frac{20+28+22+32}{24+32+24+32}\right) \cdot 100\% \\ = (1 - 0.91) \cdot 100\% = 9\%$$

The second one has  $CS_1=32$ ,  $CS_2=32$ ,  $CS_3=32$ ,  $CS_4=32$ .

$$AAE(II) = \left(1 - \frac{20+28+22+32}{32 \cdot 4}\right) \cdot 100\% \\ = 20.3\% \bullet$$

### Pipeline adaptation

Dynamic architectures must be capable of switching into configurations specific for pipeline computations. They will then be called dynamic pipeline architectures (DPA). Consider the properties a DPA should possess in order to achieve adaptation to an executed program.

#### Adaptation to parallel streams

Since a computed program may be decomposed into several pipelined streams, DPA must be capable of assuming different architectural states where each state is specified by the number of concurrent pipelines and the number of

stages in each pipeline. A transition from one state to another should be performed via software, during the time of program computation. This allows the performing of dynamic redistribution of the resource by selecting pipelines which take into account the specificity of the computed programs.

**Example.** Let a DPA be equipped with  $S$  architectural states,  $N_0, N_1, \dots, N_{S-1}$ . Then for state  $N_0$ , the entire resource goes into the formation of, say, three pipelines each containing five stages, i.e.,  $N_0=(3 \times 5)$ . For another state,  $N_1$ , it is formed into two pipelines with four stages each and two pipelines with three stages each,  $N_1=(2 \times 4, 2 \times 3)$ . For the third state  $N_2$ , it forms three pipelines with six, five, and four stages respectively, i.e.,  $N_2=(1 \times 6, 1 \times 5, 1 \times 4)$ . •

#### Adaptation on operation sequences

As was just shown, effective adaptation to a program may be achieved if the computer architecture is equipped with dedicated instructions each of which realizes a complex sequence of operations. When such an instruction is executed by the pipeline, each state of the pipeline must be assigned to one operation in the sequence. It then follows that each stage must be capable of executing any operation. This may be achieved if each pipeline stage is implemented as an  $h$ - $k$ -bit computer capable of executing any operation provided by an instruction.

**Example.** A single pipeline must be capable of implementing different sequences of operations such as  $(-, +, \times, \div)$  in arithmetic expression  $[(A-B) \times (C+D)]/E$ , or  $(\times, -, \div, +)$  in  $(A \times B - C)/D + E$ , etc. •

#### Adaptation on the number of pipeline stages

One of the basic problems of modern pipelined systems is their inability to quickly vary the number of stages contained in a single pipeline. Indeed, existing techniques<sup>55-57</sup> provide that instructions bypass the unneeded stages. But this may involve conflicts when one instruction, as a result of such bypassing, jumps to the operands prepared for preceding instructions. On the other hand, if no such bypassing is implemented, the pipeline contains a permanent number of stages specified by the instruction containing the maximal sequence of operations. All other instructions which implement shorter sequences are slowed down because they have to pass through all stages. To alleviate this problem, each instruction must activate the number of consecutive stages in the pipeline which matches the number of consecutive operations it realizes. Consequently, the duration of each instruction will depend only on the number of its consecutive operations.

**Example.** In a pipeline made of five stages the instruction which implements the formula  $(A+B) \times C - D$  containing three operations  $(+, \times)$  must be executed only in the first three stages, i.e., the computational result should be output

by the third stage and be prevented from going to the fourth and fifth stages. •

#### Adaptation to operation time in each stage

Each stage of a pipeline may speed up execution if it changes the time of operation. As was shown in References 41 and 42, such a variation may be accomplished if each  $h \cdot k$ -bit computer, implemented as a stage, is equipped with modular control organization, which can change the time of operation with a special control code  $p$ , where  $p$  is the number of minor clock periods,  $t_o$ , a processor-dependent operation requires to execute in a given size computer. As was shown in Reference 42, this code  $p$  may also reconfigure the processor into a minimal size. Therefore, if each pipeline instruction stores its own code  $p$ , then each pipeline stage will be able to reconfigure into the minimal size computer and generate the minimal time interval for a processor dependent operation. As for processor-independent operations (Boolean, shifts, conditional branches on  $=$ ,  $\neq$ , tests of flip-flops, etc.), the modular control organization may speed up their executions as well. The reason for this is that for any size computer the same clock period,  $t_o$ , the time of eight-bit addition, is used. That is, a processor-independent operation may be executed during one  $t_o$  rather than during the longer time of a processor-dependent operation.

Therefore, if each stage is realized as an  $h \cdot k$ -bit computer, then the time of operation in this stage may range from one  $t_o$  to  $t_o \cdot k$ . For instance, in a 64-bit computer with no CLA circuits,  $h=8$ ,  $k=8$  and the time of operation may range from one  $t_o$  to  $8t_o$ . If CLA circuits are used, a  $p < 8$  is selected. It then follows that if the time of an operation executed in the  $i$ th stage is also adaptable, one obtains additional executional speed-up in the pipeline.

However, the problem which must be overcome is the problem of so-called *pipeline races*. Indeed, variation of operation times in pipeline stages may lead to a situation in which an instruction containing a shorter operation executed in the  $i$ th stage may beat the preceding instruction which executes a longer operation in the  $(i+1)$ th stage. Thus, the result of the  $i$ th stage will be routed to the  $(i+1)$  stage before the  $(i+1)$  stage finishes its operation. As will be shown in the fourth section pipeline races can be easily solved in dynamic pipeline architectures by introducing synchronous movement of instructions from stage to stage. For this case, the pipeline rate is governed by the same traffic rules which are applicable to a highway traffic when a police car appears. Assume that from the viewpoint of a pipeline, a police car has a long operation time. Thus all cars (instructions) which follow a police car within the county limits (pipeline) move with the speed of this car. On the other hand, preceding cars may move with higher speed, i.e., for preceding instructions with shorter operations, the pipeline rate may increase. Therefore, the rate of both a highway and a pipeline may increase if the highway has no police car and the pipeline contains no instructions with long operations.

**Example.** Let us compare two types of pipeline:  $P_1$  with permanent rate and  $P_2$  with changeable rate. Assume

that  $P_1$  and  $P_2$  have pipeline stages implemented as 64-bit computers so that  $P_1$ 's rate is that of a 64-bit addition whereas  $P_2$ 's rate depends on the sizes of data words and operation types. Let the time of 64-bit addition,  $T(64)=400$  nsec, and the time of 32-bit addition be  $T(32)=200$  nsec. Find the times,  $T(P_1)$  and  $T(P_2)$ , required by both pipelines for execution of the same operation sequence  $((A \wedge B) + C - F) > K$  corresponding to a conditional branch instruction where  $A, B, C, F, K$  are 32-bit operands. Since the first pipeline has the same time for each stage and the operation sequence  $(\wedge, +, -, >)$  takes four operations,  $T(P_1)=400+400+400+400=1600$  nsec. As for the second pipeline, it executes 32-bit addition for  $t(32)=200$  nsec and logical multiplication for  $t_o=100$  nsec. Therefore it executes instruction  $((A \wedge B) + C - F) > K$  during the time  $T(P_2)=100+200+200+200=700$  nsec. Thus, implementation of changeable rates in pipelines is a source of additional speed-up. •

#### Adaptation on conditional branch

As was shown in Reference 55, a general weakness of pipeline architectures is pipeline drains due to conditional branching. Indeed, a pipeline architecture may have dummy-time intervals when no processing is performed if, as a result of a conditional test, the program switches to another instruction sequence which was not already being processed by the pipeline stages. The problem of conditional branch may be solved if the architecture switches into architectural states containing several independent pipelines, of which one is selected as the main and others are subsidiary. For this case true (incremental) and false (specified with jump address) program sequences may be computed respectively by two independent pipelines, main and subsidiary, where a subsidiary pipeline is switched into operation only during the respective conditional branch instruction, i.e., its instruction memory replicates the entire program. If the conditional branch is made to the instruction sequence computed in the subsidiary pipeline, then it transfers all computational results necessary for further computations to the main pipeline and stops computation.

Note, if several subsidiary pipelines are available, the architecture may effectively organize multiport branching, minimizing the number of dummy-time intervals. Since DPA may form several concurrent pipelines for a single architectural state, it may effectively solve the problem of adaptation on conditional branch.

**Example.** Let the conditional branch instruction  $I_1$  requiring execution of the conditional test  $(A - B)^2 / K + C > W$  store jump address  $A_F$ . Since decision on selection of either true or false program sequences is made only at the fifth stage of the basic pipeline, it begins execution of instructions  $I_{2T}$  and  $I_{3T}$ , which immediately succeed  $I_1$  in the true sequence, before it completes the conditional test. However, before entering the basic pipeline, instruction  $I_1$  transfers the jump address  $A_F$  to the subsidiary pipeline, which begins execution of the false instruction sequence  $I_{2F}, I_{3F}$ , etc. If the fifth stage of the basic pipeline transfers control to the

false sequence executed in the subsidiary pipeline, then each  $i$ th stage of the subsidiary pipeline ( $i=1, \dots, 4$ ) broadcasts its computational result to the  $i+1$  stage of the basic pipeline. Therefore, the basic pipeline continues computation as if it had contained the false sequence. •

#### *Adaptation to program compatibility*

As was noted above, a dynamic architecture may organize execution of a program with a sequence of computers which are different in size. Such organization speeds up computations and augments program parallelism using the same resource. However, a real performance improvement may be realized only if during a transition from one computer size to another, the program undergoes only insignificant changes in the instruction fields. Therefore an important characteristic of dynamic architecture is how well it adapts to execution of a program by a sequence of computers with variable sizes. Ideal was the case when complete universality of executed programs was achieved.<sup>41,42</sup>

This was the case requiring no modifications in instruction fields when a program was computed by different sizes computers. The following architectural solutions implemented such program universality:

1. Modular control organization,<sup>42,58</sup> which eliminated from instructions all codes which changed their meanings when computer size changed. Instead, it provided that all such codes be stored in every LSI module of an  $h \cdot k$ -bit computer.
2. A new memory allocation technique, called parallel-serial exchange, which provided (a) a unique instruction size ( $h$ -bits); (b) storage of instructions consecutively in a single memory element having the same width ( $h$ -bits); and (c) storage of an  $h \cdot k$ -bit data word in a single parallel cell of  $k$  memory elements, all specified by the same relative address. Such a storage technique maintained the sizes of data and program arrays when they were moved from one computer to another. As a result, no modifications of addresses (operand or jump) stored in the instruction field were required. However such universality was achieved only for DC group computers.<sup>41,42</sup>

Therefore, any dynamic architecture must be characterized by the time a computed program adapts, before it may be executed. This time is called the Time of Program Adaptation (TPA),

$$TPA = \sum_{k=1}^N t_k$$

where  $t_k$  is the time to modify a  $k$ th program instruction,  $N$  is the overall number of instructions which should be modified.

#### *The use of adaptation parameters in operating systems*

The adaptation parameters introduced above should be used by the operating system in order to specify what states a dynamic architecture should assume in order to enhance performance. A program written in a high-level language is preprocessed by the operating system, which consists of three subsystems—adaptation, assignment and monitor.

**The adaptation system** finds a dedicated instruction set  $IS_i$  to be activated by each user program in Dynamic Instruction Set unit.

**The assignment system** assigns the available hardware resources between user programs and constructs a flow chart of architectural states assumed by a dynamic architecture in executing a given set of concurrent programs.

**The monitor system** supervises correct execution of the flow chart constructed by the assignment system.<sup>54</sup>

Let us briefly describe each of the subsystems.

The adaptation system analyzes a program written in a high-level language in order to define a set of complex dedicated instructions which speeds up computation of this program. Since during such analysis one may obtain several sets of dedicated instructions, the adaptation system has to evaluate each such set from the viewpoint of the executional speed-up it gives. To this end it finds the speed-up on program adaptation,  $SPA_i$ , for each dedicated instruction set and selects that instruction set which gives a maximal SPA.

In case that program should be partitioned into tasks each requiring its own dedicated instruction set,  $IS_i$ , the adaptation system assigns to each task the most appropriate instruction set and specifies the sequence of different instruction sets required to execute this program. Transition from instruction set  $IS_i$  to  $IS_j$  is performed by a special program instruction which stores code  $\gamma_j$ .

Note that the adaptation subsystem should also preprocess programs which are computed by a dynamic pipeline architecture. For this case a program is partitioned into a sequence of tasks,  $TA_1, TA_2, \dots, TA_k$ , in which  $TA_i$  is characterized by the maximal length  $F_i$  of the pipeline required. Each instruction belonging to task  $TA_i$  activates only  $w$  consecutive stages in this pipeline where  $w(w \leq F_i)$  is the number of its operations, each of which is executed by one pipeline stage. The number  $F_i$  is identified by the assignment subsystem considered below.

The assignment system may have two modifications dependent on the type of computations performed by dynamic architecture—conventional and pipelined. Basic features of the conventional assignment system are considered in Reference 54. As for a pipelined system, their development is one of the objectives of current research performed by these authors.

For conventional computations, the assignment subsystem specifies a sequence of minimal size computers which may execute every user program. Reference 54 describes techniques for partitioning a program into tasks where each task is computed by a permanent size computer. Since there

are different alternatives in this partitioning, each has to be evaluated using the precision of bit size adaptation criteria, PBA, considered above. Since each PBA characterizes the delay in execution of a single task introduced by selecting an inaccurate computer size, then the partitioning should be performed which gives the minimal delay in execution of all tasks.

Next, the available hardware resources have to be assigned among concurrent user programs, each of which is executed by a sequence of the minimal size computers found earlier. Since the assignment system may find several alternatives for assigning programs to computers, for each alternative it has to compute the resource utilization factor, RUF, which shows the percentage of the equipment use achieved with this alternative. Thus, it selects the option characterized by the highest RUF.

For pipeline computations, each program is first preprocessed by the assignment subsystem and then by the adaptation system. The reason for this is as follows. In the execution of a set of concurrent problems, a dynamic pipeline architecture executes a system flow chart. Each state of this flowchart is specified by the number and lengths of concurrent pipelines. It then follows that construction of a flowchart establishes the length (number of stages) of each pipeline in each architectural state. Thus a sequence of operations assigned to one pipeline cannot exceed its length. If one sequence exceeds the length of the pipeline where it is computed, then it has to be split into several sequences, each of which has to be assigned to a separate pipeline instruction. Therefore, for each program one may find a dedicated instruction set only after construction of the system flow chart, because each architectural state of the flowchart establishes the limit on the number  $w$  of consecutive operations to be assigned to a single dedicated instruction. As was shown,  $w \leq F$ , if this instruction is assigned to a pipeline with  $F$  stages. The basic features of the monitor system for conventional computations were described in References 41 and 42.

For pipelined computations they are yet to be developed.

## DYNAMIC PIPELINE ARCHITECTURE

Earlier we established the properties needed by a dynamic pipeline architecture (DPA) in order to be effectively adapted to executed programs. Let us show that all these properties may be implemented in a DPA assembled from DC groups described in Reference 42.

Consider now how one may organize one pipeline. Its hardware resource may be formed into a single computer supervisor,  $C_0$ , and several  $h \cdot k$ -bit computers,  $C_1, C_2, \dots, C_F$ , forming consecutive pipeline stages. Computer  $C_0$  stores instructions in memory  $M_0$  and fetches them to processor  $P_0$  (Figure 4). The  $C_0$  computer's size matches that of one instruction. Each pipeline computer  $C_i$  has memory  $M_i$  for storing data, processor  $P_i$ , and general register set  $m_i$ , which stores temporary results required by the  $P_i$  pro-

cessor. These are either computed by  $P_i$  or by other processors.

Two consecutive pipeline stages  $C_i$  and  $C_{i+1}$  are separated by the connecting element  $MSE_i$ , which may assume two modes of operation:

- a. Right transfer—it receives the pipelined instruction and sends it to the next stage  $C_{i+1}$  with a delay of one interval.
- b. No transfer—the instruction it receives is not transferred to the next  $C_{i+1}$ .

Connecting elements  $ASE_1, \dots, ASE_F$ , are connected into a shifting sequence, and transfer several addresses. Each time a pipeline stage  $C_i$  receives an operand and executes the operation assigned to it by the program instruction  $i$ , receives a word shifted from  $ASE_{i-1}$ . It then follows that  $ASE_i$  is synchronized by state  $C_i$  and stores a word received from  $ASE_{i-1}$  during the time  $C_i$  executes operation. If the result of this operation should be written to some general register set  $m_j$ , the  $ASE_i$  sends the address for that set to state  $C_i$ . Thus the number of MSE and ASE connecting elements is the same and matches  $F$ , the number of pipeline stages. Both an MSE and ASE may be implemented on a universal LSI module equipped with the modular control organization.<sup>42,58</sup>

Each instruction fetched from  $M_0$  to  $P_0$  includes two portions—the pipeline portion,  $PI$ , and the address portion,  $AI$ . By passing through the bus made of MSE connecting elements, the pipeline portion,  $PI$ , propagates through consecutive pipeline stages with a delay of one interval, causing execution of an operation assigned to each stage. Concurrently, the address portion,  $AI$ , of the instruction propagates through the bus made of ASE connecting elements and specifies a pipeline stage,  $C_i$ , which should output the result, and a general register set  $m_j$ , which should receive this result.

We introduce now a format for the portions  $PI$  and  $AI$  of the instruction.

### *PI instruction*

In order to adapt to the operation, it is necessary that each  $PI$  store its own op-code  $D$ . However, when the same  $D$  propagates through the pipeline stages, it will activate the same operation in each stage. In order that each stage,  $C_i$ , execute an individual operation,  $C_i$  should store a position code,  $i$ , which shows its position within the pipeline. These two codes,  $D$  and  $i$ , achieve the selective activation of an operation assigned to stage  $C_i$  by instruction  $PI$ . The number of bits in code  $D$  is  $\log_2 \#(IS)$ , where  $\#(IS)$  is the size of an instruction set.

Adaptation to the length of the pipeline is performed with another code,  $w$ , which shows the number of consecutive pipeline stages which execute instruction  $PI$ . Clearly  $w$  matches the number of consecutive operations which are

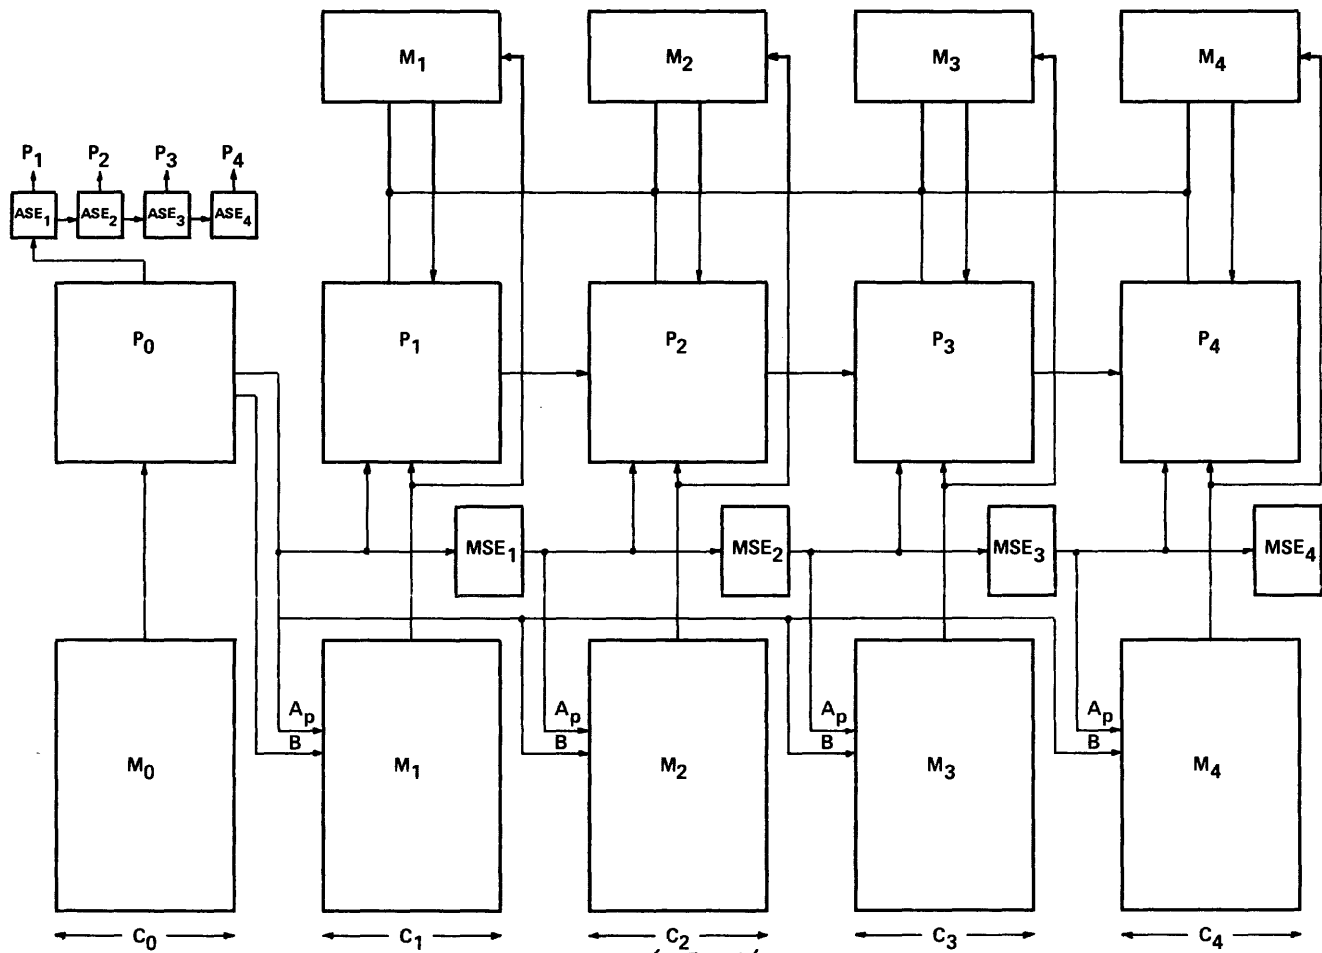

Figure 4—Dynamic pipeline architecture.

realized in  $PI$ . By propagating through each connecting element,  $MSE_i$ , containing position code  $i$ ,  $w$  is compared with  $i$ . If  $i < w$ ,  $MSE_i$  propagates this  $PI$  instruction to the next stage with delay of one time interval. If  $i \geq w$ ,  $MSE_i$  blocks further instruction propagation, ending the execution of instruction  $PI$ . Therefore, by writing a code  $w$  into the instruction field, one may select the number of pipeline stages required by a single instruction.

This technique allows one to perform a simple adaptation of the number of pipeline stages that requires no bypassing of unneeded stages and no conflict resolution associated with such bypassing. The entire problem is solved by the code  $w$  with size  $w = \log F$  bits, where  $F$  is the maximal length of the pipeline, which can be formed by Dynamic Pipeline Architecture.

Adaptation of each stage to operation time is performed with another code,  $p$ , stored in the  $PI$  instruction. Since each LSI module of processor  $P_i$  is equipped with the same modular control organization,<sup>42,58</sup> this allows one to organize variable time intervals for any processor dependent operation. To this end a special sequencer,  $CAD-M$ , is activated. It passes through a loop containing  $p$  states where each state lasts one clock period,  $t_0$ . For  $p=2$ ,  $CAD-M$

passes through a two-state loop, giving  $T_{op} = 2t_0$ ; for  $p=3$ ,  $t_{op} = 3t_0$ , etc.

For pipelines however, the modular control organization is slightly modified as compared to conventional DC groups. Indeed, in a DC-group a new meaning of code  $p$  is written to each LSI module during each architectural transition. Thus all the LSI modules contained in a computer store the same  $p$  during the time this computer exists. For pipelines, the time of operation required by stage  $C_i$  depends on the  $PI$  instruction. A new meaning of code  $p$  must therefore be brought to  $C_i$  with each  $PI$  instruction. The size of  $p$  is  $\log_2 n$  where  $n$  is the maximal computer size which may be formed by DPA.

Therefore three codes,  $D$ ,  $w$ , and  $p$ , effect a pipeline's adaptation to the operation, to the length of the pipeline, and to the time of operation executed by each pipeline stage.

In addition to adaptation codes, each  $PI$  instruction stores the relative address,  $A_p$ , of  $M_i$  memories where each memory  $M_i$  stores a word required by the  $C_i$  stage. The cell accessed by address  $A_p$  may store either an operand used for execution in the stage  $C_i$ , or an  $r_p$ -address of the general register set  $m_i$ . Using this address, a second operand is fetched to  $C_i$  from  $m_i$ . A special tag bit,  $e$ , in the cell

accessed by  $A_p$  address recognizes whether the second operand is stored in  $M_i$  or  $m_i$ .

In order not to have any limitations on the height of memory  $M_i$  and not to increase the bit size of  $PI$ , it is assumed that  $A_p$  is a relative eight-bit address. The effective address  $E$  (24 bits) is formed from a concatenation of the base address  $B$  (16 bits) and address  $A_p$  (eight bits). Base address  $B$  is fed continuously to all  $M_i$  memories during the execution of one task. It is changed when data words have to be fetched from a new page. Such organization provides that each  $M_i$  memory may contain  $2^{24}$  words. The overall size of instruction  $PI$  is:

$$PI = \log_2 \#(IS) + \log_2 F + \log_2 n + 8$$

For a DPA with  $\#(IS)=255$ ,  $F=16$ ,  $n=8$ ,  $h=8$

$$PI = 8 + 4 + 3 + 8 = 23 \text{ bits.}$$

(This means that this DPA has 255 instructions, it forms pipelines not exceeding 16 stages, each stage has no more than 64 bits.)

Therefore, in spite of its insignificant bit size, instruction  $PI$  not only brings to each pipeline stage all the necessary information about operands and operations, but it also performs effective on-line adaptation of the pipeline in order to match the sequence of operations activated by this  $PI$ . In addition, the relatively small size of  $PI$  allows one to implement each MSE connecting unit using a single universal LSI module with 64 pins.

#### AI instruction

This instruction stores the following codes: position code  $j$  of the  $C_j$  stage which should fan-out its result to a general register set  $m_b$ , position code  $b$  of the register set  $m_b$  which should receive this result, and the address  $r_p$  of the destination register in  $m_b$  where the result should be written into. Thus the  $AI$  bit size is:

$$AI = 2 \log_2 F + \log_2 K;$$

where  $F$  is the maximal length of a pipeline and  $K$  is the number of registers in each  $m_j$ . Therefore, for  $F=16$ ,  $K=256$ ,  $AI=2 \cdot 4 + 8 = 16$  bits.

Thus the  $AI$  instruction allows each pipeline stage (not just the last one) to send its computational result and permits each general register set to receive this result. Such an on-line organization of providing the stages with temporary results they might need for future computations eliminates the alternative waiting time associated with sorting and sending temporary results to stages which require them.

#### Variable time intervals

Each pipeline computer  $C_i$  is equipped with the control organization required by a dynamic instruction set. However, in order to organize a pipelined mode of operation this control organization has to be modified.

In computers with a dynamic instruction set, the DIS unit of one computer contains two sequencers,  $CAD-I$  and  $CAD-M$ . The  $CAD-I$  sequencer activates a sequence of operations which corresponds to one instruction, whereas the  $CAD-M$  sequencer specifies the time of each operation. For instance, if an instruction activates the sequence  $((A+B)-C) > K$ , then the first state of  $CAD-I$  fetches the instruction, the second state executes  $A+B$ , the third state performs  $(A+B)-C$ , and the fourth state executes the comparison  $(A+B-C) > K$ .

In a pipeline, however, all these operations are distributed among separate computers, so that computer  $C_0$  fetches the instruction, computer  $C_1$  executes  $A+B$ , computer  $C_2$  executes  $(A+B)-C$ , and computer  $C_3$  executes  $((A+B)-C) > K$ . Therefore, each pipeline computer executes only one operation out of the whole sequence. Furthermore, two consecutive pipeline computers,  $C_i$  and  $C_{i+1}$ , may simultaneously execute operations activated by two instructions,  $PI_j$  and  $PI_{j+1}$ . Therefore, for each pipeline computer  $C_i$ , its  $CAD-I$  sequencer has to establish its state only for the time interval it keeps instruction  $PI$ ; at the next time interval, when the new instruction  $PI_{j+1}$  is written,  $CAD-I$  has to establish another state which corresponds to that instruction.

It then follows that for non-iterative operations (addition, subtraction, Boolean) the  $CAD-I$  functions as a decoder, and for iterative operations (multiplication, division, etc.) it works as a sequencer. The  $CAD-I$  functioning is controlled with the following codes: the op-code  $D$  it receives with the  $PI$  instruction, position signal  $i$  produced locally by the position code  $i$ , and code  $\gamma_j$  which distinguishes instruction set  $IS_j$ .

Consider now how one may organize a variable time of operation,  $T$ , executed in stage  $C_i$  of the pipeline:  $T$  is variable, i.e.,  $T = t_0 \cdot b$ , where  $t_0$  is the time of  $h$ -bit addition in one LSI module, and  $b$  depends on codes  $p$  and  $D$  stored in instruction  $PI$ . For a processor dependent operation (addition, subtraction), that has to last  $T = p \cdot t_0$ , the output of decoder  $CAD-I$  initiates the  $CAD-M$  sequencer which executes a loop having  $p$  states. During this time  $CAD-I$  maintains output continuously, and activates operation in the processor. When  $CAD-M$  completes its loop, this terminates the  $CAD-I$  output. If the operation is independent of the processor size (Boolean, shift, etc.), then it is activated by the  $CAD-I$  decoder only. Namely,  $CAD-M$  is not initiated and the operation takes  $t_0$ , the time of one minor clock-period. If stage  $C_i$  executes an iterative operation,  $CAD-I$  executes a sequence containing several states. If a state in this sequence has to last time  $p \cdot t_0$ ,  $CAD-I$  initiates  $CAD-M$  and performs a transition to the next state only after the completion signal issued by  $CAD-M$ .

#### Routing algorithm for $PI$ and $AI$ instructions

Consider movement of instructions  $PI$  and  $AI$  within the pipeline. Let the computer supervisor,  $C_0$ , fetch instruction  $I^*$  from  $M_0$  to  $P_0$ . At the first interval, its  $PI^*$  portion is written to stage  $C_1$  and connecting element  $MSE_1$ . Since

$PI^*$  stores relative address  $A_p$  and the base address  $B$  is continuously fed by  $P_0$  to all  $M_i$  memories, memory  $M_1$ , receiving effective address  $E=B+A_p$ , retrieves either an operand for stage  $C_1$  (bit  $e=0$ ) or address  $r_p$  of the register set  $m_1$  ( $e=1$ ). This address connects the respective register contained in the  $m_1$  register set to the adder input in processor  $P_1$ . At the same time processor  $P_0$  sends instruction  $AI^*$  to  $ASE_1$  and fetches the next instruction, which follows  $I^*$ , from the memory  $M_0$ .

For the next interval the following actions are executed in the pipeline in parallel: (Assume that for one  $I^*$  instruction, its  $PI^*$  portion is stored in  $P_i$  and  $MSE_i$ , and its  $AI^*$  portion is stored in  $ASE_i$ .)

- a. The  $p$  code stored in instruction  $PI^*$  activates a new processor size in  $P_i$  and new durations of processor-dependent operations.
- b. The  $P_i$  processor ( $i=1, \dots, w$ ) which received  $PI^*$  during previous interval executes the operation provided by the  $PI^*$  instruction for the  $i$ th stage, and receives a new  $PI$  which immediately succeeds  $PI^*$ .
- c. The  $MSE_i$  connecting element compares the code  $w$  stored in the  $PI^*$  instruction with its own position code  $i$ .
  - If  $i < w$ , it sends the  $PI^*$  instruction to the next stage  $C_{i+1}$  and connecting element  $MSE_{i+1}$ , respectively.
  - If  $i \geq w$ , then  $PI^*$  instruction ends its execution.
  - If instruction  $PI^*$  passes to the next stage  $C_{i+1}$ , a word is fetched from memory  $M_{i+1}$ . Its effective address is  $E=B+A_p$ , where  $A_p$  is stored in instruction  $PI^*$ .
- d. The connecting element  $ASE_i$  compares its own position code  $i$  with position code  $b$  stored in instruction  $AI^*$  which shows that pipeline stage  $C_b$  should send its result to a general register set.
  - If  $i=b$ , the  $AI^*$  is sent to processor  $P_i$ . At the next interval,  $P_i$  will send the result of the computation it executes during the present interval to a destination address stored in  $AI^*$ .
  - If  $i \neq b$ , then  $AI^*$  is sent to the next  $ASE_{i+1}$ .
- e.  $P_0$  sends new instruction  $PI$  to stage  $C_1$  and connecting element  $MSE_1$ , and it sends new instruction  $AI$  to connecting element  $ASE_1$ .
- f. The next instruction is fetched from  $M_0$  to  $P_0$ .

Consider now the organization of vector computation when the same instruction,  $I^*$ , handles data arrays each having  $z$  words. Then the  $PI^*$  and  $AI^*$  portions propagate through the pipeline  $z$  times, and  $C_0$  stops fetching of other instructions from  $M_0$  until the vector computation ends. After each interval, the  $P_0$  processor increments the current address  $A_p$  stored in  $PI^*$  with some constant,  $a$ , stored in  $I^*$ , so that the new address equal to  $A_p+a$ , is written back to  $PI^*$ . Thus, during each interval, the  $C_i$  stage receives  $PI^*$  with a modified relative address. In addition, if the  $I^*$  instruction provides that address  $r_p$ , stored in instruction  $AI^*$ , also be changed, then during each time interval,  $P_0$  computes a new address,  $r_p+b$ , in a destination register set and writes it back to  $AI^*$  so that connecting element  $ASE_1$  also receives instruction  $AI^*$  with a modified address.

It then follows that for vector computations, in addition to the  $AI^*$  and  $PI^*$  portions, each  $I^*$  instruction should also store the constants  $a$  and  $b$  for modification of addresses  $A_p$  and  $r_p$  and a constant  $z$  showing the dimension of the data arrays in memories  $M_i$ .

#### *Advantages of dynamic pipeline architectures*

Dynamic pipeline architecture (DPA) eliminates most of those drawbacks associated with disparity between program and pipeline structures. Indeed:

- a. For existing pipelines, if a sequence of operations met in the program does not correspond to a sequence of operational units connected into the pipeline, the pipeline is switched into a new configuration in order to form a new sequence that matches the one encountered in the program. This introduces an additional delay associated with such a reconfiguration.

In the DPA no such delay is introduced because each pipeline stage is capable of executing any operation. Thus, a pipeline with  $F$  stages may execute any sequence of  $w$  operations if  $w \leq F$ .

- b. In conventional pipelines a disparity between the number of consecutive operations in the instruction and the number of pipeline stages in the pipeline which processes this instruction creates additional delays (dummy-time intervals) associated either with instruction propagation through unneeded stages or with conflict resolution when the instruction bypasses the unneeded stages and encounters operands prepared for some of its predecessors.

In the DPA no such delays occur because the number of stages the instruction propagates through is defined by the  $w$  code it stores. Consequently, on passing through  $w$  stages the instruction completes its execution.

- c. In existing pipelines the time for non-iterative processor dependent operations (addition, subtraction,  $>$ , etc.) is permanent and does not depend on operand sizes. However, selection of a permanent operation time in each stage requires that it be selected as the time of the longest operation (addition handling maximal word sizes). It then follows that all faster operations (processor dependent operations handling smaller word sizes or Boolean operations, shift operations, etc.) are slowed down because they are executed during the time of the longest processor dependent operation.

In DPA, however, no such slowdown occurs because each stage is provided with a variable time interval. It then follows that each stage is capable of generating a minimal operation time. Therefore, in DPA a pipeline is capable of working at a variable rate. If it is filled with short operations,

it fans out results much faster, at the maximal rate of the short operation.

- d. In existing pipelines, additional waiting time occurs when the computational result obtained for one instruction in one stage is required as an operand for another instruction in another stage. For instance, if the instruction executes  $(A-B)^2 + D \cdot K$ , the temporary result  $(A-B)^2$  cannot be used on-line as an operand of some other pipeline stage.

For DPA, however, a proposed addressing procedure allows each stage  $C_j$  to receive on-line a temporary result produced by another stage  $C_i$  in its general register set  $m_j$ . Thus the waiting time associated with feeding temporary results to the pipeline stages that need them may be eliminated.

- e. All existing pipeline systems cannot partition the available resources into a variable number of parallel pipelines, each of which is provided with a changeable number of stages. As a result, the number of parallel program streams is permanent and cannot be changed. Likewise, selection of pipelines with a permanent number of stages delays execution of instructions requiring a smaller number of stages.

On the other hand, DPA may perform multiple on-line switching of the resource into different states. This maximizes the number of program streams computed by the same equipment.

- f. It has been noted previously that the ability of DPA to form different states is convenient for handling conditional branching, for then no time is lost due to selection of the program sequence which currently does not fill in the pipeline. Also, switching a DPA into states with multiple pipelines allows one to organize multipoint branching.

## CONCLUSIONS

A modern dynamic architecture allows redistribution of the hardware resource forming a variable number of concurrently operating computers. This means that a parallel system may increase the number of parallel program streams executed on the same equipment by changing the number of computers it has. However, a dynamic architecture may provide the system with other powerful sources of throughput increase:

- a. It may form its resource into different types of architectures. This means that the system may turn from a multicomputer system to, say a pipeline or array system, and vice versa. Or the system may have all three types of architecture co-resident at the same time—namely, part of the resource functions as a multicomputer system. Another part behaves as a pipeline and/or array subsystems. This feature will allow to perform

multicomputer, multiprocessing, pipeline and array computations using the same hardware instead of implementation of separate dedicated subsystems.

- b. The system will be able to change via software an activated instruction set. This may be done either within a single program or on the level of several programs forming a queue.

Therefore, a merger of dynamic, reconfigurable and microprogrammable adaptations into a single adaptable architecture will allow one to create complex parallel systems with high throughput.

# Architectural considerations of the NEC mass data file subsystem

by AKIRA SEKINO and TAKUO KITAMURA

*Nippon Electric Co., Ltd.*  
Tokyo, Japan

## INTRODUCTION

During the past decade the use of computers in the on-line environment has steadily increased. In particular, there has been a drastic growth of on-line systems for business-oriented applications. We see a shift of interest in computers from their mere computational power to their data management capability, especially in these applications. User demand for the growth of on-line storage capacity in this environment is said to be much larger than the demand for the growth of computational power. We expect the business-oriented computer system to become an information utility in the future.

We have been generally using disks as our on-line storage, but the ever-growing demand for file storage capacity forced us to use more inexpensive magnetic tapes, though they are more difficult to handle in the on-line environment. Now it is quite common to see libraries of several thousand tape reels storing tens of billions of bytes of data at large computer installations. Some government data processing installations actually possess nearly 100,000 tape reels in their tape libraries. The handling of these tape reels require many operators to mount these reels manually on tape units as well as a large floor space for the tape units and the tape library. Furthermore, the traditional tape handling is by nature prone to various human errors.

Several mass storage systems (MSS) were developed to solve these problems of traditional magnetic tapes by automating the tape handling process.<sup>1-4</sup> These systems have not yet spread widely because of their high cost, but they seem to be steadily gaining popularity. We believe that these systems will gradually replace most traditional tape libraries and become essential to large information utilities in the years to come.

NEC has been engaged in the product planning and development of an MSS. We have studied the existing MSSs in light of the essential requirements of these systems and derived an MSS architecture which is believed to relax the limitations of the existing systems. As the name of mass storage systems has been historically applied to disks in NEC, we decided to call our newly-developed mass storage system the NEC mass data file subsystem or the MDF subsystem. The present paper describes the major architec-

tural considerations of the MDF subsystem in relation to the requirements of mass storage systems in general.

## REQUIREMENTS OF MASS STORAGE SYSTEMS

Before describing the architectural considerations of the NEC MDF subsystem, we must explain the background of our architectural decisions, i.e., the judgment criteria with which we designed our MSS architecture. The following gives the MSS requirements, arranged in (more or less) descending order of importance.

*Large Storage Capacity*—An MSS must have a storage capacity of up to several hundred billion bytes, equivalent of more than one hundred thousand traditional half-inch tape reels.

*Inexpensive Storage*—The cost of an MSS must be comparable to that of a traditional tape library on a cost-per-unit-capacity basis.

*Automatic Management of Storage Media*—Access to storage media should not require human interventions such as tape selection and tape mounting by human operators.

*Smaller Entry Cost*—The increase of the total system cost for migrating to one of the entry MSS models should be as small as possible.

*Flexibility of MSS Configuration*—Various MSS configurations must be possible to meet the needs of many installations and must allow easy future expansion.

*Continued System Operation Through Graceful Degradation*—An MSS must be able to automatically reconfigure itself to allow continued system operation in the event of component failure, perhaps with degraded performance, and must allow concurrent repair of the failed component.

*Smaller Floor Space*—The floor space needed by an MSS must be considerably smaller than that of the conventional tape library.

*Easy Conversion to an MSS*—Changes required in JCL statements and application programs must be none or minimal. Conversion of existing files on magnetic tapes and disks must be as simple as possible.

*Absorption of Tape-Oriented Applications*—An MSS must be capable of accommodating the existing tape applications, and hopefully make new applications possible.<sup>5</sup>

*Support of Various File Organizations*—All important file organizations currently available on magnetic tapes and disks should be available for MSS files.

*Multiple Access Modes*—It is desirable that multiple access modes are available to application programs in accessing MSS files. These should include the staging mode and the direct access mode.

*High Performance*—The performance of an MSS must be sufficiently high so that it is usable as on-line storage.

*Efficient Utilization of Storage Capacity*—The effective capacity of the MSS storage media as well as that of disk storage used for staging must be efficiently usable.

*Use of an MSS in the Multidimensional Processing Environment*—An MSS must allow simultaneous use by coexisting local/remote batch processing jobs, time-sharing terminal-oriented jobs, and on-line database jobs.

*Shared Use of an MSS by Multiple Computer Systems*—An MSS must allow the shared use by a set of loosely-coupled multiple computers as well as by multiple computers connected via a communication network.

*RASIS Considerations*—An MSS must have a high degree of reliability, availability, serviceability, integrity, and security.

*High Potential for the Future*—An MSS must have a high potential for supporting the very large data utility of the future.

In general, it is not easy to satisfy all these requirements fully, but we feel that none of these requirements can be sacrificed in favor of the others.

## MAJOR ARCHITECTURAL FEATURES

Several MSSs developed so far, notably the IBM 3850, the CDC 38500 and the Ampex Terabit Memory, represent serious attempts to satisfy the above requirements of a large file storage.<sup>1-4</sup> In the early stages of our MSS design, we examined the architectural features of these systems.<sup>5</sup> We felt that each of these systems is satisfactory in several requirements but not in all. We spent a substantial amount of time in deciding the kind of architectural features which could meet the requirements under the constraints of our development resources.

At the end of the conceptual design stage, we came to a conclusion that our MSS should support the following three major architectural features on an IBM-3850-like storage device:<sup>2</sup>

1. Use of the virtual file concept.
2. Device independence for staging disks.
3. Support of the direct access mode as well as the staging mode.

The CDC 38500 has similar features,<sup>4</sup> but a combination of the above features and our IBM-3850-like storage device would create a system with characteristics very different from either system. We decided to develop our storage device with specifications similar to those of IBM 3851 mass

storage facility, a set of new operating system components and service utility programs to support MSS functions, and a storage device controller capable of interfacing between these host software components and the storage device. We believe that this design would make up for certain limitations of the IBM 3850 architecture, as will be described later.

The virtual file concept allows users to access all the MSS files uniformly by the associated cataloged names in the staging access mode without having to know whether these files are still on the mass storage device or have been already staged to the staging disks. When an MSS file that is still on the mass storage device is accessed the entire file is staged to one of the staging disks. As a matter of fact, a user can access all MSS files as if they were ordinary disk files. This virtual file concept is our counterpart of the IBM 3850's virtual disk concept in implementing virtual file storage. The virtual file and virtual disk concepts correspond respectively to the segmentation and paging concepts of virtual memory implementation for executable programs. It follows that many comments on segmentation and paging in virtual memory apply equally to the virtual file and virtual disk concepts of virtual file storage.<sup>6</sup> However, we have observed here that an implementation of virtual file storage by the virtual file approach tends to provide more efficient operation than that by the virtual disk approach because of the relatively slow operating speed of MSSs. This point will be discussed in detail later.

Now let us describe how the NEC MDF subsystem generally works using Figure 1 to explain the architecture of our system. As this figure shows, the MDF subsystem with the mass storage device and controllers is configured to be independent of the disk subsystem which is used for storing

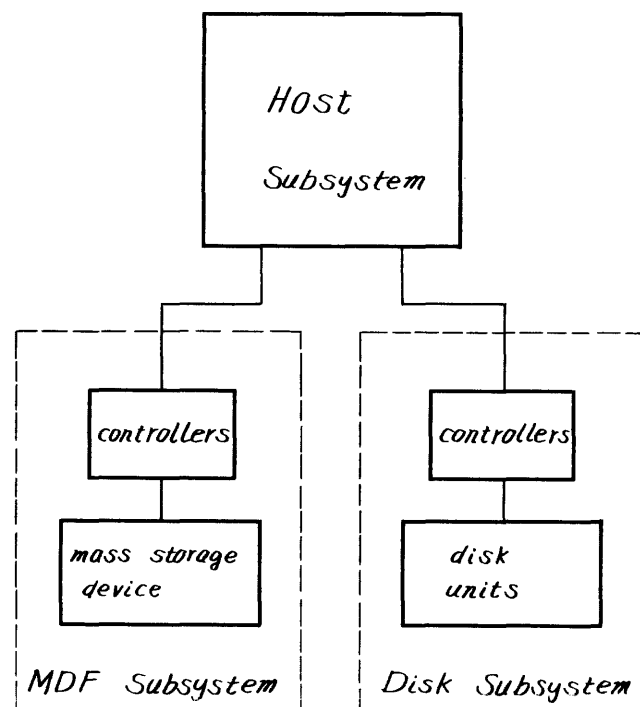

Figure 1—Structure of the NEC mass data file system.

staged MSS files as well as ordinary disk files. When an MSS file is accessed by a user job in the staging mode of operation, the operating system components residing on the host subsystem (CPU, I/O processor, memory, etc.) reserve an appropriate amount of space for the file in the disk subsystem and requests the file from the MDF subsystem. As the file is received part-by-part in the host buffer, it is piecemeal staged into the reserved space of the disk subsystem. Thus, these two subsystems do not have any direct data transfer path like the one seen in the IBM 3850 architecture.<sup>2,3</sup> Tight coupling of a mass storage device and a disk controller by a direct path in this architecture requires matching of the mass storage device and particular disks controlled by the disk controller at a complicated physical level. This would not only make this disk subsystem significantly different from the ordinary disk subsystem, but also tends to limit the types of disk units usable for staging. Our independent subsystem architecture is, however, flexible enough to allow various types of disk units for staging, e.g., 100, 200, and 317 megabyte disk units and our future larger capacity units, in an arbitrary combination.

The third architectural feature of our system is support of two access modes: the staging mode and the direct access mode for reading and writing an MSS file. The staging mode can be widely used for accessing an MSS file with arbitrary file organization, but this mode of operation becomes inefficient if the file to be staged is very large like some sequential files. Then, it is recommended to use the direct-access mode which allows direct access to sequential files without staging like a traditional magnetic tape unit. The important difference, however, is the fact that a data cartridge used as the mass storage media allows a partial data modification to any of many MSS files stored on its cartridge tape, but the traditional half-inch tape does not. Our system is designed to support the compatibility of the above two access modes for sequential files; a user may dynamically specify his choice of access mode in reading or writing a sequential file by a JCL parameter. Support of these complementary access modes is expected to provide wider usage of MSS in actual computer applications.

Finally, some comments are in order about the influence of these architectural features upon satisfaction of the above MSS requirements. First, the choice of an IBM-3850-like device with its advanced recording technology and 50 megabyte data cartridges was made especially to satisfy the first, second, and seventh requirements. It is generally advantageous to use larger capacity cartridges in satisfying these requirements. The adoption of the virtual file concept is mainly based on the eighth and twelfth requirements and other considerations such as security, recovery, and accounting. Our decision to support the device independence for staging disks using ordinary disk units aims to satisfy the fourth, fifth, seventh, and thirteenth requirements. Besides, this decision allowed us to avoid the development of a disk subsystem dedicated to MSS. Lastly, support of two complementary access modes is intended for the ninth, eleventh and twelfth requirements. We will discuss this aspect of the MDF subsystem further from the viewpoint of system performance.

## A PERFORMANCE COMPARISON OF THE VIRTUAL DISK AND VIRTUAL FILE APPROACHES

It was stated earlier in this paper that the virtual file approach tends to be more efficient than the virtual disk approach. This section proceeds to evaluate the performance characteristics of these two approaches. We begin by noting that decisions on file allocation to various types of file storage devices are usually based on the following file attributes:

- File size
- Access frequency
- File organization

The average size of files allocated to each type of file storage devices after the migration of selected tape and disk files to an MSS is typically found to be in the following range:

- Disk files 0.2-1 MB
- MSS files 1 -3 MB
- Tape files 4 -6 MB

We will mainly evaluate the performance of the staging mode operation of these two approaches where MSS files are staged in their entirety. It will be shown that the performance of the virtual file approach is relatively high in the file size range of 0-3 megabytes. We will also briefly comment on the performance of the staging mode operation of the virtual disk approach allowing cylinder faults, and the performance of the direct access mode operation of the virtual file approach. The analysis given below aims to clarify the performance characteristics inherent in the above two approaches, and is not intended to describe the actual performance of a product such as the IBM 3850 MSS or the NEC MDF subsystem. However, the analysis will help the reader gain a good perspective of the performance of MSS in general.

### *System operation*

The virtual disk approach allows a job step to access an MSS file in the following manner.<sup>2</sup> First, a data cartridge is selected from the cell-structured cartridge library by an accessor and physically moved to an appropriate data recording device (DRD) at the beginning of the job step, for the purpose of mounting the MSS volume containing the MSS file on a virtual disk unit. The cartridge is loaded into the DRD and the VTOC (volume table of contents) information recorded at the beginning of the cartridge tape is staged to a staging disk. This staging operation completes mounting of the MSS volume; the operating system can now locate the MSS file within the cartridge by reading the staged VTOC information from the disk just like locating an ordinary disk file. The cartridge is then unloaded from the DRD and returned to the cartridge library by an accessor. The duration of time starting from the accessor movement to select a cartridge and ending with the accessor movement

to return the cartridge roughly corresponds to the period of time during which a particular DRD is exclusively allocated to this cartridge. For this reason, we call this duration of time a DRD cycle in this paper. When the MSS file is OPENed during the execution of the job step, the second DRD cycle is required. The cartridge containing the MSS file is selected by an accessor to load it into an appropriate DRD. After the cartridge loading is complete, the DRD locates the MSS file and stages the entire file into an appropriate space of a staging disk. The cartridge is then unloaded and returned to the library by an accessor again. When the job step terminates eventually, the third DRD cycle is required to destage the MSS file to the original data cartridge in demounting the MSS volume. Only the modified cylinders of the MSS file are actually destaged this time.

On the other hand, the virtual file approach requires a total of only two DRD cycles. The first DRD cycle is required at the beginning of a job step. The data cartridge containing a desired MSS file is selected and loaded into an appropriate DRD. The DRD then reads the file label information, the counterpart of the VTOC information, in the direct access mode, in order to find the location of the MSS file. The located file is staged to a staging disk and the cartridge is unloaded and returned to the library. Thus, it is clear that the first DRD cycle of this approach actually corresponds to the first and second DRD cycles of the virtual disk approach. Finally, the second DRD cycle is required at the end of the job step to destage the entire MSS file.

#### Response time characteristics

Some more details of a DRD cycle must be explained in order to discuss the response time characteristics of the previous two approaches. By definition, a DRD cycle is a sequence of the following events.

- Accessor movement (library→DRD)  $t_a$  seconds
- Cartridge loading  $t_1$  seconds
- Winding for data  $t_w$  seconds
- Data transfer (staging/destaging)  $nt_s$  seconds
- Rewinding for tape head  $t_r$  seconds
- Cartridge unloading  $t_u$  seconds
- Accessor movement (DRD→library)  $t_a$  seconds

The length of the DRD cycle is called a DRD cycle time in this paper. Some components of the DRD cycle time just shown probably need explanations. The length of time required by "winding for data" is the one needed by an DRD to wind the tape from the tape head position to the data position where recording of particular data starts. Similarly, the length of time required by "rewinding for tape head" is the one needed by the DRD to rewind the tape from the data position to the tape head position. The length of data transfer time needed by staging or destaging is proportional to the amount of data. Letting  $t_s$  be the length of time required to transfer a 250 kilobyte cylinder of data, the "data transfer"

time of  $n$  cylinder data is  $nt_s$  seconds. A typical numerical example is shown below.

$$t_a=4, \quad t_1=t_u=5, \quad t_s=1$$

$$t_w=t_r = \begin{cases} \sim 0 & (VTOC) \\ 4 & (MSS \text{ file}) \end{cases} \quad (\text{seconds})$$

The choice of different values of  $t_w$  or  $t_r$  for the VTOC information and an MSS file is based on the fact that the VTOC information is recorded at the beginning of the tape while an MSS file may be recorded anywhere on the tape. It should be noted that a DRD cycle time thus defined is the ideal one; an actual DRD cycle time measured in a real situation is prolonged by randomly inserted queueing delays.

Now we proceed to evaluate the task delay time incurred in making an MSS file ready for processing on disk in the virtual disk and virtual file approaches.<sup>3</sup> This delay time is the MSS's counterpart of a manual mount time of the traditional half-inch tapes. The task delay time ( $T_{rd}$ ) of the virtual disk approach is obtained as follows:

$$T_{rd} = (\text{the DRD cycle time for mounting a virtual disk})$$

$$+ (\text{the first half of the DRD cycle time for staging})$$

$$= (2t_a + 2t_1 + t_s) + (t_a + t_1 + t_w + nt_s)$$

$$= 3t_a + 3t_1 + t_w + (n+1)t_s$$

Similarly, the task delay time ( $T_{rf}$ ) of the virtual file approach is

$$T_{rf} = (\text{the first half of the DRD cycle time for staging})$$

$$= t_a + t_1 + t_w + nt_s$$

Figure 2 shows how  $T_{rd}$  and  $T_{rf}$  compare as a function of the file size. Considering that the value of  $T_{rd}$  or  $T_{rf}$  can easily increase by a factor of two because of various internal queueing delays associated with allocations of an accessor, a DRD, and a data transfer path in a real situation, an actual task delay time of the virtual disk approach would be roughly comparable to a human tape mount time of traditional half-inch tapes while that of the virtual file approach would be about half of the human tape mount time.

We had an assumption until now that an MSS file was staged in a burst in its entirety. Next, let us briefly consider what happens if an MSS file is staged on demand cylinder by cylinder. The length of time required to process a cylinder fault ( $T_c$ ) is calculated as

$$T_c = (\text{the first half of the DRD cycle time for cylinder staging})$$

$$= t_a + t_1 + t_w + t_s$$

Noting again that the value of  $T_c$  can easily increase by a factor of two because of internal queueing delays on an actual system, we observe from this result that a single cylinder fault would typically cost a task as much as 30 seconds of lost real time. Thus, if a job encounters many cylinder faults, the turnaround time of this job would be intolerably prolonged.

Figure 2—Comparison of task delay times of two approaches.

Throughput characteristics

We proceed to evaluate the throughput characteristics of the virtual disk and virtual file approaches. The following assumptions are made about user jobs to simplify the analysis.

1. Each user job requiring access to an MSS accesses only one MSS file in a job step. The type of processing for this file includes modifications to this file.
2. Virtual Disk Approach—The MSS volume is mounted on a virtual disk unit at the initiation time of a job step. The MSS file is staged in its entirety at the file OPEN time and only the modified cylinders of this MSS file are destaged at the termination time of the job step.
3. Virtual File Approach—The access mode to be used is the staging mode (not the direct access mode) where the entire file is staged at the job step initiation time and is destaged at the job step termination time.

An actual job environment is much more complicated, but the result of the following analysis can be modified to reflect such complications.

We now derive the total amount ( $T_{i,vd}$ ) of MSS services required during a job step execution period of the virtual disk approach. Noting that a total of three DRD cycles are required by a job step, we have

$$\begin{aligned}
 T_{i,vd} &= (\text{the DRD cycle time for mounting a virtual disk}) \\
 &+ (\text{the DRD cycle time for staging an MSS file}) \\
 &+ (\text{the DRD cycle time for destaging the MSS file}) \\
 &= (2t_a + 2t_1 + t_s) + (2t_a + 2t_1 + 2t_w + nt_s) \\
 &+ (2t_a + 2t_1 + 2t_w + npt_s) \\
 &= 6t_a + 6t_1 + 4t_w + (n + np + 1)t_s
 \end{aligned}$$

where  $p$  is the probability that some portion of file data stored in a disk cylinder is modified on a staging disk. Similarly, the total amount ( $T_{i,vf}$ ) of MSS services required by a job step of the virtual file approach is

$$\begin{aligned}
 T_{i,vf} &= (\text{the DRD cycle time for staging an MSS file}) \\
 &+ (\text{the DRD cycle time for destaging the MSS file}) \\
 &= (2t_a + 2t_1 + 2t_w + nt_s) + (2t_a + 2t_1 + 2t_w + nt_s) \\
 &= 4t_a + 4t_1 + 4t_w + 2nt_s
 \end{aligned}$$

Table I shows how the above total amount of MSS service requirement by a job step breaks down into the amount of particular services by accessors, DRDs and data transfer paths. Each of these values actually represents the total amount of particular service requirement by a single MSS file.

The throughput of an MSS can be measured by the number of MSS files staged per hour. We assume that we have four MSS models which differ in storage capacity and in the number of major MSS components, as shown in Table II. Then, the throughput of accessors, DRDs, or data transfer

TABLE I—Service Requirement for Major MSS Components in the Total MSS Service Requirement by a Job Step

	Virtual Disk Approach	Virtual File Approach
(1) Accessors	$6t_a$	$4t_a$
(2) DRDs	$3t_a + 6t_1 + 4t_w + (n + np + 1)t_s$	$2t_a + 4t_1 + 4t_w + 2nt_s$
(3) Data transfer paths	$4t_w + (n + np + 1)t_s$	$4t_w + 2nt_s$
Total MSS service requirement	$6t_a + 6t_1 + 4t_w + (n + np + 1)t_s$	$4t_a + 4t_1 + 4t_w + 2nt_s$

paths is obtained by dividing the total available time by each particular service requirement of an MSS file shown in Table 1. For example, the throughput of Model 1 DRDs of the virtual disk approach is

$$2 \times 3600 / [3t_a + 6t_1 + 4t_w + (n + np + 1)t_s] \text{ files/hour}$$

A tight upper bound for the throughput of each MSS model can then be given as the minimum of the throughput values calculated for accessors, DRDs, and data transfer paths. The final result thus obtained is depicted in Figure 3.

We have the following observations from this figure.

1. The virtual file approach attains considerably higher throughput in the important file size range of 0-3 megabytes.
2. The virtual disk approach attains somewhat higher throughput for the file size greater than 3 megabytes.

The first point is due to the throughput limitation of the virtual disk approach caused by the additional uses of accessors and DRDs in the DRD cycles for mounting virtual disks. This limitation of the virtual disk approach becomes serious if many small files must be staged on a larger MSS such as Model 3 or 4. On the other hand, the second point is based on the fact that unmodified cylinders of data need not be destaged in the virtual disk approach.

Comments on direct access to MSS

Finally, this section describes the performance characteristics of the direct-access mode which is supposed to be useful in processing large sequential files. Because of the limitation of space in this paper, we will only briefly touch upon the point. The idea of including the direct-access mode in our MSS architecture originated from the well known fact that traditional tape units are much more efficient in processing sequential files than disk units. In particular, the direct-access mode of the NEC MDF subsystem has the following performance advantages:

TABLE II—Description of Four MSS Models

	Model 1	Model 2	Model 3	Model 4
No. of active accessors	1	2	2	2
No. of DRDs	2	4	6	8
No. of data transfer paths	1	2	3	4
Storage capacity (Gigabytes)	35	102	169	236

Figure 3—Throughput comparison of two approaches.

1. All the overhead time associated with file staging is avoided.
2. The access time of a data cartridge is somewhat shorter than that of a disk storage in sequential file processing.

An examination of file organization usage in actual user environments reveals that the overwhelming majority (e.g., more than 80-90 percent) of MSS files are sequentially organized. For this reason alone, sequential files might deserve a special attention by the direct access mode with the above performance advantages. It should, however, be noted that one or more DRDs is exclusively allocated to a job for the entire duration of its execution in this mode. The operating system must carefully allow jobs to use this access mode so as to avoid DRD request conflicts among jobs.

## CONCLUSION

This paper has described the implications of major architectural features of the NEC mass data file subsystem. These architectural features include the use of the virtual file concept, device independence for staging disks, and support of two complementary access modes for MSS files, as well as the adoption of an IBM-3850-like mass storage device. This MSS architecture attempts to satisfy the MSS requirements stated in this paper to the utmost extent feasible in the current state of MSS technology. It was specifically found to relax the limitations of the existing MSSs on storage capacity, system cost as well as MSS entry cost, floor space, performance, and applications among other things. This paper examined the performance aspect of our MSS architecture particularly in detail. The analysis on response time and throughput characteristics of the staging mode operation of MSS shows that the virtual file approach of the NEC MDF subsystem has significant performance advantages over the virtual disk approach taken by the IBM 3850 MSS. Our observation is that the virtual file approach attains considerably higher throughput in staging small to medium MSS files than the virtual disk approach. On the other hand, the direct access mode of the MDF subsystem gives high performance in processing large sequential files. On-demand staging of the virtual disk approach was found to be inefficient in that a job's turnaround time is likely to be intolerably prolonged by a series of slow cylinder fault handlings.

As stated earlier, the MDF subsystem is independent of the disk subsystem. This implies that the data transfer operations for staging and destaging between these two sub-

systems require services by the host subsystem. The current implementation of MSS functions on the host subsystem ordinarily requires 0-5 percent of CPU time for the data transfer services. We plan to offload this service from CPUs to input/output processors in our distributed-function architecture of NEC ACOS 800 and 900 computers. In analyzing the performance characteristics of the virtual disk and virtual file approaches in this paper, we chose to use a set of parameter values common to these two approaches because of our interest in the impact of architectural differences upon the performance. Our recent experiences, however, indicate that the independent subsystem architecture actually incurs smaller amount of contentions in staging and destaging files than the tightly-coupled subsystem architecture. Hence, the actual performance of the MDF subsystem is generally higher than suggested in this paper using a common set of parameter values.

The MSS device technology is still young and has ample room for future improvement. In particular, we may expect considerable improvement in data recording density and in data transfer rate. So long as mass storage systems satisfy the MSS requirements, they will evolve into much more easy-to-use large on-line storage as the MSS technology matures. MSS is just beginning to play an essential role in the data utility type computers.

## ACKNOWLEDGMENT

The MDF project involved a number of people over the past several years and is indebted to each of them. In particular, the authors wish to thank Y. Inada, T. Koterazawa, A. Tashiro and H. Mizutani for numerous stimulating discussions on MSS architectures.

# Error-oriented architecture testing\*

by LARRY KWOK-WOON LAI

Carnegie-Mellon University  
Pittsburgh, Pennsylvania

## ARCHITECTURE VALIDATION

### Motivation

Architecture validation is becoming more and more important as diverging cost/performance criteria and competition cause the number of models within a computer family to proliferate. Some popular architectures are now being manufactured by many different companies and the chances of a company inexperienced with the architecture making mistakes is very high. Not only will errors in an implementation cause software incompatibility, the costs of fixing them are usually prohibitively high once there are a large number of defective machines in the field. Excellent evidence demonstrating the inadequacies of present testing techniques is implementation errors discovered in the field for many major computer families. This study was initiated in the hope that an error-oriented approach to architecture testing may provide a better detection of implementation errors.

In this paper, the term *architecture* refers to the time-independent functional appearance of a computer system to its users. An *implementation* of an architecture is an ensemble of hardware/firmware/software that provides all the functions as defined in the architecture.

### Architecture validation

*Architecture validation* is the process of validating that a given machine indeed implements a specified architecture. There are three basic approaches:

1. *Verification*—prove the correctness of the design of an implementation using formal mathematical techniques.
2. *Simulation*—based on models of the physical building blocks and a description of the design, simulate the implementation to see if it behaves as expected.
3. *Testing*—establish a certain level of confidence in an

\* This research was sponsored by the Defense Advanced Research Projects Agency (DoD), ARPA Order No. 3597, and monitored by the Air Force Avionics Laboratory under Contract F33615-78-C-1151. The views and conclusions contained in this document are those of the author and should not be interpreted as representing the official policies, either expressed or implied, of the Defense Advanced Research Projects Agency or the U.S. government.

implementation by running test programs on a prototype machine.

The first two approaches are most useful when the implementation is still being designed or when architecture specifications are still being formulated. Once a machine is built, however, the only way to find out whether it actually works is to run programs on it—i.e. through testing.

Before one can set out to validate any implementation, one needs to have a specification of the target architecture. There are two basic ways to specify/describe an architecture: (i) using a formal language, e.g. ISPS,<sup>1</sup> VDL/APL;<sup>2</sup> and (ii) using a natural language, e.g. Principles of Operation,<sup>15</sup> Processor handbook.<sup>5</sup> The latter is often the most important because many architectures do not have a formal specification while a natural language description is almost always available, is more readable, and hence is read by users and implementors alike.\*\* For verification and simulation, a complete and consistent formal description is needed. For testing, a natural language description is usually adequate for the test programmer, although any ambiguities in the description must be resolved before tests can be derived for the parts affected.

Before we move on to architecture testing, we will briefly review the work that has been done in verification and simulation.

### Verification

Verification seeks to confirm absolutely, on paper, that a given implementation does meet its specifications. Two implementation-specific ways of architecture verification are microprogram verification and hardware verification.

The microprogram verification approach<sup>16,18,42</sup> can be summarized as follows: given the formal specifications of the target machine and the description of the underlying microengine, the formal verification system looks at a microprogram written for the microengine and attempts to prove that the microprogram running on the microengine would emulate (i.e. implement) the target machine. So far this approach has only been applied to very simple machines.

\*\* For a detailed exposition on architecture specification, see Reference 17.

Hardware verification<sup>24,13</sup> deals with methods to prove the correctness of hardware designs. In this approach, descriptions of low level components and a description of how they are interconnected are taken as input. The goal is to verify that the given interconnection satisfies some higher level specification.

Both microprogram verification and hardware verification can only verify paper designs. Some test programs are still needed to check out the actual hardware. They must also develop accurate models of low level components which are changing rapidly with technology.

### Simulation

Simulation has the advantage that it is easier to do than verification. Simulating computer hardware using software, however, usually results in a speed penalty ranging from a thousand to one up to a million to one. Hence it is usually impractical to test a design using simulation beyond running some very short tests that check some internal workings and critical paths. Besides the severe speed penalty, simulation also faces the problem of developing good models for rapidly advancing components and technology.

### Testing

Testing has the strong appeal that it deals directly with the physical implementation, which is what one really wants to validate, rather than some abstract description of the implementation. Testing is also much easier to do than verification or simulation. One can start writing a test program with nothing more than a natural language specification whereas verification and simulation both require modeling, formal description of the architecture and of the particular design, and a software system that can carry out the verification and simulation. These advantages make testing the most practical, though not totally satisfying, way to validate an implementation.

The drawback of testing is that it cannot give complete assurance—in practice it often gives less than satisfactory assurance. The former is a direct result of the affirmative nature of testing and of the complexity of a computer—because exhaustive testing, which is the only way to give complete assurance, is impractical for even a simple computer. The latter, however, is usually caused by the lack of good test methodologies and test programmers. It can be drastically improved if the object to be tested can be analyzed in detail before test programs using the analysis as guidelines are written.

The viability of testing as a validation tool lies in the empirical fact that implementations usually have regular structures and therefore the errors made in designing them are not totally random. To illustrate this, let us consider testing the ADD instruction of a computer. In almost all cases, only a tiny fraction of the  $2^n \times 2^n$  (where  $n$  is the word length) possibilities would be tested and then one would declare with confidence that the adder *works*, and indeed it usually *does*! The reason for this is that the tests usually

cover most of the probable errors: experience shows that the chances of having errors that could not be discovered by the tests is pretty small. If errors are truly random, however, and one is asked to test a black box whose internal structure one does not know about, then one cannot hope to achieve any high level of confidence by testing only a tiny fraction of the input possibilities. Needless to say, testing all the possibilities is out of the question—e.g.  $2^{32} \times 2^{32} = 2^{64} > 10^{19}$ . The question then is: amongst a sea of possible errors, how do we pick out the most probable ones and test for them? The error-analysis techniques developed later in this paper attempt to answer this question.

## ARCHITECTURE TESTING

### *Architecture testing defined*

*Architecture testing is functional testing* aimed at validating implementations of an architecture. An *architecture testing program* is designed to be a tool for certifying different machines claimed to implement a specific architecture. “Functional testing” means that the tests primarily aim at finding *design and logical errors* rather than problems in realization (e.g. repeatability and bit dependencies) or hardware failures. The level of confidence an architecture testing program can provide depends on the probability of having errors undetected by its tests.

### *Considerations in writing an architecture testing program*

The most crucial constraint for an architecture testing program is time. Any testing that can be done within a reasonable amount of time is but a tiny fraction of all possible tests. The critical issue in writing an architecture testing program is therefore how to select the most profitable tests and test data for a given time constraint.

Unlike diagnostics which often must locate faults rapidly in the field, architecture testing programs can have run time in the order of days. But that is still only a fraction of the test cycles one would like to have. Fortunately the tests in an architecture testing program do not depend on the results of each other and therefore different parts of the program can be run simultaneously on many prototypes in parallel to obtain more test cycles. Program size should not be a constraint since only one test needs to be in core at any one time (can simply use overlays). Because the total program is likely to be huge, however, a good testing methodology should allow automatic generation of test data and test programs to avoid the tedious task of test programming.

Ideally we would like an architecture testing program to be as *implementation-independent* as possible. However, as we have pointed out before, the only way to get high confidence in testing “black boxes” is exhaustive testing. Therefore any practical architecture testing program must necessarily make certain assumptions about the implementations it is going to be run on in order to cut down the test space. In other words, an architecture testing program must

be written with certain *classes of implementations*\*\*\* in mind. Within the target classes, the program should be *non-implementation-specific* in that it should be designed to effectively test all implementations within the classes. This is a case of tradeoff between generality and efficiency—one wants to have a program that can effectively validate as many kinds of implementations as possible while there are practical limitations as to how much resources the program can consume.

### *Recent developments and related work*

Two current developments have contributed to the recent interest in architecture testing. One is standardization efforts like the MCF project<sup>3</sup> which need independent validations of prototypes submitted by various contract bidders. The second development is the spread of microprocessors and LSI components. Many microprocessor and LSI parts are now manufactured by a half-dozen companies representing almost as many different implementations. The need for assurance of compatibility, together with pin limitation, have generated considerable interest in functional testing.<sup>19</sup>

Some research in the field of program testing<sup>20,21,11</sup> is of considerable interest to architecture testing. The work that is closest to architecture testing is that of compiler validation.<sup>12,14</sup> An area of special interest is test data selection techniques<sup>7-9</sup>—one can represent a function in an architecture by a canonical procedure written in a hardware description language like ISPS and then use the selection techniques to choose test data. Architecture testing and program testing bear many similarities, and research done in one area is likely to benefit the other.

### ERRORS IN IMPLEMENTING AN ARCHITECTURE

Why do people make errors? What errors do people and design systems make? If one knows why people make errors, one can try to prevent them in the first place, thereby getting at the root of the problem. If one knows what kind of errors are likely to occur in a particular environment, one can orient one's testing effort accordingly to maximize return on the effort. It is wasteful to test for errors that are almost certain not to occur while more likely errors are not tested for. The kind of errors that people make varies with their task environments. In implementing a computer architecture, the likelihood of different types of errors varies with technology, design tools used, experience and training of the design group, available history of previous implementation errors (designers are usually more aware of them), project management etc..

We began with the conjecture that although every imple-

mentation effort has its own error probability distribution, overall the errors are likely to fall into several general categories. Identifying these categories would give some insight into the nature of implementation errors as well as providing guidance for the writing of architecture testing programs. Instead of grouping known implementation errors into categories like what some people have done with errors in programming,<sup>10,7,25</sup> the approach of first conjecturing error categories and then calibrating them was adopted. This approach was chosen because (i) we wanted to explore implementation errors from an implementor's viewpoint, and (ii) very few error histories were publicly available.†

### *Design of the experiment*

There are four phases in our experiment: preliminary study, conjecture, case study and calibration of conjecture. Each phase is explained in detail below.

*Preliminary Study*—To find out why people make errors and what the sources of errors are, the following studies were conducted:

1. Architecture specifications (mainly those of the PDP-11§) were studied for error-prone spots.
2. Experienced programmers of the PDP-11 were interviewed. They were asked to recall "errors" they have made in learning to use the architecture. The "errors" include: wrong assumptions, unclear specifications, confusions caused by counter-intuitive features etc.
3. Existing classifications of errors in programming were used as food for thought.<sup>7,10,25</sup>

*Conjecture*—Based on the information gathered in the preliminary study, the author proposed several categories as likely sources of errors.

*Case Study*—Using the proposed categories as a guide, a "likely error analysis" of the PDP-11 computer architecture was made. The analysis was aimed at revealing the error-prone spots in the written specifications and the architecture itself. The idea is to simulate an actual architecture test programmer using the categories as guidelines for testing. Based on the results of the analysis, specific tests are recommended so that the effectiveness of the methodology can be calibrated later on.

*Calibration*—The above three phases were completed without knowledge of the actual implementations errors that have actually occurred. To see how well the methodology had done, the specific tests were compared against lists of real implementation errors which were only made known to the author *after* the tests had been developed.

\*\*\* An example of an implementation class is the family of 16 bit adders implemented by  $n$  bit full adder slices ( $0 < n < 16$ ) with carry look ahead. Another example is multiplication implemented by repeated additions, whether it is implemented in hardware, firmware, or software. Multiplication implemented by table lookup is in a different class because it requires a totally different test strategy.

† Complete error histories are rarely published. In fact, some manufacturers try their best to conceal errors they have made in the past.

§ The PDP-11 04/05/10/35/40/45 Processor Handbook published in 1975 by Digital Equipment Corporation is used throughout this study. For those who are unfamiliar with the PDP-11, see Appendix A for a brief description of the addressing modes and instructions.

### Errors in implementing an architecture

The preliminary study revealed eight likely *sources* of errors. They are:

1. Incomplete and imprecise specification
2. Interdependent side-effects
3. Asymmetry/nonuniformity
4. Logical complexity
5. Boundary values
6. Counter-intuitive and unusual features
7. Inconsistencies in nomenclature and style
8. Missing functions

Each of these categories is explained in detail in the following subsections. Real-life examples, mostly from the PDP-11, are given whenever appropriate. Since the categories overlap with one another, some examples have been somewhat arbitrarily classified.

#### Incomplete and Imprecise Specification

Whether the incompleteness in an architecture specification is intentional or accidental, the hardware of any implementation does *something* for the unspecified operations. Users are often tempted to use those peculiar "features" in their programs. If later models do not have the same "features," there is a software incompatibility problem. An incomplete specification may cause implementors to use an incompatible scheme in implementing the unspecified operations.

A specification which appears precise to its writer may be imprecise or ambiguous for others because of nontrivial implicit assumptions made by the former. Following is an example from the PDP-11 handbook:

- The overflow and carry condition code settings for the subtract (SUB) and compare (CMP) instructions are described in the processor handbook as follows:  
**V:** set if there was arithmetic overflow as a result of the operation, that is if operands were of opposite signs and the sign of the source was the same as the sign of the result; cleared otherwise.  
**C:** cleared if there was a carry from the most significant bit of the result; set otherwise.  
 One must have a good knowledge of two's complement arithmetic to be able to understand this. The setting of the carry condition code even presumes a particular way of implementing the subtract operation—complement and add. In fact, the borrow generated by a hardware subtractor would be the exact opposite of the carry generated by the presumed method. In any case, the operations should have been precisely defined to avoid any misunderstanding.

#### Interdependent side-effects

Instructions which have multiple side-effects are error-prone, especially if the outcome of the instruction depends on the order in which the side-effects are carried out. Sometimes ambiguities can occur at the interfaces of architectural features which are individually well-defined. An instruction consisting of multiple operations is inherently ambiguous if the order of the operations is not clearly specified and the effect of the instruction depends on this order. Most often this arises when there are multiple operations on the *same* register or memory location within an instruction and the order of operations is not explicitly stated in the specification.

#### Asymmetry/nonuniformity

Asymmetry/nonuniformity often causes additional complexity in programming and in implementation. Asymmetrical/nonuniform side effects, notably condition code settings, are usually counter-intuitive as well.

- The instruction MUL Rn, SRC will cause Rn to contain the low order part of the result if R is an *odd*-numbered register and cause Rn to contain the high order part of the result if Rn is an *even*-numbered register. This asymmetry would not have occurred if the multiply instruction is defined such that the low order part of the result, which is what is needed most of the time, is always stored into Rn, and not R<sub>n+1</sub>.
- The automatic sign extension that occurs in moving a byte to a register with the MOV<sub>B</sub> instruction often catches programmers off guard. One would expect a byte instruction to operate on a byte and yield a one byte result. This nonuniformity is actually caused by the more fundamental nonuniformity\* that registers are not byte addressable while all memory locations are.

#### Logical complexity

Some instructions are error-prone due to their sheer complexity. The human mind does not efficiently handle complexities beyond a certain threshold. Complex interactions that change a lot of processor states (trace traps, interrupts etc.) are conceptually hard to understand as well as difficult to implement, especially if multiple activities can occur at the same time. Extra testing is required to ensure the correctness of complex instructions.

\* We are not saying that this nonuniformity was a bad design decision; in fact it was probably a good one. We just want to point out that any nonuniformity is a likely source of errors.

### Boundary values

Boundary values for an instruction are input values that are at the boundaries of different decision regions in the input domain of the instruction. This concept is analogous to decision branches inside a program which compare input or computed values against some test values in order to determine the execution paths that the program should follow. In fact, the inclusion of this category is inspired by the frequent occurrence of boundary value errors in programming. The most prevalent kinds of errors in this category are *missing boundaries* and *off-by-one* errors. Missing boundaries are situations in which one or more of the boundaries between decision regions are missing. Off-by-one errors are errors in which a boundary is off a distance of one (for some appropriate definition of distance) away from where it should be.

### Counter-intuitive and unusual features

Features that deviate from or behave just opposite to what one would normally expect or find in other architectures are error-prone. They also considerably slow down programmers who have to deal with them. Similarly, inappropriate or non-mnemonic names for instructions invite errors. Without proper explanation and motivation, even a useful feature may create confusion.

- Some condition code settings in the PDP-11 are counter-intuitive. For example, the increment and decrement instructions do *not* affect the carry.<sup>23</sup>

### Inconsistencies in nomenclature and style

Inconsistencies and exceptions are often introduced due to carelessness or ignorance. It is often penny-wise and pound-foolish to foul up an otherwise uniform and clean style just to squeeze an extra bit of performance out of an architecture.

- In PDP-11 instruction nomenclature, instructions that end with a B are supposed to be byte instructions. The SWAB instruction, despite having a B as the last character of its name, is actually a word instruction—it takes a word operand and generates a word result. It would probably be better to call it SWAP.
- The multiply and divide instructions store the high-order word of their two-word results in  $R_n$  and the low order word in  $R_{n-1}$ , which is just opposite to the practice of storing a high byte at the *higher* address within a word. The same comment applies to the scheme of storing the high part of a floating number in the *lower* word.

### Missing features

This is not really a source of error, but it is put here as a reminder that a good test program should at least test for the existence (not necessarily the complete correctness) of every feature. It is not uncommon that relatively simple features are left out of an implementation due to the oversight or lack of experience of its designers. To illustrate what I mean by features in an architecture, the major features of two typical instructions are presented below.

#### ADD:

- Add source operand to destination operand and store result in destination.
- If there is a carry out, set the carry bit, clear it otherwise.
- If the result is zero, set the zero indicator, clear it otherwise.
- If the result is negative, set the negative indicator, clear it otherwise.
- If the addition results in an overflow/underflow, set the corresponding indicator.

#### HALT:

- If in user mode, causes an “illegal user instruction” trap.
- If in supervisor mode, stop all operations:

1. All flags are left untouched,
2. The program counter points to the next instruction following the HALT.

A major feature can often be broken down further into several minor features, depending on the complexity of the instruction. To guard against leaving some major features untouched, a comprehensive checklist for features of each instruction should be used. Each entry on the checklist roughly corresponds to a leaf on the decision tree of the instruction.

More likely than not, most features would have been exercised by tests written for other categories, thus it will only be necessary to write special tests for the items that are left untouched by other tests. In order to reduce the test space to a practical size, often only the existence, and not the correct functioning, of features can be established by such tests.

### A CASE STUDY OF THE PDP-11 ARCHITECTURE

The architecture testing philosophy advocated in this paper is rather straightforward: given the amount of resources one is willing to spend in testing, try to *minimize the probability* that an error is undetected. This implies that one should test for the most likely errors first. In fact, these are often the only errors that one can afford to test for. The crucial question here is: *what* are the most likely errors?

This section presents a "likely error analysis" of the basic PDP-11 architecture\*\* as specified in PDP-11 processor handbooks<sup>5</sup>. The likely errors are identified and classified using the proposed criteria. It must be pointed out here that what "likely errors" are depends on when in the development of an implementation the tests are made. We have been assuming all along that we will test prototypes that have most instructions "working" and that we are looking for the *obscure* errors. The PDP-11 is selected for case study because (i) it is a major computer family having numerous implementations; (ii) the history of its implementation errors is readily accessible to allow evaluation of the proposed testing strategy; and (iii) the basic architecture is simple enough for a thorough study of this sort.

The analysis is intended to be *illustrative* rather than complete—someone who is willing to spend the energy needed to analyze an architecture for likely errors can probably turn up more potential bugs. A list of recommended tests is given at the end of each section. As a whole the recommended tests should be viewed as "hole-plugging" tests to be added on top of any testing scheme that covers basic and obvious functions.

#### *Incomplete or imprecise specification*

The handling of hardware error conditions is only briefly mentioned in the processor handbook. There is no well-defined priority scheme for handling multiple, simultaneous processor trap conditions. The handbook also does not specify clearly what happens if a trap occurs in the *middle* of an instruction.

##### *Other problems in the specification:*

- The specification of the overflow V bit setting is wrong for the subtract carry (SBC) instruction. It is stated as follows in the manual:  
V: set if (dst) was 100000; cleared otherwise  
It should instead be  
V: set if (dst) was 100000 and C was 1; cleared otherwise
- The specification of the carry condition code settings in the SUB and CMP(B) instructions presume particular implementation schemes (see *Incomplete and Imprecise Specification*).

##### *Tests recommended:*

- Trap priority—special hardware is probably required to carry out this test.
- Handling of multiple trap conditions caused by a single instruction.
- Test the V bit setting of the SBC and SBCB instructions.
- Test the C bit setting of SUB and CMP(B) instructions.

\*\* For the purpose of this study, FIS, FIS, memory management, floating point instructions are not considered part of the basic PDP-11 architecture.

#### *Interdependent side-effects*

In the PDP-11, many instructions having interdependent side-effects are also inherently ambiguous because the architecture specification often does not specify the orders of execution for multiple side-effects.

##### **Multiple, explicit operations on the same register**

A double operand instruction is inherently ambiguous if (i) its source addressing mode uses Rn and its destination addressing mode is one of (Rn)+, @(Rn)+, -(Rn), and @(Rn); or if (ii) its source mode is one of (Rn)+, @(Rn)+, -(Rn), and @-(Rn) and its destination mode uses Rn. For example:

- OPR Rn,(Rn)+—if the second operand is fetched from memory (the first operand needs no fetching) and autoincrement is performed *before* carrying out the operation, the incremented Rn will be used as the source operand. But if the operands (including register operands) are first stored into temporary registers as they are fetched, the original value of Rn would be used as the source operand. The latter is more intuitive, but the processor handbook makes no statement about this ambiguity.

##### *Test recommended:*

- For all double operand instructions, test all the 64 combinations of addressing modes that are ambiguous. Of course, we would need to define how the combinations should behave before we can test them.

##### **Multiple, explicit and implicit operations on the same register**

PC (register 7) is automatically incremented each time it is used to fetch a word from memory. It is used implicitly in some addressing modes while SP (register 6) and some memory locations (notably those reserved for trap vectors) are used implicitly by several instructions. Instructions that operate on these registers or memory locations explicitly as well as use them implicitly at the same time deserve special attention.

- A double operand instruction that uses the PC is ambiguous if (i) its source is PC and its destination is one of (PC)+, @(PC)+, -(PC),@(PC),X(R), and @X(R); or if (ii) its source is one of the list just given and the destination is PC.

##### *Tests recommended:*

- Test all the 12 ambiguous combinations of PC addressing modes.

### Modification and decision on the same operand

If an instruction both modifies its operand(s) and uses it for a decision (branch, setting of condition codes etc.), then the relative order of the modification and the decision becomes critical.

#### Tests recommended:

- Test JMP (Rn)+ and JSR Rm,(Rn)+ which are both ambiguous.

#### Asymmetry/nonuniformity

### Fundamental asymmetries/nonuniformities

- Registers are not byte addressable while all the memory locations are.
- Highest page of main memory is reserved for the I/O page.
- Some memory locations are special (e.g. processor status word, stack limit etc.).
- Some memory locations are not writable (e.g. some status registers).
- Some instructions implicitly use special memory locations (EMT, TRAP, BPT, and IOT).

#### Tests recommended:

- Make sure that the I/O page is in the right place.
- Make sure that all the special memory locations are there. For instructions that use special memory locations, make sure that they access the correct special locations when executed.

### Other asymmetries/nonuniformities

- Logical instructions COM(B), BIT(B), BIC(B), and XOR have different condition code setting conventions. In COM(B), the V bit is cleared but the C bit is *not changed*.
- The autoincrement deferred addressing mode @(Rn)+ always increments Rn by 2, even for byte instructions, whereas (Rn)+ increments Rn only by 1 for byte instructions. Similarly, @-(Rn) always decrements Rn by 2, even for byte instructions, whereas -(Rn) decrements Rn only by 1 for byte instructions.
- Automatic sign extension in MOV<sub>B</sub> -,Rn (see *Asymmetry/Nonuniformity*).
- MUL & DIV instructions store low order part of result into R v 1 (see *Asymmetry/Nonuniformity*).

#### Tests recommended:

- Test COM(B) for the correct setting of the C bit.

- Test @(Rn)+ and @-(Rn) for incrementing/decrementing Rn by *two*.
- Test sign extension in MOV<sub>B</sub> -,Rn.

#### Logical complexity

There are not many complex instructions or features on the basic PDP-11. The MARK instruction and trace trap are probably the most complex features and the trap instructions (EMT, TRAP, BPT, IOT, RTI, RTT), SOB, JSR, and RTS instructions deserve some extra testing effort.

#### Tests recommended:

- Test the previous instructions/features to make sure that the right *sequences* of operations are performed when they are invoked.

#### Boundary values

It is straightforward to figure out the boundary values for logical instructions—just test all four combinations for each bit position. It is often the case for arithmetic instructions, however, that there are too many boundary values and subsets must be chosen among them. Without going into detailed arguments, we assert that testing just a few key points on a boundary is almost as good as testing all the points on the boundary. This approach is illustrated below through a “boundary value analysis” of the ADD instruction.

The input domain is partitioned into different decision regions\*\*\* for each of the four condition codes N,Z,V, and C (which stand for Negative, Zero, overflow, and Carry respectively). For example, one region would consist of all input values that generate results which are less than zero and will therefore set the N bit while the complement of this region would consist of those input values that generate results which are not less than zero. There are well-defined boundaries between the partitions (see Figure 1). For example, the boundary values lying on the two sides of the longest N bit boundary are given by  $y+z=1$  and  $y+x=0$  respectively (Figure 2). Note that the partitioning is symmetrical with respect to the line  $y=x$  because ADD is a commutative operation and that the partitions for different condition codes often have common boundary values. Besides correct setting of condition codes, one may also want to test for the following: the correct operation of each output bit†, correct generation and propagation of carry from each

\*\*\* A region may not appear contiguous on a two-dimensional graph. The input domain actually wraps around. For example,  $2^{15}-1$  (011111<sub>2</sub>) and  $-2^{15}$  (100000<sub>2</sub>) are neighboring points. “Neighboring” means that the distance between the two points is one for *some distance measure*. In this case, the distance is measured by numerical difference. In other cases, we may want to use the geometric code distance measure in which neighboring points are those points that differ from the original point by one bit—hence there are  $n$  neighboring points for each point (where  $n$  is the word length).

† In the case of the ADD instruction, adding 00 . . . 00 & 11 . . . 11, 01 . . . 01 & 10 . . . 10, 10 . . . 10 & 01 . . . 01, 11 . . . 11 & 00 . . . 00, and 11 . . . 11 & 11 . . . 11 can test each output bit individually.

- Region in which the C (Carry) bit should be set
- Region in which the N (Negative) bit should be set
- Region in which the V (oVerflow) bit should be set

Boundaries:

- N:  $y+x = 0$  &  $y+x = -1$ ;  $y+x = 2^{15}-1$  &  $y+x = 2^{15}$ ;  $y+x = -2^{15}$  &  $y+x = -(2^{15}+1)$
- Z:  $y+x = 0$  &  $y+x = -1$  &  $y+x = 1$ ;
- V:  $y+x = -2^{15}$  &  $y+x = -(2^{15}+1)$ ;  $y+x = 2^{15}-1$  &  $y+x = 2^{15}$ ;
- C:  $y+x = 0$  &  $y+x = -1$ ;  $y = -1, x \geq 0$  &  $y = 0, x \geq 0$ ;  $x = -1, y \geq 0$  &  $x = 0, y \geq 0$ ;

Number of points on the boundaries

$2^{18}$

$3 \times 2^{16}$

$2^{17}$

$2^{18}$

Figure 1—Boundary values for condition code settings of the ADD instruction.

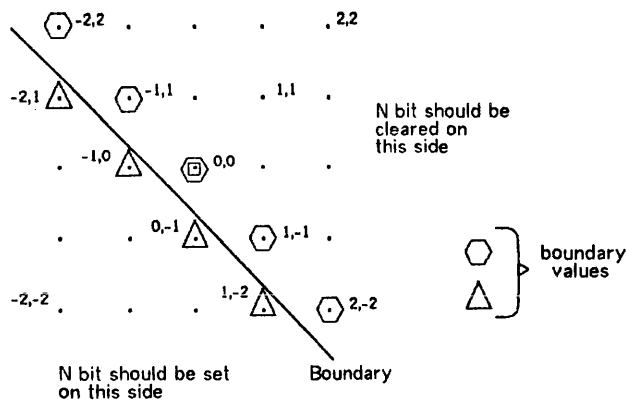

Figure 2—A close look at the N bit boundary.

position . . . Each of these have their own set of boundary values that need to be tested. In general, one first determines the things (actions) that one wants to check out, then partitions the input domain into decision regions for each particular action and finally picks out the boundary values as test data.

Ideally all boundary values of an instruction should be included as test points in testing the instruction. If one cannot afford to test all of them (e.g. in a 32 bit machine), a subset of "key points" could be chosen for testing. The minimum set of test points recommended are those values that are either at the "corners" of boundaries or at extreme points of the input domain. The existence of a boundary can be tested by crossing it from one boundary value to a neighboring value on the other side of the boundary. The process of selecting the key points is illustrated in Figure 3.

*Tests recommended:*

- Verify the operation (condition code settings, etc.) of each logical and arithmetical instruction for *all* its

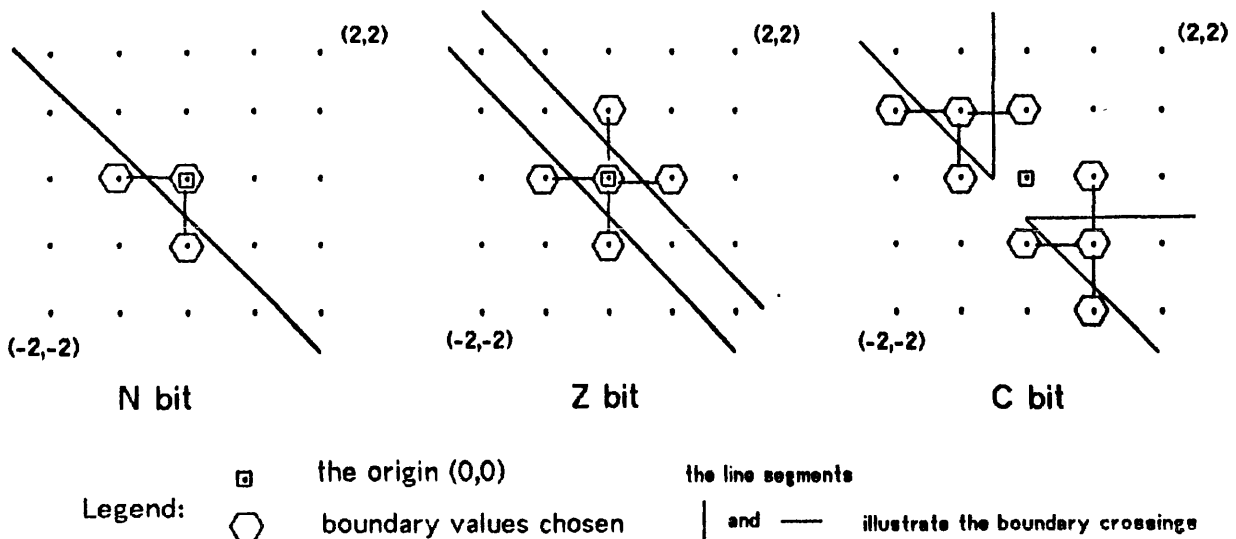

Figure 3—Three examples showing the selection of test data based on boundary crossings.

boundary values. If this is not practical, pick a subset of "key points." For logical instructions, the simplest test is to assume independence among different bits in a word and apply the input pairs of 000000 & 000000, 000000 & 177777, 177777 & 000000, and 177777 & 177777.§

*Counter-intuitive and unusual features*

- Complement (COM), a logical instruction, sets the C bit instead of leaving it untouched.
- The increment (INC) and decrement (DEC) instructions do not affect the carry.

*Tests Recommended:*

- Test the C bit setting of the COM(B) instruction.
- Test that the carry bit is truly unaffected by INC(B) and DEC(B) instructions.

*Inconsistencies in nomenclature and style*

- The usage of the "contents of" notation, (. . .), is inconsistent.
- The notation used to represent a register is also inconsistent.

*Test recommended:*

- None. In this case none of the inconsistencies is very serious. If one is writing a complete test program, however, then it would be worthwhile to pay special attention to even minor inconsistencies.

§ A better test is to apply some algorithmic patterns (like walking 0's and 1's) to systematically check for cross-coupling between bits.

### Missing features

A good test program should try to test for the *existence* (not necessarily the complete correctness) of as many features as possible.

### Tests recommended:

- The existence of all major features should always be checked out.
- As our resources permit, test for the existence of as many minor features as possible.

## RESULTS AND CONCLUSIONS

The eight error categories are conjectures established based on their *potential* of causing implementation errors. To examine how well they capture actual errors, the tests recommended in the previous section were calibrated against two error histories. The first one is a list of incompatibilities among models of the PDP-11 and the second one is a list of errors found in an ISP "implementation." In both cases, only errors in implementing the basic architecture\* are considered.

### Comparison with published incompatibilities among various models

This error history is published by DEC itself<sup>5</sup> and it lists known differences among five implementations of the PDP-11 architecture (see Appendix B). These are usually obscure errors that have slipped through the conventional validation tests. Among the 14 implementation errors, eight would definitely be caught by the recommended tests, three would probably be caught and the remaining three would likely slip through. All, however, fall into five of the eight categories and hence would likely be caught by more detailed tests (which requires a more detailed analysis of the PDP-11 architecture than what was done).

### Comparison with errors found in the PDP-11 ISP

The ISP description of a computer architecture can be considered an implementation of that architecture through emulation on the "Register Transfer Machine."<sup>1</sup> A PDP-11 ISP description was recently written and debugged.\*\* A rather complete history of the errors that have been discovered in the description has been kept. The comparison (see Appendix C) revealed that eight of the 13 errors would definitely be caught by the recommended tests. Two would probably be caught and the remaining three would likely slip

through. All, however, fall into the error categories and would conceivably be detected by more detailed tests.

### Discussion

The above comparisons suggest the following:

1. An error-oriented architecture testing program written with the proposed categories as primary test targets can augment existing test schemes. In the first case, the recommended tests caught a significant percentage of obscure errors that have slipped through conventional tests. More encouraging is that all the implementation errors in both cases fall into the eight categories. Hence if someone devotes enough time (perhaps months, a reasonable investment for a major computer family) to develop an architecture testing program using the proposed methodology, most of these errors can conceivably be caught by the detailed tests.
2. Exercises like the "likely error analysis" presented can help architects to improve their specifications and reduce implementation errors caused by problems in the specification. Such exercises are also useful in spotting error-prone areas, which often cause difficulty in implementation as well as programming, in the architecture itself.

In retrospect, other than a few categories like *boundary values* which can conceivably be rigorously defined, most of the proposed categories have rather "soft" criteria and require human judgment in applying them. A lot more work is still needed to make them more specific and more amenable to automation. In addition, difficult areas such as floating point instructions have not been dealt with. We nevertheless hope that the proposed categories can serve as helpful guidelines for those who are going to write architecture testing programs. Analyzing an architecture specification to identify potential errors is a very time-consuming process, however, and the usefulness of any testing methodology ultimately depends on automation. Toward this end, research should continue on analysis techniques and the automatic generation of test data and test programs.

## ACKNOWLEDGMENT

The author would like to thank Dan Siewiorek for initiating the study and helping along the way. Thanks are also due to Mario Barbacci, Len Shustek, Bob Sproull, Richard Swan, and the referees for their valuable suggestions.

## APPENDIX A

### *A brief description of PDP-11 addressing modes and instructions*

Single operand instructions have the format *OPR destination* and usually perform  $d \leftarrow op d$ .

Double operand instructions have the format *OPR source, destination* and usually perform  $d \leftarrow s op d$ . Each operand can be accessed using one of eight addressing modes, giving

a cross-product of 64 ways of addressing operands in a double operand instruction.

### *Addressing Modes*

<i>Modes</i>	<i>Symbolic</i>	<i>Description</i>
0	R	(R) is operand
1	(R)	(R) is address
2	(R)+	(R) is adr., increment R after fetching
3	@(R)+	(R) is adr of adr., incr. R after fetching
4	-(R)	decrement R before fetching, (R) is adr.
5	@-(R)	decr. R before fetching, (R) is adr. of adr.
6	X(R)	indexing, (R)+X is adr.
7	@X(R)	(R)+X is adr. of adr.

## APPENDIX B

### *Architectural incompatibilities among five implementations of the PDP-11*

The incompatibilities listed below are compiled from a list in *Microcomputer Handbook* published by Digital Equipment Corporation in 1976. The list, entitled "LSI-11, PDP-11 Programming/Hardware Difference List," listed the known differences among five implementations of the PDP-11 architecture: LSI-11, PDP-11 05/10, 15/20, 35/40, 45. In compiling the following, differences among features that are not part of the basic PDP-11 architecture are not considered. Next to each of the architectural incompatibilities is listed the error category that the incompatibility belongs to and an indication of whether it would have been caught by the tests that we have recommended.

<i>Incompatibility in</i>	<i>Category</i>	<i>Would It Be Caught With the Tests?</i>
1. OPR R,(R)+ or OPR R,-(R)	Ambiguity in Sequence	yes
2. OPR R,@(R)+ or OPR R,@-(R)	ditto	yes
3. OPR PC,X(R) or OPR PC,@X(R)	ditto	yes
4. JMP (R)+, JSR Rm,(Rn)+	ditto	yes
5. JMP R, JSR Rm,Rn (both illegal instructions) trap differently	Nonuniformity	yes
6. SWAB does not change V in some models	Missing Functions	yes
7. Bus addresses of the registers are special	Nonuniformity	yes

8. Power fail trap has different priority w.r.t. RESET instruction	Incomplete Spec.	no	each of the errors is listed the category that the error belongs to and an indication of whether it would have been caught by one of the tests that we have recommended.		
9. RTT instruction not implemented	<deliberate omission— doesn't count>		<i>Error</i>	<i>Category boundary value</i>	<i>Would It Be Caught?</i>
10. RTI behaves differently with the T bit set	Logical complexity	probably	1. DEC did not set V bit when destination was 100000.	asymmetry	yes
11. Priority between trace trap and interrupt is different	Incomplete spec.	yes	2. MOV B did not sign extend byte moved to register.	missing fn.	yes
12. Trace trap will sequence out of WAIT instruction on some models	ditto	probably	3. SBC did not set the V condition code	missing fn.	yes
13. Direct access to Program Status Register (a special memory location) can change the T bit in some models	Nonuniformity	yes	4. SWAB did not assign the result of the SWAB back to memory	nonuniformity	no
14. Odd address/non-existent traps using the stack pointer	Incomplete spec.	no	5. Byte instruction using indexed deferred addressing mode didn't work correctly.	logical complexity	yes
15. Guaranteed execution of the first instruction in an interrupt routine	Incomplete spec.	no	6. MARK instruction reset the stack pointer wrong	nonuniformity or missing fn.	yes
16. Odd address trap not implemented on the LSI-11	<deliberate omission>		7. PSW did not have bus address 177776.	asymmetry	no
17. Effect of bus errors on PC/register modification	<part of error handling, whether this is part of the architecture is arguable>		8. SOB dropped highest bit of offset	missing fn.	yes
APPENDIX C			9. ASRB instruction operates on wrong field that is off by one bit.	incomplete spec.	no
			10. ASHC & ASH: C and V bits are not set correctly (spec. not clear).	peculiar to ISP, would probably be caught by boundary value tests.	
<i>Errors found in the PDP-11 ISP</i>			11. MUL stores intermediate result in a 17 bit register instead of a 16 bit register		
			12. DIV; when source register addr. is odd garbage is produced.		
			13. DIV: divide by zero did not set condition codes and abort.	missing fn.	yes

# A survey of methods for intermittent fault analysis\*

by YASHWANT K. MALAIYA and STEPHEN Y. H. SU

State University of New York  
Binghamton, New York

## INTRODUCTION

As digital circuits grow in complexity, and as they are used in more and more critical applications, their reliability becomes an important consideration. This directs the attention of researchers involved in this field to two basic questions—first, how to design more reliable systems; second, how can something be said about the reliability of a particular system?

Causes leading to permanent failures can easily be examined. A class of faults called permanent or solid faults was identified and it has been extensively studied. Some solid faults in some lines in digital systems behave as if they are permanently connected to a logic 0 or a logic 1. They are called stuck at 0 or stuck at 1 faults. Significant analytical results are available to handle such faults.

Another class of faults, called intermittent or transient faults, are responsible for a very significant number of failures. The effects of such faults appear and disappear randomly. It has been noticed that an overwhelming proportion (up to 90 percent) of faults can be estimated to be intermittent. As these faults are more difficult to isolate and fix, they account for most of the field maintenance costs. Ball and Hardy<sup>1</sup> in their study found that, while the test and maintenance costs due to the permanent faults tend to decrease drastically with time, the costs incurred per unit time due to intermittent faults change very little. McConnel and Siewiorek<sup>2</sup> report that in an LSI-11 system with 24k words of dynamic MOS memory, one would expect a transient failure every 100 hours, whereas a solid failure can be expected in every 7700 hours. Needless to say, the problems of intermittent failures are very significant.

In this paper, a brief survey of the significant results available today is presented. These aspects of intermittent faults will be considered. First, physical reasons for intermittent faults will be considered. Second, various suggested models for intermittent faults will be examined along with the basic assumptions. Testing and reliability analysis are considered next. Finally, design methods are examined which take intermittent faults into consideration.

## APPROACH

Some have suggested that a distinction between transient faults and intermittent faults be made on a quantitative basis. We will, however, refer to the entire class of such faults as intermittent faults or transient faults interchangeably. We distinguish between an intermittent fault being *present* and being *active*. When an intermittent fault is present, it can either be *inactive* without affecting the correct operation; or it can be *active*, and can cause the system to operate incorrectly. The activity of *signal-independent* faults does not depend on the inputs or the present state of systems. These are easier to handle, much as the analyses done so far assume only signal-independent faults. The activity of signal-dependent faults may depend on the logical values present in the system. An intermittent fault is said to be *well behaved*, if it behaves as a permanent (stuck-at) fault whenever it is active.

As the activity of intermittent faults is random, it is not easy to characterize them. The randomness makes it necessary to use probabilistic methods. The activity can be characterized by a set of parameters, which may be estimated by using statistical methods. These parameters would be utilized in arriving at various analytical results. Probabilistic methods have been successfully used to model random occurrences of permanent faults in digital systems, and related parameters have been estimated. Such parameters have been empirically correlated with system complexity (gate and pin count for example).<sup>3,4</sup> While the intermittent faults behave in a more complex fashion, the use of probabilistic methods should be expected to yield practically usable results. Often expected reliability measures<sup>5</sup> are given in a design specification which implies use of probabilistic and statistical methods.

## PHYSICAL CAUSES OF INTERMITTENT FAULTS

Physical causes of intermittent failures could be external to the system, like temperature, or internal like loose connections. A combination of the two types can be suspected in several cases.

Yen<sup>6</sup> has reported that in four-phase MOS circuits, some nodes in some circumstances may have voltages lower than

\* This work is supported by the Division of Mathematical and Computer Science of the National Science Foundation under grant No. MCS78-24323.

normal, making them very susceptible to noise. Noise can be suspected to be a significant cause of intermittent faults. All electrical devices are inherently noisy; noise generated by a device can sometimes be correlated with the temperature and the electrical characteristics.<sup>7</sup> Additional noise could also result because of strong electromagnetic fields in the area, which often accompanies switching of large currents.<sup>8</sup> Switching in the same system can cause noise. It has been noticed that significant amounts of noise can be generated due to refresh operation or instruction execution.<sup>9</sup> One of the suggested models, for intermittent faults, characterizes noise on a bus.<sup>10</sup>

Loose or poor electrical connections can cause intermittent failures; such faults may be activated by either electrical or mechanical causes. Faults on the semiconductor chips are known to cause signal-dependent types of intermittent faults. Because of coupling between physically adjacent cells or faulty decoders, some patterns in a semiconductor memory may cause faults.<sup>11</sup> Some microprocessor chips have been found to possess instruction sensitivity.<sup>12</sup> Such faults will exhibit themselves intermittently. Some parts of an integrated circuit chip may get heated after some time period of use, and may display intermittently faulty behavior.

Temperature and radiation (especially in outer space) are examples of external causes. Proper operation of semiconductor devices is defined only in small ranges of these, and if they exceed the specified limits, or stay at the limiting value for a prolonged duration, components may behave erratically. Variations in the power supply can also cause intermittent failures. Airborne computing systems might encounter atmospheric electric discharges.

Usually causes of intermittent failures are not known. The only choice is to regard them as random processes. In a particular environment, their effect can be characterized by a specific set of parameters, which can be determined statistically or using empirical methods.

## MODELING

Breuer<sup>13</sup> suggested a two-state discrete-parameter model, using the assumption that the activity of the fault can be represented by a Markov process. His model provides a good starting point for studying the modeling of intermittent faults. If the outcome of a Markov process is known at an instant  $t$ , then for the duration following  $t$ , the history of the process before  $t$  is immaterial. If an intermittent fault is present, then the system can either be in state fault-not-active (FN) or in state fault-active (FA). As shown in Figure 1, two transitions for a state can be defined. Let the state of the system be described after every  $\Delta t$  seconds (called time-step). Then the parameters indicated in Figure 1 denote the probability of the appropriate transition in time  $\Delta t$ . If  $p_0(q)$  and  $p_1(q)$  are the probabilities of being in states FN and FA at time  $t_q$  respectively, then

$$(p_1(q+1), p_0(q+1)) = (p_1(q), p_0(q)) \begin{bmatrix} r & \bar{r} \\ s & \bar{s} \end{bmatrix}$$

Clearly the estimated values of both  $\bar{r}$  and  $s$  depend on the

Figure 1—Two-state discrete parameter.

time-step chosen, and they have to be re-estimated if the time step is changed. The same problem is encountered if one uses Spillman's approach,<sup>14</sup> as he uses the same discrete parameters as Breuer for his analysis and numerical comparison. This is restrictive, as the time-step is not an attribute of the fault, rather it is chosen to correspond to a particular clock-rate. This model, like all others to follow, assumes signal-independent intermittent faults.

A zero-order Markov model, which is simpler to use, has been utilized by Kamal and Page<sup>15</sup> to find procedures for fault-detection when a digital circuit may have a multiple number of faults. In their model, the behavior of the fault is fixed at all times. They define a conditional probability of malfunction ( $e_i$ ), for each intermittent fault  $f_i$ , which is the probability of the fault being active, given its being present. This model has been used by Kamal,<sup>16</sup> Koren and Kohavi,<sup>17</sup> and Shedletsky.<sup>18</sup>

Merryman and Avizienis<sup>19</sup> use a model which characterized intermittent faults by an arrival rate,  $\tau$ , which is assumed to be constant over the life of the system, and the transient duration (in which faults remain active)  $D_\tau$ . The transient duration  $D_\tau$  is random, with a density function  $f_{D_\tau}$ . This density function was assumed by them to be

$$f_{D_\tau}(t) = \gamma e^{-\gamma t} \quad (2)$$

where  $\gamma$  is a parameter.

This is a lucky assumption, as it will allow us to correlate this model with the next one. This model has been used by Ng.<sup>20</sup>

A continuous-parameter Markov model has been used by Su, Koren and Malaiya.<sup>21</sup> The model is based on these causal considerations. If the system is in a fault-not-active (FN) state at a certain time, then the probability that it will be found in fault-active (FA) state after a short time  $\Delta t$ , should be proportional to the duration  $\Delta t$ . If a constant of proportionality  $\lambda$  is assumed, then  $Pr\{\text{system will be in FA at } t + \Delta t | \text{it was in FN at } t\} = \lambda \Delta t$ . Similarly, for a reverse transition,

$$Pr\{\text{system will be in FN at } t + \Delta t | \text{it was in FA at } t\} = \mu \Delta t \quad (3)$$

These two assumptions generate a continuous parameter Markov model shown in Figure 2. This model has several desirable characteristics. It is easily conceived, amenable to mathematical analysis and poses fewest restrictions. Later, this model will be used to correlate different models.

A continuous-parameter Markov model can be represented by a pair of differential equations. If  $p_0(t)$  and  $p_1(t)$

Figure 2—Continuous-parameter Markov model.

are the probabilities that the system is in state FN and FA at time  $t$ , respectively, then<sup>22</sup>

$$\begin{aligned}
 p_0(t) &= p_0(t_0)e^{-(\lambda+\mu)t} + \frac{\mu}{\lambda+\mu} (1 - e^{-(\lambda+\mu)t}) \\
 p_1(t) &= p_1(t_0)e^{-(\lambda+\mu)t} + \frac{\lambda}{\lambda+\mu} (1 - e^{-(\lambda+\mu)t})
 \end{aligned}
 \tag{4}$$

Occasionally, transitional probabilities  $P_{i,j}(t)$  are more convenient to use;  $P_{i,j}(t)$  is the probability of being in state  $i$  at time  $t_0$ . It should be noted here that  $1/\mu$  is the average duration the fault remains active continuously and  $1/\lambda$  is the average duration it is inactive.

Siewiorek, Canepa and Clark<sup>10</sup> have used a model in which faults take the form of noise signals added to the bus signals. It is characterized by two parameters,  $F$ , which is the probability that a receiving device will read the bus line incorrectly in the presence of a fault; and  $N$ , the duration fault remains active (in bus cycles). These parameters were used to compute a reliability measure for a fault-tolerant multiprocessor.

An adaptation of Breuer's model is used by Lala and Hopkins.<sup>23</sup> They have used parameters  $\alpha$  and  $\delta$ , which are called frequencies of transition, to characterize the transitions between the two states. The ratio  $\alpha/\delta$  is referred to as the latency factor; the higher it is, the higher the percent of time fault is inactive and hence invisible.

These models can be correlated by using the continuous-parameter Markov model.<sup>24</sup> Breuer's discrete-parameter model will approach this model as the time-step becomes small. The parameters then can be compared when the time-step is assumed to be sufficiently small.

Using Equation 4 it can be seen that if  $t \rightarrow \infty$ , then  $P_0(t) \rightarrow \mu/(\lambda + \mu)$  and  $P_1(t) \rightarrow \lambda/(\lambda + \mu)$ , i.e., the probabilities will assume "steady-state" values. If the state of the system is examined only after long durations (i.e.,  $e^{-(\lambda+\mu)t} \approx 0$ ), then the probabilities associated with the two states could be regarded as constant, and the model will reduce to Kamal and Page's model.

In Merryman and Avizienis' model, the parameter arrival rate  $\tau$  corresponds to  $\lambda$  in the continuous-parameter model. However as  $\tau$  is constant, a fault may "arrive," even though the fault which had arrived before had not disappeared. Clearly, for a correlation it must be assumed that the fault duration is small. Their parameter  $\gamma$  corresponds to  $\mu$ .

Parameters  $F$  and  $N$  used by Siewiorek, Canepa and Clark can also be correlated to the continuous-parameter model.

The correspondence is, however, not as simple as in previous cases. The model employed by Lala and Hopkins is equivalent to the continuous-parameter model. These correspondences are summarized in Table I.

Varshney<sup>35</sup> has suggested some models which incorporate some memory in the fault behavior. One way memory can be incorporated is to describe the system by a multistate Markov model, in which some states correspond to faulty behavior and the rest to fault-free behavior. Other methods suggested by him use conditional probabilities  $p(m/n)$ ; which is the probability that a fault-free duration is of length  $m$  given the preceding fault-free duration was of length  $n$ .

MODELS FOR RELIABILITY CALCULATIONS

The continuous-parameter Markov model just discussed assumes that the intermittent fault is present all the time. Sometimes an intermittent fault may become present only after a duration of time. This can be modeled by providing another state in which the fault is not present, and then providing the appropriate transition.

Koren and Su<sup>25</sup> have suggested the model shown in Figure 3. The fault is not present in state FNP, it is present but not active in state FN and it is both present and active in state FA. A somewhat more general model shown in Figure 4 is suggested by Malaiya and Su<sup>26</sup> in which transition is also allowed from state FNP to FA. This model is a result of merging two concurrent Markov processes.<sup>24</sup>

The model of Figure 3 reduces into the well known model for permanent faults by letting  $\mu \rightarrow 0$  and  $\lambda \rightarrow \infty$ . The same can be achieved by using the model of Figure 4, by simply letting  $\mu = 0$ .

In a somewhat similar model, Lala and Hopkins<sup>23</sup> allow a transition from FNP to FA. Transitions from FNP to FN are not allowed. This restricts their model, as the transition from FNP to FN should be possible.

Recovery is a commonly used way to counter-act for

TABLE I.—Relationships between Existing Models and the Continuous Parameter Model

Model	Parameter	Symbol	Correspondence to	Correspondence valid when
Breuer	Transition probability	$s$ $\bar{r}$	$\lambda \Delta t$ $\mu \Delta t$	time step $\Delta t$ is very small
Kamal & Page	Conditional probability of malfunction	$e$	$\frac{\lambda}{\mu + \lambda}$	time between two successive samplings is large
Merryman & Avizienis	Average arrival rate Average duration	$\tau$ $\bar{D}, 1/\gamma$	$\lambda$ $1/\mu$	fault duration is extremely small
Siewiorek, Canepa & Clark	Probability of incorrect read operation Duration	$F$ $N$	$\frac{\lambda(1 - e^{-(\lambda + \mu)t_c})}{\lambda + \mu}$ $1/\mu t_c$	applicable to faults on the bus-line
Lala & Hopkins	Frequencies of transition	$\alpha$ $\delta$	$\mu$ $\lambda$	apparently equivalent

Figure 3—Model suggested by Koren and Su.

intermittent faults.<sup>27</sup> In processors, recovery is initiated after an intermittent fault is detected. Merryman and Avizienis<sup>19</sup> assume that  $T_d$ , the time between fault occurrence and fault detection is random, probably governed by an exponential distribution law.  $T_r$ , the time between fault-detection and the end of the recovery is assumed to be constant. They have also used these parameters.

$$C_i \triangleq Pr \{ \text{recovery from transient} | \text{transient occurs} \}$$

$$1 \triangleq Pr \{ \text{transient fault is interpreted as permanent} \}$$

Lala and Hopkins<sup>23</sup> have used a parameter governing the transition from state fault-active (FA) to the state fault-not-present (FNP). This parameter can be called recovery rate. Therefore, their model remains Markovian even after inclusion of the recovery process. Ng<sup>20</sup> has also assumed that the overall process can be modelled by a Markovian process, as the recovery time can be assumed to be short. These assumptions are, however, open to question.

Modeling a multiple number of intermittent faults in the same system can be complicated. For Kamal and Page's model this does not pose much of a problem, as behavior is assumed to be independent of time. Su, Koren and Malaiya<sup>21</sup> have assumed that only one of the possible intermittent faults can be present in the circuit. Malaiya<sup>24</sup> has modelled a multiple number of independent faults by independent Markov processes.

One important question that needs to be asked is "Given a model, how are the parameters to be estimated?" Some preliminary statistical methods have been considered in Reference 24. Parameters could be dependent on the kind of environment the system operates in; therefore, experiments

Figure 4—Model suggested by Malaiya and Su.

for parameter estimation must take place in a real or closely simulated environment. If any kind of empirical relationships exist between the parameters and the environmental attributes (like temperature), they could be used to predict the parameters in a certain environment, also they could be used for "accelerated testing."

Most models can be used to model the behavior at a certain node, as well as the behavior at the output port.<sup>24</sup> If a model is used to characterize the output-port behavior, the parameters will be dependent on not only the physical behavior of the fault; but also the inputs and the state of the system.

### TESTING INTERMITTENT FAULTS

The integrated circuits must always be tested if they are to be used in a reliable system. Most types of IC testing is done for permanent faults only. The importance of testing intermittent faults is apparent, as was stated by Yen.<sup>6</sup> However, one problem for testing intermittent faults is that the faults may not be active when the test is applied. Therefore, to be reasonably sure that an intermittent fault is not present in the circuit, the test would have to be repeated a number of times. The repeated testing would be terminated after either the fault has been detected or a prespecified time has been spent for testing. How often a test is to be repeated has been of significant concern, as the total testing time available is always limited.

Breuer<sup>13</sup> defined a confidence level CL, which is the probability that a test would detect the presence of an intermittent fault. He then derived the number of times that the test has to be repeated. He has also suggested how tests can be generated to detect a particular intermittent fault.

Kamal and Page<sup>15</sup> have considered detection procedures for combinational circuits which could be used for circuits with several possible intermittent faults; however, it is assumed that at most one intermittent fault can be actually present. It is also assumed that the faults are well behaved and signal-independent; these assumptions have been used by others, who have considered testing strategies for intermittent faults. They have suggested that the total number of times a fault is to be tested can be found using one of the two decision rules. One decision rule is to stop when the a-posteriori probability (i.e., the probability after testing) of an intermittent fault being present in the circuit, drops below a specified number, say,  $10^{-6}$ . The other decision rule is to stop when a ratio of probabilities, called a likelihood ratio, becomes less than a small number called the threshold.

They have extended the results for the general case. Considering a set of intermittent faults ( $f_1, f_2, \dots, f_n$ ), and a set of tests ( $t_1, t_2, \dots, t_m$ ), a fault matrix  $A=(a_{ij})$  can be defined such that

$$a_{ij} = \begin{cases} 1 & \text{if } t_j \text{ tests for } f_i \\ 0 & \text{if } t_j \text{ does not test for } f_i \end{cases}$$

Using this matrix, and an appropriate decision rule, an integer programming problem can be set up. The solution of

this integer programming problem would give the required number of repetitions of each test, so that the total number of repetitions is minimum.

The method is further developed by Kamal.<sup>16</sup> He has suggested a procedure to identify the intermittent faults. After an intermittent fault is detected, a fault identification procedure is initiated. This is done by sequentially ruling out the possibility of having a particular set of intermittent faults. Finally only one fault is left as a possible candidate and is thus identified. He has shown that the total number of tests is finite; therefore, the identification procedure will eventually terminate.

Savir<sup>28</sup> has considered random testing for intermittent faults in irredundant (nonredundant) combinational circuits. Testing is random in the sense that the sequence of tests is random. The tests chosen for random testing are members of an "optimal generating set." To get an optimal generating set, one starts with the set of all possible tests. From this set a test is deleted, if another test can be found which detects the same faults or additional ones. Deletion is carried on until none of the remaining tests can be deleted, giving the optimal generating set. A non-linear optimization problem then can be set up. This will maximize the probability that a fault will be detected, given that the circuit is faulty. The optimization problem will then generate the relative frequency of various tests in the optimal generating tests. Finally the total number of tests required can be found by considering a pre-specified "escape probability," which is the probability that the circuit will be declared fault-free after testing, even though it is faulty.

Koren and Kohavi<sup>17</sup> have considered the problem of locating intermittent faults in combinational networks. They have defined a cost function, which equals the number of distinguishing tests required to locate a fault. A procedure using dynamic programming is given, which generates a sequential decision tree minimizing the cost function. The sequential decision tree gives the order in which tests are repeatedly applied. They have suggested another method in which only "reasonably minimum" decision trees are generated, however, computation time is considerably saved.

Su, Koren and Malaiya<sup>21</sup> have suggested that signal-independent faults in combinational circuits can be tested more efficiently by continuous testing. In continuous testing, tests are applied continuously for a duration of time, and outputs are monitored continuously (asynchronously). For both continuous testing and repetitive testing (which can be used for both combinational and sequential circuits), a duration of testing time is calculated, so that the probability of missing the faults is below a specified number. They have considered the optimum fault-detection experiment for the general case when a set of tests is available, each test detecting one or more faults. They have assumed that only one of the possible faults is present at a time; however, this restriction can be removed as shown in Reference 24.

## RELIABILITY ANALYSIS

The objective of reliability analysis is to be able to predict the performance of a system with respect to time. If only

permanent faults are considered, one reliability measure is usually enough.

$$R(t) = Pr\{\text{a system will operate correctly at time } t\} \quad (5)$$

If intermittent faults are also considered, then several reliability measures can be defined. A somewhat stricter reliability measure, which can be called durational reliability, can be defined as

$$R_d(t) = Pr\{\text{system operates correctly during } (t_0, t_0 + t)\}. \quad (6)$$

This measure is suitable for critical systems, in which failures of short duration would render them useless. An example of such systems could be the navigational system of a missile, designed to hit very selectively.

In other cases instantaneous reliability defined below could be a more suitable measure.

$$R_i(t) = Pr\{\text{system operates correctly at } t\}. \quad (7)$$

Instantaneous reliability is also referred to as availability.<sup>31</sup> This could be a more useful reliability measure, for example, for the communication control system of an artificial satellite.

The two reliability measures will be the same if only permanent faults are considered. When intermittent faults are also considered, they are different; in fact, no general relation to compute one directly from the other can be found. As one will expect,

$$\begin{aligned} R_d(t) &= R_i(t) \text{ for } t = t_0 \\ R_d(t) &< R_i(t) \text{ for } t > t_0 \end{aligned} \quad (8)$$

As permanent faults are a special case of intermittent faults, the existing results for permanent faults can be used to check the results for intermittent faults.

If the definition of durational reliability is modified as shown below, the resulting measure is called "survivability."<sup>19</sup>

$$S(t) \triangleq Pr \{\text{no fatal failure in duration } (0, t)\}$$

This definition allows for successful recovery operations.

Sometimes a reliability measure can be specified in terms of mission time.<sup>31</sup> The *mission time* is the duration in which a reliability measure is above a given number, say 0.90. The mission time, thus is the expected duration, in which a system will operate reliably.

A scan of literature regarding the reliability of systems with permanent faults will reveal that there are several techniques in existence. Sometimes, parameters for individual components are the starting point,<sup>4</sup> sometimes parameters chosen characterize a whole system.<sup>31</sup> In the following discussion, it is assumed that the parameters are estimated at the output ports of the individual subsystems.

The reliability of hardware redundancy systems has been considered by Koren and Su<sup>25</sup> and Malaiya and Su.<sup>24,26</sup> No repair or recovery is assumed. The different modules are assumed to be completely shielded from each other.

In Reference 25, the model of Figure 3 is used. Using this

model, analytical results are presented which enable one to compute the duration reliability of a simple Triple-Modular-Redundancy (TMR) system when each module may potentially possess some faults from a set of all possible faults. By assuming a set of parameters, substantial improvement in reliability by using a TMR system was found. Results are extended to N-module redundancy systems.

The slightly more general model of Figure 4 was used in References 24 and 25. Using this model, several hardware redundancy schemes have been examined to evaluate their reliability. It should be remembered that it is the methods to compute reliability which are more interesting; the numerical results hold good for only a specific set of values of parameters. They have examined the well known Triple-Modular-Redundancy (TMR) and N-Modular-Redundancy (NMR) schemes, the NMR/Bipurge scheme (called by Ng<sup>20</sup> as NMR/Simplex), the NMR/Unipurge scheme (self-purging,<sup>32</sup> called NMR/S by Ng<sup>20</sup>), hybrid redundancy scheme and the reconfiguration scheme.<sup>37</sup> In the NMR/Unipurge system only the faulty module is purged out. In NMR/Bipurge system, two modules (one good, one bad) are purged in order to maintain an odd number of active modules.

An expression for instantaneous reliability in most cases can be found in a straightforward way. The analytical results are presented in Table II. It can be easily verified that in each case if  $\mu$  is set equal to zero, results reduce to the well known results for systems with only permanent faults.

Durational reliability is harder to compute. One can take either one of two possible approaches—one involves solving a system of differential equations iteratively, the other uses a closed form general expression to get an approximate figure. As the system of differential equations may be "stiff," i.e., solutions may become unbounded if the proper step-size is not used and the approximate value can be used to check if the solution is bounded. If it is not within the bound, step-size may be reduced, and computations re-started from the previous step.

The basic model of Figure 4 can be used to graphically represent a fault-tolerant scheme, which can be described by an equivalent system of equations. Figure 5, for example represents a simple 5MR scheme. Only one possible fault in any module is assumed. Each state in Figure 5 is labelled by the numbers, the first gives the total number of modules with an intermittent fault present in it, the second is the number of modules with the fault active in it. The system leaves a state  $(i, j)$  in one of four ways.

1. Fault in one module with fault active may become inactive. In this case state  $(i, j-1)$  will be reached.
2. Fault in one module with fault inactive, may become active, state  $(i, j+1)$  will be reached.
3. Fault in one module may become present, but remain inactive, state  $(i+1, j)$  will be reached.
4. Fault in one module may become present and active at the same instant, state  $(i+1, j+1)$  will be reached.

Notice that the instant any three modules have the fault active in them, the system lands in the failed state, which is labelled  $F$  in Figure 5. As durational reliability definition

 $= \prod_{i=1}^n [\exp(-\nu_i t) + \mu_i' \{1 - \exp(-\nu_i t)\}]$   
 $G' = Pr\{a \text{ module operates correctly in duration } [0, t]\}$   
 $= \prod_{i=1}^n [\exp(-\nu_i t) + [\nu_i \mu_i' / (\lambda_i - \nu_i)] \{ \exp(-\nu_i t) - \exp(-\lambda_i t) \}]$   
 $n = \text{number of intermittent faults}$   
 $N = \text{number of modules}$   
 $s = \text{number of spares}$   
 $k = \text{number of faulty modules}$   
 $q = \text{number of good spares}$

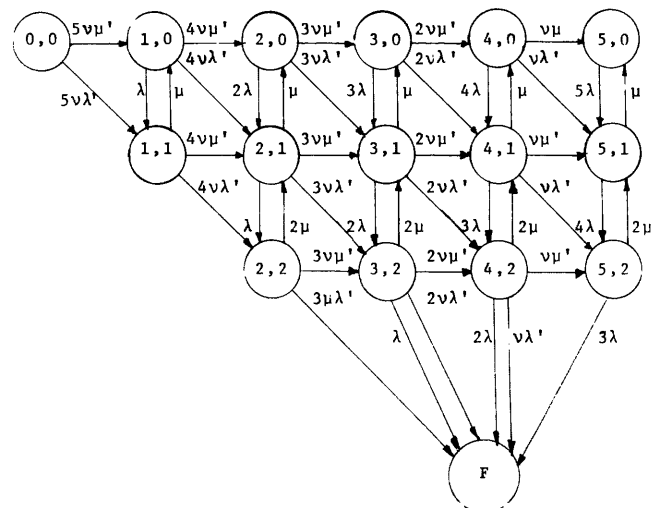

Figure 5—Model of a 5MR system with a single fault.

requires continuous correct operation, transitions back from the failed state need not be considered. The durational reliability of the system is given by the probability of the system being in a state other than the failed state. The reliabilities of various schemes are compared in Figure 6. Except for the case of the single module, all the schemes employ five modules.

From Figure 6 it should not be interpreted that the simple NMR scheme is always superior. For very different values of the parameters, some other schemes might be superior than the simple NMR scheme.<sup>24</sup> In the general case, there might be many possible intermittent and permanent faults with different parameters, then the best scheme for that value of parameters can be chosen by comparing curves for different schemes.

An algorithm has been presented<sup>26</sup> which would compute the reliability of various hardware redundancy schemes in

the general case when a mixture of permanent and intermittent faults are possible in a module.

Merryman and Avizienis<sup>19</sup> have considered a recovery process in enhanced TMR systems. They have calculated the probability that a system will fail within the mission time. This probability is the sum of the probabilities of these two events (i) two modules become faulty at the same time (ii) with one faulty module, recovery in another fails. Recovery may fail if recovery is initiated before the fault becomes inactive, or if the recovery process is imperfect. They have presented results of numerical computation showing improvement in survivability in TMR systems if recovery is also used in addition to the massive redundancy.

Lala and Hopkins<sup>23</sup> have also considered the recovery process in a triple redundant system. They have modeled recovery as a transition, considering the overall process still to be Markovian. The same assumption is used by Ng.<sup>20</sup>

Figure 6—Comparison between various schemes.

Effects of this assumption, however, need to be investigated.

## DESIGN CONSIDERATIONS

In a processor, an intermittent fault can become active and inactive again, however, its effect might not disappear immediately. If it effects the control part of the system, the system will be desynchronized and will continue to operate incorrectly until it gets synchronized again. In a fault-tolerant multiprocessor Cvm<sup>2</sup> desynchronization is reported to occur 25 percent of the times. Desynchronization is the most undesirable affect of intermittent faults. It should greatly improve reliability, if systems could be designed which are desynchronization-resistant and/or easily resynchronizable. Desynchronization-resistant designs may incorporate redundancy in the control part of the systems. Wakerly<sup>34</sup> has considered easily resynchronizable designs. Sequential circuits may be designed without global feedback, which possess special characteristics; such circuits can be resynchronized only by applying two successive vectors. Synchronization can also be easily achieved if extra reset inputs are provided. Such systems can then use TMR voting to keep them in synchronization.

Diagnosability of systems with interconnected units, which are capable of testing each other has been considered for permanent faults. Diagnosis capability may be an important consideration in a system design. For systems with permanent faults two measures of diagnosability are defined: a system is  $t_p$ -fault diagnosable without (with) repair if one test routine is sufficient to identify all (at least one) of the permanently faulty units, provided the number of such faulty units does not exceed  $t_p$ . Mallela and Mason<sup>36</sup> have defined a measure for intermittent fault diagnosability. A system is  $t_i$ -fault diagnosable when it is such that if no more than  $t_i$  units are intermittently faulty then a fault-free unit will never be diagnosed as faulty. Two different measures for intermittent fault diagnosability similar to permanent fault case can be defined, both of them, however, can be shown equal to the measure previously defined.<sup>36</sup> Mallela and Mason have also established least upper and greatest lower bounds for  $t_i$  in terms of  $t_p$ . A two-part procedure is given for determining  $t_i$ , which avoids exhaustive search.

## FUTURE DIRECTIONS

We have only begun to know how to approach the problem of intermittent faults. While much of this area remains unexplored, one should expect to see results for the problems mentioned below.

Modeling and testing methods are suited for only signal independent faults. It can be safely said that a significant number of intermittent faults are signal-dependent. To obtain generalized modeling and testing methods is an unsolved problem. We need more insight into the physical nature of faults, specially when they are induced by noise.

Techniques to model burst type (faults which become

active and inactive many times in a short duration) and harbinger type (intermittent faults which eventually turn into permanent faults) are to be developed. In most analyses it is assumed that redundant modules are independent. However, the study at Carnegie-Mellon<sup>2</sup> has revealed that about 10 percent of all transient errors are simultaneous in different modules. This small fraction becomes significant when one considers the fact that such errors will cause failure in a simple TMR system. Probabilistic methods to handle such coupling between modules need to be developed. Methods to compute reliability, should be extended to include the possibility of simultaneous errors.

Methodology to estimate parameters in all cases have to be developed. The methods to estimate parameters can also be extended to check validity of the associated model, and will provide a means to correct a model if needed.

Suitable generalized hardware redundancy methods are needed, which will optimize the reliability performance when a set of intermittent as well as permanent faults are considered. Design methodology is needed to design easily synchronizable and/or desynchronization resistant systems.

# Architectural and design perspectives in a modular multi-microprocessor, the DPS-1

by KELLS A. ELMQUIST

InterSystems Inc.  
Ithaca, New York

## INTRODUCTION

For the last decade, one of the most active and exciting areas in computer architecture is the interconnection of computers to form parallel or concurrent systems. These systems are generally called "multiprocessors" or "distributed processors" and may range in organization from processors sharing a common memory to geographically isolated computer installations connected as a network. The low cost and ease of implementation of LSI microprocessors make them extremely attractive design possibilities for the implementation of general-purpose multiprocessor systems. Furthermore, the MOS technology used to implement the majority of microprocessors limits the instruction execution rates such that many applications are compute bound rather than limited by other system bandwidths. This indicates that a number of microprocessors may be effectively interconnected to increase the general system performance.

In this paper we will discuss the general system characteristics of all multiprocessor systems and attempt to derive a set of design requirements for a modular, microprocessor-based multiprocessor. Given this set of characteristics and design requirements, we will discuss two general interconnection schemes, the Global Bus and the Dual Port Memory, and analyze their suitability. The architecture and implementation of the DPS-1 modular multiprocessor will then be described and modeled in terms of limitations on system throughput and optimum cost-effectiveness.

## MULTIPROCESSOR SYSTEM CHARACTERISTICS

Anderson and Jensen<sup>1</sup> have given a general taxonomy of computer interconnection structures which may be briefly summarized as follows: The basic element of communication between processors is the *message*. No distinction is made between different types of messages such as requests for service, data blocks, etc. The most basic taxonomic decision to be made in the design of a multiprocessor is whether messages will be transmitted *directly* from the source to the destination, or whether they are transmitted *indirectly*, requiring the intervention of some process which routes the message to a number of alternate destinations. The next decision to be made is whether messages will be transmitted

over paths which are dedicated or shared. A *dedicated* path is defined as one which is accessible from only two points, while a *shared* path may be accessed by an arbitrary number of points.

From these basic taxonomic decisions, we may classify the sundry multiprocessor architectures and analyze them in terms of certain system characteristics:

*Modularity*, the cost of making incremental changes in system capability. Modularity is most severely impacted by the choice between shared or dedicated message paths. Note that if all messages travel over dedicated paths, the cost of adding the *n*th processor requires the addition of *n-1* interconnection paths, whereas if all messages share the same path the cost is merely that of the processor.

*Fault-tolerance*, the system costs of different failures, the costs of their detection, and the costs of system reconfiguration to allow operation in degraded mode.

*Bottlenecks*, the performance limitations inherent in different message communication structures.

To these we may add:

*Degree of coupling*, the message transfer delay from sender to receiver.

*Cost/performance ratio*, impacted mostly by the costs of the interconnection paths.

## DESIGN REQUIREMENTS

Given these system characteristics and their mutual optimization as criteria, we may postulate a set of design requirements suitable for implementation in LSI components either available now or available over the next few years:

1. The system must have low cost-modularity. The cost of adding one processing unit to the system should not greatly exceed the cost of the processing unit itself.
2. Each processing unit should have a local failure detect mechanism that would detect a local failure and suspend local operation before the processing module gained system access. Further, the system should be signaled of this condition.
3. The system should have a large address space, at least 1 megabyte but preferably 16 megabytes.

4. All data transfer protocols should accommodate both byte and word parallel transfers, to accommodate new 16 bit processors and peripherals.
5. System interrupt response should be optimized since real-time applications will be common.
6. All processors should be able to access all other processors and all resources global to the system.
7. Both direct and indirect message communication strategies should be allowed by the architecture. A great deal of research and experimentation is currently being conducted in the design of multiprocessor operating systems using both these communication methods, and the hardware architecture should not limit the installation of either type.
8. All contenders for shared paths should be capable of receiving dynamic priority allocation from the operating system.
9. Care must be taken to minimize loading on all shared paths.
10. Cost of the total system must be somewhat commensurate with the cost of its components. (\$1000 worth of processor modules and \$20,000 worth of interconnection would not be considered commensurate.)

## ARCHITECTURE

For reasons of cost-modularity and general cost/performance (ratio considerations) with low bandwidth processors, complete interconnection via dedicated paths has been rejected. It can be seen that the cost of the interconnection scheme rapidly obscures the cost/benefits of micro processors, and that addition of one processor requires extensive system modification, and expense. Also, if we are to meet our design requirement that both direct and indirect message strategies be allowed, we must reject star configurations, since they do not allow direct message transfer. This leaves two major interconnection schemes, the time shared common bus and the multi-port memory.

The time-shared common bus has a number of cost advantages and meets a number of our design requirements. It has the lowest overall system hardware cost, and the least logical complexity of interconnection. The modularity of the common bus is excellent, both in terms of the cost of adding additional processor modules, and in terms of the homogeneous/non-homogeneous nature of the modules. This allows modules with special, dedicated functions to be added with the same ease as a general purpose modules, and it allows the system designer to increase performance only where it is needed, relieving a bottleneck by modularly adding intelligence. In this case it becomes the responsibility of the system designer to partition the system requirements in such a way that a specialized processor justifies its cost, rather than being an under-utilized feature, or conversely, its absence an inherent limitation in a general purpose system.

If we dedicate one processor on the bus as a message switch, and all messages are routed through this processor, then we have configured the system for indirect message transfer. If, on the other hand, we treat all processors

equally, the system may be used with direct transfer strategies and no hardware reconfiguration is necessary. Note also that, in a common bus system, large messages may be communicated very quickly by the passing of address pointers.

The drawbacks to a common bus system are obvious. First, the bandwidth of the common bus is the upper limit on total system throughput; each processor's throughput must degrade every time a new processor is added to the system. Second, while the failure reconfiguration cost of common bus systems is very low and failure-effect with respect to processors is also very good, the failure-effect with respect to the common bus is usually catastrophic. Anderson and Jensen<sup>1</sup> make two comments pertaining to these drawbacks of common bus systems: First, that the common bus is not likely to saturate from communications alone, that is, if processors run programs in private or local memory, system bandwidth becomes very large before the common bus reaches saturation. And second, the low logical complexity tends to mediate somewhat the failure-effect in central message switching systems.

In order that processing modules be capable of running programs from local memory, and that we meet our design requirement that all processors be capable of accessing all memory, let us summarize the characteristics of a dual-port memory. A dual-port memory is a memory unit which may accept memory requests both from a local processor without creating a system bus access, and from the system bus, to which it appears as a normal single-port memory unit. Such a configuration has a number of advantages for a common bus multiprocessor. First, since programs may be run from local memory and the system bus may be reserved from global references or message transfer, there is the potential for a very high total system transfer rate. The bandwidth of the system bus is still the limiting factor in total throughput, but an order of magnitude increase in throughput is observed. Indeed, experience with the CM\*<sup>2</sup> multiprocessor indicates that between 82 and 99 percent of all memory references are to local memory. The marginal cost of configuring memory units in this way, while being small to begin with, is far outweighed by the increase in performance. Second, the modularity of the common bus system, with all its advantages, is preserved. And third, since the memory is accessible to the whole system, the local processor need not become involved in transferring data to and from local memory. This is especially important in the transfer of long messages, where the message may be switched by simply passing an address pointer.

The DPS-1 multiprocessor uses a combination of both the common, time-shared system bus and the dual-port memory to achieve the majority of the design requirements.

## INTERRUPTS IN MULTIPROCESSOR SYSTEMS

The parallel nature of multiprocessors makes their application to real-time computing problems very attractive. If this application is to be effective, however, the interrupt response of the system, that is, the worst case response time

to asynchronous service requests, and the ease with which the system may be reconfigured to provide service, must be optimized. Jaswa<sup>3</sup> has determined four independent levels of interrupt applications in a real time multiprocessor, each level of which should be optimized. They are:

1. *Intra-processor communication and control.* This interrupt level responds to events which occur during an instruction execution by a local processor. An interrupt generated on this level generally informs the local processor that some unacceptable error condition has occurred, (illegal system bus reference, parity error, illegal memory reference, attempted write to protected memory, etc.) and that the processor should discontinue program execution and notify the operating system.
2. *Intra-system communication and control.* This interrupt level responds to service requests from system peripherals, whether they are local to the processor or global system peripherals. Optimization on this level involves such considerations as dynamic priority assignment, masking options, and processor selection for interrupt servicing.

3. *System executive control.* At this level the system executive (whether it is centralized or decentralized) may interrupt any local processor. The basic executive controls are (1) receive message at  $j$ , (2) execute task at  $j$  (3) pause.
4. *Interprocessor communication.* This level is used to initiate status and data transfers between processors. This level is only important in direct message transfer systems, in indirect systems it is contained in (3).

Mutual optimization of these interrupt levels indicates that a number of interrupt levels be available at each processing module, the highest priorities dedicated to error response and recovery, the next priorities dedicated to system executive control, and the remaining levels to peripheral requests, both on the local and global levels. If the shared system bus, however, has a number of interrupt vectoring levels, and if each processor is to be capable of responding to any level, then the number of priority levels at each processor module becomes unwieldy. Further, if every processor in the system is to be capable of responding to any system interrupt, either the interrupt service routines must be duplicated in each processor's local memory, or they

Figure 1—DPS-1 Distributed Processing System.

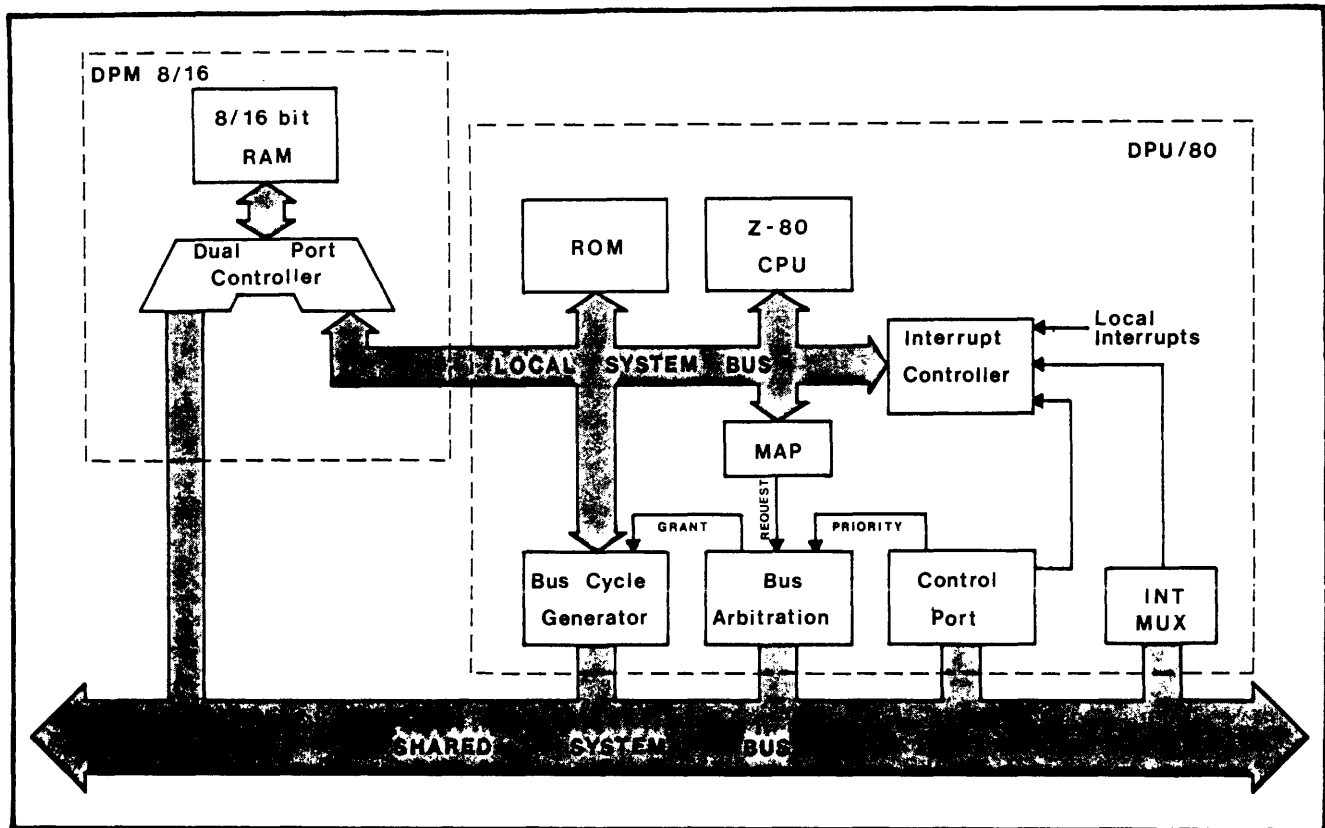

Figure 2—Distributed processing unit.

must be kept in global memory and run via the shared system bus, degrading total system throughput. Another problem with decentralized interrupt response is that it becomes cumbersome for the system executive to control the relationship between task priority and interrupt priority.

One common solution to these problems with decentralized interrupts is to assign one processor in the system as an interrupt processor. While this approach solves most of the problem noted above, it places two important restrictions on system interrupt response time. The first is that two processors become involved in handling a single interrupt, first the interrupt processor and then the processor whose task is concerned with the information. The second is that simultaneous servicing of two or more interrupts is no longer possible, since only one processor may respond to system interrupts. These two factors combine to seriously degrade the total interrupt response time of the system.

Our solution in the DPS-1 multiprocessor has been to implement a partially decentralized interrupt response strategy. There is an interrupt processor in the system capable of responding to all system vectored and system error interrupts, masking, rotating priorities, etc. Also, on each local processor a number of interrupt vectors are implemented. These respond to local error conditions, system executive interrupts, local peripheral service requests, and one vector level may be multiplexed among the global interrupt vectors under software control, or masked out altogether. By combining these strategies we thus provide the

flexibility of assigning any system interrupt to any processor for fast response, of simultaneous interrupt servicing, and also the simplicity of central interrupt servicing for all non-time-critical interrupts.

Further, we have specified two distinct types of interrupt response vectoring. In the first of these, locally vectored interrupts, an LSI interrupt controller supplies the response vector to the processor. This type of interrupt response does not require a global bus access for vectoring. In the second response mode, globally vectored interrupts, the responding processor accesses the system bus, placing the accepted vector level on the address bus, and the interrupting device places its response vector on the data bus. This mode is extremely useful when implementing newer LSI device controllers in interrupt driven systems. These chips have many internal conditions which may cause an interrupt, but without a globally-vectored response mode, the exact condition cannot be determined.

#### DISTRIBUTED PROCESSING SYSTEM ONE— IMPLEMENTATION OVERVIEW

The system (see Figure 1) is composed of up to 16 processing modules connected to a common, time-shared bus. The common bus is specified for a large (16-megabyte) address space, and both byte and word (16-bit) parallel transfers are specified such that both 8 and 16 bit masters and

slaves may co-exist in the same system. Bus Arbitration is performed in a parallel encoded format capable of very fast priority resolution (less than 100 nsec.) and proceeds on a single cycle basis unless a bus lock function is imposed by the processor currently in possession of the bus. Global memory units and global input/output devices may also be connected to the common bus.

Each processing module consists of a Distributed Processing Unit (DPU) which may contain an 8- or 16-bit CPU, a dual-port memory (DPM), and may be connected to a number of input/output devices. The dual-port local memory may be of any size up to 64 K bytes, and each processing module is assigned one 64 K page of total system memory. This memory unit, while normally accessed by its local processor, may be accessed by any processor in the system via the global bus, temporarily suspending the operation of the local processor. The memory unit is designed such that it is capable of both byte and word transfers, not only with respect to the global system bus, but also with respect to the local processor's bus. Note that this memory unit may be used as a two-port buffer between the global bus and a high speed data collection device (video frame grabber, etc.). Memory cycle times down to 70 nsec. may be attained.

Each processing module may be assigned its bus arbitration priority dynamically by the operating system. This is extremely important in real time systems, since any number of asynchronous events may alter the system-wide priority of running tasks. If priority were not dynamically allocated, tasks would have to be switched to another processing module, whose task may again be displaced, etc. It is estimated that the decrease in task switching overhead will improve the real time response of the system nearly an order of magnitude.

Eight levels of vectored interrupts are defined for the global bus, as well as two error interrupts, parity error and illegal memory reference. The interrupt processor may respond to all of these interrupts, as well as interrupts from local timers, or it may mask them and assign them to individual processing modules. Each processing module has eight levels of interrupts local to it. Two of these are assigned to local error conditions, an illegal system bus access and a local parity error. Three are assigned to interrupts from the system executive. Two are assigned to local peripheral service requests, and one may be software multiplexed to respond to one of the eight global interrupt vectors.

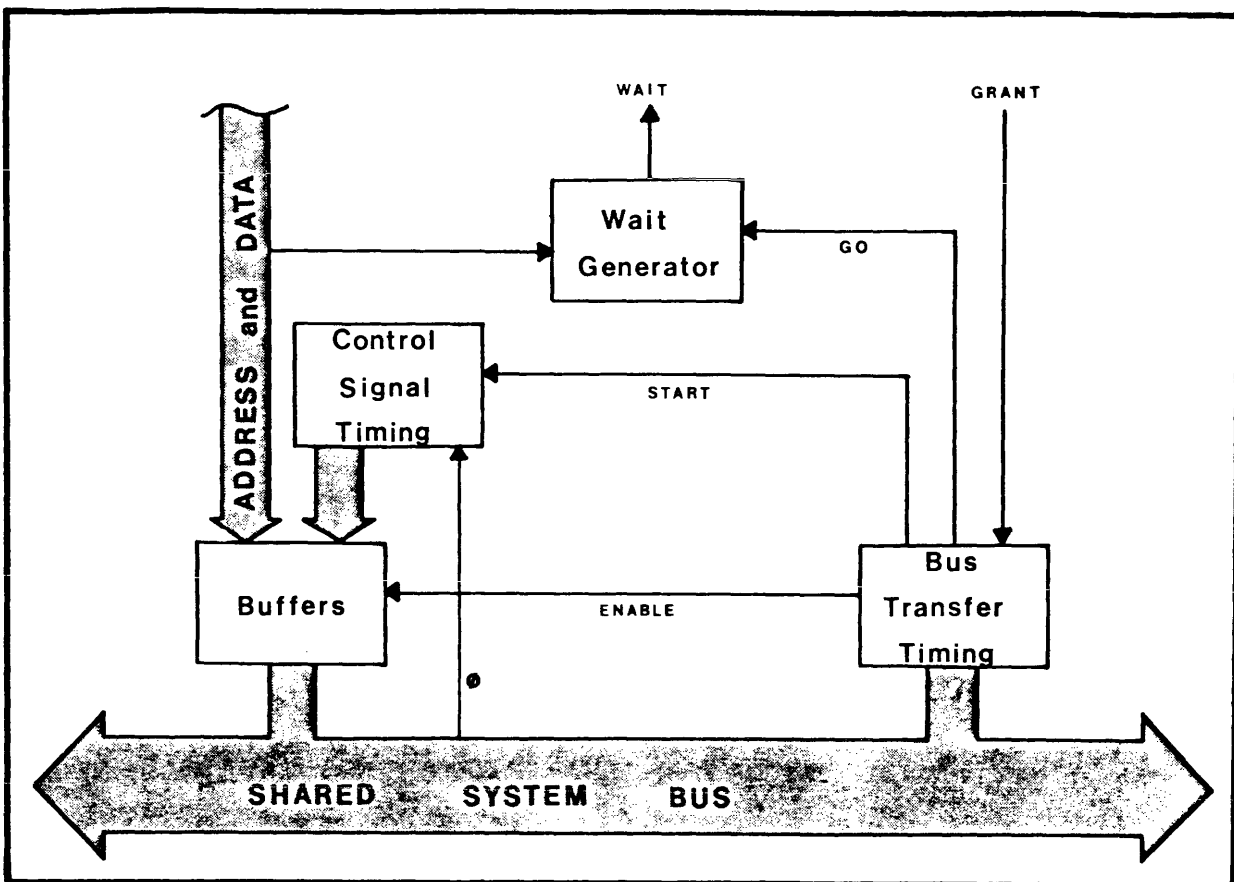

Figure 3—Bus cycle generator.

## DPU/80

The distributed processing unit (see Figure 2) is based around the Zilog Z-80 microprocessor. Sockets for up to 8 K bytes of ROM are provided to hold an initialization procedure, a self-test/interface-test procedure, interrupt service routines, and a message communication kernel, for message transfers to the system executive. A power-on or reset jump to the first byte of the ROM is provided for system initialization. An LSI interrupt controller is dedicated to handling the local interrupts described above, and is interfaced directly to the local system bus. A control port, accessible via the system bus, is used to assign priority to the bus arbitrator and to gage system executive interrupts to the interrupt controller. A locking mechanism is provided such that either the global system bus or the dual-port memory can be locked, allowing implementation of indivisible test and set operations. Three elements in the design have been implemented in proprietary integrated circuits, these are: the bus arbitrator, the dual-port controller and the control signal timing generator.

Extended address management is accomplished for the Z-80's short (16-bit) address bus by dedicating a segment of local address space as a mapping area. This map is divided into two segments, and extension bit registers are provided for each segment, providing two bus access "windows." On the DPU/80 8K of local address space is dedicated as a map, giving two 4K bus windows. A local access to this area generates a bus request and places the local processor in a wait state. When the system bus becomes available, the bus arbitrator performs an arbitration with other requestors and if it has the highest priority, receives a bus grant. A bus transfer, under the control of the bus transfer timing unit (Figure 3) conducts the transfer of the bus to the processing module, starts the control signal timing, and releases the processor from the wait state. Note that the location of the mapping area, the location of the ROM and the location of the memory are all independently selectable, and that the bus address and the local address of the ROM are not related.

## SYSTEM BUS SATURATION

The determination of total system throughput as a function of the number of processors in the system is of prime importance. System throughput is a function of the number of processors in the system, the throughput of each processor, and the amount of bus interference that exists with respect to contention for the common system bus. It is clear that saturation of the system bus will impose the upper limit on system bandwidth.

The maximum throughput of the system occurs when there is no contention for the shared system bus, and may be written

$$T = nP$$

where  $T$  is the total system throughput,  $n$  is the number of

processors in the system, and  $P$  is the throughput of each individual processor.

The amount of bus interference in the system is a function of the bus utilization requirements of the individual processors. To model this we must define a utilization parameter,  $b$ , as the fraction of available bus cycles required by each individual processor. If there were no local memory in the system,  $b$  would be very close to 1, and the bus would saturate very quickly. Experience with the Cm\* multiprocessor<sup>2</sup> indicates that  $b$  ranges from .2 to .01 depending on the application, and averages about .1. Clearly the worst case for system throughput would be if all processors accessing the bus had to wait  $(n-1)$  bus cycles before being granted access to the bus. This minimum throughput has been shown by Reyling<sup>4</sup> to be:

$$T = \frac{nP}{1 + b(n-1)}$$

This relation is illustrated in Figure 4 for values of  $b = .5$  and  $b = .1$ .

Average throughput is derived by considering all possible states, the probability of each, and the probability of a transition from one state to the next. Ravindran and Thomas<sup>5</sup>

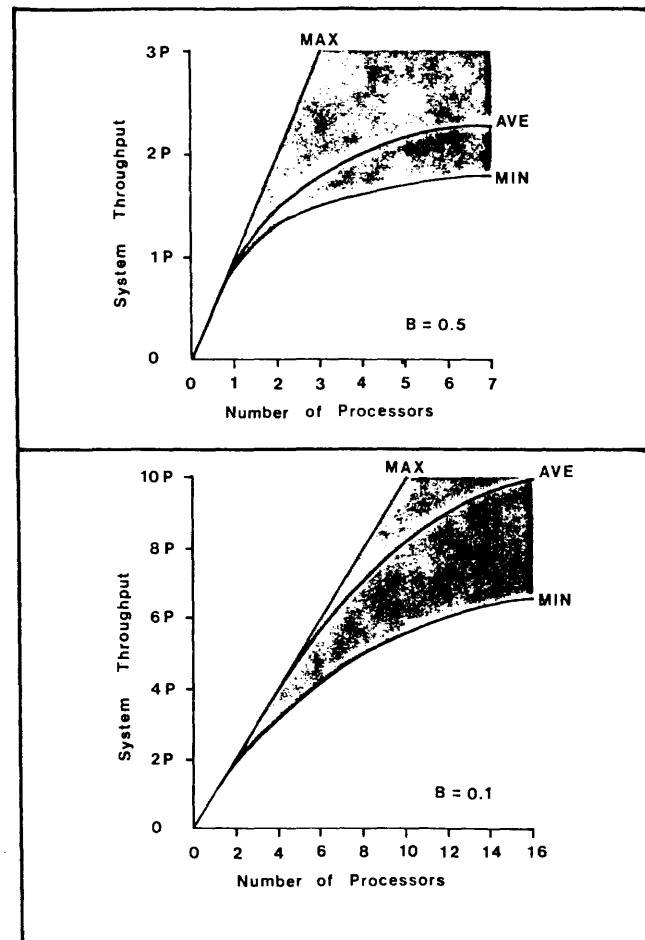

Figure 4—System throughput.

have shown this to be:

$$T_{ave} = P \sum_{j=1}^n j \sum_{i=1}^n p_i A(i, j)$$

where  $p_i$  is the probability of  $i$  processors requesting the bus, and  $A(i, j)$  is the probability of a transition from state  $i$  to state  $j$ . This is also illustrated in Figure 4.

## CONCLUSION

The implementation and architectural implications for the design of a cost-effective, microprocessor-based, modular multiprocessor, the DPS-1, have been discussed and illustrated. The design has been shown to be cost effective for both small and larger multiprocessor systems. A number of features have been included not found on other multiprocessors, such as dynamic priority allocation, wide address bus, co-existence of 8 and 16 bit masters in the same system, and a versatile, partially decentralized interrupt scheme. The system has excellent cost modularity, and may be configured for many levels of performance.

## ACKNOWLEDGMENT

I would like to thank Jeff Moscow and Bill Hemsath, both of Cornell University, for their constant consulting on mul-

tiprocessor operating system design, and Steven Edelman, of InterSystems, for consulting on bus structures and systems design.

# Work flow view of a distributed application

by J. R. HAMSTRA

Sperry Univac  
Roseville, Minnesota

## INTRODUCTION

Work Flow Management is a unified set of concepts for the definition, implementation and operation of Application Systems. A companion paper<sup>1</sup> to this one provides a more general treatment of the requirements motivating Work Flow Management. An Application System is a major function of the work of a computer system as perceived by the customer. Thus Application Systems often mirror the structure or work of the customer enterprise. In this paper we shall consider a credit card processing application, forming a major function of the work of the hypothetical Masterkey Credit Corporation (MCC). The portion of this application performed on the MCC distributed computer system is called the Credit-Cards Application System. MCC also uses its computer system for other applications, including personnel and payroll, financial information, and the development and maintenance of applications.

People relate to an Application System in various roles, including end user, systems analyst, programmer and operator/administrator. Figure 1 illustrates these relationships. Work Flow Management attempts to facilitate communication among these various parties including the Application System, by supporting high-level descriptions expressed in the Work Flow Definition Language.

Within an Application System certain kinds of work are performed repeatedly. This is called recurring work, as opposed to *ad hoc* work performed once. Recurring work, the primary concern of Work Flow Management, may be parallel (e.g. charge slips are processed concurrently in each of 10 regional data centers, and may indeed be processed concurrently within a single center) or cyclic (e.g., customers are billed monthly based in part on their previous statements) or both. Recurring work is more easily described by defining the underlying structure of the work, than by explicitly enumerating or generating the instances.

In general, a schema (pattern, diagram, schematic) provides a structured "template" of information for generating and controlling instances of complex entities. A Work Flow Schema is the description of an Application System expressed in the Work Flow Definition Language. It describes the structure of the recurring work of an Application System, with provision for the dynamic introduction of modifications and *ad hoc* work.

A Work Flow Schema is compiled into an internal form

interpreted by the run-time system. This produces, in effect, a customized applications executive providing a complete simulated environment, including facilities for production work, as well as application modification, testing and training, and auditing and recovery. Thus the Work Flow Definition Language can be classified as a simulation language, albeit a special purpose one since the classes of simulated entities are predetermined (see Figure 2).

In the remainder of this paper we will develop the basic Work Flow concepts and show how they are represented in the Work Flow Definition Language. Being an overview, this paper must omit some components, and the descriptions of those presented are necessarily simplified. Nevertheless, it is intended to give the reader some insight into the scope, style and power of both Work Flow Management and the Work Flow Definition Language.

## WORK FLOW CONCEPTS

### *Functional distribution*

As previously suggested, the work of the Credit-Cards Application System proceeds simultaneously in 10 regional data centers. These centers are logical processing environments perceived by Work Flow Management as Applications Environments called Regional-Data-Centers. The portion of the work of Credit-Cards performed within each Regional Data Center is called a Regional-Operations Sub-Application System.

Figure 4 illustrates these relationships, using the structure notation defined in Figure 3 and the symbols for Sub-Application System and Sub-Applications Environment shown in Figure 2. Note that the relationship between Regional-Data-Center and Regional Operations is transient, since the logical work of one Regional-Operations may be moved to a different actual Regional-Data-Center if some untoward event, such as a flood, renders the first Regional-Data-Center unavailable.

We have considered the first-level decomposition of the Credit-Cards Application System. At this level, it comprises similar functions (Regional-Operations) distributed among similar processing environments (Regional-Data-Center) in a pre-determined yet alterable manner. Work Flow Management encourages and supports the functional decomposition of Application Systems and the controlled distribution of the

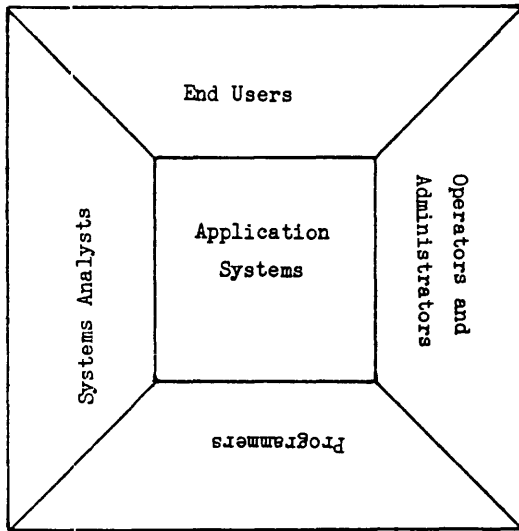

Figure 1—User roles and relationships.

Figure 3—Schematic structure notation.

functional components. This contrasts with the emphasis on load-sharing or data base distribution found in many other approaches to distributed processing, although Work Flow Management does not preclude either of these. Indeed, it requires certain forms of data distribution. MCC distributes its work by dividing the United States into 10 regions and keying both credit card and merchant identification to these regions.

Considering the requirements of credit card processing within a Regional-Operations Sub-Application System, it is reasonable to decompose them into functions associated with the cardholders serviced by that region, called Cardholder-Operations, and functions associated with the merchants serviced by that region, called Merchant-Operations. MCC derives revenue from both Cardholder-Operations (membership fees and interest) and Merchant-Operations (service charges and discounts). Considering that each Regional-Operations is a separate profit center, while cardholders may use their cards anywhere in the country (MCC has no direct international operations), we conclude that management will desire, and accountants and auditors require, separate control of inter-regional financial transac-

tions. These functions are provided by an Inter-Regional-Operations Sub-Application System within each Regional-Operations. Figure 5 illustrates the structure of Regional Operations.

Although further decomposition of Credit-Cards into Sub-Application Systems is possible, it is not essential to this presentation and will not be pursued.

*Data flow*

Information processing is the work of transforming and communicating data. Availability of the data is both a necessary precondition and a major stimulus for performing this work. Thus information processing systems (organic and mechanical) are largely driven either implicitly or explicitly by data flow. Work Flow Management relies heavily on data flow to control the Application System. In the remainder of this section we consider the flow of charge information from the merchants to the cardholder accounts. This example will illustrate the key Work Flow concepts of Transaction Groups, Tasks and Queuing Points.

Merchants participating in the MCC system accumulate batches of charge slips. Each slip contains merchant and cardholder identification encoded in a suitable optical-character-recognition (OCR) font. A merchant will periodically deliver these batches to his MCC Regional-Data-Center, either directly or via his bank. The merchant is reimbursed for the total amount of these charges, less a computed discount. The amounts on each slip are OCR-encoded, then the batches are read into the computer system via an OCR-

Figure 2—Schematic entity classes.

CC - Credit-Cards  
 RDC - Regional-Data Center  
 RO - Regional-Operations

Figure 4—Credit Cards structure.

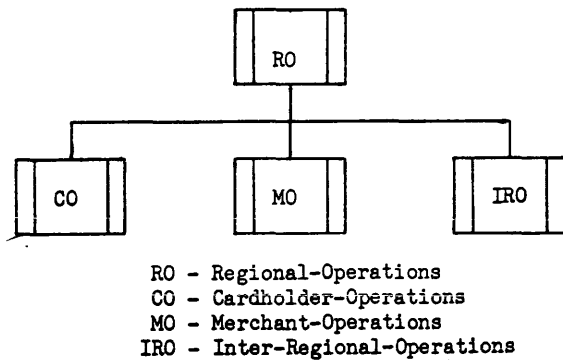

Figure 5—Regional-Operations structure.

reader. This is the first operation perceived by the Application System.

The internal form of a batch of charge slips is a Transaction Group called Sales-Inputs. A Transaction Group can be thought of as a bundle of transactions to be routed and processed together; however, its actual internal structure is considerably more complex than this, to satisfy the combined requirements of program data access and the Work Flow integrity/recovery architecture. A Transaction Group need not represent an external entity such as a batch of charge slips. Transaction Groups are the units of data flow within an Application System.

Sales-Inputs Transaction Groups are generated within the computer system by the operation of OCR-readers. Within a Merchant-Operations Sub-Application System this is represented by Optical-Character-Reader Tasks. A Task is a basic instance of work within an Application System. Tasks are the users of data, i.e., they produce, utilize and/or consume Transaction Groups. In addition to Optical-Character-Reader Tasks, the flow of Sales-Inputs Transaction Groups involves two other kinds of Tasks. The first is the crediting of the merchant accounts within Merchant-Operations, called Update-Merchant-Accounts Tasks; the second is the debiting of the cardholder accounts within Cardholder-Operations, called Update-Cardholder-Accounts Tasks.

Figure 6 illustrates the complete flow of Sales-Inputs Transaction Groups within the Application System, using the schematic structure notation. In addition, the arrows on the horizontal line show the direction of flow; more specifically they represent the sequence of transitions of the Sales-Inputs flow control state. After Update-Cardholder-Accounts the Sales-Inputs Transaction Groups are no longer necessary and they cease to be active entities within the Application System, although they are retained as archival entities for auditing and recovery purposes. We conclude this topic by noting that a Work Flow Schema contains a complete producer/consumer model of data flow within the Application System.

*Commitment control*

The foregoing treatment of the flow of charge information would be satisfactory were cardholders not permitted to make purchases outside their home regions. The absence of

this restriction poses complications not readily resolved even if Update-Cardholder-Accounts has access to a global cardholder data base distributed among the ten Regional-Data-Centers. First, all Regional-Data-Centers may not always be available, a fact that should not hinder local processing at other centers and one that we wish not to expose to the individual Tasks running elsewhere. Second, each Regional-Operations is a separate profit center requiring a separate reckoning of inter-regional financial transactions, which would be hidden in a single distributed data base. Third, we do not wish to submit transactions to a remote region until we have some degree of confidence in the results of the processing that produced them, nor do we wish to post transactions from a remote region without similar control. We will now address these problems.

The first part of the support for remote purchases is the introduction of Remote-Purchases Transaction Groups to effect the flow of this data among the various Regional-Operations as shown in Figure 7. Each Update-Cardholder-Accounts Task can optionally produce one Remote-Purchases Transaction Group for each of the nine Regional-Operations other than its own. This is called data flow fan-out. A new kind of Task called Remote-Cardholder-Updates accepts Remote-Purchases Transaction Groups from one or more other Regional-Operations and debits the local cardholder accounts accordingly. This is called data flow fan-in. Figure 7b illustrates this arrangement for three Regional-Operations.

We now consider the support for inter-regional financial accounting of Remote-Purchases Transaction Groups. This consists of two kinds of Tasks within the Inter-Regional-Operations Sub-Application Systems, Outbound-Remote-Balancing to post outgoing Transaction Groups and Inbound-Remote-Balancing to post incoming Transaction Groups. Figure 7c illustrates the general flow of Remote-Purchases Transaction Groups.

Our treatment has regarded data flow as essentially par-

allel and asynchronous. However, application integrity and recovery control require that certain phases in processing be synchronized. This requirement was first explicitly applied to the flow of Remote-Purchases Transaction Groups among Regional-Operations, but we have in fact relied on it throughout this presentation. Furthermore, the fact that work will proceed at different rates and with different levels of actual concurrency in different parts of the system and at different times imposes additional requirements on the synchronization of data flow. These requirements are subsumed under the general notion of controlled commitment.

Commitment (consigning, binding over for use) occurs whenever data produced by one Task is made available for use by other Tasks. This may occur when data in a shared data base is unlocked; however commitment in this manner is not very amenable to higher-level control, being neces-

sarily synchronized to the internal operations of the Task. Transaction Groups make the flow of data between Tasks explicit. This explicit flow can best be utilized for Application control if an external agency is interposed between the relinquishing of control of a Transaction Group by one Task and the acquisition of control by another. This agency is a Queuing Point.

Queuing Points are mail boxes for Transaction Groups. They serve as brokers to acquire and dispose of Transaction Groups for Tasks, the actual users of data. Thus they serve to decouple individual Tasks from what, when and where other Tasks exist. The availability of data at a Queuing Point may be the stimulus for scheduling work, or the data may be held at Queuing Points pending some other stimulus such as time or administrator action.

We can satisfy the remaining requirements for control of the flow of Remote-Purchases Transaction Groups with appropriate Queuing Points. Within the Inter-Regional-Operations Sub-Application System of each Regional-Operations Sub-Application System we establish one Remote-Region Queuing Point for each other Regional-Operations. The Remote-Region Queuing Points accumulate Transaction Groups bound for the other Regional-Operations. Upon a suitable administrator command, Outbound-Remote-Balancing removes each Transaction Group from the selected Remote-Region Queuing Point, posts appropriate information to the Inter-Regional-Operations database, and forwards the Transaction Group to Inter-Regional-Operations within the remote Regional-Operations.

Each Inter-Regional-Operations accumulates incoming Transaction Groups at a single Inter-Regional-Transactions Queuing Point. Upon a suitable administrator command, Inbound-Remote-Balancing removes each Transaction Group from the Inter-Regional-Transactions Queuing Point, posts appropriate information to the Inter-Regional-Operations data base, and forwards the Transaction Group to the appropriate place within this Regional-Operations. In the case of Remote-Purchases Transaction Groups, this is Remote-Cardholder-Updates.

Figure 8 illustrates the complete flow of charge information into the appropriate accounts, applying the principle that all Tasks are decoupled by Queuing Points. This figure shows the power of the schematic definition concept. It shows the flow of work through the Application System in an inherently parallel manner, yet it admits of the necessary synchronization and control. The Queuing Points provide for the unification of a network communications model (data flow) with a hierarchical processing model (data transformation).

The names of the entities in Figure 8 are actually names of types of entities within the classes of entities denoted by the shapes in Figure 2. At any given time there exist multiple occurrences of entities of each named type, e.g., multiple Tasks of type Update-Cardholder-Accounts and multiple Queuing Points of type Remote-Region. Note that there might even exist multiple Application Systems of type Credit-Cards, e.g. for testing within MCC, or because a software house has applied this application to companies other than MCC. Much of the power of the Work Flow Definition Language derives from its ability to define com-

plex application structures in terms of the underlying types of entities, while associating enough information with these named types to adequately control the actual occurrences. In the next section we will show how this is done.

WORK FLOW DEFINITION LANGUAGE

Global structure

We have presented the structure of an Application System as a schematic diagram, and we will now examine its expression in the Work Flow Definition Language. The following prose description of the language is presented to explain the appendices, which are intended to convey a better understanding of the language. Appendix A summarizes the conceptual structure of the Work Flow Definition Language. The language is basically block-structured with recursive nesting of the higher-level constructs, i.e., Sub-Application Systems and Sub-Applications Environments. The representation is free-form with punctuation and indentation optional.

(Sub)-Application Systems comprise application-blocks delimited by terminal constructs. Application-blocks describe nested spheres of control of work within an Application System. Application-blocks may contain, in addition to nested higher-level constructs, the declarations of types of lower-level entities of the categories internal, external and environmental. These will be described further in subsequent sections.

(Sub)-Applications Environments comprise environment-blocks delimited by terminal constructs. Environment-blocks describe processing environments which do not directly perform any work, although they may contain Sub-Application Systems which do perform work. Environment-blocks may contain a subset of the entities contained in application-blocks, internal and external entities being excluded.

Appendix B is a sample Work Flow Schema for the portion of the Credit-Cards Application System described in the second section. While this schema conforms to the structure shown in Appendix A, it contains assertions more detailed than shown in Appendix A. It is the assertions appearing as rules or policies associated with the structural entities, that

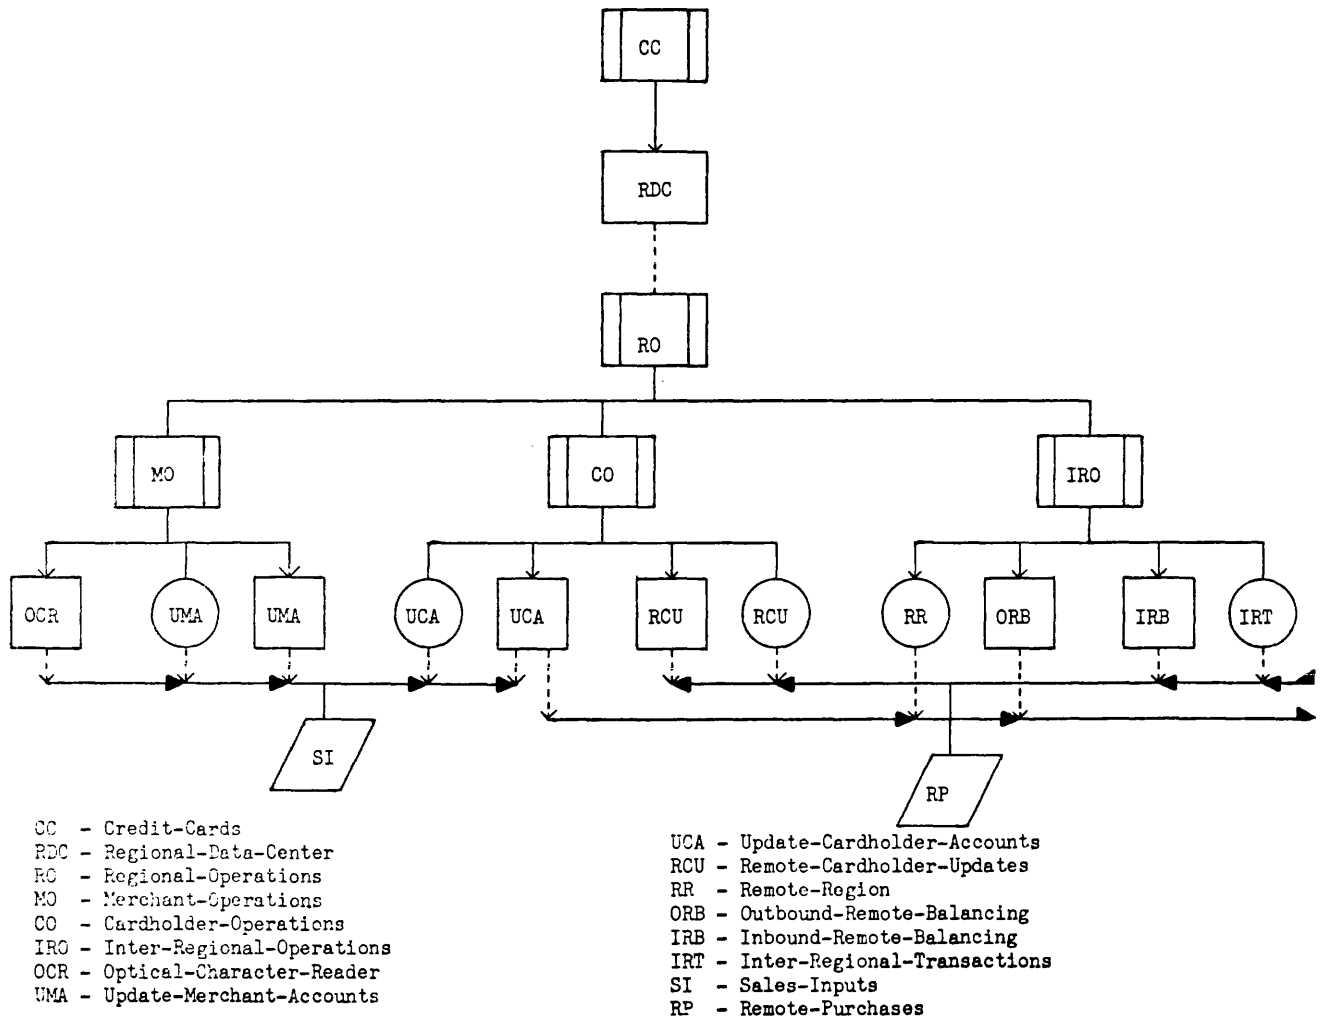

Figure 8—Complete flow of charge information.

give much of the meaning to the schema. These assertions apply generally or by default within the scope of the declarations containing them. Many more kinds of assertions can be made than are illustrated in the sample schema; however, the sample should illustrate the concept.

#### *Internal entities*

The classes of internal entity types in a Work Flow Schema are Transaction Groups, Application Modules, Queuing Points, Clocks and Calendars. These define the work performed internal to, and under complete control of, the Application System.

As previously stated, Transaction Groups have extensive internal structure, although this has been deliberately omitted from the example in the interest of clarity. This structure may be partly described in the Work Flow Schema, but is usually completely defined in a data schema. An extensive repertoire of control functions exists for Transaction Groups, and a few examples are given. Initiate creates a Transaction Group and attaches it to a Task. Terminate is the inverse of Initiate. Export transfers control of a Transaction Group from a Task to a Queuing Point. Import is the inverse of Export. Pass is an Import/process/Export sequence.

An Application Module is a program and related control information defining a type of Task. Tasks may be scheduled explicitly, or implicitly on data arrival. Assertions associated with the Application Module define the local data environment for the Task. These assertions may also generate a Queuing Point type of the same name.

Queuing Points are usually generated from Application Module declarations; however, they may be explicitly declared when specific routing and control functions are desired. These functions include, e.g., Hold, which inhibits the Import of data from the held Queuing Point, and Release, which is the inverse of Hold. Normally one occurrence of the named type of Queuing Point will be generated for each occurrence of the containing or generating type of entity, e.g., Application Module, Sub-Application System or Terminal Group. The occurs-clause in the Remote-Region declaration specifically controls the generation of occurrences of Remote-Region Queuing Points.

Multiple named Clocks and Calendars may exist within a Sub-Application System. Clocks and Calendars are entirely synthetic. While they may represent real-world time, they may, on the other hand, represent nothing more than logical state in some abstract event space. Further discussion of Clocks and Calendars is beyond the scope of this paper.

#### *External entities*

The classes of external entity types in a Work Flow Schema are Terminal Groups, User Groups, Conversations and Workstations. These define the work performed at the interfaces to, and under partial control of, the Application System. Terminal Groups are types of external interfaces to an Application System. They manifest themselves as types

of Tasks within the Application System. Queuing Points may also be generated for them. The information provided in the Work Flow Schema, in conjunction with communications configuration information, can be thought of as controlling a "daemon module" which defines the Task. These functions are provided by the implementor of the computer system, since it is generally unrealistic and undesirable to expect the customer to implement them.

User Groups and Conversations represent, respectively, types of external users of, and types of their interactions with, the Application System. External users may actually be organic (human), mechanical, or other Sub-Application Systems. They manifest themselves as types of Tasks and Queuing Points within the Application System, controlled as with Terminal Groups. Conversations manifest themselves as Transaction Group types within the Application System. Further discussion of User Groups and Conversations is beyond the scope of this paper.

Workstations represent locations for tracking data flow external to the computer system, and have utility primarily for external production control. Further discussion of Workstations is beyond the scope of this paper.

#### *Environmental entities*

The classes of environmental entity types in a Work Flow Schema are Data Bases, Scheduling Classes, Resource Budgets and Control Points. These exist primarily to resolve the mapping of the work of an Application System onto the supporting processing environments. Thus the actual nature of the named entity types is largely resolved beyond the scope of the schema.

Data Bases are identical to Transaction Groups except that their existence is controlled external to the Application System. The possibility that they may be shared with other (Sub)-Application Systems is also presumed. The internal structure of Data Bases is identical to that of Transaction Groups.

Scheduling Classes and Resource Budgets represent, respectively, the quality of service (e.g., priority, response time) and the quantity of service (e.g., resource consumption) provided for various units of work within an Application System. Further discussion of Scheduling Classes and Resource Budgets is beyond the scope of this paper.

Control Points are the means of exchanging Application System control information among interested parties. Further discussion of Control Points is beyond the scope of this paper.

## CONCLUSION

### *Summary*

In this paper we have introduced the general notions of schemas and Application Systems. We have presented the basic concepts of Work Flow Management, including functional distribution, data flow and commitment control. We have shown how they apply to a hypothetical credit card

processing application. Then we have presented the Work Flow Definition Language, considering the global structure of the language and its external, internal and environmental component entities. Finally, we have described a portion of the credit card processing application in this language, illustrating many of these constructs.

Any introductory presentation of a subject must omit certain components. Chief among those omitted here are:

1. Overall application control, including events, conditions, Clocks, Calendars and Work Flow Procedures.

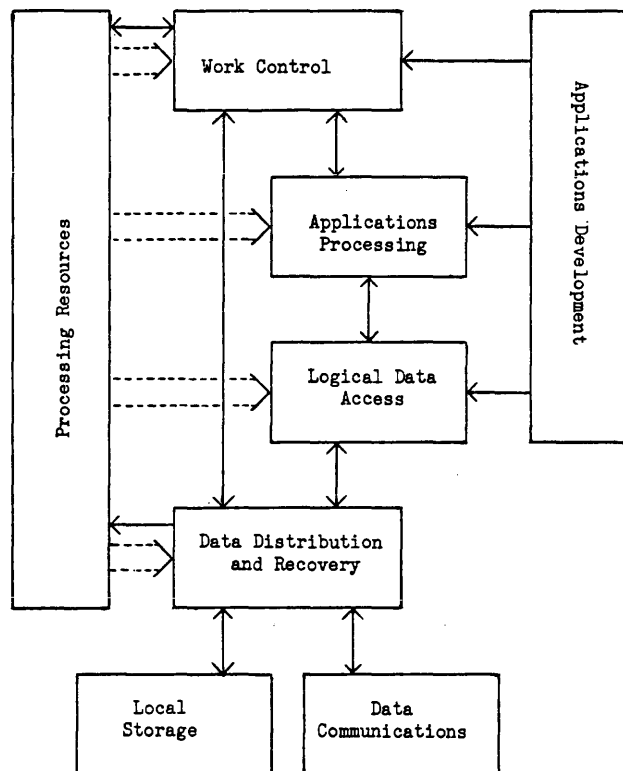

Figure 9—Overall system structure.

2. The administrators' and programmers' views of the system, inssofar as they extend beyond that of the systems analysts as reflected in the schema.
3. The end users' view of the system, including interactive conversation control and display management.
4. Production control, including work performed according to a schedule rather than on demand, and the correlation of internal data flow with external data flow.
5. Integrity control, including auditing, security and recovery.
6. Application development, testing and training.

Figure 9 illustrates the overall structure of a running Work Flow Management system and its relationship to other parts of a computer system. While not all components shown are part of Work Flow Management, they are all essential to a useful computer system. Work Flow Management brings these components together to provide a unified set of tools for the support of customer applications.

#### ACKNOWLEDGMENTS

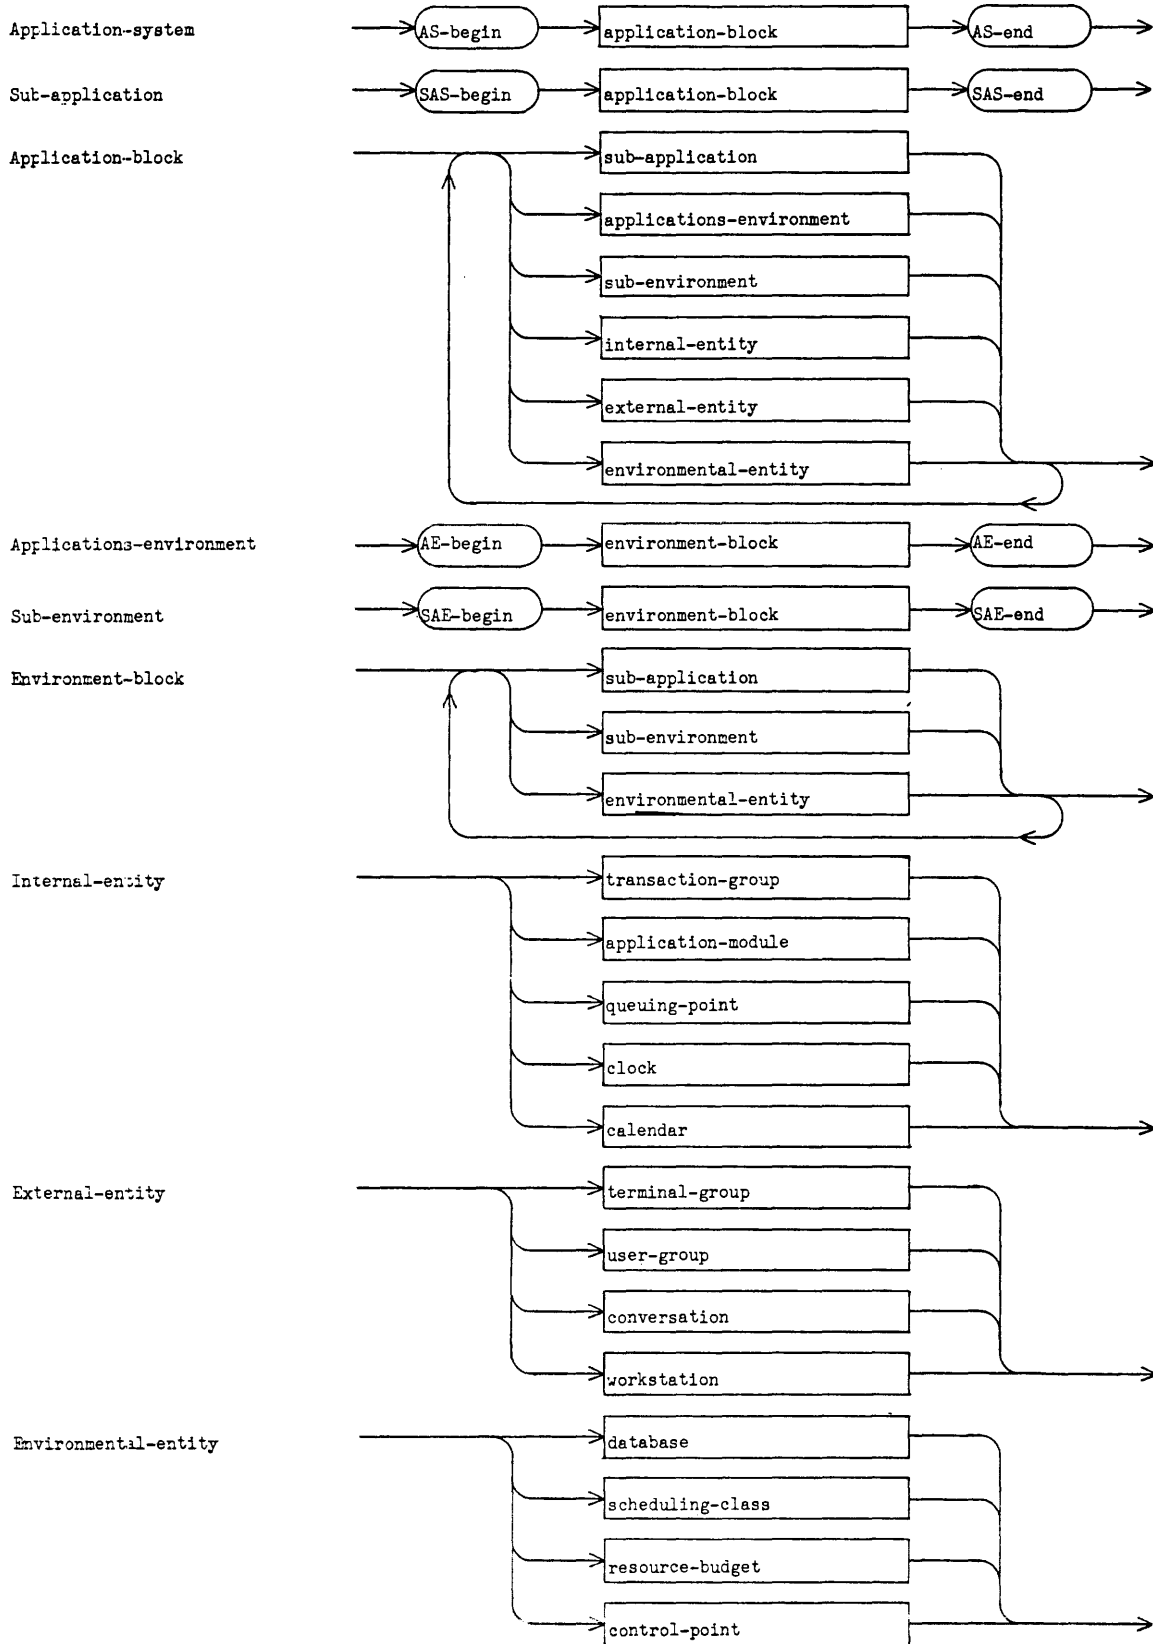

Many people have contributed to the ideas presented here, including the current members of the Work Flow group—Marv Beriss, Nigel Dolby, Tony Jenkins and Frank Streine. I am particularly indebted to Neville Black, who first proposed the idea of Work Flow Schemas, and to John Blasdale, who stated the requirements of credit card processing as a sample problem.

The views expressed in this paper are those of the author, and not necessarily those of Sperry Univac.

# The use of self-inverse program primitives in system evaluation

by JOHN E. MACDONALD, JR.  
*International Business Machines Corporation*  
 Poughkeepsie, New York

## INTRODUCTION

Performance comparisons among two or more central processors of a computer system usually involve the execution of special, rather arbitrary test programs called benchmarks. A fundamental difficulty arises when more than one such benchmark is used in the comparison process, namely the absence of any common measure of the power or complexity of the contending benchmarks.

This paper defines such a common measure and shows how to use it. Essentially, we place additional conditions on the benchmark program which force it into the realm of information theory and allow us to apply the theoretical arsenal of results due to Shannon<sup>1</sup> and those who followed in his footsteps.

Our approach is different from that of Hellerman.<sup>2</sup> Briefly, Hellerman defines the work of a computational process as the information content, in the sense of Shannon, of the table-lookup implementation of the process. In making his definition, Hellerman further assumes that all possible inputs to the process have the same relative frequency. A critique of Hellerman's approach and Hellerman's response are found in References 3 and 4, respectively. Other efforts to assign a work and/or complexity measure to computations have been made by Savage<sup>5</sup> and Johnson.<sup>6</sup>

Shannon's measure of the information content of a source depends only on the relative frequencies of the letters used by the source. In the simplest case, namely the zero-memory case, these relative frequencies are independent of any past output of the source. For a source alphabet of  $N$  letters we then have

$$H_2 = - \sum_{i=1}^N P_i \times \log_2 P_i \text{ (bits/letter)} \quad (1)$$

where  $P_i$  is the relative frequency of the  $i$ th letter, and  $H_2$  is the average information content of the source. The subscript on  $H$  corresponds to the choice of the base of the logarithm function. Base 2 is by far the most popular choice, but any base would do. Note that a source with exactly two letters each used with relative frequency 0.5 would yield a value of 1.0 for  $H_2$ . It is convenient to think of this as a standard source. The value of  $H_2$  has a specific implication for the possible one-to-one coding of strings of source letters

into strings of standard binary symbols. Consider the following example.

*Example 1*—A source has two letters with

$$\begin{aligned} Pr(A) &= 0.9 \\ Pr(B) &= 0.1 \end{aligned}$$

Then

$$\begin{aligned} H_2 &= -(0.9 \times \log_2 0.9) - (0.1 \times \log_2 0.1) \\ &= 0.469 \text{ bits/source letter} \end{aligned}$$

Huffman<sup>7</sup> has given an explicit method of encoding sequences of  $S$  source letters one-to-one into variable length sequences of binary symbols in such a way that the average number of binary symbols per source letter approaches  $H_2$  as  $S$  increases. Huffman's technique yields in Example 1 the following:

$S$	Average Number of Binary Symbols per Source Letter
1	1.000
2	0.645
3	0.533

The actual codes produced by Huffman's method are given in the Appendix.

*Example 2*—A source has 3 letters with

$$\begin{aligned} Pr(A) &= 1/3 \\ Pr(B) &= 1/3 \\ Pr(C) &= 1/3 \\ H_2 &= -1/3 \times \log_2 1/3 - 1/3 \times \log_2 1/3 - 1/3 \times \log_2 1/3 \\ &= \log_2 3 \\ &= 1.586 \end{aligned}$$

$S$	Average Number of Binary Symbols per Source Letter
1	1.667
2	1.611
3	1.605
4	1.605
5	1.589

It is convenient to think of a standard channel as a device capable of transmitting one symbol per second when transmitting sequences generated by the previously defined standard source. The mappings from sequences of source letters into sequences of symbols for the standard binary channel is then one-to-one and hence invertible. To illustrate, consider the Huffman code for Example 1 with  $S$  equal to 3.

Source Sequence	Channel Sequence
AAA	0
AAB	100
ABA	101
BAA	110
ABB	11100
BAB	11101
BBA	11110
BBB	11111

The invertibility of such codes is guaranteed by the prefix property. The prefix property guarantees that no complete channel code is also the front end of another complete channel code when the code is read from left to right.

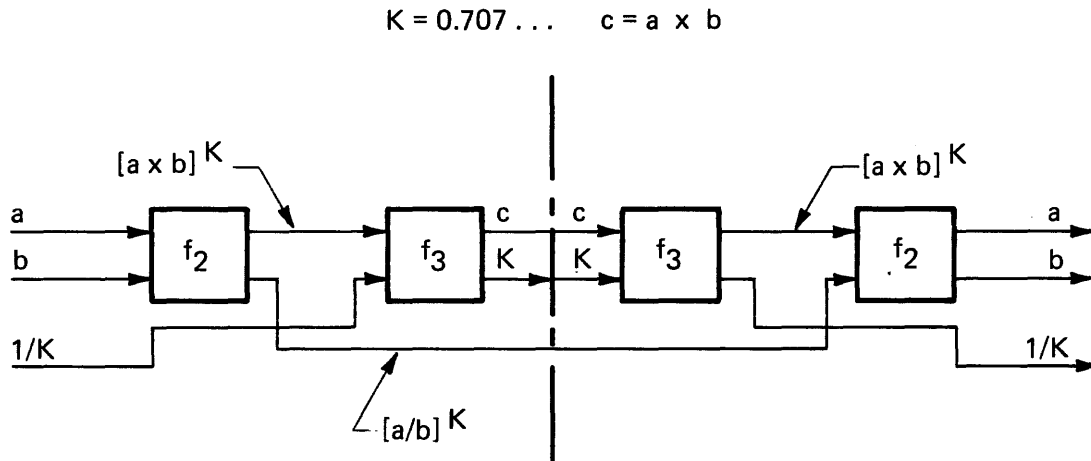

Consider a tandem arrangement of source, source-sequence-to-channel-sequence encoder, channel, channel-sequence-to-source-sequence decoder, and sink. Suppose we had a long sequence of source symbols from Example 1 to transmit to a remote point and a binary channel with a capability of 10 standard channel symbols per second. If we choose  $S$  equal to 3, we can say that we are transmitting information at a rate

$$\frac{10 \text{ (standard binary symbols)/second}}{0.533 \text{ (standard binary symbols)/source letter}} = 18.76 \text{ (source letters)/second}$$

We have tacitly assumed that any delay due to encoding and decoding has been made negligible through some buffering scheme.

If we want a theoretical upper bound on source letter transmission rate in the above calculation, we would substitute  $H_2$  for 0.533, obtaining

$$\frac{10 \text{ (standard binary symbols)/second}}{0.469 \text{ (standard binary symbols)/source letter}} = 21.32 \text{ (source letters)/second}$$

Storage Contents

<u>Initial</u>	<u>After Step 1</u>	<u>After Step 2</u>	<u>After Step 3</u>	<u>After Step 4</u>
a	$[axb]^K$	c	$[axb]^K$	a
b	$[a/b]^K$	$[a/b]^K$	$[a/b]^K$	b
1/K	1/K	K	1/K	1/K

Figure 1—Network for Example 4.

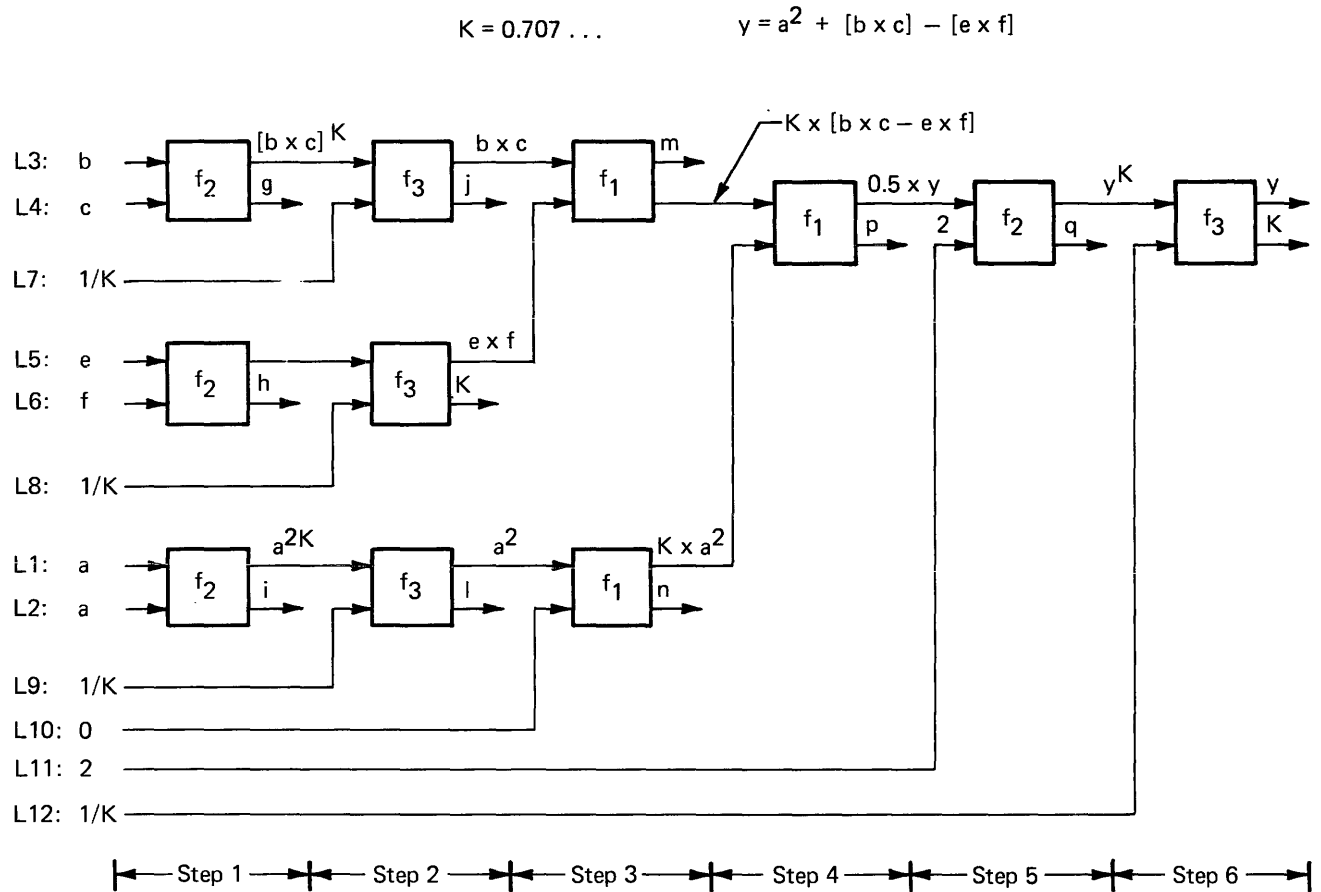

Figure 2—Direct network for Example 5.

Conversely, suppose we had access only to the source and sink. It would be possible first of all to compute  $H_2$  for the source by means of Equation 1. Then, for any given implementation or implementations we could measure the average time to transmit source letters from source to sink. The reciprocal of this figure is the average transmission rate in source letters per second. If we then assume an internal mechanism in the implementation which produces ideal encoding (very large  $S$ ), we can compute the internal channel rate as a figure of merit for a particular source and a particular implementation. It is very important to recognize that changing the source or the implementation or both will in general change the figure of merit value. This is crucial to our soon-to-be-made assertion that we can compare different benchmarks on the same computer system and/or the same benchmark on different computer systems and/or different benchmarks on different computer systems.

Thus, if we compute the  $H_2$  for Example 1 as 0.469 and then measure an implementation for transmitting this alphabet at 21.32 source letters per second, the figure of merit would be

$$0.469 \times 21.32 = 10 \text{ (standard binary symbols)/second} \\ = 10 \text{ bits/second}$$

### CREATION OF INVERTIBLE BENCHMARKS

A key requirement for the method described in the introduction is that the end-to-end system implement a one-to-one mapping from source letters into sink letters. Usually this mapping is the identity function in data transmission applications. When we attempt to apply the idea directly to a data processing benchmark, an unexpected difficulty presents itself. Namely, data processing is almost never a one-to-one mapping. Consider a two-input modulo 3 adder as a simple example.

Example 3— $c = (a + b)_{\text{mod } 3}$   
C:

	b	0	1	2	$H_2(a, b) = - \sum_{a=0}^2 \sum_{b=0}^2 p_{a,b} \times \log_2 p_{a,b}$
a	0	1	2		
0	0	1	2		
1	1	2	0		
2	2	0	1		

$$H_2(c) = -(p_{0,0} + p_{2,1} + p_{1,2}) \times \log_2 (p_{0,0} + p_{2,1} + p_{1,2}) \\ - (p_{1,0} + p_{0,1} + p_{2,2}) \times \log_2 (p_{1,0} + p_{0,1} + p_{2,2}) \\ - (p_{2,0} + p_{1,1} + p_{0,2}) \times \log_2 (p_{2,0} + p_{1,1} + p_{0,2})$$

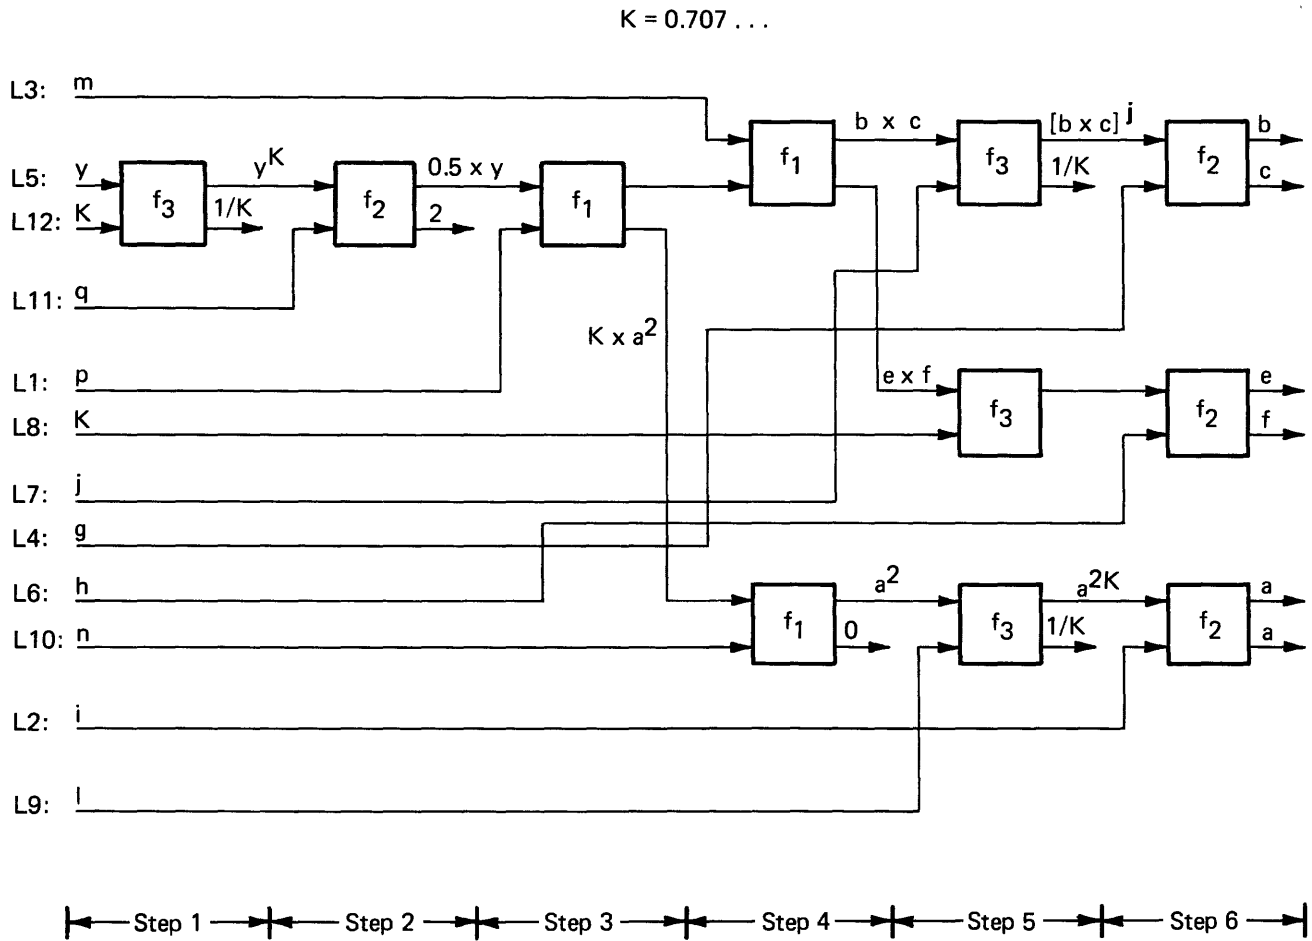

Figure 3—Inverse network for Example 5.

It is easy to show (see Appendix) that

$$-(p_x + p_y) \times \log(p_x + p_y) < -(p_x \times \log p_x) - (p_y \times \log p_y)$$

It follows that

$$H_2(c) < H_2(a, b)$$

We have thus illustrated a situation which has some of the elements of a paradox. To wit, data processing usually reduces information content. In the sense of Shannon, this is actually true. What is missing is the notion that the knowledge of  $(a+b)$  is more valuable than the knowledge of  $(a, b)$ . Shannon's theory contains no concept of the value of information.

The seeming paradox is resolved if we insist that  $(a+b)$  be computed in such a way that  $(a, b)$  can be recovered from  $(a+b)$  plus auxiliary information. Then the entire end-to-end operation will be the identity operation and hence one-to-one, while at the same time the process produces the originally desired result  $(a+b)$  as a sort of intermediate output. We know that  $(a, b)$  can be computed from  $(a+b, a)$  or

$(a+b, b)$  or  $(a+b, a-b)$  or endless other possibilities. Our choice is a set of primitive invertible programs (PIPs) which implement addition, subtraction, multiplication, division, exponentiation, and reciprocation.

Ordinarily, it would be a very difficult task to implement a benchmark in such a way as to guarantee invertibility while simultaneously computing a desired output. This task is rendered trivial by designing the PIPs in such a way that they are self-inverse. More specifically, each PIP has two inputs and two outputs, and implements

$$f(f(a, b)) = (a, b) \tag{2}$$

Thus any network of PIPs, however complex, has a simple mirror-image as its inverse network.

An obvious response to our requirements in the example above is to begin with  $(a, b)$  and produce  $(a, b, a+b)$ . We have rejected this approach because the required storage grows with the complexity of the computation. The PIPs which we present in the next section require a constant amount of storage during the entire benchmark computation.

SELF-INVERSE PRIMITIVE INVERTIBLE PROGRAMS

In all that follows, let  $K$  represent the reciprocal of the square root of 2. That is,

$$K=0.707\dots \tag{3}$$

The complete set of primitive invertible programs is given by

$$f_1(a,b)=(K \times (a+b), K \times (a-b)) \tag{4}$$

$$f_2(a,b)=((a \times b)^K, (a/b)^K) \tag{5}$$

$$f_3(a,b)=a^b, 1/b \tag{6}$$

Straightforward calculation shows that  $f_1, f_2,$  and  $f_3$  each exhibit the self-inverse property of Equation 2.

EXAMPLES OF INVERTIBLE BENCHMARKS

*Example 4*—Use PIPs to implement  $c=a \times b$ .

A network using two PIPs is shown in Figure 1 which yields the required result. The network requires three stor-

age locations. Figure 1 is drawn in such a way as to emphasize the mirror image property of the inverse network.

*Example 5*—Use PIPs to implement  $y=a^2+(b \times c)-(e \times f)$ .

A network employing 11 PIPs is shown in Figure 2. This solution requires 12 storage locations and six time steps. The PIPs associated with a given time step can be executed in any order or even simultaneously if the hardware permits. A trace of the storage location contents is shown in Figure 3. If the intermediate results are incidental to the required result, they have been given arbitrary names such as  $g, h, i, \dots, p, q$  in Figure 2 and Table I. The inverse of the network of Figure 2 is illustrated in Figure 3. A trace of the time steps associated with the inverse network is shown in Table II.

APPLICATION AND DISCUSSION

In the practical world of computer system selection, a few systems are candidates, each with its supporters. Similarly, a modest number of benchmarks are usually proposed.

TABLE I.—Direct network for Example 5.

Storage Location	Storage Contents						
	Initial	After Step

It has been difficult in the past to put a common measure on the benchmarks. Thus, a standoff results when System A is faster on Benchmark 1 while System B is faster on Benchmark 2. It appears that the use of the techniques of this paper can help to resolve such a situation. For example, an aggregate benchmark could be constructed by weighting Benchmark 1 and Benchmark 2 according to some estimate of their relative frequency of execution in the actual job mix. For each benchmark an information content,  $H_2$ , can be computed. Then for any given system the figure of merit in bits-per-second can be computed from measurements on the average number of source symbols transmitted per second by an invertible benchmark. A figure of merit for each competing system can then be computed by weighting individual benchmark figures of merit in accord with the relative frequency of execution. It seems reasonable to assign the implementation of the three PIPs for a particular system to the proponent or proponents of that system.

It is clear from our discussion that there are many PIP network implementations of any given benchmark. It may be possible in the future to find a systematic way of discovering the best implementation. However, any acceptable

definition of best should recognize the potential for trading speed for storage requirements. The PIP network approach exposes both of these factors to view and also allows us to count the necessary PIPs of each type.

Finally, it is possible that the idea of invertible benchmarks can be exploited in the direction of assisting in the development of checkpoint, rollback and restart properties for ordinary programs. Note that an invertible program can be suspended indefinitely after any step and resumed at leisure. This can be important to a system which encounters emergency shutdowns and also to a system which features a priority interrupt scheme.

PROOF OF

$$-[p_a + p_b] \times \log(p_a + p_b) < -[p_a \times \log p_a] - [p_b \times \log p_b]$$

Assume

$$p_a \leq p_b \tag{1}$$

Then

$$\frac{1}{p_b} \leq \frac{1}{p_a} \tag{2}$$

and

$$\left[ \frac{1}{p_b} \right]^{p_a} \leq \left[ \frac{1}{p_a} \right]^{p_a} \tag{3}$$

So

$$\left[ \frac{1}{p_b} \right]^{p_a} \cdot \left[ \frac{1}{p_b} \right]^{p_b} \leq \left[ \frac{1}{p_a} \right]^{p_a} \cdot \left[ \frac{1}{p_b} \right]^{p_a} \tag{4}$$

$$\left[ \frac{1}{p_b} \right]^{p_a + p_b} \leq \left[ \frac{1}{p_a} \right]^{p_a} \cdot \left[ \frac{1}{p_b} \right]^{p_a} \tag{5}$$

But

$$\frac{1}{p_a + p_b} < \frac{1}{p_b} \tag{6}$$

so

$$\left[ \frac{1}{p_a + p_b} \right]^{p_a + p_b} < \left[ \frac{1}{p_b} \right]^{p_a + p_b} \tag{7}$$

Combining (7) with (5) gives

$$\left[ \frac{1}{p_a + p_b} \right]^{p_a + p_b} < \left[ \frac{1}{z_a} \right]^{p_a} \cdot \left[ \frac{1}{z_b} \right]^{p_b} \tag{8}$$

Taking logarithms in (8) completes the proof.

# A loosely-coupled applicative multi-processing system\*

## INTRODUCTION

The architecture of highly-parallel machines has received increased attention from researchers over the past decade. At first, because of the machines' novelty, workers were content with proposing elaborate machine architectures without giving due consideration to how such machines would ultimately be programmed to exploit their available computational power. Experience with Illiac IV, Star-100, etc. has shown this to be a mistake. Indications are that programming languages deserve consideration at the earliest stages of architectural conception. Included in such considerations are issues such as storage and task management.

This paper describes a proposed machine, AMPS (Applicative Multi-Processing System). It features a *loosely-coupled architecture*, incorporating a large number (say 1000) of processors functioning independently to a large extent, but effectively interacting when necessary. Furthermore, the programs supported are not tied to the structure of the machine, thereby facilitating expandability. Such expandability is further enhanced by the particular physical organization to be described. The architecture of AMPS attempts to bring costs of communication among processing units to a manageable level by taking advantage of *locality of reference*.

Our architecture is currently in the development stage. We present in this paper some of our major philosophical considerations, along with an execution model for a subset of the machine language.

## LANGUAGE ISSUES

Heretofore, research on highly-parallel machines has predominantly emphasized statically-structured, usually numerical, computation. We are orienting our design toward dynamically-structured, often symbolic, computations. Although we do not exclude numerical applications from AMPS, we are designing it to provide direct support for

languages such as Lisp which have been invented for symbolic computation. In fact, the machine language for AMPS itself resembles a dialect of Lisp. By retaining a close relationship between a higher-level language and its supporting machine language, debugging is facilitated. Furthermore, the *applicative* (i.e. based on *function application*) nature of our machine language obviates many pre-processing transformations of the type used to extract parallelism. Such transformations are really just means of extracting functional dependencies which are easily determined from an applicative program.

To further clarify, consider the task of counting the leaves of a binary tree. Figure 1a presents an applicative program for this task, whereas Figure 1b presents a corresponding non-applicative program employing a stack. Clearly, Figure 1a is easier to understand and its inherent parallelism is easier to detect than that of Figure 1b.

Lisp, with some minor extensions, such as *lenient cons* discussed in the seventh section (*cf.* References 9 and 12) seems to include all opportunities for exploitation of concurrency that proposed data flow languages do, and more. It provides concurrent operations on tree or graph data structures during their creation, and natural ways for dealing with conceptually infinite structures. By supporting such a language at the machine level, we also provide a natural means of communication between processes and their environment, e.g. file systems and I/O devices. Space limitations preclude discussing these issues here, but related ideas may be found in References 10 and 22. It is also worth mentioning that our machine language can directly support other languages which deal with infinite structures such as those in References 5, 2 and 13.

## BASIC ARCHITECTURE

The physical arrangement of components in AMPS is a tree structure with two types of nodes. The scaled-down version in Figure 2 is merely meant to be suggestive, as we envision trees with 1000 or more nodes as being feasible in the next decade. Combined processor/memory units are attached as leaf nodes. The internal nodes of the tree structure are combined communication and load-balancing units. Other more specialized units might also be present, attached

a. Applicative Program

```

leafcount(t) = if atom(t)
                then 1
                else leafcount(left(t)) + leafcount(right(t))

```

b. Non-Applicative Program

```

leafcount ← 0;
stack ← {t};
while non-empty(stack) do begin
  pop T from stack;
  if atom(T)
    then leafcount ← leafcount + 1
    else begin
      push left(t) on stack;
      push right(t) on stack
    end
end
end

```

Figure 1—Applicative and non-applicative versions of leafcount.

closer to the root node for enhanced accessibility and utilization, but we do not further discuss this possibility here.

This paper makes the assumption of a binary tree for simplicity, although technology considerations suggest that a 4-ary or 8-ary tree might be more appropriate. For expedited communication, we may eventually include additional links laterally connecting the tree, possibly as suggested in Reference 8.

A processing unit in AMPS is roughly the size of a conventional micro-computer, but its architecture is substantially different. It is able to carry out local computation, particularly with respect to assembly and dissemination of information, and to initiate actions for fetching information from other nodes of the tree. It is able to execute program tasks sequentially or in an overlapped mode, and to allocate storage in response to the execution of *invoke* instructions. *Invoke* instructions create tasks which are then executed either in the local processing unit or in another processing unit, as system loading dictates (see the eighth and ninth sections).

The primary memory of the system is distributed among the processing units. Each processing unit has direct access to that segment (e.g. 64K words) of memory located within it. It also has access, through the *communication network*, to the segments of memory located at other processing units. Even though the memory is distributed among the processing units, there is only one *unified address space*. Given the address of a datum, any node in AMPS is able to logically access it without address translation. Such addresses do not appear at the assembly language level, as they are generated by the system dynamically. The internal nodes of the communication network are responsible for any required routing of data. Access to auxiliary memory and other forms of

external communication takes place through special-purpose leaf processors, which will not be discussed here.

## COMMUNICATION NETWORK

The communication network in AMPS is designed to take advantage of locality of information flow, thereby reducing communication costs. Information first travels up the tree towards the root node until it encounters a node which spans the destination leaf, whence it proceeds down the tree until it finally reaches the desired destination. Thus, for sending or receiving information from neighboring leaves, it is not necessary for the information to travel the entire depth of the tree. Relatively local data flow therefore takes less time and the overall communication cost of the computation is thereby improved.

A second function of the communication network is to provide a reasonably balanced distribution of the computing load. Such a function is useful since the machine allocates tasks dynamically. Each node of our communication network periodically obtains *load monitoring signals* from its subordinates, which indicate their current degrees of utilization. When such signals indicate a sufficiently unbalanced state, the node can cause the transfer of uninitiated tasks from one subtree to the other (see the section on Load Balancing).

## LOCALITY

One of the most important concepts of our architecture is an attempt to improve performance by exploiting locality of information flow. Locality is an established phenomenon in program execution, which should therefore be exploitable within applicative programs. Locality will be enhanced by the fact that functions are naturally apt to confine their references to certain portions of data structures. Secondly, repeated global references to the same data will become localized by a *caching effect* incorporated in the referencing scheme of AMPS. Note that the read-only nature of data in applicative systems greatly simplifies the implementation of such caches.

If computations which interact heavily with one another are allocated space in leaves that are a short average distance apart in the communication network, the overall time spent in information flow will be reduced. It is important to note that even if it is not possible to allocate space for a new computation in the storage space at the invoking leaf, the correctness of the overall computation will be maintained, even though the speed of the computation may be decreased. This is aided by the uniformly acceptable address space and the deferred binding of program blocks to physical addresses. Moreover, such locality should tend to cause traffic flow to decrease with node level, thereby balancing bandwidth with demand.

In designing a highly-parallel machine, care must be taken that costs associated with creating new tasks and communicating with them do not outweigh the speed advantage

Figure 2—Physical form of AMPS.

gained from overlapped execution of these tasks. Consequently, our design prescribes that computation is divided into blocks in such a way that all computation local to a block (i.e. exclusive of communication with other blocks) will be done within one processing unit. Since such blocks are identical with the code blocks of the program (see the eighth section), locality is further enhanced by the clustering of connected operators within blocks. The global structure does not seek gains from parallelism on the level of, say, a simple arithmetic expression. Instead, this effect is achieved within the processing unit itself.

Another anticipated effect which will contribute to locality might be called the *seeding effect*. When a task A in execution creates a second task B, the latter may be allocated its storage in any of the processing units in which there is sufficient space. Since B may cause the creation of other tasks C1, C2, . . . , Cn, locality is enhanced if the storage for the latter is allocated in processing units near to that of B in the tree. Hence even if B is a long distance from A, thus incurring non-trivial communication cost between the two, this cost may be balanced out by the lower costs of communicating between B and C1, C2, . . . , Cn.

The seeding effect creates a tradeoff in resolving a choice of how far away a created task should be placed. It also

demonstrates the possibility of a certain amount of *natural re-localization* in recovering from bad task-placement decisions by the system. For example, even if B were placed in a congested area, the storage from completing tasks near B could eventually be reclaimed to provide more space for C1, C2, . . . , Cn. Although such a scheme will not always work with optimal efficiency, it will work until all space is in use.

#### INFORMATION FLOW

The characterization of information flow within the machine is dependent on the conceptual level being considered. For example, at the *task level*, we are concerned with the flow of operands among tasks, which we implement in a *demand driven* fashion. In the demand-driven scheme a task may actively seek additional pieces of data after its initiation. In contrast, most proposed data flow machines are primarily data-driven, in that an instruction never asks for data to be sent to it. Instead, it waits to receive data itself, and when all necessary operands have been received, it initiates the computation, the result of which is then sent to all other designated instructions.

At the *communication network level*, we find the infor-

mation flow separated into the flow of *tasks* (which at this level are always *invoke* instructions), *operands* (single data words), and *blocks* (multiple data words), and requests for the latter two. All such pieces of information are accompanied by a destination address. All information transmitted through the communication network is handled by *packet switching* (i.e. *store-and-forward*). Line-switching is not used because of the potential congestion caused by tying up long paths through the network.

A node of the communication network communicates to its parent through a form of handshaking. For block transfers, a *burst mode* of communication is used in which the handshaking occurs only before and after the entire block has been transferred, thus drastically reducing the associated overhead.

## MACHINE LANGUAGE

As its language, AMPS executes a compiled dialect of Lisp called *FGL*, for *Flow-Graph Lisp*, or *Function Graph Language*. Although FGL programs are stored as blocks of compiled code, we prefer to present them using *function graphs*, as described in Reference 15. FGL allows us to display clearly the data flow between operators and thus the potential concurrency within programs.

A program in FGL consists of a main function graph, together with *productions* for programmer-defined functions. These productions specify how a node containing a function name (the *antecedent* of the production) is to be replaced by a function graph (the *consequent* of the production). FGL provides a repertoire of basic operators (e.g. the primitive functions of Lisp) that may be used in constructing function graphs.

For the sake of this presentation, let us suppose that data structures are *trees*, with integers and *nil* as atoms. Conditional evaluation is obtained through the use of the function *cond*, which causes the evaluation of its second or third argument, depending on whether its first argument is non-*nil* or *nil*, respectively.

Trees are built using the *cons* operator, which forms trees from atoms or other trees by connecting its arguments as subtrees of a common root. The selector functions *car* and *cdr* extract the left and right subtrees respectively of a tree built by *cons*. The *cons* of FGL is in fact *lenient cons*, which allows the machine to exploit concurrency which it could not with conventional *strict cons*.<sup>9</sup> More precisely, FGL semantics provide that the identities  $car(cons(x,y))=x$  and  $cdr(cons(x,y))=y$  hold independent of whether *x* and *y* are convergent.

For simplicity, we do not discuss input of trees. Rather, we assume them to be resident at the beginning of the computation, built by an appropriate graph of *cons* operators and atoms. Conceptually, trees flow on the arcs of an FGL graph. In actual implementation, however, the flow of a non-atomic tree is represented by the flow of a pair of pointers to its subtrees. For the current presentation, iteration is implemented by recursion, in the manner of Reference 19. This can be shown to give automatically the same

concurrency-detection effect of "look-ahead" processors, which "unfold" iterations to achieve concurrency.<sup>14</sup>

To cause a result to be printed, a *demand* is generated at some *print* node in the function graph. This causes propagation of the demand to the operator feeding the *print*. When that operator ultimately produces a value, it will then be printed.

Evaluation consists of a combination of transmutations to the graph and the application of basic operators. In this sense, AMPS is a *reduction machine*,<sup>4</sup> executing a *reduction language*.<sup>3</sup> By exploiting the richer connectivity of graphs, we can avoid much of the *combinatorial explosion* which takes place in purely string-oriented reduction machines.

Figures 3 through 7 give examples of programs in FGL. Figure 3 presents a production for the function of Figure 1a, which counts the leaves of a tree. This example uses the *strict* operator (i.e. one which demands *both* of its arguments) *add* to cause the creation of instances of operators which can be evaluated concurrently. Figure 4 shows a possible snapshot of the program during its application to a specific tree. Several concurrent sub-computations are visible.

In Figure 5a, we present a *main program* which calls a recursively-defined function NATNUMS, the graph of which is presented in Figure 5b. Intuitively, NATNUMS(*n*) "computes" the infinite sequence  $\{n, n+1, \dots\}$  by constructing its representation in the form of a tree as shown. In the context of the main program, the value printed is the second element of the sequence where  $n=2$ , i.e.  $car(cdr(NATNUMS(2)))$ . Adjoined to the graphs in Figure 5 are listings of their FGL assembly code, the meaning of which is explained in the next section. The parenthetic labels on the graph indicate the correspondence between the graph and the code.

Figure 6 presents a program which employs the function NATNUMS to generate the prime numbers in increasing order. The reader may wish to refer to the similar examples in References 2 and 13.

Figure 3—FGL production for the leafcount function.

Figure 4—One possible snapshot of the program of Figure 3 during its computation on a tree. Unlabeled leaves are those of the original tree. The ultimate result will be the number 256.

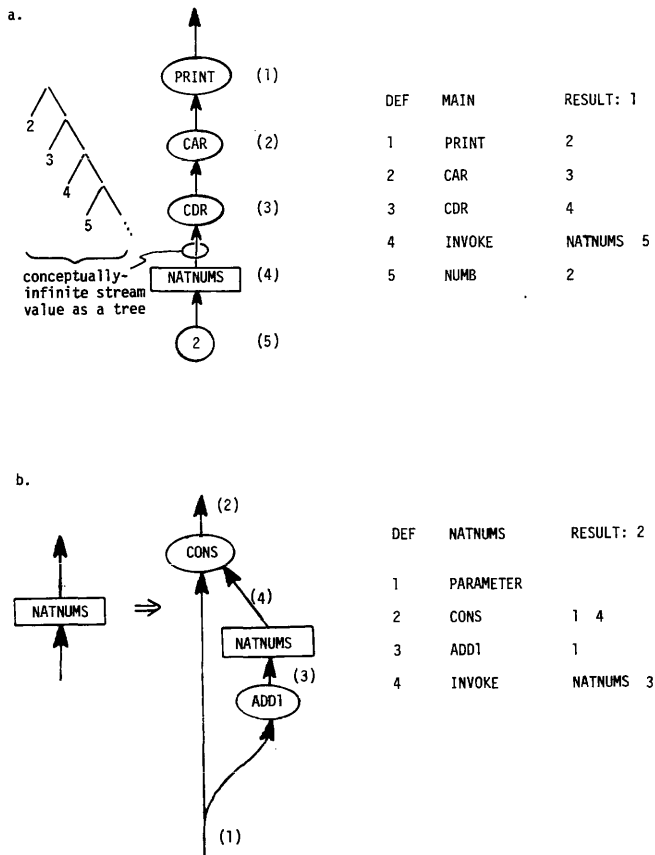

Figure 5—Sample FGL main-program (a) and production for defined-function NATNUMS (b) with assembly-language listings.

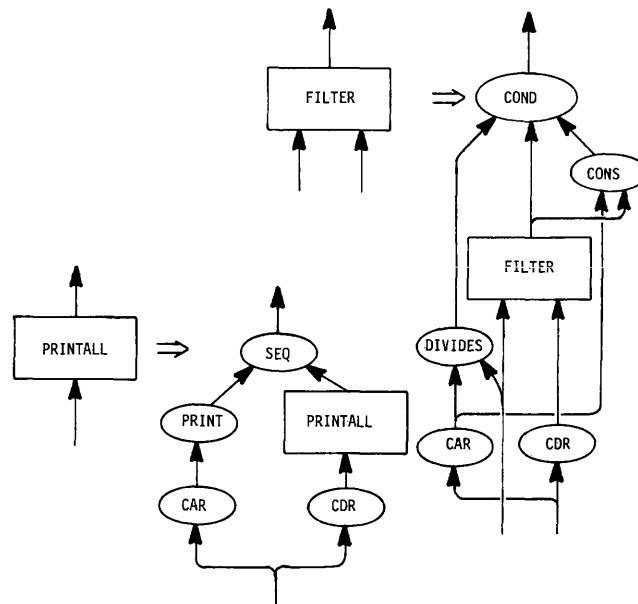

Figure 6—FGL program for printing prime numbers in increasing order. The production for NATNUMS is given in Figure 5. The primitive function *divides* yields *nil* unless its second argument evenly divides its first. The primitive *seq* causes its arguments to be evaluated in sequence.

It can be proved that every well formed interconnection of FGL operators computes a unique function (*cf.* Reference 16), even an interconnection involving cycles. Cycles provide one means of efficiently implementing bi-directional communication between two functions. Such an example is shown in Figure 7, which illustrates a program for the breadth-first production of all atoms in a tree. Detailed description of the recursively-defined functions *PASSATOM*,

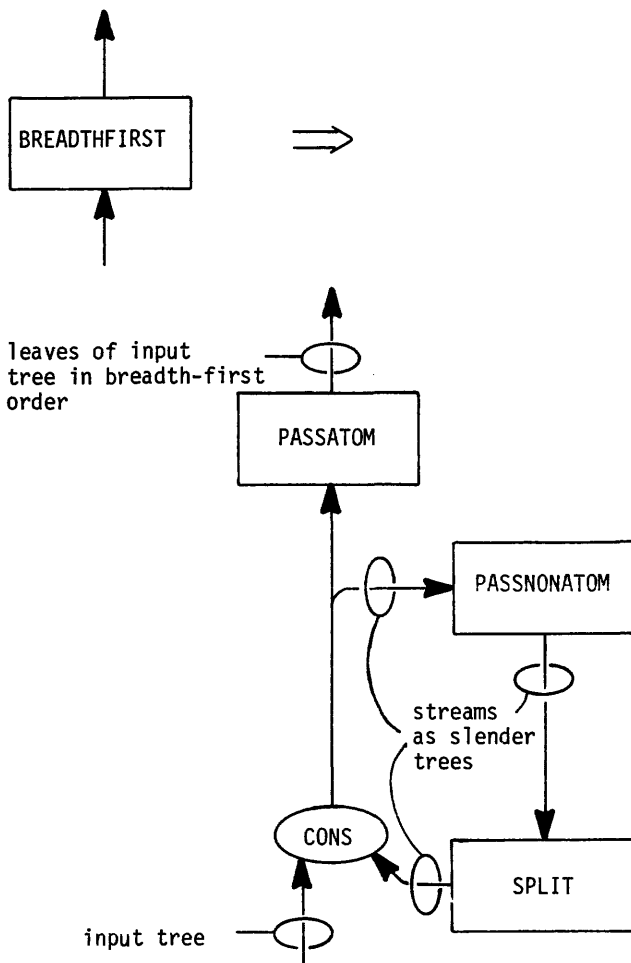

Figure 7—Production defining a function which produces the leaves of a tree in breadth-first order. Productions defining PASSATOM, PASSNONATOM, and SPLIT are not shown.

PASSNONATOM and SPLIT are not presented here. It should be noted that FGL employs fan-out of arcs to effectively avoid recomputation of the same value, an effect which must be obtained by recognition of common sub-expressions in some applicative languages.

In the next sections we describe, in more detail, program storage, task execution, typical operators, and production application via the special operator *invoke*. We do not discuss storage reclamation here, for lack of space.

## PROGRAM STORAGE AND EXECUTION

All storage is allocated in *blocks*. The use of blocks makes storage management more efficient, and is consistent with trying to keep the *locality* of a computation contained within one processing unit. A block is either a *data block* or a *code block*. The contents of a code block form a linear representation of an FGL graph, which is copied as the source of

initial code to be stored in a newly allocated data block. This copying may be viewed as the application of an FGL production, i.e. replacing the antecedent node with its consequent graph. Each word in a data block is initially a code word or a literal value. A code word may get changed to a literal value during execution. The *ready bit* distinguishes whether the word is a value or a code word.

A code word in a data block corresponds to a node in an FGL graph. A value corresponds to what eventually appears on the output arc of that node. The code word contains the local addresses of words corresponding to nodes at the opposite end of its input arcs, i.e. the sources of its operands. Local addresses are relative to the start of a block. We assume here for simplicity that each operator has only one output arc, although such arcs may fan out as necessary.

In addition to specifying the input arcs of its operands, an instruction word may include *notifiers*, which are local addresses of operators which have this operator's output arc as one of their input arcs. These are usually set dynamically as demands occur, although it is possible to have them pre-set in the initial code.

In addition to an *operation code*, the following fields may or may not be present, depending on the nature of the particular operation:

1. Local addresses of *arguments* of the operator.
2. *Notifiers*, i.e. local addresses of *notified* code words, which are instructions which have demanded this instruction's value.
3. A single *global address*, used to provide linkage across blocks, and for specifying the code block in the case of an invoke instruction.

The *invoke* instruction, when demanded, causes the allocation of storage for a data block and the copying of a code block into that storage. The demand driven approach thus provides a natural means of deciding whether and when to trigger the invocation of a defined function, which requires the allocation of a storage block. An *invoke* instruction also initializes various linkage instructions which provide an interface between the nodes of the graph containing the antecedent of the production and those of the consequent, since local addresses cannot be used to provide this linkage. Details on these linkage instructions may be found in Reference 18. Linkage instructions are not shown in the code blocks in Figure 5, as they are supplied automatically by the assembler.

Regarding efficiency, the use of local addresses achieves economy in code word storage, and avoids relocation in copying. The copying of code blocks may be contrasted with approaches such as that in Reference 21, which interpret a pure code block without copying. The approach taken here is more effective in keeping references local to a processing unit. It also eliminates separate fetching of code and data words for each task. Due to the use of a burst mode, blocks are copied more efficiently than the same number of words individually.

## TASK EVALUATION

Although code words may be conceptualized as representing functions, we must describe how these words are interpreted by the machine to cause values to be produced. The loosely-coupled aspect of task evaluation is achieved in AMPS through a *task list* organization, which allows many processors to partake in the evaluation of *tasks*, i.e. particular instances of operators with their associated data. The task list is decomposed into two separate lists which may be served independently. These are:

*demand list*—Contains addresses of operators for which evaluation is to be attempted.

*result list*—Contains addresses of operators, along with their corresponding values after evaluation.

The *invoke* tasks on the demand list are distributed to individual processing units by the communication network, which takes into account the current processor load profile. Only such tasks are considered for distribution, since it is only these which might profitably be executed in another processing unit, due to the communication costs incurred in their transmittal. Hence, each processing unit has its own *invoke list*, a sublist of the demand list containing only *invoke* instructions.

Figure 8 shows the organization of the task evaluation mechanism. The diagram is to be interpreted in an informal sense, and is less akin to conventional flowcharts than indicative of the flow of tasks in the system. Further details may be found in Reference 18.

Initially, the address of the word which will produce the "main result" is put on the *demand list*. The word itself is then fetched. The instruction specifies certain arguments, which are also fetched. If the arguments are all ready, the function is evaluated. If not, then demand is propagated to each unready argument not previously demanded by placing its address on the demand list and setting a notifier in it. A word may contain several notifiers indicating which instructions have demanded it. The presence of at least one notifier is used to signify a previous demand. Figure 9 sketches symbolically the flow of demand in the example of Figure 5, along with the corresponding production applications and evaluations which take place.

Once evaluated, a result value replaces the code word as *ready* data. Via the result list, any instructions which were specified by notifiers as awaiting this result as an argument are then notified by putting them on the demand list to be retried. Observe that all demanded operators remain accessible until they are replaced by ready data, either through being put on the demand list or through being referenced by a notifier of an accessible operator.

Forms of evaluation other than pure demand evaluation can be supported by judicious pre-setting of notifiers and demand bits and advanced placement on the demand list. Special operators are also available to the programmer which have the purpose of generating advanced demand to enhance parallelism, and for postponing demands to avoid premature allocation of data blocks.

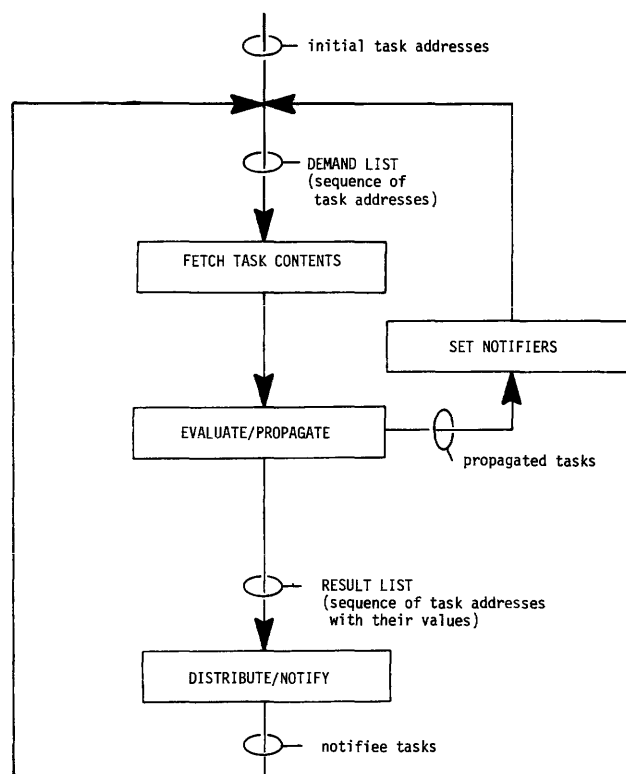

Figure 8—Simplified task processing flow.

## PROCESSING UNIT ARCHITECTURE

We do not go into great detail here on the organization of individual processing units. As described in the previous section, each unit selects tasks from its demand list. While on this list, a task is represented by its address in memory. The content of this address is fetched and, if a code word, an attempt is made to evaluate it. This normally entails reference to one or more additional words in the memory.

Since a referenced word might reside in the physical memory of any processing unit, fetching may involve transmission of words through the communication network. In order that the processor need not be idle while such a fetch is taking place, we provide a *staging area* for buffering a set of such tasks while their operands are being assembled. The staging area is conceptually similar to a conventional *pipeline*, except that order of task execution is unimportant, all essential ordering being explicit in the program graph.

The size of the staging area is chosen to maintain reasonably good utilization of the function units within the processing unit, which carry out each operation once its operands are assembled. Of course, each function unit could itself be pipelined, depending on economic advantages which would accrue under particular application loads. Design of such a staging area is fairly routine and therefore will not be discussed further here.

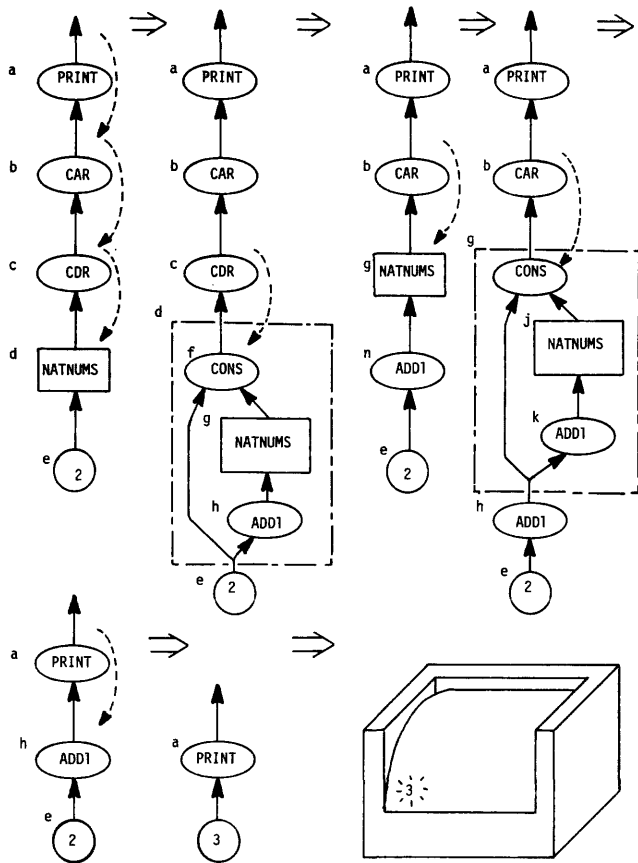

Figure 9—Snapshots of the evaluation of an FGL program. Perforated arrows illustrate demand propagation.

## LOAD BALANCING

Load balancing occurs through the redistribution of tasks from the invoke list of one processing unit to that of another. This is a function of the communication network which is separate from, but topologically compatible with, the routing of operand data.

By the *load* at a processing unit, we mean the storage requirement of tasks on the invoke list at that unit. In a similar manner, we can define the *load* at any node of the communication network to be the sum of the loads at its spanned leaves, divided by the number of such leaves as a normalizing factor.

Again, to simplify the explanation, we are assuming that the communication network is a binary tree. Each node of the communication network maintains desired lower and upper limits,  $L$  and  $U$ , on the loads of its immediate descendants. These are functions of the amount of storage currently in use by the leaves spanned by those descendants. If the load of one descendant is above  $U$  and that of the other below  $L$ , the network attempts to shift tasks from the invoke list of the overloaded descendant to that of the underloaded one. If loads of both its descendants are above  $U$ , this will be communicated to its parent (if any), so that the latter may try to shift some of the load to one of its

descendants having load less than  $L$ . In this way, the balancing function is distributed throughout the communication network, with each node thereof applying the same balancing strategy.

The effectiveness of the balancing scheme relies on the loosely-coupled nature of the system. That is, no task is bound to a particular processor until storage is allocated for it.

## COMPARISONS WITH RELATED MACHINES

The data flow machines of References 7 and 1 originally influenced the structure of AMPS. The communication network in AMPS plays the role of the arbitration and distribution network of the Dennis data flow machine. However, the processing units which assemble instructions and initiate information flow are of a higher level, as are the processors in Reference 1.

Even though the architecture of AMPS has a tree like structure, it is not a "recursive architecture" in the sense of Reference 6. The hierarchical structure and method of storage allocation in the Davis machine seem to impose certain constraints on the creation of new computations and on the flow of information in the machine. For example, when a processing element creates a task, the latter must be placed either in the space of the processor carrying out the application or in the space of a subordinate processor, even if all subordinates are crowded for space and the machine has other processors which have plenty of space. This problem does not occur in AMPS, due to the construction of the communication network, the uniformity of the address space, and load balancing.

A common feature of all of the previous architectures is that they are data-driven rather than demand-driven, as is AMPS. One might be led to think that the latter presents some additional overhead. However, closer examination reveals that FGL programs are often simpler in that they do not require explicit instructions for the gating of data.

In data-driven machines, a form of ready-acknowledge signalling is often used for transmission of data via storage words. This is, in fact, a special case of demand-driven computation, in which the demand for an operand is equated with readiness of its recipient. The demand-driven approach seems to provide more flexibility in the relationship between elaboration of a programmer-defined function and the evaluation of its arguments. It is also clear that the demand-driven feature is a necessity in supporting lenient *cons*. On the other hand, demand-driven computation could possibly be *engineered* on other architectures by treating demands as data, but this seems cumbersome.

The tree-structured reduction language machine of Reference 20 is fundamentally different in its operation from AMPS. In the former machine, an expression to be evaluated is mapped symbol by symbol onto the leaves of the tree. In AMPS, an expression would first be converted to function graphs which then reside in the memory space of one or more processing units of the machine.

Our system has in common with those just cited the desire

to integrate architectural, communication and language considerations. This is one of the ways it differs from superficially similar systems, such as Cm\*.<sup>23</sup> In Cm\*, parallel processing is based on the concept of interacting sequential processes that run on conventional processors (DEC PDP-11's), while AMPS is capable of directly evaluating function graphs, integrates considerations of evaluation and local balancing, and directly supports communication among tasks.

## CONCLUSIONS AND FUTURE RESEARCH

We have stated that machine architectures should be developed with greater attention paid to ultimate programmability. With this motivation, we have presented a loosely-coupled parallel processing system AMPS which executes an applicative language, FGL. We have sketched the internal representation of programs in AMPS and the execution of programs on it.

Our implementation seems to be the first detailed one presented for Lisp programs on a parallel machine. An implementation has been described qualitatively in Reference 11. However, their description relates mainly to the issue associated with *colonel* versus *sergeant* tasks, sergeants being distinguished from colonels as tasks whose evaluation may never actually be required, but which provide a potentially useful way of employing otherwise idle processors. In contrast, all tasks in the machine described here are of the colonel variety, whose existence may be traced to certain *strict* operators, such as *add* in the leaf count example of Figure 3. On the other hand, subtle details, such as occur in the implementation of a *global notifier* scheme, have been discovered in the course of designing our evaluator.<sup>18</sup> How such subtleties interact with an implementation which does offer sergeant tasks remains a topic for future investigation.

The ideas presented here were derived after considering many possible alternatives. We may, of course, elect to return to one or more of these alternatives after more experience in programming the machine has been gained. A simulator for the evaluation model has been written in Pascal to assist in such a venture. Thus far, the simulator has been used to verify that the evaluation mechanism works and to experiment with additions to the language FGL. Construction of a Simula-67 simulator for the tree architecture is now in progress. We have no immediate plans for construction of a physical realization of the machine.

Issues remaining to be investigated include the necessary support for FGL in terms of storage reclamation and scheduling. We are currently contemplating how best to organize the distributed heap for efficient medium-term data storage.

We have preliminary results on how to deal with other features of Lisp, such as *funargs*, *setq*, and *prog*. A description of the handling of *funargs* appears in Reference 18. Efficient access of array-like structures is handled by extending *cons* from pairs to tuples and providing an indexed selector function.

A related issue is whether *indeterminate* computations should be supported, as there are some indications that they

permit efficiency gains not otherwise achievable.<sup>17</sup> Under investigation also is the use of machine operators for the support of resource allocation. These have been programmed into the experimental simulator and seem to fit very naturally with our method of evaluation. The usefulness of applicative programs in allowing graceful backup when a processing unit fails also remains to be exploited. Thus many issues, at levels from detailed processor construction to more fundamental language problems, await us.

## ACKNOWLEDGMENTS

# A prototype data flow computer with token labelling

by IAN WATSON and JOHN GURD

University of Manchester  
Manchester, England

## INTRODUCTION

Computer users in many areas of scientific study appear to have an almost insatiable desire for processing power. Many of the computations exhibit a high degree of parallelism which is not exploited in conventional computer structures. Considerable interest has been shown in parallel computer architectures in the last decade in order to make use of this property.

The two main approaches toward this goal have become known as SIMD (array processor) and MIMD (multiprocessor) architectures which are typified by the ILLIAC IV and the C.mmp systems respectively. It is not appropriate to describe these architectures in detail here, but it should be noted that a number of inadequacies have come to light as these systems have been applied to many problems. There are two basic difficulties which appear in both architectures in slightly different guises. The first concerns the arbitrary choice of a fixed number of processing units in an architecture (64 in the case of ILLIAC IV, 16 in the case of C.mmp). The difficulty that is occasioned by this choice derives from the fact that it is often inconvenient, if not impossible, to organize the problem to be solved so that it is exactly the "width" of the architecture. The second problem arises when sections of essentially serial programs are processed. The problems in SIMD architecture are clear; in MIMD systems the difficulty usually appears when a critical area of memory becomes "locked-out" while many processors are trying to access it. Evidence is accumulating that relatively little of the potential speedup of SIMD and MIMD systems can actually be achieved for a broad spectrum of problems: Minsky's conjecture,<sup>1</sup> Flynn's analysis<sup>2</sup> and Enslow's view of operating system overheads in multiprocessors<sup>3</sup> all attest to this opinion.

More recently, interest has arisen in data driven computation for the expression of programs (known as Data Flow). A computation is expressed as a data dependent directed graph with nodes representing computational operations and the arcs representing the flow of data. The nodes become ready for execution when all their input data are available. The expression of parallelism in terms of data dependencies rather than in spite of them, leads to a far more natural and flexible picture of parallel program execution.

The theoretical basis of data driven computation can be traced to the paper of Karp and Miller in 1966.<sup>4</sup> An extension of this line into machine architecture was pioneered by the team led by J. B. Dennis at MIT.<sup>5,6</sup>

The architecture described in this paper follows the same broad principles as the MIT work but introduces the concept of token labelling as a mechanism to support re-entrant code structures. It is believed that this leads to a more efficient use of storage resources and provides a greater potential for the utilization of parallelism. Another important aspect of the design is the use of pseudo-associative store to perform token matching; this is achieved by reducing the nodes to a simple machine instruction level with a maximum of two inputs.

## DATA FLOW PRINCIPLES

In order to illustrate the principles of a directed graph representation, consider the 'Butterfly' of a Fast Fourier Transform shown in Figure 1. The expressions being evaluated are:

$$A' = A + C \cos \alpha + D \sin \alpha$$

$$B' = B - C \sin \alpha + D \cos \alpha$$

$$C' = A - C \cos \alpha - D \sin \alpha$$

$$D' = B - D \cos \alpha + C \sin \alpha$$

These can be built up from six simple nodes performing the functions of addition, subtraction, multiplication, sine, cosine and duplication of a value. A node becomes executable when its input values (normally called tokens) are available. Following this principle it can be seen that, assuming at least four execution units, the computation can be performed in seven steps as indicated by the number adjacent to the nodes. The total number of nodes in the graph is 21 and therefore the computation has an average parallelism of three.

The graph shown uses only simple operational nodes. In order to specify a more comprehensive computational model it is necessary to introduce a much wider set of primitives which provide control functions such as conditional branch-

Figure 1—Graph of an F.F.T. Butterfly.

ing. A complete description of a practical order code is beyond the scope of this paper but can be found in other literature.<sup>7</sup>

PROBLEMS OF RE-ENTRANCY

A complete Fast Fourier Transform is an iterative computation performed on a large array structure. Ignoring, for the moment, practical implementation mechanisms, consider the problems associated with using the graph of Figure 1 as a complete description of the arithmetic computation. The input values are not simple scalars but arrays of the form  $A[1] \dots A[N]$ ,  $B[1] \dots B[N]$ , etc., for each iteration. In a flexible parallel machine, there is no reason why further iteration steps may not proceed even though one iteration has not been completed for all points in an array. The inputs to the graph can then be of the general form  $A[n]_i$ ,  $B[n]_i$ , etc., where  $n$  represents the array index and  $i$  the iteration level. It is then no longer possible to declare a node executable by the presence of any two tokens on its input as they may belong to totally different parts of the computation.

There are three possible solutions to this problem:

1. The use of a re-entrant graph is prohibited; each point of the array and each stage of the iteration must be described by a separate graph.

2. The use of the graph is limited by allowing one token to reside on an arc of the graph at any one time. This can be achieved by only allowing a node to become executable when both its input tokens are present and no token exists on its output arc.
3. The tokens are assumed to carry with them their index and iteration level as a label. The rules are extended to require two tokens with the same label before a node can be declared executable.

The first mechanism may require large amounts of code storage and, in problems where the iteration depth is only known at run time, the necessity for dynamic code generation. It is believed that this could be a significant overhead in a practical system. The second implies a sequential but pipelined use of the code. This will severely reduce the exploitation of potential parallelism.

The labelling method permits the use of pure static code and enables maximum usage of any parallelism which exists in the problem specification. This is clearly at the expense of the extra information which needs to be carried by each token.

Assuming that it is desirable to utilize the maximum amount of parallelism available, then the limitation of one token per arc must be rejected in the general case. Of the remaining two methods, it is our contention that token labelling will result in much lower overheads in a practical system.

One major use of re-entrant code, that of the procedure, has not yet been mentioned. Parallel invocation of procedures can be supported by ensuring that a unique identifier is allocated to each input token at the procedure call.

It is not possible in this paper to describe all the implications of token labelling. Techniques are required to support nested iterations, recursive procedure calls and index manipulation in data structures. These can be achieved by nodes which operate on the label fields of tokens rather than the data values. More comprehensive information on the labelling concept can be found in descriptions of our own work<sup>7</sup> and that of Arvind and Gostelow at the University of Irvine, California, U.S.A.<sup>8</sup>

THE MACHINE ARCHITECTURE

Although it may be profitable to use a Data Flow computational model to describe parallel activities in a wide range of architectures, it is likely that a hardware structure which reflects the model directly will result in the most efficient implementation.

The basic elements of a Data Flow machine must contain parallel processing units which perform the nodal operations, a stored description of the directed graph and a mechanism for collecting and matching tokens. The first two requirements can be realized using standard processing and storage techniques; the matching operation is more complex.

During a computation, tokens will be produced by processing units which must await the arrival of other tokens with identical labels which are directed to the same node.

They can then form an executable package to be allocated to a free processing unit. This storage and matching function can be simplified greatly if the maximum number of node inputs is limited to two; an associative storage technique can then be used.

Figure 2 shows the basic architecture of the Manchester Data Flow Prototype which uses these principles.

The Instruction Store is a random access memory which holds the directed graph description. Each entry is in the form of a nodal operation and the addresses of the subsequent nodes to which the output token(s) will be directed. Note that in this practical implementation, nodes are able to specify two output destinations for their result. It is also possible to specify a literal value as one input to the node.

The processing units are microprogrammed microprocessors with a distribution and arbitration system. The distribution system, on receipt of an executable package, will select any processor which is free and allocate the nodal operation. The arbitration system controls the output of tokens from the processors.

The switch provides input and output for the system. Initial tokens are directed to the starting nodes of the computation. A special destination address in the final nodes of the graph allows tokens to be output.

The Token Queue is a First In First Out buffer which equalizes data rates around the system.

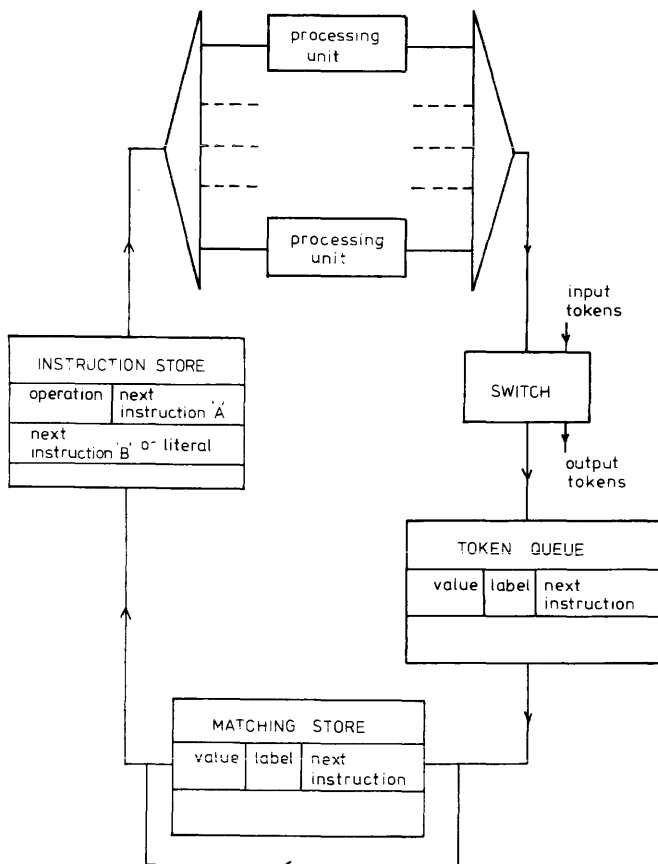

Figure 2—Basic architecture.

The Matching Store is associative in nature, although it is implemented using conventional random access store with hardware hashing techniques. The associative field is formed from a concatenation of the label and next instruction fields; the value field is the token value. There is a requirement in a practical instruction set for single input nodes which require no matching operation. A control digit in the next instruction information allows a bypass of the Matching Store in this case.

In order to execute a program, the graph description is entered in the instruction store. The initial data tokens are input to the Token queue via the switch. As an example of this, Figure 3 shows a very simple graph to form the sum of the product of two pairs of numbers, together with an indication of the Instruction Store entries and initial token formats. The label is not used in this case and is thus set to zero.

The tokens, on reaching the front of the Token Queue, can access or bypass the Matching Store dependent on the Next Instruction Information. An access to the Matching Store will cause an associative search of the store. If a token is found with the same label and Instruction Address it is removed to form a token pair. If no match is found, the incoming token is written to the store.

Token pairs from the Matching Store, or single tokens which have bypassed it, now access the Instruction Store

Instruction Store entries

ADDRESS	OPERATION	NEXT INSTRUCTION 'A'		NEXT INSTRUCTION 'B'	
		ADDR	L.H./R.H.	ADDR	L.H./R.H.
1	MPY	3	L.H.	NONE	
2	MPY	3	R.H.	NONE	
3	ADD		OUTPUT	NONE	

Initial Tokens

VALUE	LABEL	NEXT INSTRUCTION		M.S. BYPASS
		ADDR	L.H./R.H.	
W	0	1	L.H.	NO
X	0	1	R.H.	NO
Y	0	2	L.H.	NO
Z	0	2	R.H.	NO

Figure 3—A simple graph and its machine representation.

and form an executable package. This is distributed to any free processor for execution. Tokens produced by the processors are entered on the back of the Token Queue via the Arbitration Unit and Switch.

This operation proceeds in a pipelined manner around the ring structure until the computation is complete and any output tokens have been produced. Each unit communicates with its successor and predecessor by a two-way handshake interface. This ensures that if, for example, all processing units are busy, the ring operation is suspended until the necessary resources become available.

In order to facilitate the description of the architecture, certain simplifications have been made. It does, however, contain the underlying principles of the prototype Manchester Data Flow machine.

IMPLEMENTATION OF THE MACHINE UNITS

*The token queue*

The Token Queue is implemented using Random Access Memory with pointers indicating the front and back of the queue. The store is divided into two independent stacks which permit concurrent read and write operations. Although it is not intended to include storage hierarchies in the prototype design, it is felt that use could be made of shift register devices if a much larger queue were required.

*The matching store*

The pseudo-Content Addressable Memory required for the matching operation uses hardware parallel hashing techniques similar to those described by Goto and Ida.<sup>9,10</sup> However, as the order of propagation of results around the ring is unimportant, use can be made of an overflow hashing mechanism rather than a re-hash. The advantage of this is that the average store access time can be reduced and a backing store structure can be introduced.

*The instruction store*

No special techniques are necessary in the Instruction Store. It is simply a linear Random Access Memory which is addressable by the Next Instruction Information field.

*The processing units*

Ten Processing Units are constructed from Schottky 'bit-slice' microprocessor elements. They contain alterable microprogram store in order that the instruction set can be changed with ease. All processors are connected to a common bus with a distribution mechanism to allocate executable instructions to free processors and allow the output of results. A preliminary study of arithmetic operations has indicated that an average instruction execution time of 3μS can be achieved in each processor.<sup>11</sup>

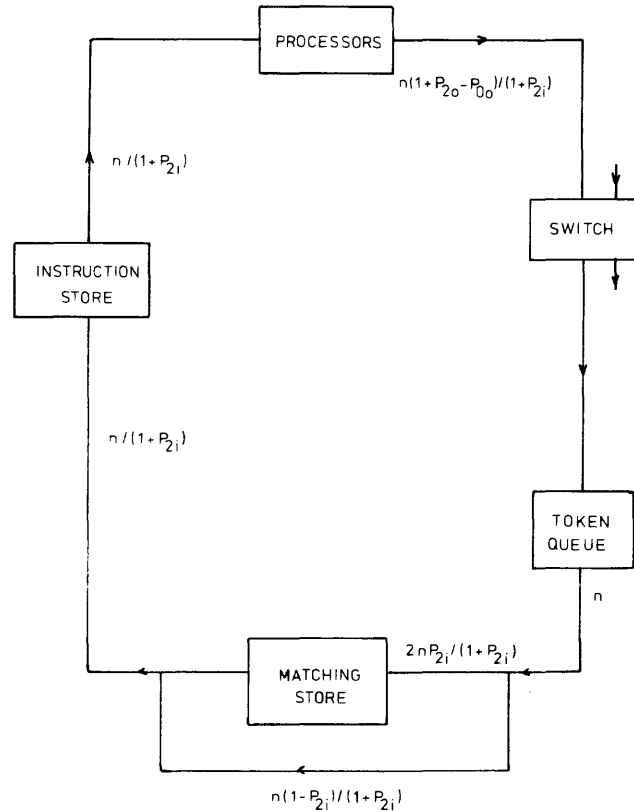

Figure 4—Data rates.

SYSTEM PERFORMANCE

The processor speed has already been stated as an average instruction time of 3μS. If all ten processors can be utilized fully then an instruction execution rate of 3.3 MIPS can be achieved. It is necessary to estimate the storage speeds which are consistent with this.

With reference to Figure 4 we define four values:

- n      Tokens per unit time read from the token queue.
- P<sub>2i</sub>    Probability of an instruction requiring two inputs.
- P<sub>2o</sub>    Probability of an instruction producing two outputs.
- P<sub>0o</sub>    Probability of an instruction producing zero outputs.

The following relationships can be derived:

- 2nP<sub>2i</sub>/(1+P<sub>2i</sub>)      Tokens will access the matching store.
- n(1-P<sub>2i</sub>)/(1+P<sub>2i</sub>)    Tokens will bypass the matching store.
- nP<sub>2i</sub>/(1+P<sub>2i</sub>)      Pairs of tokens will exit from the matching store.
- n/(1+P<sub>2i</sub>)          Instruction accesses will be made, and executable instructions formed.

$n(1+P_{z_0}-P_{o_0})/(1+P_{z_1})$  Tokens will be produced by the processors, pass through the Switch, and be written to the token queue.

The constraint imposed by the processing unit is that:

$$n/(1+P_{z_1})=3.3 \times 10^6$$

For a typical program it appears, from simulation experience, that the following values of the probabilities are realistic for typical problems.

$$P_{z_1}=0.5$$

$$P_{z_0}=0.6$$

$$P_{o_0}=0.1$$

Using these we see that:

$$n=3.3 \times 10^6 \times 1.5 = 4.95 \times 10^6$$

From this we can derive the following required operation times for the units:

1. *Token Queue Read*—Given by  $1/n=202nS$ .
2. *Matching Store Access*—A token reaching the matching store, requires one read cycle plus one write cycle whether or not it is a successful match. Therefore the times are given by

$$\begin{aligned} \text{Read time} + \text{Write time} &= (1+P_{z_1})/2nP_{z_1} \\ &= 303nS \end{aligned}$$

3. *Instruction Store Read*—Given by  $(1+P_{z_1})/n=303nS$
4. *Switch Operation*—Given by  $(1+P_{z_1})/n(1+P_{z_0}-P_{o_0})=202nS$
5. *Token Queue Write*—Same as Switch Operation= $202nS$

From these figures it can be seen that the storage units must have access times of the order of 200nS to maintain the execution rate of ten processors. This speed can be readily achieved by low cost MOS storage devices currently available.

## ARCHITECTURAL EXPANSION

In order to obtain very high speeds from any parallel computer system it is necessary to exploit parallelism in processing, storage and information transfer. The critical "bottlenecks," particularly in MIMD machines usually appear in the form of crossbar switches, common highways or common stores through which all the processors in the system may wish to communicate. The reason for this can be traced to the need for a processor to demand, and require rapidly, data from any other part of the system. In addition, there is a necessity to control access to data which has yet to be formed; this can also introduce significant communication overheads.

In a data driven environment, a processor is not required

to perform a section of a computation until all the data are presented to it as an executable package. Rapid data access to other parts of the system and access control are then unnecessary. This suggests an architecture containing a mechanism which accepts tokens from all processors and then distributes them to parallel but independent storage and processing resources.

In the Manchester architecture, this can be achieved by extending the input/output switch to become the intersection point of many identical "rings." A strategy is adopted, using the label and instruction address fields, which distributes tokens from different parts of the computation across the parallel rings.

The switch could be a crossbar, but this would suffer from the same problems as in a MIMD machine. Due to the pipelined nature of the rings, the requirement is for a high throughput rate rather than a fast transfer across the switch. A parallel pipelined structure can therefore be used which does not create a "bottleneck" in the system. The prototype will only contain a single "ring" as described previously. The switch will be constructed to enable the connection of further identical rings at a later date.

A more comprehensive description of the implementation and estimated performance of the multi-ring architecture can be found in other literature.<sup>7</sup>

## PROGRAMMING A DATA FLOW MACHINE

This section is intended to provide a brief outline of the methods available for programming a Data Flow machine.

It would seem that the natural way of expressing a directed graph would be via a graphical language, and such languages have been investigated.<sup>12</sup> However, textual languages are far more familiar and it can be argued that features such as data structures are easier to express into a textual form.

One approach is to take a conventional language and translate it into a Data Flow graph. The principles involved in such a translation were originally suggested by Miller and Rutledge.<sup>13</sup> More recently, Whitelock<sup>14</sup> has developed an experimental compiler for a subset of PASCAL which compiles code for the Manchester machine.

Another class of languages, the Single Assignment Languages, are more naturally suited to the expression of parallelism in a Data Flow form. Some of these languages, for example Id,<sup>15</sup> TDFL<sup>16</sup> and LAPSE,<sup>17</sup> have been developed specifically for this purpose. Other similar languages such as LUCID<sup>18</sup> have developed independently with emphasis on the proof of correctness of programs.

It is too early to forecast with certainty which of these approaches will be most fruitful. The Manchester single assignment and conventional compilers produce code for an architecture simulator; they are being evaluated at the present time.

It is certain that a Data Flow machine can be programmed without great difficulty, with no requirement for a knowledge of the underlying architecture which supports the ex-

ecution. The exact form of languages which will gain acceptance is yet to be decided.

## CONCLUSIONS

The expression of computations in data dependent graphical form provides a natural method of determining the parallelism which is present. In the design of practical execution mechanisms, problems exist in the implementation of re-entrant code. An architecture has been proposed which attempts to overcome many of these problems by introducing a label which is carried by every data token. This, together with a pseudo-associative token matching store, results in an architecture which can be constructed at low cost using components which are readily available.

A prototype machine is in the process of design and its performance is being evaluated by simulation. It is not intended that this prototype should be of very high speed but should provide a research vehicle for studies of the potential of Data Flow machines for the solution of real problems. The architecture is extensible by using copies of the basic design and this will proceed if the initial investigations are successful.

No attempt has been made in this paper to address the problems of programming a Data Flow machine. Research is, however, being conducted both at Manchester and many other places which promises to produce high-level languages which will allow a machine independent formulation of parallel programs.

# A view of dataflow\*

by KIM P. GOSTELOW and ROBERT E. THOMAS

University of California  
Irvine, California

## INTRODUCTION

In 1946 John von Neumann outlined an organization for computers<sup>1</sup> that has dominated the languages and architecture of machines to this day—the familiar sequential, one-word-at-a-time instruction stream which modifies the contents of a memory. Although the von Neumann model has proved to be a viable and powerful approach to computation, we have chosen to explore other models of computation to determine if they offer advantages in ease of programming, exploitation of concurrency and performance. A primary motivation is new technology such as large scale integration (LSI) which has greatly expanded the range of choice in computer design.

*Dataflow* is an alternative model of computation which is particularly promising. The basic principles of dataflow are asynchrony and functionality, and thus are in distinct contrast to the von Neumann model. Readers familiar with look-ahead processors<sup>2</sup> such as the IBM 360/91 and the CDC 6600/7600 will find that the principles of dataflow are not new. However, our goals in exploiting the principles of dataflow are of a more fundamental nature than the goals of the above systems. Rather than using dataflow simply to improve the performance of von Neumann processors, we have adopted the semantics of dataflow as the base semantics of our system. A primary reason for this direction is a desire to explore the full generality of dataflow. Another reason, perhaps of greater importance, is our impression that the functional nature of dataflow simplifies the semantics of programming languages and thus may reduce the cost of software (especially in the case of multiprocessor systems). Our approach is first to design a fully-integrated system before attempting to construct hardware. This includes the design of a base machine language, a preliminary high-level language,<sup>3</sup> a user protection facility,<sup>4</sup> and a high-level exception handling facility,<sup>5</sup> all of which are based on the semantics of dataflow.

The following sections discuss details of the principles of dataflow with emphasis on a method of interpretation developed at Irvine. The general version of this interpreter is known as the *unfolding interpreter* and is described in the following section. (Details on a specific unfolding interpreter

are available elsewhere.<sup>3</sup>) The third section presents implementation techniques for dataflow systems while the fourth section discusses some principles of multiprocessor design currently being developed.

## BASIC PRINCIPLES OF DATAFLOW AND THE UNFOLDING INTERPRETER

The present section concentrates on the logical implications of dataflow semantics without regard to physical implementations, efficiency, etc. These latter topics are discussed in later sections.

### *Asynchrony and Functionality*

The following introduces dataflow by showing the correspondence between constructs in the high-level dataflow language *Id* (for *Irvine dataflow*) with schemata in a graphical dataflow machine language. The goal is twofold—first to show by example that programs need not be written in dataflow machine language, and second, to provide some intuition for understanding the execution of dataflow programs. We wish to emphasize that our purpose is to present the basis of dataflow and not to discuss the syntax of a particular dataflow language (*Id*), or the details of a particular machine language.<sup>3</sup>

Consider the following *Id* constructs:

```
s ← (initial sum ← 0
      for i from 1 to n do
        new sum ← sum + f(i)
      return sum);
```

 (2.1)

```
procedure sum (i, k)
  (return (if i > k then 0
           else f(i) + sum(i + 1, k)));
```

 (2.2)  
 $s \leftarrow \text{sum}(1, n);$ 

both of which can be expressed in mathematical terms as

$$s = \sum_{i=1}^n f(i)$$

Statement (2.1) is an assignment statement whose right-hand side is an *Id* loop expression. The statements in (2.2) are a

\* This work was supported by NSF Grant MCS76-12460: The UCI Dataflow Architecture Project.

procedure definition followed by an application of that procedure. Each of these constructs has a number of inputs—a value for  $n$ , a definition for the function procedure  $f$ , and in the case of the sum procedure definition, the value of  $i$ . In addition, both (2.1) and (2.2) produce the same result. We abstract these two definitions of “sum” by considering each to be a “black box” as shown in Figure 1a. Each dark spot in the figure represents the presence of a data item referred to as a *token*. For now, we can consider a data item to be an instance of an integer, real, or boolean value.

The mechanics of computation within a black box can be ignored as long as three conditions are met: 1) a complete set of input values (i.e. tokens) is consumed, 2) the computation within the box has no effect on other computations except perhaps to compete for resources (i.e. there are no semantic side-effects), and 3) a complete set of result tokens is always produced if the computation terminates. A black box meeting these requirements is a *function*. The basis of dataflow is the definition and operation of interconnected functions. One way, for example, to interconnect functions is by composition (Figure 1b). Other dataflow interconnection schemes including cycles have been devised<sup>3,6,7</sup> but are not discussed here.

As opposed to the sequential, one-instruction-at-a-time memory cell semantics of the von Neumann computer, the basic principles of dataflow are:

1. Operations execute when and only when the required operands are available (asynchrony).
2. Operations are functions (there are no side-effects).

These principles imply that the order of execution of two functions, such as  $e$  and  $g$  in Figure 1b, is irrelevant since the computations internal to  $e$  and  $g$  cannot interact. Thus  $e$  and  $g$  can be computed concurrently. Such concurrency, present in the interconnection graph itself, is called *static parallelism*. A more interesting example of the asynchrony achievable in dataflow occurs when a function is executed more than once, either by iteration or by recursion (for example, function  $f$  in (2.1) and (2.2) previously). As shown in Figure 1c, suppose that a dataflow machine replicates the function  $f$  and its input and output lines for as many times as  $f$  is executed. Since  $f$  has no side-effects, each copy of  $f$  can be computed in any order or concurrently. This concurrency is called *dynamic parallelism* since the concurrency potential depends on the number of repetitions (determined at execution time) of the function  $f$ . Dynamic

Figure 1b—Composition of functions

parallelism is of particular interest because it can affect the time complexity of an algorithm. For example, suppose the time complexity of function  $f$  in (2.1) and (2.2) is  $O(m)$  (i.e. assume that  $f$  has an additional parameter  $m$ ). Then on a sequential machine the time complexity of either (2.1) or (2.2) would be  $O(nm)$ . However, on a dataflow machine capable of dynamic parallelism, the processing time complexity would be  $O(n+m)$  because the time required is  $O(n)$  to generate the  $n$  instances of  $f$ , plus  $O(m)$  to simultaneously compute all instances of  $f$  (assuming  $O(n)$  processors are available), plus  $O(n)$  again to sum the resulting values. The total is  $O(n+m+n)=O(n+m)$ , where for simplicity we have ignored some important considerations such as communication conflicts.

It is important to note that the input and output lines of a function are replicated for as many times as the function is executed. This implies that at most one token will ever travel on any given line instance, thus preserving functionality. In addition, the situation shown in Figure 2 is precluded by the “single-assignment rule” present in the high level language.

The replication of  $f$  and its input and output lines does not alone ensure dynamic parallelism since data dependencies in the program may inhibit it. For example, if the previous definition of sum is changed to

```

s ← (initial sum ← 0; x ← 5
for i from 1 to n do
  new x ← f(x);
  new sum ← sum + new x
return sum)
    
```

that is

$$s = \sum_{i=1}^n x_i$$

where  $x_i = f(x_{i-1})$  for  $x_0 = 5$  and  $1 \leq i \leq n$

Figure 1a—Abstraction of the Id construct sum

Figure 1c—Instances of function  $f$

Figure 2—An illegal connection

then the input to  $f$  depends on the value computed by the previous instance of  $f$ . That is, the instances of  $f$  must be computed sequentially.

### The Unfolding Interpreter

Using the simple notions of asynchrony and functionality discussed above, we present an interpreter which manages a *context* for each value produced and consumed in the system. The purpose of context management is to logically separate and direct the values to the proper instance of each function.

At this point we note that other dataflow interpreters have been defined<sup>6,7</sup> which rely on either fixed-size buffers and request/acknowledge communication between functions, or the assumption of an unbounded FIFO queue between each interconnected function. The unfolding interpreter is capable of far more asynchronous operation than these other interpreters because of the function copying it performs.

Each execution instance of a function is called an *activity* and is uniquely identified by an *activity name*. An activity name comprises two parts denoted  $u.l$  where  $u$  is the context part and  $l$  is a unique label referencing the description of the function to be computed by that activity. In addition, the referenced function description specifies the destination labels to be used for transmission of result tokens. A *dataflow object program* is a set of labeled function descriptions. The actions of the interpreter can now be stated:

1. Tokens generated by the execution of activities are grouped by activity name.
2. When the input tokens to an activity become available, the activity is executed according to its description.
3. Output tokens are produced by tagging the values resulting from the execution of an activity with the destination's activity name. The  $u$  part of the destination activity name is derived from the  $u$  part of the activity name of the producing activity according to a set of rules (some examples are given below). The  $l$  part is derived from the output destination information which is part of the description of the function executed by that activity. Note that the act of computing a destination activity name is equivalent to creating a "logical line instance" extending from the producing activity to the destination activity.

To illustrate, consider the dataflow object program in Figure

3a. Let the activity name of an instance of  $e$  be  $u.l$ . The rule for function composition says that the context of the output is identical to the context of the input, and the label of the output is specified by the description of the function being executed, i.e. the program code. This results in activity  $u.l$  producing an output token with destination activity name  $u.t$ . Now consider the case when an activity itself comprises (smaller) activities, for example a procedure call, which is provided for by the base machine language primitives  $A$ ,  $BEGIN$ ,  $END$ , and  $A^{-1}$  as shown in Figure 3b. This figure shows the creation of a new set of activities resulting from the application (call) of procedure  $f$ . Note that the description of procedure  $f$  is one of the input values to the procedure application box. (We will not be concerned here with the representation of procedure values.) Activity name generation for procedure call is as follows:

- *The  $A$  (activate) primitive*—Assume that the activity name of an instance of  $A$  is  $u.l$ . Since the procedure call represents a change in context, the  $A$  primitive "stacks" the context part  $u$  within the new activity name, thereby creating a unique context for the activities within  $f$ . The activity name produced is  $u'.beginf$  where  $u'=u.l$ . Also by convention, the  $A$  primitive groups into one vector value all of the input arguments so that exactly one input argument token is always delivered to the newly created instance of  $f$ .
- *The  $BEGIN$  primitive*—The purpose of  $BEGIN$  is to distribute the input arguments to the activities within  $f$  with no further change in the context  $u'$ .
- *The  $END$  primitive*—The  $END$  primitive "unstacks" the context  $u'$  to reveal the outer context and the label  $l$ . It then constructs the activity name  $u.t$  (the activity to which the result of the procedure is to be returned) which can be accomplished in a number of ways. For example,  $t$  could be computed from  $l$  according to an agreed-upon rule. Also, by convention, the  $END$  primitive combines all output values onto one token for transmission to the  $A^{-1}$  activity.
- *The  $A^{-1}$  (terminate) primitive*—The purpose of the  $A^{-1}$  primitive is to distribute the results of  $f$  to activities in the outer context with no further change in the context  $u$ .

Though not presented here, other schemata for the un-

Figure 3a—a Composition of functions

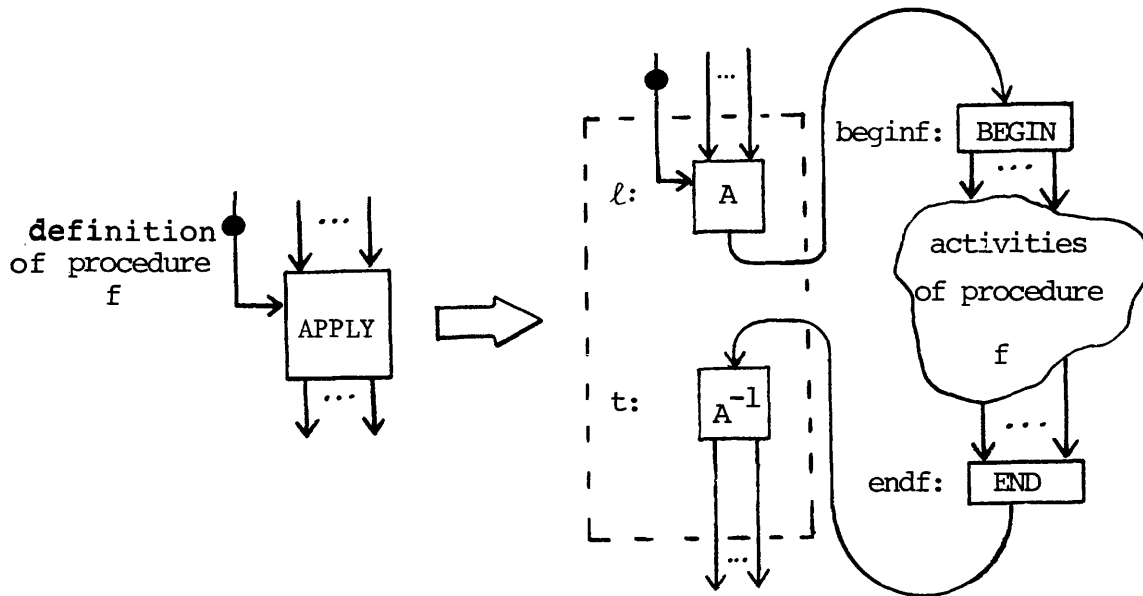

Figure 3b—Application of procedure f

folding interpreter have been devised.<sup>3</sup> In particular there is a *loop schema* which “unfolds” the loop body (including nested loops) to expose dynamic parallelism. (The unfolding interpreter gets its name from this capability.) The loop schema depends on adding a new field, *i*, to the context part of an activity name to yield (u.i).*i*. Like recursion, each iteration of a loop exists in a distinct context generated simply by incrementing the *i* field in the activity name.

IMPLEMENTATION SCHEMES

In this section we discuss techniques for efficient implementation of dataflow. Although von Neumann computers may be used to implement these techniques within a dataflow system, we rigidly maintain that the semantics of dataflow are the only semantics visible external to the system—a principle we consider vital to the success of dataflow.

*Dataflow Structures and Memory*

Operation of the unfolding interpreter requires many copies of program code. Logical copies are sufficient and can be created simply by copying the pointer to a physical copy since all code (and data) is read-only. (Note that the label *l* in an activity name is equivalent to a pointer.) Of course in a multiprocessor environment, having just one physical copy may imply a bottleneck. In this case, we consider it the responsibility of a particular implementation to selectively make physical copies (in distinct memories) to reduce the bottleneck.

Similar remarks hold for the transmission and replication of values larger than simple integers, reals, booleans, etc. The need for logical copies is especially evident when a

value, such as an entire matrix, is transmitted between two functions and the receiving function utilizes only a small part and discards the rest. Also, a common programming task is the production of a data object which differs in only small ways from another (perhaps large) input data object. Because dataflow values can never be modified, an entire new object must be created, making the straightforward copy-all approach quite expensive.

Dennis has shown<sup>6</sup> that the amount of copying can be reduced by properly defining a SELECT and APPEND operation on “structured” data residing in a conventional memory. A *dataflow structure* is a set of (selector:value) pairs where a *selector* is an integer or string and a *value* is any dataflow value (including another structure). A dataflow structure is always a tree (e.g. Figure 4a). The SELECT function (subscripting) has two arguments, a structure value and a selector, and it yields the value at the specified selector. The APPEND function has three arguments: a structure value, a selector, and a value to be appended to the given structure at the specified selector. APPEND does *not* modify the given structure but instead makes a logical copy of it with the new selector and value appropriately placed. This

Figure 4a—A dataflow structure

Figure 4b—APPEND ( $\alpha, s, \gamma$ ) $\rightarrow\beta$

can be implemented (with pointers) such that a physical copy need be made only of the “top level” of the original structure value. Thus sub-structures can be shared between any number of structure values without violating dataflow semantics. A simple example is given in Figure 4b where both structures (logical trees) physically share the sub-structure at selector r.

Since the definition of dataflow structures precludes the construction of internal cycles, a simple reference count scheme can be used to reclaim structures no longer needed. The reference count method is also helpful in detecting the special case of an APPEND to a structure when there is only one logical copy of that structure (i.e. reference count equals one). In this case APPEND can quickly produce its output by simply updating the old structure in place.

In the following we consider several explicit representations for dataflow structures. When a dataflow structure has contiguous integer selectors, a vector of contiguous memory words may be used where one value (or a pointer to a value) is stored per memory word. This is termed *array* representation. It is easy to see that in array representation a (one level) SELECT can be done in constant time while APPEND requires  $O(n)$  time (for copying), where  $n$  is the number of words in the result memory vector.

A second representation, termed *selector vector*, is a fairly compact representation when string or sparse integer selectors appear in the dataflow structure. Again a contiguous memory vector is used but the (ordered) selectors are explicitly stored with the values. SELECT can then be done in  $O(\log n)$  time using a binary search while APPEND requires  $O(n)$  time where  $n$  is the number of selectors.

A third representation of a dataflow structure is a modification to a “balanced” tree scheme such as an AVL tree, B-tree, or B\*-tree.<sup>8</sup> In the following we have selected a

specific B-tree, the 2-3 tree, to illustrate the concept. A 2-3 tree is a tree in which every vertex that is not a leaf has either two or three sons, and every path from the root to a leaf is of the same length.<sup>9</sup> A dataflow structure and its 2-3 tree representation is given in Figure 4c. Each internal vertex of a 2-3 tree contains the value of the largest selector appearing in its sub-tree. These values are used in the SELECT (and APPEND) operation to guide a modified binary search requiring  $O(\log n)$  time, where  $n$  is the number of leaves in the tree. APPEND can also be done in  $O(\log n)$  time,<sup>10</sup> where none of the vertices of the original tree are disturbed (except perhaps for reference counts) and most of the original 2-3 tree is shared between the argument and result structures without affecting functionality. The 2-3 tree representation also promotes efficient concatenation of dataflow structures (an operation quite useful in programs such as quicksort, fast Fourier transform, etc.) with constant time required in the best case and  $O(\log n)$  time required in the worst case, given certain restrictions are met in the input structures.<sup>10</sup> However, a significant disadvantage with 2-3 tree representation is the extra memory required for the internal vertices of the tree; and while asymptotic behavior is good,  $O(\log n)$ , the constant factor in the equation also could be significant.

The reader may note that the design of an efficient dataflow memory system involves problems (i.e. memory management, garbage collection, choice of representations, etc.) which also occur on conventional systems. Currently these tasks are reprogrammed to some extent by each application program that is written. Our feeling is that by embedding these tasks within the system as close to hardware as is practical, a significant burden is removed from the application programmer, and if a good design is obtained, average performance will improve.

Figure 4c—Dataflow structure represented as a 2-3 tree

### *Implementation of the Unfolding Interpreter*

One problem with the theoretical unfolding interpreter is the unbounded length of activity names, the primary purpose of which is to logically separate the tokens so that the inputs to each copy of each function are uniquely determined. For this purpose a unique number,  $N$ , for each context combined with the label  $l$  is sufficient. For example, starting with activity name  $N.l$  for the  $A$  activity in Figure 3b, the context is changed by obtaining a new unique number  $N'$  to form activity name  $N'.beginf$ . In addition, an association is made in memory between  $N'$  and the activity name  $N.t$ ; alternatively a token carrying  $N.t$  can be sent from the  $A$  to the  $END$  activity. In either case, the return from the inner context is accomplished by the  $END$  activity which fetches the information  $N.t$  associated with the number  $N'$  and uses it as a logical "return address" to the outer context.

The major question in this approach is the method of generating and managing the unique numbers. If enough bits (say, 60) are used to store  $N$ , uniqueness of  $N$  can be guaranteed to extend over the life of the system. However, if the system guarantees that none of the activities (and their associated tokens) exist from the previous use of  $N$ , a value  $N$  can be reused and significant savings achieved. This is generally not a problem in context management on sequential machines; however, due to the asynchrony of dataflow it is possible, for example, that an  $END$  activity finishes execution before all of the activities in the procedure have finished, even when the system guarantees that all such activities will eventually finish. One workable solution is to prevent  $END$  from finishing execution before all other activities and tokens of that procedure application have been consumed. With this restriction, a simple scheme such as a tree of stacks (cactus) can be used to implement unique number management with reusable names.

A second problem with the unfolding interpreter is the requirement for system-wide unique labels for object code. As is common in conventional systems, a tree-structured directory system with path specifications may be used to implement dataflow labels. If desired, path specifications can be included within activity names. For example,  $l$  can be split into two fields  $p.s$  where  $p$  is a pointer to a procedure and  $s$  is a function (statement) number in that procedure.

### MULTIPROCESSOR DESIGN PRINCIPLES

Although dataflow principles can be advantageously applied to conventional systems, we believe that new concepts in computer architecture must be developed to take full advantage of the concurrency and functionality of the dataflow model. This final section is largely speculative because of the difficulty of accurately predicting the performance of proposed architectures. However, we have simulated variations of a specific dataflow architecture and the results are reported in detail elsewhere.<sup>11</sup> Moreover, since the design of this architecture contains much detail and changes rapidly, we summarize our experience with it in the form of tentative principles for the design of one

possible form of dataflow machine. These principles are not new and have been applied to many systems. However, such a statement serves as a point of comparison with other views.

Our goal is to design a general purpose computing system which

1. Can effectively distribute small pieces of a computation over many processors in the machine;
2. Is modular enough so that additional blocks of processors can be easily added to increase the capacity of the machine;
3. Has a measure of fault tolerance so that hardware failures may decrease performance but will not necessarily halt the machine (i.e. fail-soft);
4. Does not require knowledge of the number and configuration of processors to write programs which effectively utilize these resources;
5. Does not depend on expensive interconnection schemes (e.g. crossbar switch) or extremely fast circuit speed for good performance;
6. Can support a number of simultaneous users.

The first principle of multiprocessor design (evidenced by simulation results) is the program-dependent tradeoff between distribution and localization of computation. Distribution may allow concurrent execution of a program, but it also tends to increase communication costs. Thus for any particular architecture and computation, there exists some optimal degree of distribution (perhaps as little as one processor) for which execution time is minimized. Locality (e.g. "the working set" in paging systems) is an established principle of conventional systems. Moreover, we believe that locality will be present to an even greater extent in dataflow due to the absence of side-effects and due to the high degree of structure imposed by our high level dataflow language. To take advantage of locality, we must consider two features of a dataflow system: 1) how the topology of the architecture allows reduced communication costs when physical locality is present and 2) how program locality is preserved in the mapping to physical hardware.

One topology which supports locality is a hierarchy of modules. For example, a primitive module could be a processor with memory which can execute any dataflow machine language instruction or group of instructions, including an entire dataflow program (the extreme case of locality). Primitive modules are connected to form larger modules which are then connected, etc., such that any module can be considered to consist of some processing power and some associated memory. This structure supports locality to the extent that communication within any given module can be made less costly than communication off the module.

A second aspect of locality is the mapping of program locality to physical locality in the machine. Assume each processor in the machine to have a distinct physical address. We have found that the activity names themselves constructed by the unfolding interpreter contain much of the locality information present in the source program. For example, activity names with the same context part belong to

the same instance of a procedure (or loop). In addition, the labels  $l$  in the object program can be assigned by the compiler such that numerically-close labels suggest close connection of functions. These pieces of information can be used by an activity *assignment function* which maps from logical activity names to physical processor addresses. The resulting physical address is placed on each output token to guide its transmission in the communication network. The selection of an appropriate assignment function is similar to the problem of selecting an appropriate hash function for a scatter table but with the additional consideration of preserving locality where appropriate. Note that the assignment function and the communication network perform a partial sorting of activity names by physically directing tokens to their destinations. The final sorting is done by each processor on only those activity names which map to its physical address.

As a practical matter, designing a fairly good assignment function which distributes computation while preserving locality is not too difficult to do (at least for the small selection of programs we have executed on our simulator). However, the selection of an optimal assignment function is a difficult problem requiring further investigation. We also note that it is possible for the machine to tune its assignment function(s) at execution time for improved performance.

The second principle of multiprocessor design we have adopted is that the communication delay (ignoring conflicts) between any two processors should be no more than  $O(\log n)$  where  $n$  is the total number of processors. If we rule out complete interconnection schemes, this principle also suggests a hierarchical interconnection of modules. However, a tree is not the only structure with the  $O(\log n)$  property. Two other examples are the boolean  $n$ -cube<sup>12</sup> and the interconnection network of Wittie.<sup>13</sup> Both of these networks can be viewed as trees in which sufficient additional connections have been made such that the root node has become indistinguishable. (In other words, pick any node in the network; then appropriate connections can be deleted so that a tree remains.) Although much investigation remains to be done before selecting a particular interconnection network, we feel that a more highly connected structure than a tree is appropriate for two reasons: 1) the extra connections provide some measure of fault tolerance and 2) more flexibility is allowed to map the logical tree structure of many programs into the many physical trees present in the network. Currently we are favoring a modification of the Wittie network due to its lower implementation cost.

The last principle of multiprocessor design is recognition of the potential benefits of redundant copies of data and program code. Conventional systems have already developed this concept to some extent, primarily in the area of virtual memories and high speed caches. However, dataflow can take further advantage of redundant copies because values are never modified. We have three goals in pursuing the concept of redundancy: 1) to improve performance through concurrent access of data in distinct memories, 2) to improve performance through a caching scheme which localizes data to where it is most used, and 3) to identify each data copy so that if one copy is damaged, a search can

be instituted to obtain another valid copy. For those readers interested in possible mechanisms to achieve some of these goals, Reference 11 should be of some help.

## CONCLUSIONS

The decision to incorporate the full generality of dataflow is not without its costs. We have seen that the principles of dataflow sometimes suggest implementations which make "inefficient" use of memory. Of course better implementations may yet be found but we suggest that problems with memory be viewed in the context of the following points: 1) the full generality of dataflow is not always required—for example a program like matrix multiplication can be executed within the semantics of dataflow and still require little more memory than does a conventional machine, 2) duplication of data and code can have various benefits such as concurrent memory access and the possibility of recovering from hardware faults, and 3) the cost of hardware and memory is decreasing while the cost of software and system failures will probably continue to increase. Thus in a few years the "efficient" use of memory in many situations might be viewed quite differently.

An introduction to dataflow is not complete without mentioning other issues and capabilities. Dataflow *streams* and *managers* are available to program history-sensitive applications such as airline reservation systems, resource management, etc. directly in a high-level language;<sup>14</sup> in addition, abstract data types are available.

# A hardware-independent virtual architecture for PASCAL\*

by VISWANATHAN SANTHANAM

Wichita State University  
Wichita, Kansas

## INTRODUCTION

Since its introduction in 1971, PASCAL language has received rapid acceptance as a structured programming tool in a wide variety of applications ranging from computer science education to systems programming in production environments. It is, therefore, not surprising that numerous reports relating to implementation of PASCAL compilers on various computers continue to appear in the current literature (References 1,4,6,12 for example). Many of these implementation reports relate to adapting an existing compiler to another computer. In many instances, these compilers are themselves written in PASCAL which makes it easy to adapt them using one of these procedures:

1. Implement the target machine of the original compiler as a virtual machine in the current hardware by means of an interpreter or microprogram. Now, the original compiler and its output can be executed on the current machine.
2. Alternatively, change the code generation phase of the original compiler to generate object code suitable for the current hardware. Then cross-compile the modified compiler (under the original compiler) and transport the object code to the current computer.

The second alternative is superior if efficiency is important. In fact, many implementors take a two-phase approach whereby the compiler is adapted quickly by the first approach, and it is refined later by the second approach to achieve better performance. When such a transition is made from the original virtual machine code to a more suitable object code, the best choice is not always the native instruction set of the present hardware. There are a number of situations where another virtual machine may be a better choice. For example, the hardware may be microprogrammable, in which case a well designed virtual machine could not only yield compact object programs but could also lead to better execution speeds. Another situation where virtual machine code may be preferred over native code is where a number of small PASCAL programs execute concurrently and interactively. This latter situation arises in instructional

environments where object code compactness and diagnostic capabilities outweigh execution speed.

The objective of this paper is to present a virtual machine design for PASCAL without basing the design on any specific hardware. The abstract machine is called VAMP for "Virtual Architecture Made for PASCAL," and its features are based on the PASCAL language, but they may also be adapted for use with other similar languages, such as ALGOL, SAL<sup>13</sup> and BCPL.<sup>11</sup>

There are a few other virtual architectures, some reported in the literature while the others are handed down from one implementor to the next, which are designed expressly for PASCAL-like languages. Notable among these are the P-machine<sup>10</sup> and, more recently, EM-1.<sup>13</sup> The P-machine is based on a 30-bit word-oriented processor, and it does not lend itself for efficient adaptation to other computers, such as the IBM 360/370. Nevertheless, many of the present PASCAL compiler implementors have adapted it in some form or the other due to the availability of a well written well documented compiler generating code for it. The architecture of EM-1 is also hardware-dependent to the extent that the code address space is assumed to be organized into eight-bit bytes. A more important difference between EM-1 and the current work is in the basic objectives. EM-1 is an architecture to match the needs of PASCAL-like languages and minimize the object code size of programs within the constraints of a specific underlying hardware. VAMP is an abstract machine designed only to match the needs of PASCAL-like languages, regardless of the hardware used to implement it. An implementor of VAMP has the choice to trade code size for execution speed, execution speed for firmware size and so on. Furthermore, VAMP is designed to meet the needs of full PASCAL language and not a typical subset of it. Once again, an implementor may omit selected features of VAMP if only a subset of PASCAL is to be implemented.

Despite the differences in the basic objectives, many of the architectural features of VAMP were motivated by similar features in these other virtual machines. In fact, as we point out in the section on implementation guidelines, an efficient implementation of VAMP will perhaps incorporate many of the ideas contained in the descriptions of these virtual machines.

The hardware-independent virtual architecture and the rationale for the design choices are presented in the next

\* This research was partially funded by a grant from the Wichita State University Research Committee.

section. Some guidelines on how to adapt VAMP for a specific hardware are included in the third section of this paper.

## ORGANIZATION OF VAMP

We describe in this section the organizational details of an abstract machine called VAMP for "Virtual Architecture Made for PASCAL." As the name implies, the features of VAMP are oriented specifically toward efficient support of PASCAL. However, because of the many similarities between PASCAL and other block-structured languages such as ALGOL, it is possible to adapt many of the features of VAMP for use with these other languages as well. The reader is assumed to have basic familiarity with PASCAL or a similar language. An excellent treatment of PASCAL can be found in References 14 and 9. Features of concurrent PASCAL are outlined in Reference 3.

The description of VAMP to be presented in this section is hardware-independent. The unit of memory, the forms of data representation, the number and purpose of hardware registers and other similar details regarding the processor on which VAMP is to be implemented, are unspecified. Of course, these and other hardware characteristics of the processor will determine the performance of VAMP, but they do not dictate the feasibility of implementation.

The term "efficient support," used earlier in this section, needs elaboration. The primary concerns of a language-based virtual machine design include (a) ease of compiler implementation, (b) object code compactness and (c) speed of execution. By design, there is a direct correspondence of features between VAMP and PASCAL. This correspondence significantly reduces the complexity of a compiler by eliminating the need for complex register and storage assignments that other compilers may need. At the same time, the design allows compilers to make trivial optimizations, such as combining a conditional branch with a preceding test, to reduce number of instructions. Also, by design, the number of object instructions per source statement is much smaller for VAMP than for a processor with a general-purpose instruction set. Such a low ratio of object code to source statement assures a certain degree of object code compactness regardless of the underlying hardware. In addition to this, the implementor can usually trade object code size for execution speed and vice versa, which is another degree of freedom that a virtual machine designed for a specific hardware does not provide.

An added advantage exists when a hardware-independent virtual machine is chosen as the target machine for compilers. Programs can be compiled into truly portable "object code" (as opposed to intermediate code that must be processed by a non-trivial translator) that is readily assembled into executable code for a specific implementation of VAMP.

### General features

VAMP has five address space types that are accessible to a program. These are identified as CODE, PARM, DATA,

STACK and HEAP. There is one occurrence each of the CODE and HEAP spaces per program, whereas there is one occurrence each of the PARM, DATA and STACK spaces per active block. (An "active block" is one whose procedure has been called but has not returned yet.) The CODE space contains object instructions and constants. The reason for not providing an independent 'constants' space is to allow separate compilations of procedures. The HEAP is intended for dynamic allocation of variables through the use of the PASCAL data type *pointer*. A PARM space contains the actual parameters of the block; a DATA space contains the local variables; and a STACK serves as the work area for the procedure. The size of the CODE space is fixed. The sizes of PARM and DATA spaces of a given block can be determined at compilation time. An estimate of maximum size for a STACK space can be determined at the time of activation of the block. The size of HEAP is not specified by the program, but it is usually determined by the availability of memory in the operating environment.

It is not intended that these address spaces be allocated and managed independently. A typical implementation may integrate these address spaces into a single partition of memory (See References 1,10,13 for example). Because of this, we assume that every address space is realized from the same basic memory which is made up of *cells*. The size of a cell is unspecified, but it must store at least two distinct values. It is required that the cell be effectively addressable. Direct addressability in hardware, though not a requirement, should yield better performance.

The rationale for introducing five different address spaces is that it provides higher flexibility in compiling PASCAL programs and it divides information into logical compartments. CODE space, for example, may be write-protected. Though PARM and DATA spaces are fixed in size for a given block in PASCAL, some special procedures (such as READ, WRITE etc.) may be written to handle a variable number of parameters. VAMP allows for this possibility. Similarly separating STACK space from DATA space allows the allocation of dynamic arrays at block entry time. These features are not standard in PASCAL, but we anticipate the need for some non-standard functions in most systems for better efficiency or for being able to interface with external non-PASCAL environments.

### Data representation

VAMP implements five basic data types—*integer*, *natural*, *real*, *pointer* and *packed naturals*. All these types, except the pointer, may have one or more variable size representations in memory. The size of a variable length data item will be specified in the address used to access it (see *operand addressing* in this section). The minimum size for the types integer, natural and real is one cell. The maximum sizes, also called *standard sizes*, for these types are set by the implementor. For elements of the packed naturals type the minimum size may be a fraction of a cell, and this too is determined by the implementor. The maximum size for an element of this type is the same as that of the type

natural. The variable size representations just described apply only to addressed operands; operands on any stack are always represented in their standard sizes. Furthermore, there are well defined procedures for conversion of a data item from one size to another.

Integers and reals are defined in the traditional manner with well defined procedures for the usual conversions in both directions. Natural is an unsigned integer with the requirement that its standard size representation be identical to the standard size integer with the same magnitude. Once again, well defined procedures are provided for conversion from a natural to integer, and from a non-negative integer to natural.

With the exception of the type *pointer*, all the basic data types of PASCAL (all scalars, their sub-ranges and reals) are to be implemented with the integers, naturals and reals of VAMP. The rationale for variable size representations of these types is based on this principle. This is essential if we wish to achieve reasonable storage efficiency when representing such a wide range of basic types with the small set of VAMP data types. If an implementor chooses a fairly large unit of storage (e.g., 16 bits or more) as the cell, then there will be less need for variable size representation. On the other hand, if the cell is chosen to be a small unit of memory (say, eight bits or less) better packing of data in memory can be achieved, but variable-size representation is inevitable. VAMP design leaves the choice up to the implementor by specifying one as the minimum number of representations to be implemented in each category.

Even after judiciously choosing an 'optimal' size for a cell, an implementor may find it hard to pack data satisfactorily, especially in relation with *packed arrays* of PASCAL. For example, the choice of an eight-bit byte for the cell may satisfactorily implement most basic data types, but it may be unsuitable for implementing a packed array of booleans, or a packed array of scalar such as (MON, TUE, WED, THU, FRI). The need for efficient packing also arises in conjunction with the common implementation of the PASCAL type *set* as a bit map (or packed boolean array). VAMP provides for the type packed naturals to achieve a higher level of storage compaction in these cases at the expense of packing and unpacking overhead at run time. The number of direct manipulation facilities is also limited when an array of naturals is so packed.

The VAMP pointers are used for two main purposes. They implement the PASCAL type *pointer* and also represent *var* parameter in procedure calls. A VAMP pointer is required to be of fixed size and capable of representing an address in any of the currently active address spaces. This includes the CODE space, the HEAP space, the DATA, PARM and STACK spaces of all active blocks. The implementor may place a limit on the number of such active blocks to be allowed.

#### *Operand addressing*

When an instruction needs an operand it is located by an *address*. The VAMP address may locate an operand either

as an *immediate* operand or by identifying an address space and a cell offset. An immediate operand may be in-line, following a suitable prefix in the address, or it may be obtained by popping the current stack top element. The former mode is useful in compiling operand references to small constants whereas the latter mode provides a powerful method for realizing single and zero-address operations from a standard two-address or one-address instruction. For example, VAMP includes only one "store integer" command with two addresses—one for the source operand and the other specifying the destination in memory. The same instruction can also "pop" the current top of stack integer to memory by simply specifying a "stack-top-immediate" mode for the source operand. This is not only intended to reduce the size of the interpreter needed to implement VAMP, but also yield compact object programs as this facility is available to all operations that use addressed source operands. The potential increase in the size of addresses themselves can often be eliminated by judiciously encoding the address modes.

An addressed operand (as opposed to an immediate operand) may reside in any of the address spaces that are directly accessible to the current procedure. This includes the CODE space, the current STACK space and the DATA and PARM spaces of the most recently activated blocks at lexicographic levels lower (outer) or equal to the current level. (Operands on the other stacks are strictly local to the blocks owning them, while operands in the HEAP space can only be accessed via pointers). This means that a VAMP address need only reference  $2^{*n}+4$  address spaces while executing a procedure at level  $n$  (counting from 0 for the program level). The implementor may place a limit on the maximum value for  $n$ .

A memory operand may also be addressed indirectly by a VAMP pointer. In this mode of addressing, known as *indirect addressing*, the final operand may reside in any of the currently active address spaces. However, the pointer itself must reside in one of the directly addressable spaces or be popped from the current stack top. (There is no provision for "in-line immediate" pointers, as PASCAL doesn't provide for pointer constants other than *nil*). It should also be noted that there can only be one level of indirect addressing in any one address computation as a pointer is not capable of indicating an indirect mode.

In all cases except when the operand is obtained as an immediate operand from the stack top, the address also includes an operand size indicator. The number of different sizes represented in an address may vary depending on the operand type that it locates and it is determined by the implementor. This freedom to choose many different lengths for one type (say, natural) and possibly only one length for another type (say, real) makes VAMP design a flexible one without adding unconditional overheads to the interpretation process. In the case of indirect addressing, the size information in the address applies to the final operand, not the intermediate pointer. This is why VAMP pointers are required to be of a fixed size.

Independent of how the final address is arrived at, the cell offset of that address may be modified by adding a natural

called *index*. If indexing is indicated in the address, the current stack-top natural is popped and saved before proceeding further with the address computation. As in the case of indirect mode, only one level of indexing is permitted in VAMP. If both indexing and indirect addressing are specified only the final operand address can be indexed in one operation. This design favors object code compactness for the more common cases of *var* parameter arrays and pointer-based arrays over the case of array of pointers.

The reason for popping the index value from the current stack top rather than deriving it from an "index register" is many-fold. Since all arithmetic is carried out on the current stack-top, the index value is resident on stack-top to begin with. Furthermore, the introduction of an index register will require the implementor to come up with equivalent hardware features on his machine to implement VAMP. Such features may not exist in his machine. Even if high-speed registers are available in the hardware they could be better used as extensions of the stack top rather than set aside for indexing only. On the other hand, if the hardware includes registers that are intended for the sole purpose of indexing, the VAMP interpreter could still "pop" the index values to those registers and carry out the final indexing from there. Finally, the lack of need for complex register assignments takes a major burden off the compiler.

The various formats of a VAMP address are depicted in Figure 1 as a "variant record" tree. The nodes represent tag

fields and information fields, and the branches discriminate the cases of tag fields. It should be pointed out that the variant record representation is merely a way to illustrate the various address modes of VAMP, not a required implementation scheme.

*Instruction formats and execution*

The object instructions of a PASCAL program reside in the CODE space of VAMP. There is a "register" in VAMP called PC (for Program Counter) that contains the cell offset of the next instruction. The VAMP interpreter always refers to this register to locate the next instruction to execute.

Each instruction begins with an *opcode* which defines the operation. There may be additional fields following the opcode depending on the functions. These fields may be *literal fields* or *address fields*.

A literal field provides the value of an instruction parameter directly in-line. Typically these are integer and natural fields, represented by *I* and *N* respectively, whose values are known at compilation time. Each literal field is of a pre-defined length set by the implementor. An address field is a VAMP address whose format was described in the preceding subsection.

It is not required that the individual subfields of an instruction be some integral number of cells in length, even though such an implementation may significantly reduce the chores of interpretation. It is, however, required that the total length of any instruction be an integral multiple of cells, as the PC is not capable of addressing subunits of a cell.

The execution of a VAMP instruction proceeds in two phases—*fetch phase* and *execute phase*. The fetch phase is always completed before the execute phase begins. In the fetch phase, the current instruction is scanned from left to right 'decoding' individual fields as they occur. Decoding here means extracting literal fields into some standard length internal registers, evaluating address fields, and fetching the operands or simply computing an effective address, whichever is needed by the operation. Table I lists all the instructions of VAMP using a special notation which is described below.

The "fields" column of the table lists the component fields of an instruction. The order of the fields is important as is the mnemonic used to describe it. Table II provides a complete list of field mnemonics and the associated fetch phase functions they involve. For example, an *AI* refers to an addressed integer source operand. An *SI* refers to an integer operand storage address; that is, an immediate value may not be returned from address computation. Sometimes a trailing decimal digit is appended to a field mnemonic to distinguish it from another field of the same type within the same instruction.

The column labeled "function" outlines the execute phase functions of an instruction. The symbol "←" stands for assignment of value to an operand in storage. The notation "(SI)←AI" stands for "assign the integer value AI to memory location SI." The term *itos* refers to the integer which is currently at the top of the stack. Similarly *ntos*, *rtos* and

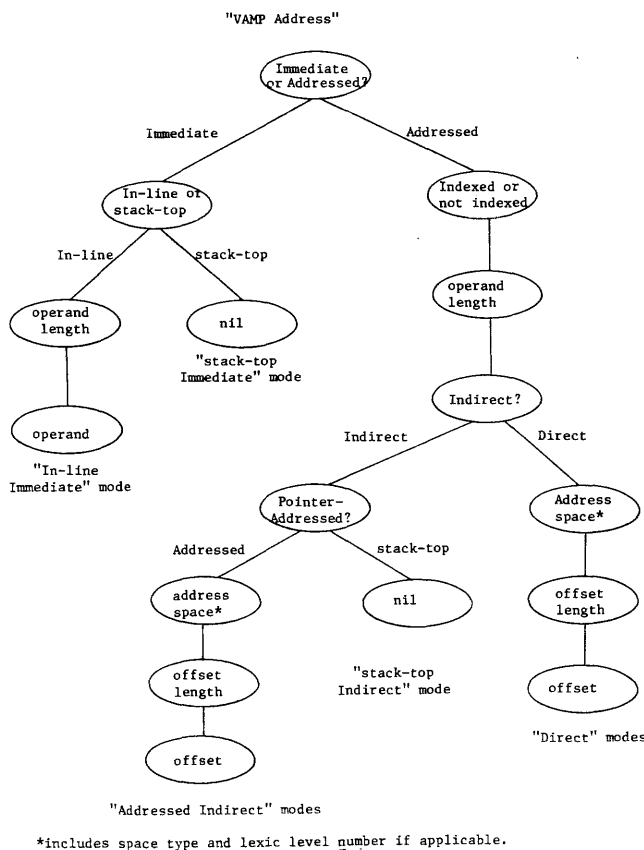

Figure 1—Address modes for VAMP.

TABLE I

Opcode Mnemonic	Opcode Description	Fields	Function
<b>Arithmetic Group</b>			
ADD	Add	AI	$itos \leftarrow itos + AI$ .
Similarly SUB, MUL, Div (real result), IDIV (integer quotient), MOD; and ADDN, . . . , MODN for naturals			
ABS	Absolute	AI	$iPush( AI )$ .
Similarly NEG (negate); NEGN (negate natural).			
ADDR	Add Real	AR	$rtos \leftarrow rtos + AR$
Similarly SUBR, MULR and DIVR.			
ABSR	Absolute Real	AR	$rPush( AR )$ .
Similarly NEGR.			
EQS	Equal?[Skip]	I.AI	If $I < > 0$ then [if $ipop=AI$ then $PC \leftarrow PC + 1$ ]; else [if $ipop=AI$ then $nPush(1)$ , else $nPush(0)$ ].
Similarly NES, LTS, GES, GTS and LES; and EQNS, NENS, . . . , LENS for natural operands.			
Also, EQRS, NERS, . . . , LERS for real operands (with "AI" replaced by "AR" and "ipop" by "rpop").			
ITOR	Integer to Real	AI	$rPush(AI \text{ converted to real})$ .
Similarly TRUNC and ROUND for a real operand AR.			
SUBTIS	Subscript Translate Integer[skip]	AI.SX.I	SX: points to a record of i1: integer (lower bound), all of predefined i2: integer (upper bound), lengths. n3: natural (multiplier). If $AI < i1$ or $AI > i2$ then; else [ $nPush((AI - i1) * n3)$ ; $PC \leftarrow PC + 1$ ].
Similarly SUBTNS for a natural operand AN.			
<b>Logical Group</b>			
ANDS	And?[skip]	I.AN	If $I < > 0$ then [if $npop$ and AN then $PC \leftarrow PC + 1$ ]; else [if $ntos$ and AN then $ntos \leftarrow 1$ , else $ntos \leftarrow 0$ ].
Similarly ORS.			
NOTS	Not?[skip]	I	If $I < > 0$ then [if $not$ $npop$ then $PC \leftarrow PC + 1$ ]; else $ntos \leftarrow not$ $ntos$ .
SKT	Skip on True	I	If $npop$ then $PC \leftarrow PC + 1$ .
Similarly SKF.			
<b>Data Movement Group</b>			
PUSHI	Push Integer	AI	$iPush(AI)$ .
Similarly PUSHN, PUSHR, PUSHP (Push Pointer).			
PUSHPN	Push Packed Natural	AN.SPN	$nPush(elem(SPN)[AN])$ .
STORI	Store Integer	AI.SI	$(SI) \leftarrow AI$ .
Similarly STORN, STORR, STORP.			
STORPN	Store Packed Natural	AN1.AN2.SPN	$elem(SPN)[AN2] \leftarrow AN1$ .
STISIS	Store Subrange Integer[Skip]	AI.SI1.SI2.N	SI1 points to an array of two integers i1; Lower bound, i2; upper bound. If $AI < SI1$ or $AI > SI2$ then; else [ $(SI2) \leftarrow AI$ ; $PC \leftarrow PC + N$ ].
Similarly STSNS (Store Subrange Natural [Skip]).			
MVC	Move Cells	SX1.AN.SX2	For $j:=0$ to AN-1 do $cell(SX2)[j] \leftarrow cell(SX1)[j]$ .
PACKN	Pack Naturals	SN.AN.SPN	For $j:=0$ to AN-1 do $elem(SPN)[j] \leftarrow elem(SN)[j]$ .
Similarly UNPKN.			
EQCS	Equal Cell String?[Skip]	SX1.AN.SX2.I	$temp \leftarrow (cell(SX2)[j] = cell(SX1)[j])$ for $j:=0$ to AN-1); If $I < > 0$ then [if $temp$ then $PC \leftarrow PC + 1$ ], else $nPush(temp)$ .
Similarly NECS, where "temp" is replaced by "not temp" in the 2nd step of function.			
GTCS	Greater Cell String?[Skip]	SN1.AN.SN2.I	$temp \leftarrow ($ for some $0 \leq k \leq AN-1$ , $cell(SX2)[k] > cell(SX1)[k]$ and $cell(SX2)[j] = cell(SX1)[j]$ for $j:=0$ to $k-1$ ); If $I < > 0$ then [if $temp$ then $PC \leftarrow PC + 1$ ], else $nPush(temp)$ .
Similarly LTCS.			
Also, GECS and LECS with $temp \leftarrow$ condition for GTCS (LTCS) or condition for EQCS.			
Similarly EQPNS, NEPNS, GTPNS, LTPNS, GEPNS and LEPNS for packed natural strings with SN1, SN2 replaced by SPN1, SPN2 and "cell" replaced by "elem"			
INCPNS	Inclusion Packed Natural?[Skip]	SPN1.AN.SPN2.I	$temp \leftarrow (elem(SPN2)[j] \geq elem(SPN1)[j])$ for $j:=0$ to AN-1); If $I < > 0$ then [if $temp$ then $PC \leftarrow PC + 1$ ], else $nPush(temp)$ .
Similarly EXCPNS with ">=" replaced by "<=".			
DIFPN	Difference Packed Natural	SPN1.AN.SPN2	For $j:=0$ to AN-1 do $elem(SPN2)[j] \leftarrow elem(SPN2)[j] - elem(SPN1)[j]$ .
Similarly UNIPN (union packed natural) and INTPN (intersection packed natural) with ">" replaced by "or" and "and" respectively.			

TABLE I.—(Continued)

Opcode Mnemonic	Opcode Description	Fields	Function
<b>Flow Control Group</b>			
SKIP	Skip	I	PC←PC+I.
BRA	Branch Absolute	AN	PC←AN.
FORUP	For Up	N	Top of stack contains i1,i2: integers with i2 on top. if i1≤i2 then[iPush(i1); i1←i1+1] else [ipop;ipop; PC←PC+N].
Similarly FORDN.			
CASEI	Case Integer	SI	SI locates an array of records of n1: natural of predefined length, n2: natural of predefined length, il: array [1 . .n1] of integers of length specified by SI. temp:=ipop; j:=1; repeat PC←PC+n2[j]; for k:=1 to n1[j]do if il[j,k]=temp then exit until n1[j]=0.
Similarly CASEN (Case Natural).			
<b>Procedure/Function Linkage Group</b>			
Note: The statements regarding procedures in this group apply equally to functions except when noted otherwise.			
CALL	Call Procedure	SX	SX points to record of naturals of predefined lengths, n1: lexicographic level number of target procedure. v n2:offset in CODE space of target procedures entry point. If n1≤current procedure's lexicographic level number then all PARM, DATA and STACK spaces at the levels n1 through current are saved and made unavailable to the target procedure. The current value of PC and the current level number are also saved. Current level←n1; PC←n2.
ENTRB	Enter Block	SX	SX points to a record of 3 naturals: n1, n2, n3 of independent predefined lengths. A PARM space of n1 cells is allocated at the current level. n1 cells are moved (with deletion) from the caller's STACK top to this PARM space. A DATA space of n2 cells and a STACK space of n3 cells are also allocated. The stack is initialized to empty.
RET	Return from Procedure	AN	AN defines the number of cells to be transferred from the base of the current PARM space to the top of the calling procedure's stack (value returned by a function). The current PARM, DATA and STACK spaces are freed, the saved address spaces are made accessible to the calling procedure and PC is loaded with the return address in the calling procedure.
EXITB	Exit Block	SX	SX points to a record of naturals: n1,n2,n3 of predefined lengths. n1 defines the lexicographic level number of the target procedure to which control is to be transferred. The target block is the most recently activated block of that procedure. The DATA, PARM and STACK spaces of that block and all those at lower(outer) levels are made accessible to the target procedure. Cells from the top of the target procedure's stack are deleted until only n3 cells remain in its STACK space. Finally, PC←n2.
<b>Miscellaneous Group</b>			
ADJS	Adjust Stack	AI	The top of stack pointer is adjusted by AI cells. If AI is positive, this is equivalent to allocating space on the stack; if AI is negative, words are deleted from the stack.
GENP	Generate Pointer	SX	A VAMP pointer to the address SX is generated and pushed on the current stack.
GENHP	Generate Heap Pointer	AN	A VAMP pointer referring to the HEAP space with an offset AN is generated and pushed on the current stack.

*ptos* are used to refer to natural, real and pointer operands at the top of the current stack. These terms are to be distinguished from *ipop*, *rpop* etc. which include an actual popping of the respective operands from the stack. The function *iPush* (*x*) refers to pushing the value of *x* as a standard integer on the current stack; similarly for *nPush*, *rPush* etc.

When a memory operand is an element of an array it is referred to by the notation *elem*(address) [*j*]. Thus, '*elem* (*SPN*)[1]←*AN*' means assign the natural *AN* to the first element of the packed naturals array beginning at *SPN*. The reader's full understanding of these notations is essential for the discussion of the instruction set design that follows.

TABLE II

Field Mnemonic	Field Description	Fetch Phase Function
AI	Addressed integer	Returns a standard size integer.
AN	Addressed natural	Returns a standard size natural.
AR	Addressed real	Returns a standard size real.
AP	Addressed pointer	Returns a VAMP pointer.
SI	Storage address of integer	Returns an effective address and length of an integer.
SN	Storage address of natural	Returns an effective address and length of a natural.
SR	Storage address of real	Returns an effective address and length of a real.
SP	Storage address of pointer	Returns an effective address of a VAMP pointer.
SX	Storage address	Returns an effective address of an unspecified data type.
SPN	Storage address of packed natural	Returns an effective address and element length for a packed natural array[0..max].
I	Literal Integer Field	Returns a standard size integer.
N	Literal Natural Field	Returns a standard size natural.

### Instruction set design

Throughout the design of the VAMP instruction set, careful thought was given to

- Simplifying code generation in the compiler.
- Eliminating unnecessary shuffling of stack top elements.
- Providing opportunities for simple, but effective code optimization.
- Providing instructions that are capable of handling the most general program constructs, yet yield efficient code for simpler, more common cases.

We illustrate each of these features with examples.

Code generation is simplified by the provision of such features as "store sub-range Integer" (which checks the integer value against its bounds before storing), "Subscript Translate" (which provides for converting a subscript into a cell offset or index after bounds checking), "Move Cell" (which is used in record and array assignments), "pack and unpack naturals" and "For up/down." These features of the virtual machine can not only reduce object code size but make it simpler to translate some of the more complex constructs of the language.

It should be pointed out in this context that the PASCAL case statements are not always to be translated into the case instructions provided in VAMP. The case statements often can be compiled into far more efficient code than a linked list of case values and case addresses. These efficient translation schemes usually involve the use of "branch tables," which option is available in VAMP and should be exercised. But in the most general case, there may not be any better scheme than to compare the case expression against individual case values in some sequential order and branching when a hit is found. These are the situations under which the VAMP case instructions are useful.

The design of the instruction subfields and their order also contributes toward this simplicity and can save unnecessary re-ordering of top of stack elements. Consider compiling an

assignment statement such as:

$$a[i] := b[i+1]$$

It is most naturally translated into this code sequence

```
compute i on the stack
translate it into an index for a
compute i+1 on the stack
translate it into an index for b
store b (indexed) into a (indexed).
```

Thus, the order of appearance of source and destination addresses in the store instruction saves us from having to reverse the indexes on the stack. This also holds if we had to push  $b$  on the stack explicitly (e.g. for type conversion) before "popping" it to  $a$ . A similar reasoning was applied to the design of every VAMP instruction.

The VAMP instruction set allows the compiler to generate "optimized code" without the need for complex optimization passes. Consider a simple *if . . . then . . . else* in PASCAL:

```
if a > b then s1 else s2
```

An unoptimized sequence of object code may appear as follows:

```
push a
push b
push boolean a > b
Branch on boolean=false to s2.
etc.
```

If  $a$  and  $b$  are of compatible types, the "push  $b$ " step can be avoided. But if we recognize also that a branch is to follow we can generate "compare and skip" instruction directly instead of "push boolean." If the skip offset field is large enough, one could even eliminate the "Branch on boolean" that follows. Similar savings can also be demonstrated in the case of *repeat . . . until* loops. Another case

of simple optimization occurs in assignment statements involving simple expressions on the right hand side and a compatible variable type on the left hand side, such as:

```
a[j]:=0
```

or

```
c[3]:='?'
```

In these cases one can generate a single store instruction (not counting the index computation) rather than a push/pop sequence.

A reader familiar with other stack machines may find some 'standard' stack operations missing. The lack of 'Pop' statements is one such case, which we have shown as equivalent to a 'store' with 'stack top immediate' mode of addressing for the source operand. Similarly a 'Duplicate' can be achieved by a 'Push' with the source address referring to the current STACK space. An 'exchange' is not provided as the need for it should be rare. Even then a sequence of push and store (pop) operations can yield the desired result.

The design of VAMP is oriented toward implementing the full PASCAL language, not a "typical subset" of it. For example, the PASCAL *goto* that allows leaving the current block and transferring control to a statement in a surrounding block is one of the more difficult features of the language to implement. The "Exit Block" feature of VAMP aids in transferring control out of a block in an orderly manner. On the other hand a simple use of the *goto* can most often be realized in terms of a "Skip" or a "Branch" and, perhaps, an "Adjust Stack" instruction. Similarly, "sub-range store" instructions may be generated only when bounds checking is desired; the ordinary "store" instructions can yield better speed if performance is important.

Before concluding the discussion on the VAMP instruction set, we wish to point out the design consideration for some of the less obvious instructions. The "For up/down" instructions are executed after pushing the initial and final values of the control variable on the stack. These values are always interpreted as integers which, on the stack, are indistinguishable from naturals. The initial value integer will also serve as the "control variable image" during future iterations. When the "For" statement is executed, a copy of this image variable is provided on top of the stack unless the end condition is met. This is so that an appropriate store instruction can be used to store it into the actual control variable by the first instruction in the loop. This avoids the need for typed "For" instructions.

The "call procedure" instruction specifies the lexicographic level number and the CODE space address of the target procedure. Three other pieces of information—the sizes of the PARM, DATA and STACK spaces for the target procedure—are specified in an "Enter Block" statement which should be the first instruction in the target procedure. These parameters may appear as a record within any of the address spaces normally accessible to that procedure except its own PARM, DATA and STACK spaces.

The "Exit Block" instruction is intended to "clean up"

the activities of all intervening procedures when a *goto* transfers control from a called procedure to a label in a calling procedure. It also provides for "cleaning up" of the target procedure's STACK space to the state expected by the next instruction in that procedure. This is achieved by specifying the number of cells that should remain on the stack when that instruction is begun. It should be noted that the size of the current stack is a unique number for a given point in the program and it can be determined at compilation time.

The "case" instructions are implemented using a linked list of case values and associated case addresses (see Figure 2). As we pointed out earlier, most common instances of the PASCAL *case* statement will probably lend themselves to translation to more efficient VAMP code than the proposed "case" instructions. A compiler should reserve this general form for those *case* statements that don't easily translate to another more efficient form of code.

The features provided for manipulation of packed naturals are motivated by the expected use of this VAMP type. If character strings were mapped into (unpacked) array of naturals then the "compare cell string" type of instructions will be used for string comparison which is permitted in PASCAL. On the other hand, if they are mapped into the packed naturals type, then the "compare packed natural string" type instructions will apply. The "Inclusion/Exclusion" comparisons and the "Difference/Union/Intersection" operations with packed naturals are provided for the set comparisons and set operations that are permitted in PASCAL. The "Pack/Unpack" facilities aid implementing the corresponding "standard procedures" of PASCAL (see Reference 9).

The next section deals with the issues of adapting VAMP to a specific hardware.

## IMPLEMENTATION GUIDELINES

No matter how well it is designed in abstract, an architecture such as VAMP must be adapted judiciously to a given hardware before claims of better efficiency can be made. In this section, we attempt to list some of the major trade-offs that an implementor of VAMP will be faced with, and offer some guidelines on how to make such trade-offs. We also present examples of possible adaptations for two contrasting architectures, namely the IBM 360 and the Burroughs B1700.

### *Adapting VAMP for a specific hardware*

The choice for "cell" is by far the most crucial one to make. It must match the underlying hardware. It should be at least one byte for byte-addressable machines like the 360; it could be as small as a bit for the B1700s. For machines with smallest addressable unit of memory that is several bits long (e.g. CDC 6600 with 60-bit word) the choice should be guided by other factors such as code compaction versus execution speed. Any choice of less than 60 bits for the

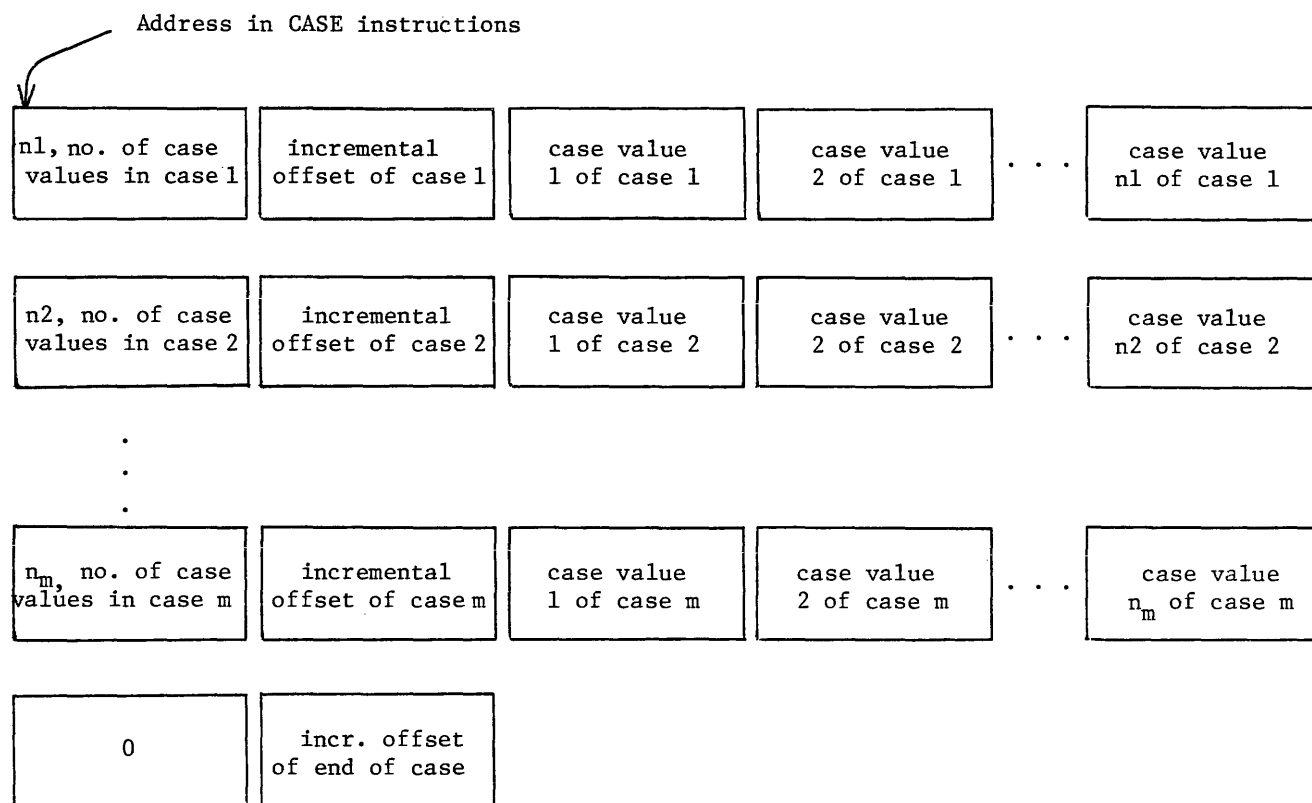

Figure 2—The CASE instructions of VAMP.

CDC 6600 will require software "simulation" of addressability and probably lead to some speed degradation.

The best choice for the unit "cell" is not always the smallest addressable unit of the hardware. On the B1700, for example, choosing a larger unit such as eight bits (or 12 bits) could lead to a reduction in the average instruction size due to fewer bits needed per VAMP address. Furthermore, on some machines, operands may have to be aligned at specific address boundaries for efficient access. One way to counter this problem is to define cell to be an "aligned unit" of storage. The compiler that generates code for the specific implementation of VAMP could then assign aligned addresses to data types as it processes their declarations. If we were to generate "portable" VAMP code, then the data map must be included with the object code. The translator that would convert this code into a specific VAMP code can take care of alignments and related address adjustments needed.

The next major choices are in the standard sizes for the basic data types. For the naturals, integers and reals the arithmetic capabilities of the hardware dictate the most suitable sizes. The standard size for a VAMP pointer is determined by the choices for the maximum number of active blocks and the maximum size of an address space.

After this, the implementor should consider what types are to have variable size representations and how many. For the type real, there is less to be gained by a variable size

representation, as PASCAL does not permit sub-ranges of reals as a data type. Integer sub-ranges are permitted and therefore shorter representations could lead to storage compaction. The most significant gains are to be expected from variable size naturals, as all of the following PASCAL types are to be represented as naturals—standard scalars—*char*, *boolean*, user-defined scalars, sub-ranges of *char*, and non-negative sub-ranges of integers. This is why a single representation for the natural is likely to result in poor use of the memory. For the 360, two or three representations (besides the standard one) may be useful—one, two and three-bytes. For the B1700 with eight-bit cells and a 24-bit standard natural, two smaller representations of eight bits and 16 bits may be valuable.

The next issue to tackle is whether or not "packed naturals" are to be really packed. For VAMP machines with eight-bit cells, packing of naturals could yield significant storage savings in relation with packed boolean arrays. Additional sub-cell representations, such as two-bit or four-bit packed naturals, may not be justifiable unless main storage is scarce and/or hardware addressability permits it easily. Based on this observation, we could choose a one-bit packed natural representation for the 360s and one-bit and four-bit representations for the B1700.

The choice for VAMP address formats is confronted next. As Figure 1 suggests, there are a number of sub-decisions to be made here. Do we wish to allow variable size offsets?

TABLE III

VAMP Feature	IBM 360	Burroughs B1700
Machine Name	VAMP/360	VAMP/1700
Hardware Memory	Byte addressable; 16M bytes memory	Bit addressable; Max. 64K bytes (model dependent)
Definition of "cell"	8-bit byte	8-bit field
Standard sizes		
naturals & integers	4 cells	3 cells
reals	4 cells	6 cells (real arith. not supported in hardware)
Variable sizes		
real	no	no
natural	1 cell, 2 cells, 4 cells	1 cell, 3 cells
integer	2 cells, 4 cells	2 cells, 3 cells
Alignments		
stack	full-word	none
real	full-word	none
natural	half-word for 2-cell full-word for 4-cell	none
integer	half-word for 2-cell full-word for 4-cell	none
Packed Naturals		
Permitted?	Yes	Yes
Sizes	1-bit	1-bit, 4-bit
Vamp Address	See Appendix I for details	See Appendix II for details
Max. static nesting	128	7
Max. address space size	16M cells in CODE, HEAP spaces 64K cells in all others	64K cells
Variable offsets?	Yes	Yes
Variable in-line imm.?	Yes	Yes
Pointer	see Appendix I for details	same as for VAMP/ 360
Max. dynamic nesting	4096	4096
Size	4 cells	4 cells

Do we wish to allow variable size (in-line) immediate operands? Many of these issues are dealt with in the same manner as we did previously. They usually boil down to a trade-off between execution speed and object code compaction. The issue of compiler complexity could also contribute to a decision of this nature, but in the author's opinion, a certain degree of complexity in compilation should be tolerated if it could lead to run-time savings.

Table III summarizes these major implementation choices for the IBM 360 and the B1700. These choices are neither "optimal" nor "absolute." They are merely intended to serve as a "first-cut" choice for adapting VAMP. Code generated from these design choices can then be monitored for efficiency and fine-tuned accordingly.

It is most appropriate to point out that there are a number of special considerations that should be taken into account during the adaptation of VAMP. Tanenbaum<sup>13</sup> lists the average frequencies (static and dynamic) with which the common features of PASCAL-like languages are used in systems programs. This information along with Huffman's<sup>8</sup> coding techniques will help the implementor achieve better compaction and execution speed for VAMP programs.

## CONCLUSION

The design of VAMP was motivated by the numerous implementations of PASCAL and similar languages with virtual target machines, many of which were designed for specific (real) machines and adapted by others with little or no change to match their own hardware. There was no systematic way to distinguish features made necessary or desirable by PASCAL from those that were dictated by the specific hardware. The purpose of this work has been to collect those features directly attributable to the needs of PASCAL language and present them as an abstract hardware-independent virtual machine which we call VAMP.

The most direct use of the architecture presented in this paper will be in conjunction with target language design for PASCAL compilers. Another interesting possibility that it presents is the notion of a "universal target language." If we carefully design such language and write a compiler to generate code in that language, it could make PASCAL programs "portable" at or near object code level. The author is currently involved in the design of such a language and a translator that will produce the VAMP/1700 (see the third section) code from it. The results of this investigation will be reported in a later paper.

There are a number of other directions for further research in this area. While the popularity of PASCAL is growing at an unprecedented rate, there are a number of efforts underway to refine the language. One of the weak points of present PASCAL is that there are no provisions for exception-handling in the language. This deficiency makes it less attractive for use in development of crucial programs such as operating systems. If and when such a facility is accepted into the language, VAMP would have to be redefined. While the need for organized exception-handling may be seen even in the absence of corresponding provisions in the higher-level language, we chose not to include any such features in VAMP in the spirit of being concerned more or less with the "standard" features of PASCAL.

The works of Bowles,<sup>2</sup> Goodenough<sup>5</sup> and Hill<sup>7</sup> may provide directions on how to implement exception-handling along with VAMP. Reports of difficulties and how they were overcome could provide valuable information for extending PASCAL to include this important feature.

There are other topics for investigation that are perhaps more ambitious. Almost every computer system, mini or maxi, supports a multitude of high-level languages. Typically, there are the popular languages such as COBOL that the end user needs, and there is a "software development language" (to use one vendor's name) which is suitable for writing parts of the operating system and utilities. Because of the diversity in the features of these languages, a single virtual machine may not be ideally suited for all of them. Yet, the software developers could save a lot of effort and time if a minimal union of these virtual machines can be designed. It is not known, for example, whether an acceptable virtual machine can be designed to support COBOL, FORTRAN and PASCAL. Answers to such questions will be highly beneficial to software houses writing and selling portable software products, especially compilers.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to the referees of this paper for their valuable criticism. Special thanks are due to Herb Mayer whose suggestions, comments and enthusiasm greatly influenced the quality of this paper.

APPENDIX I

VAMP/360 address format and pointer design

1. Address Format:

1 byte                      0-3 bytes  
depending on prefix.

Prefix:

- (hex) 00 - immediate, stack-top.
- 01 - 03: immediate, in-line, 3 operand length variations.
- 04 - 0F: immediate, in-line, special constants such as 0,1-1,10, char ' ', pointer nil, etc.

Remaining modes;  $h_1 h_2$  (hex), with  $h_1 \geq 1$ .

$$h_1=1-F: \left\{ \begin{array}{l} \text{stack-top indirect} \times 3 \text{ op.length variations} \\ \left\{ \begin{array}{l} \text{direct} \\ \text{indirect} \end{array} \right\} \times 2 \text{ offset length variations} \\ \qquad \qquad \qquad \times 3 \text{ op. length variations} \end{array} \right\}$$

$h_2=xn$ : where  $x$  is "indexed-or-not" bit and  $n=0-7$ :

\*others  $\Rightarrow$  2nd Prefix byte including the following information:

- a. lexicographic level number (7 bits)
- b. DATA or PARM space (1 bit)

Offset Length variations:

- length 1 = 1 byte.
- length 2 = 2 bytes for all address spaces except CODE.
- 3 bytes for CODE space.

Operand length Variations:

Depends on operand type (see Table III).

2. Pointer Format:

Fixed length = 4 bytes.

First byte (or 2 bytes) contents:

(hex) 0x=nil

1x=CODE (next 3 bytes define offset)

2x=HEAP (next 3 bytes define offset)

3xxx=DATA (xxx defines dynamic block number, next 2 bytes define offset)

4xxx=PARM (same as for DATA)

5xxx=STACK (same as for DATA)

APPENDIX II

VAMP/1700 address format design

Address Format: (with cell=8-bits)

1 cell                      0-2 cells  
depending on prefix

Prefix;

(hex) 00: immediate, stack-top  
 01: immediate, in-line.  
 02-0F: immediate, in-line special constants such as  
 0,1,-1,10,char " ", pointer nil, etc.

stack-top indirect CODE, direct Local STACK, direct Local STACK, indirect	}	X indexed? X 2 op. Lengths
--	---	-------------------------------

Remaining codes for "addressed" modes—

1x: with x=0-F from

Remaining codes yx interpreted as follows:

y=2-F from (7 lexic levels X DATA or PARM)  
 and x=0-F from  
 (indexed? X 2 op. lengths X 2 offset lengths X indirect?)

## INTRODUCTION

There is at present a broad consensus that a capability-based architecture is the best approach to safe systems.<sup>5,3,6</sup> However, at the bare hardware level, a machine should provide for a set of basic mechanisms (e.g. processor assignment, manipulation of queues of processes, definition of and manipulation on domains) without prejudging of any policy to be applied to these elements. The internal structure of the objects referred to by capabilities, the way they are organized into capability lists and the evolution of these lists in relation to various events appearing throughout the life of a program and of its possible activations should appear at some higher level, so that they can be modified without disturbing the hardware. This demands flexibility (the capability for emulating, for instance), adaptability (to future modifications) or the ability to define a machine which could be orientated, on demand, toward a certain class of applications (see for instance, the Burroughs B1700 approach). In the following, we shall be concerned mainly with this level, which we shall call "virtual architecture level." Considering a basic architecture, which we describe briefly, we define a virtual architecture for higher-level languages (namely PL/1, COBOL, FORTRAN and the system implementation language LIS,<sup>13</sup>) called the HLL-machine in this discussion. The objectives of the HLL-machine are the following:

- To define a virtual architecture as clean and homogeneous as possible, on which compilers may become more simple, and debugging aids more powerful.
- To define a minimum of intermediate languages, ideally, just one, for supporting PL/1, COBOL and FORTRAN.
- To define a set of run-time mechanisms enforcing safety.
- To obtain more compact object programs, as compared to third generation computer systems, so as to reduce the working sets of programs.
- To abide by the error confinement principle, which states that a procedure should not have at its disposal

more capabilities than actually required for its execution.

- To improve overall system performance.

## CONCEPTS AND TERMINOLOGY

All the system resources are defined as *objects*, an object being the unit of naming, sharing and protection. An object is referenced through a *capability*, which specifies access rights for this object and contains a reference to its realization. Capabilities cannot be created, modified or destroyed but at the basic architecture level; they must be protected against unauthorized modification and are grouped into C-lists, which are distinct from the objects, called *data sets*, which are accessible to the user.\*\*

The addressing scheme of the basic architecture provides a process with a capability list, two call/return stacks—CS (Capability Stack) for capabilities and VS (Value Stack) for other information, and a set of base registers. A procedure is considered as composed of four parts:

1. Definition of a set of objects.
2. Definition of entry points into this procedure.
3. Instructions manipulating the objects defined in 1.
4. References to entry points of other procedures.

Some of the objects defined in a procedure are purely local to it (not accessible from the outside), while others (called external objects), may be shared among several procedures. A procedure, which is an object of the cataloging system, may be referenced by means of one of its entry points.

In the following, we define a domain as a connected partial subgraph of a graph  $G$  of the above kind. A domain is therefore a construction on procedures.

*Example*—Given four procedures  $P_1$ ,  $P_2$ ,  $P_3$ ,  $P_4$  and assuming  $P_1$  references  $P_2$  and  $P_3$ ,  $P_2$  references  $P_3$ ,  $P_3$  references  $P_2$  and  $P_4$ , and  $P_4$  references  $P_2$  and itself, the graph  $G$  is as shown in Figure 1a. Possible domains for this graph are  $G$  itself, or  $G_1$  or  $G_2$  as shown in Figures 1b and

\* This study was sponsored by the French DRME, Direction des Recherches et Moyens d'Essais, under contract 74/450.

\*\* Due to considerations of data representation compatibility with other systems, the tagged architecture scheme was not retained, in spite of its merits.<sup>7</sup> The partition principle has been retained.

Figure 1a—Graph G.

1c, respectively. A *program* is a domain in which an entry point of a specific node of the graph has been specified; this node then corresponds to the main procedure. A *process* is a particular activation of a program; control enters the main procedure specified by a program and walks along edges of the graph  $G$ .

In a procedure, as it is constructed by a compiler, references to external objects or entry points are symbolic: actual access to an object implies that symbolic references be transformed into (virtual) addresses. Two extreme possibilities may be considered for these transformations:

1. Prior to any program specification, all references are transformed into addresses—the complete domain (corresponding to the graph  $G$  above) is constructed at one time; this corresponds to the well known static linking strategy.
2. The transformation of references into addresses is performed on demand—the domain is constructed edge-by-edge during the process activation. This corresponds to the dynamic linking strategy, as it is implemented in MULTICS,<sup>10</sup> for instance.

Any linking policy appears as a particular way of constructing domains.

With the notion of domain in mind, a classification of objects can be issued according to their scope and lifetime. The *scope* of an object corresponds to the existence of an entry for this object in the cataloging system. It may be

- *System-wide*—For instance, a file which is accessible by several processes.
- *Domain-wide*—Local to a domain (e.g. a STATIC EXTERNAL variable in PL/1).
- *Internal*—I.e., local to a procedure.

Figure 1b

Figure 1c

The *lifetime* of an object is related to the existence of a realization for this object; inside its scope, an object may or may not have a realization.

### ADDRESS SPACE—ACCESS PATHS

In order to achieve protection and error confinement, the informations which constitute the address space of a process have to be grouped inside distinct areas, according to three characteristics of the objects they are to contain:

- Scope
- Lifetime
- Access rights

In the first step, we define the areas which are necessary for a PL/1-like language, then we define relations between these areas—that is, the access paths to information.

#### Addressing space areas

The different areas are introduced in the order of their creation, from the compilation of a procedure until its execution in a specific domain.

- Procedure areas are defined at compile time. They consist of three parts:
  1. A CODE area containing object code instructions.
  2. A DC area containing descriptors and constants.
  3. A LINK area, a list of capabilities containing references to this procedure realization and entry points, and to the objects that this procedure may manipulate whose scope is not internal.

The first two areas are distinguished because their access attributes are different—CODE is 'execute-only,' whereas DC is 'read only.'

As long as the procedure is not destroyed, a single copy of CODE and DC areas will ever exist (object code is reentrant), whereas a new copy of the link area is created every time the procedure is linked to a new domain.

- Domain area. A domain must have its own (domain)

LINK area, which is a concatenation of copies of procedure LINK area. This is necessary because some objects referenced by a LINK are domain-wide, and the resolution of the reference to such objects in a LINK area is domain-dependent.

- Execution time areas. A distinction is introduced according to the lifetime of the objects.

Three classes—known from PL/1—are introduced:

- Static. An object of this class has a single realization all over the process activation.
- Automatic. The lifetime of an object in this class is related to the activation of blocks and/or procedures.
- Controlled. The existence of a realization which may consist in several 'generations' is under programmer's control.

The following areas are introduced:

- ST, static area, contains the realization of static objects whose scope is not larger than the domain. System-wide objects are realized in individual areas called DS (Data Sets). The ST area, created when a domain is activated, is enlarged every time a procedure is activated for the first time. As for the domain LINK area, only a part of the ST area—called *slot*—is accessible at a given time; it corresponds to the currently executing (external) procedure.
- Objects of the automatic class are realized in a value stack VS if they are local to the domain, or referenced from a capability stack CS if they are not (then their realization is in a DS area).
- Controlled objects cannot be system-wide; they are realized in a value heap area, VH, to which some garbage collection algorithm must be associated.

- Dangling references. A dangling reference is a reference to an object which currently has no realization in the address space. A safe implementation must detect such a circumstance, which may arise whenever the lifetime of an access path to an object is larger than the lifetime of this object. The problem is complicated since by means of pointers, parameters or overlay definitions, several access paths to an object may coexist. A solution consists of introducing tombstones<sup>9</sup> indicating whether a realization for the object currently exists, and forcing all the access paths to the object to use this tombstone.

For automatic objects, tombstones may be defined on a block basis. As regards controlled objects, one tombstone per generation is required. A major characteristic of tombstones is that, once allocated, they can never be reused. Due to this, tombstones are realized in a particular area, called the tombstone space (TS).

### Access paths

Three kinds of information are manipulated in the addressing space—addresses, descriptors and values. Values may

appear in ST, VS, VH, or DS areas, according to their scope and lifetime.

For protection purposes,<sup>1</sup> objects are associated with descriptors; these may be completely defined at compile time, then they are implemented in the read-only DC area, or they are not fully defined before execution, then they have to be constructed dynamically in VS or VH areas, according to the object class (automatic or controlled).

Access to an object is gained through indirections across the address space areas. These may communicate between each other according to certain restrictions. Three kinds of communications have to be considered—capabilities, addresses and pointer values. The Appendix exhibits the authorized communications between areas, from which address formats can be derived. Before describing these formats (in the third section) a few words about pointer values and program structure are necessary.

### Pointer values

The use of pointer values, if they are to be implemented just as addresses, is a means of violating the rules of languages concerning the manipulation of variables in relation with their types. One way to avoid this is to associate not only a reference to an object, but also a descriptor of this object, to a pointer value.<sup>4</sup> By this means, a descriptor is associated with every access path to a variable, and therefore control can be exercised on the type of access which is attempted to it whatever access path is used.

### Program structure handling

Block structure is taken under consideration by means of activation records (see for instance, the BURROUGHS B6700<sup>11</sup>) on capability and value stacks, CS and VS. An activation record contains the following information:

- Dynamic links (DC, DV) to the block which activated this block.
- Type—block, procedure.
- Lexicographic level.
- Exit information indicating through which statements control can leave the block.
- Reference to the tombstone associated with the activation record.
- Condition enabling information.
- Display information characterizing the activation records of the blocks which statically encompass this block.
- Loop control information.
- Parameters area (see below).
- Realization of automatic objects (values and/or descriptors).

As regards parameters, since formal parameters define a new access path to an actual parameter, they should be considered as pointer values, so that the protection requirements just defined can be met.

Figure 2—Operand addresses.

## ADDRESS FORMATS DESCRIPTORS

### Addresses

Three kinds of addresses are introduced, which allow a realization of the access paths in accordance with the restrictions defined in the appendix. Bit patterns are given as an indication.

- Operand addresses appear inside instructions, as shown in Figure 2, where

AT: Specifies the area and the kind of address defined in AD—direct or indirect.

AD: Is a displacement within the area or slot defined by AT. If AT specifies a stack, then AD is a pair (11, d) indicating the lexicographic level and a displacement inside the activation record.

- Internal addresses are purely dynamic and are used for special purposes (i.e. tombstones), as shown in Figure 3, where

AT: Same as before.

V: Validity field—If set to 0, indicates a dangling reference.

d: Displacement in the area specified by AT.

- General addresses may be created at compile time in the descriptor area DC, or at a run-time, to implement pointer values in particular. They may contain up to three kinds of information:

- The descriptor of an object or a reference to it (D).
- A reference to the next area of the access path (R).
- An additional displacement (P) used either when the reference R does not lead directly to the object, or for aggregate elements (see the following).

These three informations are not always required and four types of addresses are defined:

- Type 0 contains field D.
- Type 1 contains fields D and R.

Figure 3—Internal addresses.

- Type 2 contains fields R and P.
- Type 3 contains fields D, R and P. This type is used to represent pointer values.

Type 3 addresses are shown in Figure 4, where

T: Type of the address.

AT: Specifies the area and the kind of address. There is a particular AT value which indicates that R contains a value, and not an address; this is used for intermediate results.

V: Validity field; V=0 indicates a null pointer value.

### Descriptors

The data structures which are taken under consideration are elementary items, arrays and aggregates.

- Elementary item descriptors appear in the D field of Type 1 or Type 3 general addresses. They specify the different attributes of the object (arithmetic, string, . . .). For strings, they contain the length of the area allocated to the string. For arithmetic data, base, scale, mode and precision are encoded.
- Array descriptors define both the array structure and the array element. This allows the detection of out-of-bounds references, and unauthorized manipulations on an element. A descriptor for a two-dimensional array is represented in Figure 5, where

N: Number of dimensions.

RVO: Relative virtual origin, i.e. displacement to the (virtual) element with subscripts 0, 0, . . . , 0.

LB, UB: Lower and upper bounds of subscripts for this dimension.

M: Displacement from one element to the next one in the same dimension.

- Aggregate descriptors consist of Type 0 addresses (corresponding to the main aggregate and any sub-aggregate) and a collection of Type 1 or Type 3 addresses (one for each terminal aggregate component). The Type 0 address contains the number of elementary components in the (sub-) aggregate, and a displacement to the descriptor of the first component. An example is shown in Figure 6. By this mean, an item is accessed in the same manner, whether or not it belongs to an aggregate. An array of aggregates is described as an aggregate of arrays.

Figure 4—Type-3 addresses.

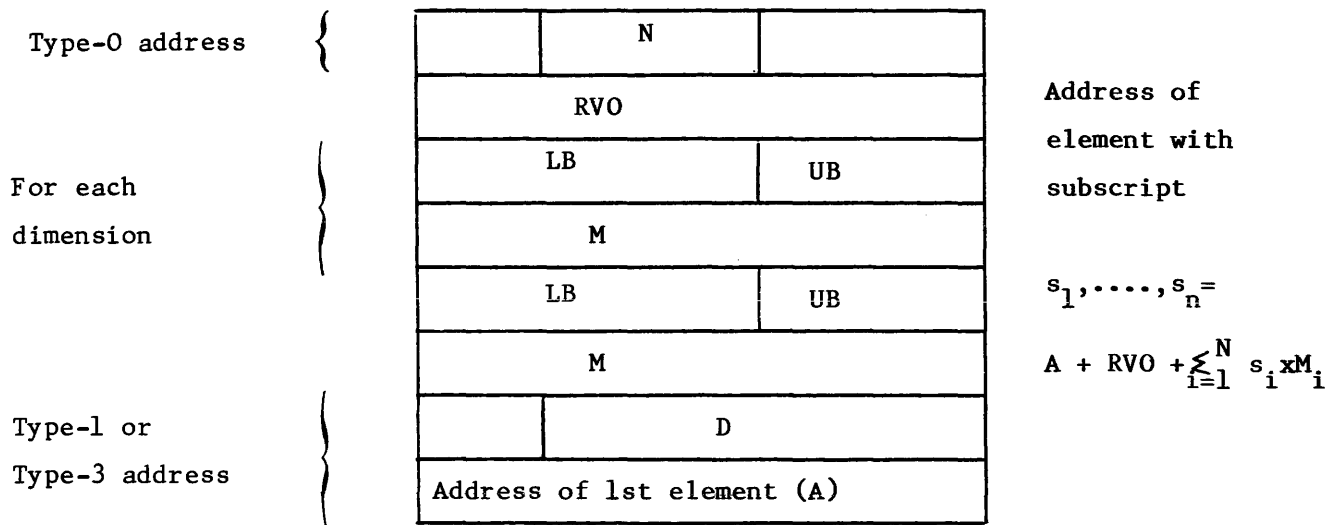

Figure 5—Array descriptor.

INSTRUCTION SET

The first question in designing the instruction set concerns the number of intermediate languages—should one define a single intermediate language, as it is done in most systems, or a high-level language, as it appears in the Burroughs B1700? Considering microprogram memory size, maintenance problems, training of software people and development costs, the best solution is to have a single intermediate language. As regards PL/1, FORTRAN and COBOL, a design based on PL/1 includes nearly all the language constructions of COBOL and FORTRAN. Only a few additional features are necessary to cope with particular constructions. It would be necessary to estimate the performance loss—if any—when executing COBOL or FORTRAN programs onto a PL/1-based architecture.

The following objectives must be kept in mind when designing an instruction set:

- *Safety*—The error detection must be as precise as possible, and appear as soon as possible.
- *Efficiency*—The most frequently used language constructions should be treated efficiently. Thus, the designer must have some knowledge about how the language is actually used, which implies run-time measurements in source programs.<sup>12</sup>
- The instruction set should provide facilities for compiler designers, and for the implementation of high level debugging aids.
- *Generality*—A few general mechanisms should be used, rather than locally-optimal implementation tricks.

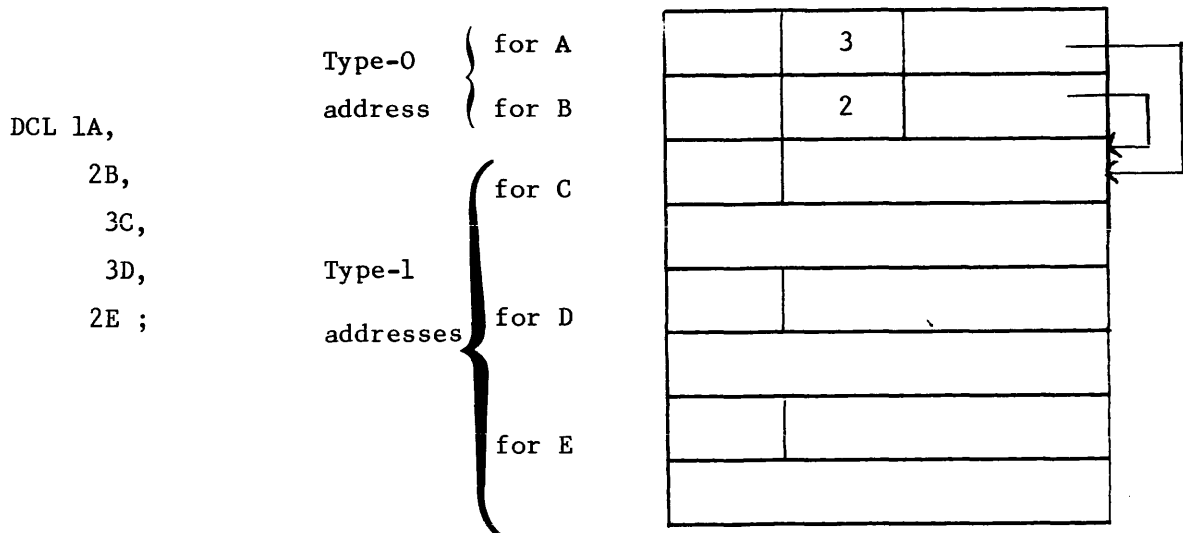

Figure 6—Aggregate descriptors.

Let us consider the various forms of instruction streams and related hardware architectures.

- *Stack machine and zero-address instructions.* This category may be illustrated by the Burroughs B6700—single or double precision data items are stacked, otherwise descriptors are stacked. Such a structure requires that operand values or descriptors be explicitly pushed on the top of the stack prior to any computation.
- *General registers and one-address instructions*—IBM/370 or CDC 6600 can be found in this category. Its major interest lies in an optimal handling of intermediate results. It requires that registers be explicitly loaded by instructions. In a descriptor-based architecture, it is mandatory that a description register be associated to each general (data) register. As a practical consequence, the complete register must be large enough to contain the largest data item, which may be too costly for small to medium machines.
- *Three-address machines* are reminiscent of the pioneer days; they may be illustrated by the Burroughs B3700 system. They are well suited to variable length items handling but two problems require special attention—intermediate result handling and array accessing.

Intermediate results or constants are represented as a special form of general addresses called IDV (Immediate Descriptor and Value). An IDV contains both the description and the value of an item, which saves one indirection. Some instructions may specify the creation of an IDV as the result of an operation; this is specified in the instruction opcode (I option). Source program measurements show (see, for instance, Reference 8) that the arithmetic expressions are generally extremely simple and do not involve any intermediate results. This is an argument in favor of three-address code, which generates instruction sequences which are more compact (and, therefore, interpreted more efficiently), as long as no intermediate result is required, with the counterpart of a higher cost for the execution of more complex expressions.

Again, according to program measurements, it appears that one reference among three is to array element; this means that array handling instructions should be given special care. On stack or general register machines, a rather long sequence of instructions is required. We suggest that two instructions be introduced:

- *build index list*  
 $BINDL\ n,\ OPA_0,\ OPDA_1,\ \dots,\ OPDA_n$

which builds a list of  $n$  index values with operands  $OPDA_1, \dots, OPDA_n$  at location  $OPD_0$ , and

- *index*  
 $INDEX\ OPDA_1,\ OPA_2,\ OPA_3$

which selects an element from the array defined by  $OPDA_1$ , with the index list found in  $OPA_2$ , and stores it in  $OPA_3$ . The instruction also performs subscript range checking, ac-

ording to the information found in the array descriptor. In the examples of instructions exhibited below,  $OP$  stands for *OP*erand,  $OPDA$  for *OP*erand *D*escriptor *A*ddress, and  $OPA$  for *OP*erand *A*ddress. Instructions may be classified as follows:

- *Computational*  
*Examples:*
  1.  $ADDI\ OPDA_1,\ OPDA_2,\ OPA_3\ (OP_3 := OP_1 + OP_2)$   
 $I$  in  $ADDI$  indicates that an intermediate result (IDV) is created at the location specified by  $OPA_3$
  2.  $INC\ OPDA_1,\ OPDA_2\ (OP_2 := OP_2 + OP_1)$
  3.  $DECI\ OPDA_1\ (OP_1 := OP_1 - 1)$
- *Computational data movement*  
*Examples:*  $MVNZ\ OPDA_1$  moves numeric zero to  $OP_1$ .
- *String operations, which require the use of descriptors*  
*Examples:*
  1.  $CAT\ [I]\ OPDA_0,\ OPDA_1,\ OPDA_2$  is the concatenation of two strings
  2.  $SUBSTR\ [I]\ OPDA_0,\ OPA_1,\ OPA_2$  selects a substring in  $OP_0$ , according to two integer values (origin and length) found in  $OP_1$  and creates string descriptor for the string in  $OPA_2$ .
- *String move instructions*  
*Examples:*
  1.  $MOVE\ [I]\ OPDA_1,\ OPDA_2\ (OP_2 := OP_1)$
  2.  $MVS\ OPDA_1$ : sets string  $OP_1$  to 'spaces'
- *Index manipulation*—see  $BINDL$  and  $INDEX$  above.
- *Branching*—several forms of branching are considered. Relative to the current instruction, indirect (to cope with COBOL's PERFORM and ALTER statements), local to a block, or outside the current block. Note that this last case implies a lot of housekeeping work, especially on the stacks. A typical branch instruction contains operand(s) address(es) and branching address.  
*Examples:*
  1.  $BRLESS\ OPDA_1,\ OPA_2,\ BADDR$   
 (if  $OP_1 < OP_2$  then go to  $BADDR$ )
  2.  $BRS\ OPDA_1,\ BADDR$   
 ( $OP_1 = \text{spaces}$  then go to  $BADDR$ )
- *Procedure and block control*—Call instructions specify the address of a list of parameter descriptors represented as an aggregate, and the address of an entry descriptor. For safety purposes, leaving a block resets its activation record to zero. When entering a block, the activation record is initiated by means of computational data, or string, or address movement instructions.
- *Address movement instructions* are the only way to alter the contents of a pointer value.  
*Examples:*
  1.  $SETPTR\ OPDA_1,\ OPDA_2$  forces pointer  $OP_2$  to reference item  $OP_2$ . The pointer value inherits the item description, and the reference to the item may be indirect, if it is accessed through a tombstone (then the pointer will reference this tombstone).
  2.  $RESETPTR\ OPDA_1$  resets pointer  $OP_1$  to the null value.

- Miscellaneous instructions contain among other things allocate and free statements on the heap, and instructions for the dynamic construction of descriptors.

CONCLUDING REMARKS

The instruction set we have briefly presented leads to compact object programs—a ratio of two has been observed for typical COBOL programs,<sup>2</sup> as compared with the IBM 370 code. Obviously, this instruction set should be tuned according to further measurement and to hardware and/or firmware requirements and constraints. The design of the HLL-machine has shown that a unique architecture may support PL/1, COBOL and FORTRAN. A great attention has been given to safety problems (e.g. dangling references) and programs could be run safely on this architecture. As regards efficiency, this architecture cannot be considered as realistic unless specially tailored hardware and/or firmware be defined for it.

# A programming language for high-level architecture

by YAOHAN CHU

University of Maryland  
College Park, Maryland

and

EDWARD RAY CANNON

International Computing Company  
Bethesda, Maryland

The machine language of a computer is the programming language that the bare hardware can accept and interpret. In a von Neumann architecture, it is essentially a set of machine instructions and data formats. In a high-level computer architecture,<sup>7,8</sup> the machine language is a high-level programming language since the hardware high-level architecture accepts and interprets this high-level language. Therefore, the programming language for a high-level computer architecture is the *high-level machine language*. For this reason, the programming language to be presented in this paper is called the *HLM language*.

Since the constructs of a high-level machine language affect intimately the constructs of the interpreting high-level computer architecture, the design of a high-level architecture begins with the design of a high-level machine language. This paper presents the design of a high-level machine language, while a separate paper describes the high-level architecture which implements this high-level machine language.

## DESIGN CONSIDERATIONS

Before the HLM language is described, major design considerations that result in the choices of the particular data types, structures, operations and constructs are presented. These considerations serve as guidelines for the language design and are as follows:

- a. The overall consideration is *understandability* and *simplicity* of the language.
- b. The HLM language should have adequate language constructs for writing programs in applications of system programming, data processing, scientific computing and process control, since it is a *programming language*.
- c. The HLM language should have language constructs that typical programmers can *understand* well so that they can effectively use the language.
- d. The HLM language should have language constructs that facilitate the writing of *reliable* programs.

- e. The HLM language should have language constructs that help in creating a *simple* and *clean* interactive direct-execution architecture<sup>4,8</sup> for its implementation.
- f. The HLM language should not be *over-designed* merely for the sake of seeking power and elegance of the language.
- g. The HLM language should have adequate language constructs for writing *high-level software*, since the high-level architecture may have software. For example, the HLM language may be used to write an interpreter for a high-level or a very-high-level language.
- h. The HLM language is designed with a particular regard to *microprocessor* implementation.
- i. The HLM language may become a *family of programming languages*. It will be a family because member languages will have a uniform syntax and a similar structure, but with a different choice of data types. Each member language will be simpler to implement since it will meet a limited need, yet it will be adequate for its programming purpose.

In case of a conflict among the previous considerations, a compromise is guided by the overall consideration.

## PROGRAM

A program declares data and specifies data operations for data processing or computing. To specify complex operations, sequences of data operations are needed. Control operations are needed to sequence the data operations. These data operations and their sequencing in a program create the data flow and the control flow, respectively, of the program. This section introduces the concept of data flow and control flow of a program, and then describes the program elements and program structure of the HLM language.

### *Data flow and control flow*

In any program, there are two flows—the data flow and the control flow. The data flow is the flow of the data

changes in the program as a result of data operations; it is described by *data flow statements*. The control flow is the flow of data operations sequences when the program is being executed; it is described by *control flow statements*. Examples of a data flow statement and a control flow statement are the assignment statement and the "if" statement, respectively.

In the HLM language, the data flow and control flow are organized so that all data flow statements are *embedded* in control flow statements. In this way, the order of executing the data flow statements is entirely directed by the control flow statements. Visibility of both the data flow and control flow to the HLM language programmer is one of the unique language features of the HLM language; this helps the programmer to understand program execution better.

*Program elements*

The program elements of a high-level language are those constituents which make up a viable program. The program elements of the HLM language are:

- a. Macro definition
- b. Data declaration
- c. Procedure definition
- d. Control flow statement
- e. Data flow statement
- f. Comment statement

Macro definitions describe the macros of a HLM program. Each macro definition specifies some program text for "substitution" when the macro name is later called. An example is shown in Figure 1 where macro *x* denotes "123," and macro exchange (*y,z*) denotes "y:=y+z."

Data declarations declare the names of the data storages together with their types and structures. An example is shown in Figure 1 where buffer *i* of data-type number of two digits, buffer *j* of data-type string of 10 characters, buffer *m* of data-type status of 'TRUE,' 'FALSE,' and 'dont\_know;,' and array *k* with 10 array elements of data-type number of two digits are declared.

```

/*This is an example of the HLM language program*/
MACRO x=123 ENDM;
MACRO exchange(y,z)=y:=y+z ENDM;
BUFFER i OF NUMBER[2],
      j OF STRING[10],
      m OF STATUS[TRUE,FALSE,dont_know];
ARRAY k[10] OF NUMBER[2];
PROCEDURE a;
  BLOCK i:=INPUT(0); ENDB;
  CALL b(i);
  BLOCK OUTPUT(0):=i; ENDB;
ENDP a;
PROCEDURE b(BUFFER x OF NUMBER[2]);
  BLOCK x:=x*8; ENDB;
ENDP b;
ENDPROGRAM;
    
```

Figure 1—An example showing program elements and program structure.

Procedure definitions describe the procedures of a HLM language program. Each procedure consists of control flow statements and optionally local data declarations. An example is shown in Figure 1 where Procedures *a* and *b* are defined. Procedure *a* has three control flow statements but no parameters. Procedure *b* has buffer *x* of data-type number of two digits as the parameter which is called by reference. It has only one control flow statement.

Data flow statements specify data operations. Control flow statements specify the data flow statements to be next executed. Two types of control flow statements are shown in Figure 1—BLOCK and CALL. There are three BLOCK statements, each specifying one or more assignment statements to be executed. There is one CALL statement which calls Procedure *b*.

The comment statement provides an explanatory remark for improving readability and documentation. It is a string of characters from the character set enclosed by a pair of symbols, /\* and \*/, and may appear anywhere a space character can except inside of a character string. An example of the HLM program is also shown in Figure 1. A more detailed example is shown in Reference 9.

*Program structure*

The program structure of the HLM language is chosen to be simple because simplicity is an overall design consideration. As illustrated in Figure 2, a HLM language program consists of macro definitions, data declarations, procedure definitions, and a statement to indicate the program end. An example of program structure is also shown in Figure 1. The order to the appearance of these program elements may be changed as long as a name is declared before it is referenced. The first procedure definition is the main procedure where program execution begins. The other procedures are to be called by the main procedure directly or indirectly. (A procedure is called indirectly if it is called through more than one procedure calls.)

Data

In designing a programming language, there are several aspects of data<sup>5</sup> that need be considered—data types, data structures, data operations and data flow. In addition, there are control data types, control data structures and control data operations.

Figure 2—Program structure for a HLM language program.

Data types are the primitive elements which may be numerical, physical, or others that are chosen to represent the data. They determine the scope of the language to describe the data. Data structures are the program elements which actually contain the data; they offer the facility in the language to access the data. Data operations are those operations which operate on the data types and data structures. Merely providing a data type or a data structure in a programming language without an adequate provision of data operations does not make that data type or that data structure particularly useful. The "programmability" of programming language is often limited by the data operations available for the data types and data structures. Data flow refers to the changes of the values in the data structures. Control data types and control data operations refer to those data types and data operations that affect the control flow during the program execution. These aspects of the HLM language are discussed next.

#### Data types and operations

There are many data types in current programming languages. Examples are data types of real and label in Algol 60, fixed and floating-point numbers in Fortran, record in Cobol, printers and files in PL/1, integer and string in SIMPL-T and byte and address in PL/M. In Pascal, data types may also be defined by the programmer. In the HLM language, five data types are chosen—decimal number, character string, byte string, time and status.

Decimal numbers represent numerical objects. Character strings represent symbolic objects. A byte string represents

a bit string; however, a byte string is restricted to bit strings of multiples of eight-bit lengths. Time represents real time from which relative time, incremental time and delay can be derived. Status represents the condition after a test. A special case for status is the boolean status, which has the values of TRUE and FALSE.

In the HLM language, data operations for the five data types are shown in Table I. The five arithmetic operations are +, -, ×, /, and modulo; they are provided for decimal numbers, byte strings and time units. The four logical operations are .A., .O., .E., and .C. which represent logical and, or, exclusive-or, and complement, respectively. They are provided for byte strings. The six shift operations are SHL, SHR, ROL, ROR, RCL and RCR which represent logical shift left and right operations, rotate left and right operations, rotate-with-carry left and right operations, respectively; they are available only for the data type of byte string.

Concatenation, finding-length, finding-substring and conversion operations are provided for both character strings and byte strings. In addition, delay and conversion operations are provided for data type of time units, and the set operation is provided for data type of status.

#### Data structures and operations

There are many data structures commonly used in programming. Examples are arrays, queues, stacks, tables, trees, files and list structures.<sup>8</sup> In the HLM language, data structures are declared in data declarations. Examples of data declarations are shown in Figure 3. The available data structure types are buffers, one-dimensional arrays, stacks, ports, clock, and files.

A buffer is a data storage which may store any one of the five data types (it is equivalent to the simple variable in a programming language where the variable stores a mathematical object). An array is a linear list of a fixed number of array elements which have the same data type. Each array element can be referenced by a subscript. Only one-dimensional arrays are adopted to keep the hardware array structure simple. A stack is a linear list of a varying number of stack elements of the same data type. It is a first-in-last-out structure. Only one end of the stack is accessible for insertion and deletion of stack elements.

A port is a "data storage" through which input data or output data flow. A clock is a special type which generates the real time, and a timer is a special type where time units are being accumulated. Both accept only the data type of time units. A file is a list of related file elements commonly called records. (The records physically reside on an external storage device.) Each record may be structured or unstructured. A structured record consists of fields and subfields and it can be of fixed or variable length. An unstructured record can be interpreted by means of a structured template.

The data operations for the data structures are shown in Table II. In brief, there are two operations for buffer, four for array, seven for stack, two for port, eight for file and one for clock.

TABLE I—Data Type Operations and Data Flow Statements

Data Type	Data Operations	Data Flow Statements (examples)
decimal number	5 decimal arithmetic operations	a: =b+c/d;
character string	Concatenate strings x and y Find length of string x Find sub-char string in string x, starting at ith char for j chars Convert char string to byte string	x:=x  y; i:=LENGTH(x); y:=SUBCHAR(x, i, j); a:=CONVBYTE(x);
byte string	4 logical operations 5 byte arithmetic operations 4 shift operations Find subbyte string in string f, starting at ith byte for j bytes Convert byte string to char string Find length of string x	i:=j.A.k; k:=j+k; i:=SHR(j, a); f:=SUBBYTE(f, i, j); x:=CONVCHAR(a); i:=LENGTH(x);
time units	Convert x msec into date-and-time Delay n time units 5 integer arithmetic operations increment/decrement buffer x by 5 time-units	datetime:=CONVTIME(x); a:=a DELAY n; t1:=t2+t3; X:=INC 5; X:=DEC 5;
status	set buffer x to status on	see note

Note: This is a control operation which is to be specified by a control flow statement as shown in Table IV.

Any data structure may be subdivided into any number of fields or sub-fields which are organized by level numbers. Examples of data structures with fields are shown in Figure 3.

Following conventional usage, the names of data structures in a data declaration may sometimes be referred to as *variables*.

### Control data types

A control data type is the data type which affects the flow of control in program execution. For example, the value of a test in an if-statement is a control data type since this value causes a change of control flow. In a conventional programming language, the control data types are not specially recognized; they are not considered as separate data types.

In the HLM language, there are two control data types—status and time units; they have been shown in Table I. A status is a datum stored in a data storage specifically for control flow modification. The datum can be numeric, boolean (i.e. TRUE or FALSE), or symbolic (such as “on” or “complete”). The time unit represents such units as hours, minutes, seconds and microseconds of time. For convenience, it may be abbreviated as *tut*.

### Data flow statements

A data flow statement specifies one or more data operations. It consists of a sequence of operands and operators. The syntax of a data flow statement requires it to begin with a data-operator keyword such as PUSH and SIZE. Examples of data flow statements are shown in Tables I and II,

where each data flow statement begins with a data storing operation indicated by the data operator “:=”. The data storing and data reference operations together with the input and output data flows, the timing reference and the operator precedence are subsequently described.

### Data reference

Data reference is the appearance of a declared name in a data flow statement. It is a data operation since the appearance means the access of the value of the name. It is the most common data operation. If an operator were chosen to represent this operation, this operation could be “fetch *a*” or “access *a*” where *a* is a declared name. No operator is used to represent this data operation in programming languages. This practice is followed in the HLM language.

### Data storing

Another often-used data operation is data storing which stores an operand into a data storage. The operand is the value of a declared name or the value of an expression; the data storage is a declared data structure. If an operator is to be chosen to represent the data storing operation, this data operation could be: “store *a* into *b*” or “store *a+b* into *c*,” or “assign *a* into *c*.” Common practice in programming language uses an assignment operator such as “:=” to represent it. In the HLM language, this practice is followed. However, the assignment statement or statements are enclosed by the reserved control flow delimiters, BLOCK and ENDB to enhance the visibility of the data flow statements and allow a simpler implementation.

Figure 3—Examples of data declarations.

TABLE II—Data Structure Operations and Data Flow Statements

Data Structure Type	Data Operations	Data Flow Statements (examples)
buffer	reference buffer x store into buffer x	y:=x; x:=y;
array (one-dim.)	reference array element x[n] store into array element x[n] find number of elements of array x search array x for argument y	y:=x[n]; x[n]:=y; y:=SIZE(x); y:=SEARCH(x) FOR (y);
stack	reference nth element from top of stack x push down y into stack x pop up from stack x into buffer y test stack x for empty find number of elements of stack x initialize stack x to empty search stack x for argument y and return index from stack top for the first occurrence of y. (return -1 if none found)	y:=x[n]; x:=PUSH(y); y:=POP(x); x=EMPTY; y:=SIZE(x); x=EMPTY; z:=SEARCH(x) FOR (y);
port	input from port 1 into buffer cmd output '@' to port 0	cmd:=INPUT(1); OUTPUT(0):='@';
file	open input file x open output file x close and save file x close and delete file x read DIRECT file x record n write DIRECT file x record n read SEQUENTIAL file x write SEQUENTIAL file x	OPENIN(x); OPENOUT(x); CLOSESAVE(x); CLOSEDELETE(x); READIR(x[n]); WRITEDIR(x[n]); READSEQ(x); WRITESEQ(x);
clock	read clock x in declared time units	READ(x);

### Input and output

In the HLM language, the input data or the output data flow through a pseudo-data storage called "port." An I/O device is connected to a particular port; this connection is determined by the system configuration. There are a maximum of 128 input ports and 128 output ports; the port is represented by the reserved words INPUT or OUTPUT, and the port number is indicated by a numerical subscript. Examples are shown in Table II.

### Clock

A clock is a data source which generates the data type of time. It generates real time for time referencing and for synchronizing hardware processors. Reserved word CLOCK is used to represent the real time clock. A data declaration is needed to declare the names and time\_units desired for

one or more clocks, though all the clocks give the same real time. A reading operation to CLOCK gives a reading in its declared time\_units.

### Expressions

An expression is concatenation of operands and operators to specify a sequence of operations. A numerical expression is a sequence of numerical operands and arithmetic operators. In the HLM language, there are five types of expressions corresponding to the five data types. The order of evaluating the operations in an expression follows the precedence of the operators. In the HLM language, the precedence follows common convention.

### CONTROL

Control refers to those language constructs that may change the path of program execution. There are several aspects of control that need to be considered—control types, control operations, control flow and control structures. These aspects for the HLM language are discussed next.

#### Control types

The control type refers to the manner in which the control flows during program execution. In a conventional programming language, the control flow follows the written order of the statements of the program; this type of control is sequential. There are other types of control. For example, PL/1<sup>1</sup> has the concurrent type of control in the name of multiple-tasking. PL/M<sup>3</sup> has the interrupt type of control to meet the needs of a microprocessor system. CDL<sup>2</sup> permits non-sequential execution of statements.

In the HLM language, two control types are selected—sequential and interrupt. The sequential type of control permits the execution of control flow statements according to the order of the control flow statements in a procedure. The execution begins with the main procedure which calls directly or indirectly the other procedures.

The interrupt type of control permits the suspension of the control flow and transfers the control flow to a predefined interrupt procedure. This interrupt procedure is then executed and returns to where the control flow was interrupted. The interrupt type of control also permits interruption by software.

#### Boolean expression

The application of a relational operator (i.e. =, ≠, >, <, ≥, ≤) to two data storages of the same type yields an expression of the control type boolean. All six relational operations are available to four data types, and only two (=, ≠) are available to the remaining data type STATUS. (See Table III.)

TABLE III—Control Data Operations and Boolean Expressions

Data Type	Control Data Operation	Boolean Expression (examples)
decimal number	6 relational operations 4 boolean operations	$x < y$ AND $y > z$
character string	6 relational operations 4 boolean operations	$x < y$ AND $y > z$
byte string	6 relational operations 4 boolean operations	$x < y$ OR $y < z$
time units	6 relational operations 4 boolean operations	$x < y$ OR $y < z$
status	2 relational operations (= and $\neq$ ) 4 boolean operations	$x = \text{on}$ $x = n$ AND $y = \text{off}$

The value of a boolean expression can be negated by prefixing it with the unary boolean operator NOT. Two boolean expressions can be joined by one of the three binary boolean operators (AND, OR, or XOR) to form a more complex boolean expression.

Note that all boolean expressions must contain at least one relational operator with one exception. If a data storage of type STATUS's value is either the status constant TRUE or FALSE then it is considered to be a boolean expression.

#### Control flow statements

Control flow refers to the order in which the control flow statements are executed. Since the data flow statements are embedded in the control flow statements, control flow also refers to the order in which the data flow statements are executed.

In the HLM language, there are two control types—sequential and interrupt. Skeleton control flow statements are shown in Table IV. The control flow statements for the sequential control type are:

- a. Block statement
- b. If statement
- c. While statement
- d. Call statement
- e. Return statement
- f. Macro statement
- g. Procedure statement
- h. Set statement

Each of these control flow statements is single-in-single-out. These simple control constructs make the HLM language a structured programming language.

The control flow statements for the interrupt control type are:

- a. Interrupt statement
- b. Disable statement
- c. Enable statement

TABLE IV—Control Operations and Control Flow Statements

Control Type	Control Operation	Control Flow Statement (skeleton)
sequential	grouping	BLOCK ... ENDB;
	alternative	IF ... THEN ... ENDI; IF ... THEN ... ELSE ... ENDI;
	looping	WHILE ... DO ... ENDW;
	macro declare	MACRO ... ENDM;
	procedure declare	PROCEDURE ... ; ... ENDP; PROCEDURE ... RETURNS ... ; ... ENDP;
	procedure call	CALL ... ;
	procedure return	RETURN; RETURN ... ;
interrupt	set a status	SET ... TO ... ;
	execution interrupt	INTERRUPT ... ;
	disable interrupt	DISABLE ... ;
	enable interrupt	ENABLE ... ;

The interrupt statement suspends the current control flow, and transfers it to a specially defined procedure. The enable and disable statements enable and disable the ability of the interrupt to occur, respectively.

#### Control structure

Control structure refers to the manner in which the declarations and statements are organized to steer the control flow. For modularity, declarations and statements are allowed to be grouped together in a certain manner. For example, the compound statement in Algol-60 and the do-end group in PL/1 allow the grouping of statements. In Algol-60 and PL/1, both statements and declarations may be grouped into a so-called block structure; the block structure may permit a complex interaction between the data flow and control flow of a program.

In the HLM language, simple control structure is sought-after. There is no ALGOL-like block structure. Only three control structures are permitted—nesting structure, macro substitution and procedure structure. The nesting structure allows the nesting of two or more control flow statements (e.g. *if* statement enclosing a *while* statement). The macro and procedure structure are described in the next sections.

#### Macro

As mentioned before, macro definitions in a HLM language program describe the macros of the program. Each macro definition specifies some program text for substitution. The program text is substituted at where it is called. Syntax of this program text is not recognized until after the macro is called and the textual substitution is made.

In the HLM language, macro definitions within a macro definition are not allowed for simplicity in implementation. Nevertheless, they serve the useful functions of text substitution and text compacting.

### Procedure

As mentioned before, procedure definitions in a HLM language program describe the procedures of the program, and the first procedure is the main procedure.

#### Procedure structure

There are three relations among the defined procedures, which are the procedure defining, calling and returning relations. These relations are called collectively the *procedure structure*.<sup>5,6</sup>

In the HLM language, simplicity of the procedure structure is sought-after. As a result, a "simple" procedure structure is chosen which has the following characteristics:

- a. No procedure may be defined within another procedure (i.e. no nested procedure definitions).
- b. No procedure may be defined or called recursively.
- c. Each procedure always returns to where it is called.

The simplicity of the previous procedure structure contributes toward simpler program writing and in turn more reliable programs.

#### Procedure parameters

A procedure may need no parameters if all variables are declared globally. However, in the HLM language, there can be local data declarations and parameters are permitted in a procedure definition. The parameter can be the name of any data structure of any data type. However, it can be neither a procedure name, nor a macro name. All parameters are called *by reference* or *by value*.

It should be noted that procedure parameters contribute to the interaction between the data flow and the control flow of the program. This interaction is needed, but it should be minimized and made visible for the purpose of contributing toward reliable programs.

#### Function

It is common to have functions in a programming language. For example, there are function subprograms in Fortran and typed procedures in Algol-60. In the HLM language, no specific designation is provided for functions. For most commonly-used functions, they may be pre-declared as data operators. Otherwise, a function is regarded as a special case of procedure where the procedure returns with a single value for any data type and a call statement is still required.

### LEXICALITY

Lexicality deals with the symbols and codes of the language. It plays an important role since it greatly influences

the appeal of the language to the potential users as well as the implementability of the language on a computer system. In this section, we choose the character set and code. We describe how constants are written. We specify how names are spelled, and what the operators and reserved words are.

#### Character set and code

The seven-bit ASCII X3.4-1968 code consists of the following two types of symbols:

- a. **Single character symbols** which consist of 52 letters, 10 digits and 33 special characters.
- b. **Control symbols** which consist of 33 reserved words.

An escape function represented by symbol ESC is provided in order to allow the ASCII code to be expanded beyond the 128 characters.

In order to guarantee that the character set is capable for information interchange between computer systems and communication systems, the 95 single character symbols of the seven-bit ASCII code are chosen as the character set of the HLM language. From this character set, the constants, the identifiers and the operators are formed.

#### Constants

Constants are data values. The constants for the data types of the language are described below.

##### Numerical constants

A number is a numerical constant. For the data type of decimal numbers, a numerical constant is written as a decimal number, which can be positive or negative. A decimal point may exist if it is needed. Examples of numerical constants are:

-579, 579.0 and +57.95

The permissible range of decimal numbers is to be chosen during implementation; the default range is chosen to be 15 digits including a sign.

##### Character-string constants

A character-string constant is a string of characters enclosed by a pair of apostrophes. In case an apostrophe is a character of the string, this apostrophe is written as a double-apostrophe. Examples of character-string constants are:

`ABC\$\*+ =/?` and `ABC` `DEF` `GHI`.

The size of a string is limited by the available memory space.

### Byte-string constants

A byte-string constant consists of one or more bytes in concatenation (i.e. 8, 16, 24, etc. bits). It can be written in hexadecimal, octal, or binary form. The constant must be preceded by letter H, Q, or B and followed by a hexadecimal, octal or binary number in a single-quote pair. Examples are:

H'A1B2C3', Q'234567', Q'255', and B'10101010'.

### Status constants

A status constant is an identifier or a decimal number. It first appears when the status is defined in a data declaration. It represents a condition to be used as an operand in a boolean expression in either the SET, IF or WHILE control statements. Examples of status constants are: 321, on, off, TRUE, FALSE, and ready\_queue\_empty.

### Time constants

A time constant is a numerical value in time units. The time units can be microseconds, seconds, minutes, hours, days, months, years or combinations thereof. Examples are 10 microseconds, 15-hour/20-minute/25-second, 1977/april/15. The time units of a clock are declared in a clock declaration. The generic term for a time-unit is coined to be a "tut."

### Identifiers

Identifiers are the names for data types, data structures, procedures, macros, statuses, subscripts, fields, etc. Examples have been shown in Figure 3. An identifier name is a character string consisting of letters, digits and character underscore; with the first character being a letter. Although there is no limit to the length of the identifier name, the identifiers in a program are distinguished by the first eight characters. This choice makes the size of the hardware's symbol table reasonable.

### Operators

Operators are the terminals of the language. They consist of single-character operators, two-character operators, and reserved words. There are 20 single-character operators, 7 double-character operators, and 84 reserved words. Note that a blank is also a delimiter which is required for separating symbols.

## A FAMILY OF LANGUAGES

The aforementioned programming language can be organized into a family of member languages. In this way, the

programmer needs to learn only a member language and the compiler/interpreter can be simpler. It is a family because all the member languages have the same program structure, control structure and data structure. Their differences are in the choice of the data types and control types and their associated data and control operations.

A member language for software implementation may choose all the five data types and both control types since it needs all of the descriptive power of the language. A member language for computation needs only the data types of number and status and the sequential control type. A member language for data processing needs to choose the data types of number, character string, file and status and the sequential control type. A member language for real-time control needs the data types of number, byte-string, status, time and both control types. A member language for microprocessors needs the data types of byte-string, status and time and both control types; this choice of data and control types is made to match the microprocessor capability.

For each of the member languages of the family, a compiler or an interpreter or both may be constructed. The implementation can be made simpler for the whole family by providing a family of software modules so that the compiler or interpreter of a member language could be built from a subset of these software modules.

## CONCLUDING REMARKS

A programming language serves as a bridge between the programmer and the computer hardware. In the past, a programming language may have been designed for its power and elegance. The language as a result may have become hard to understand, long to learn and costly to implement. The language may well have been over-designed. The design of the HLM language has been an engineering undertaking with both the programmer's viewpoint and the language implementation taken into consideration.

To the programmers, the language is designed with a primary consideration of simplicity and understandability. The following language concepts and constructs have been adopted.

1. The concept of the data flow and control flow in a program and visibility of their interaction.
2. Inclusion of the data types of status and time and their data operations.
3. Data structures can all be declared with fields and subfields.
4. Data operations are provided for all data types and all data structures.
5. Treatment of inputs and outputs as data sources and sinks, respectively. Input and output data transfers are treated as input and output data operations, respectively.
6. Provision of a real-time clock is provided together with data operations.

7. Simplicity of control structure. There are no block structures, no recursive procedures, no nested procedure definitions and no nested macro definitions.
8. The use of single-in-single-out control flow statements.
9. Provision of both sequential and interrupt control types.

For implementation considerations, the language is designed to give a simple interpretation model. Costly and unnecessary constructs are avoided or eliminated. Implementation by both compilation and interpretation is considered. The following are the specific considerations:

1. Separation of the data flow and control flow interpretation.
2. Simplified model as a result of no block structures, no recursive procedures, no nested procedure definitions and no nested macro definitions.
3. Presence of reserved words at the beginning of each declaration or statement.
4. Declaration of the number of digits, characters and bytes for the data types of number, character string and byte string, respectively.

The following language constructs should be excluded for the sake of simpler implementation, but they have not because of more effectiveness in programming:

1. Provision of field and subfield definition for any of the data structures.
2. Provision of data operations for all of the data types and data structures.
3. Provision of procedure parameters.

The HLM language is now under an experimental and evaluation phase. During this phase, the language is used for writing programs. An interactive interpreter for a member language is being designed and implemented for experimental and evaluation use. The HLM language will be revised and refined as a result of this phase.

# Data management in distributed data bases\*

by C. V. RAMAMOORTHY and BENJAMIN W. WAH

University of California  
Berkeley, California

## INTRODUCTION

The recent advances in large-scale integrated logic and memory technology, coupled with the explosion in size and complexity of the application areas, have led to the design of distributed architectures. Basically, a *Distributed Computer System (DCS)* is considered as an interconnection of digital systems called *Processing Elements (PEs)*, each having certain processing capabilities and communicating with each other. This definition encompasses a wide range of configurations from an uniprocessor system with different functional units to multiplicity of general-purpose computers (e.g. ARPANET). In general, the notion of "distributed systems" varies in character and scope with different people.<sup>30</sup> So far, there is no accepted definition and basis for classifying these systems. In this paper, we limit our discussion to a class of DCSs which have an interconnection of dedicated/shared, programmable, functional PEs working on a set of jobs which may be related or unrelated.

Due to the information explosion and the need for more stringent requirements, the design of efficient coordination schemes for the management of data on a DCS is a very critical problem. Data on a DCS are managed through a data base. A *Data Base* is a collection of stored operational data used by the application systems of some particular enterprise,<sup>6,12</sup> and a *Distributed Data Base (DDB)* can be thought of as the data stored at different locations of a DCS. It can be considered to exist only when data elements at multiple locations are interrelated and/or there is a need to access data stored at some locations from another location. Due to the ever-increasing demand for on-line processing, there is a need for decomposing very large data bases into physically or geographically dispersed units and/or integrating existing data bases held in physically isolated nodes into a single, coherent data base that will be available to each of the distributed nodes.

In this paper, the design issues and solutions for resource management of data on a DDB are studied. The different aspects of resource management are categorized in the next section. These management issues are part of the issues related to the operational control of a DDB and are con-

cerned with the management of data as resources. They can be divided into three related levels, namely, the query level, the file level and the task level. The query level is concerned with the processing of user queries and requests so that parallelism in processing can be maximized, and the amount of communications on the system can be minimized. On the file level, the related issues are the compression of data files for efficient storage and communication, as well as the placement and migration of files for efficient accesses. On the task level, the objective is to schedule the requests so that overlap in processing can be maximized. These issues and some of the corresponding solution algorithms are studied in detail in the third to sixth sections respectively. Finally, the seventh section provides some concluding remarks.

## RESOURCE MANAGEMENT OF DATA IN DDBS

There are many issues in the design of a data base, among which are the issues in logical organization, architectural designs, operational control and evolution. These issues have been discussed in Reference 31 and will not be repeated here. A summary of the issues in the design of a DDB are shown in Figure 1. In this paper, the resource management issues of data and files on a DDB are studied. The specific data management issues investigated are:

### *Query decomposition on DDBs*

A *query* is an access request made by a user or a program in which one or more files have to be accessed. When multiple files are accessed by the same query on a DDB, these files usually have to reside at a common location before the query can be processed. Substantial communication overhead may be involved if these files are geographically distributed and a copy of each file has to be transferred to a common location. It is therefore necessary to decompose the query into sub-queries so that each sub-query accesses a single file. These sub-queries may then be processed in parallel at any location which has a copy of the required file. The results after the processing are then sent back to the re-

\* Research supported by Ballistic Missile Defense Contract DASG60-77-C-0138.

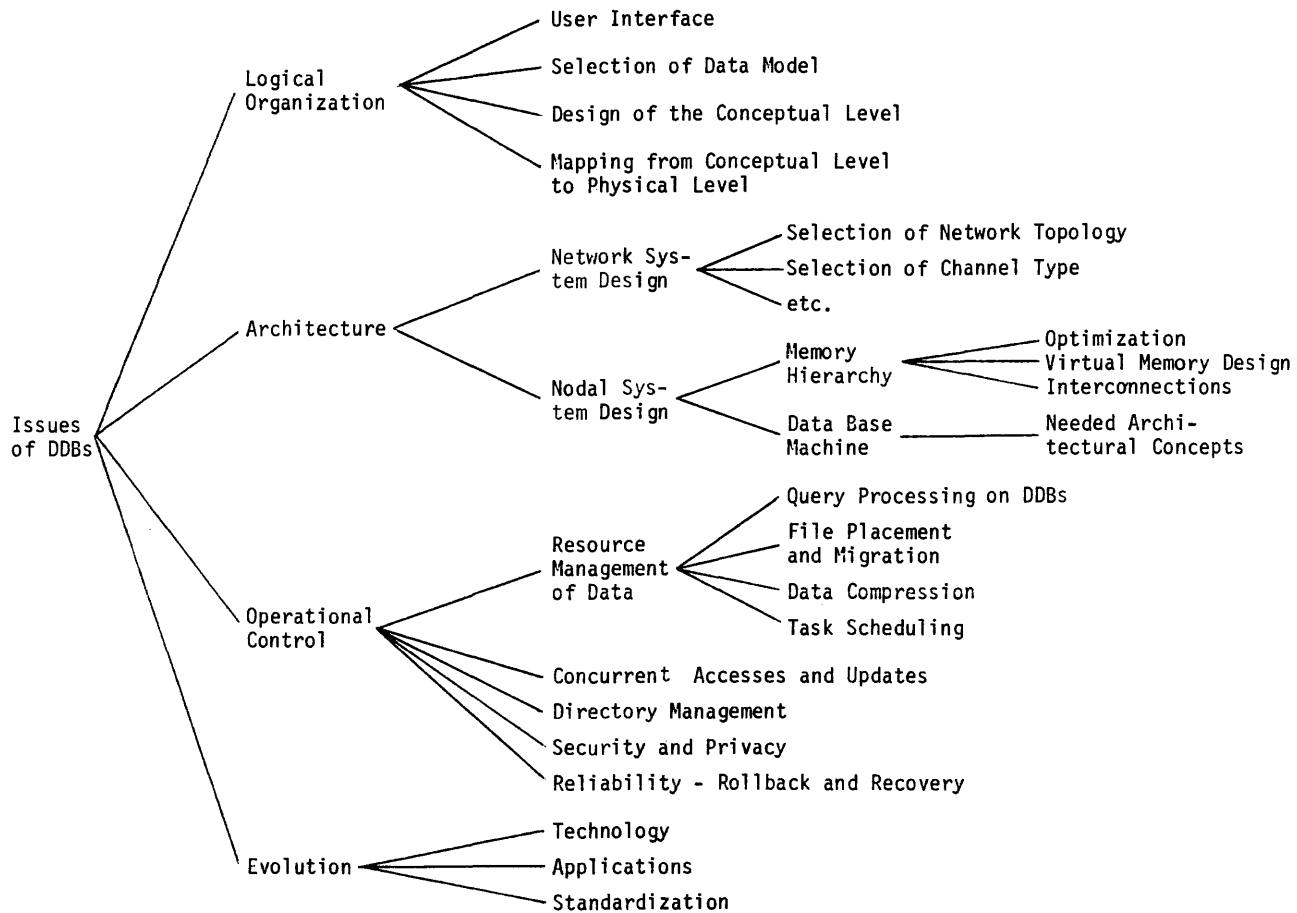

Figure 1—Classification of issues in distributed data base systems.

questing location. It is generally true that the amount of communications needed to transmit the results is much smaller than the amount needed to transmit the files. This approach has been proposed in the design of the centralized version of INGRES<sup>41</sup> and is extended to the design of SDD-1,<sup>42</sup> and distributed INGRES.<sup>8</sup> However, in some cases decomposition is impossible and some file transfers are still necessary. In order to avoid these extra transfers, a technique is proposed in the third section so that redundant information is added to the files and non-decomposable queries can still be processed without any file movements.

#### Data compression

Data compression is any reversible encoding technique that produces a measurable reduction in the size of the data encoded. By reversible, it is meant that the original data is recoverable from the compressed form. Due to the growth in the size of information processing, it is necessary to develop good data compression techniques which reduce the size of the stored information and the amount of inter-node communications. This issue is discussed in the fourth section.

#### File placement and migration

This issue relates to the distribution and migration of data base components, namely, files and control programs, on the DDB with the objective of minimizing the overall storage, migration, updating and access costs on the system. A file assignment algorithm is proposed in the fifth section.

#### Task scheduling

Requests on the DDB must be scheduled so that high parallelism and overlap can be achieved. The request may be a single word fetch or it may be a page or file access. The parallelism on the DDB is important because in order to attain high throughput, the parallel hardware and resources must be efficiently utilized. The control of task scheduling can be distributed or centralized. In distributed control, each node may act independently and coordinate with each other. In centralized control, there is a primary node in which all scheduling control will be performed there. The decision of which is the better control mechanism depends very heavily on the interconnection structure and the

communication overhead involved. This issue is discussed in the sixth section.

The relationships among the various data management issues are shown in Figure 2 where a relation  $\rightarrow$  is said to exist between two design issues  $\hat{a}$ ,  $\hat{b}$ , i.e.  $\hat{a} \rightarrow \hat{b}$ , if the solution of  $\hat{b}$  is transparent to the solution of  $\hat{a}$ . That is, the solution of  $\hat{a}$  is not affected by the solution to  $\hat{b}$ , but not vice versa. The solution to  $\hat{a}$  can therefore be developed independent of  $\hat{b}$ . In Figure 2, it is seen that generally, task scheduling is transparent to file placement and migration which in turn could be transparent to data compression and query decomposition. Algorithms for data compression and query decomposition can therefore be developed independently. In developing algorithms for file placements and migrations, the solutions for data compression and query decomposition should be taken into account. However, in most cases, assumptions can be made about their solutions and the file placement and migration problem can be solved independently. For example, it may be assumed that all queries which access multiple files may be decomposed into sub-queries that access single files. The file placement and migration problem for multiple files is therefore decomposed into many single file optimization sub-problems. It must be noted that other operational control requirements may also impose restrictions on the solutions to the data management issues. For instance, different reliability requirements may demand different lower bounds on the number of copies of a file on the DDB; different concurrency control mechanisms may have different costs on the file placement problem; etc. Reasonable assumptions must therefore be made about these operational control requirements in order to determine their effects on the resource management issues and to solve these issues independently.

#### QUERY DECOMPOSITION ON DDBS

The approach using query decomposition is geared towards relational data bases.<sup>4</sup> In a relational data base, data

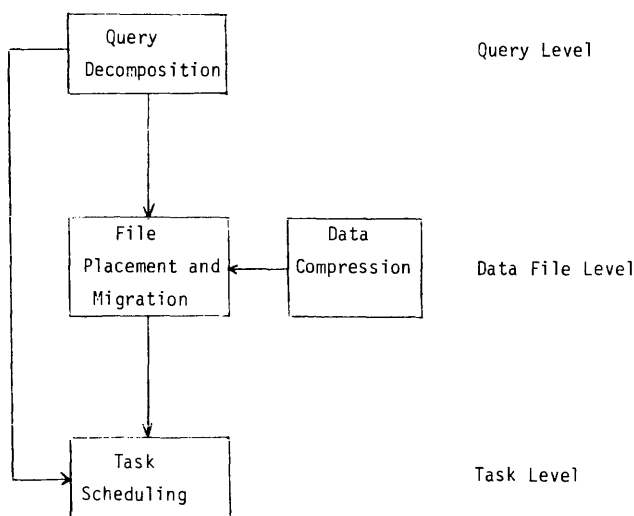

Figure 2—Relationships among various data management issues.

is viewed as relations of varying degree, the degree being the number of distinct domains participating in the relation. Each instance of a relation is known as a tuple, which has a value for each domain of the relation. Thus a relation can be simply represented in tabular form with columns as domains and rows as tuples. In query decomposition, optimization is performed on the processing of a single query originated at a node. The objective is to decompose a multiple relation query into as many single relation sub-queries as possible so that data (relation) movements from one node to another can be minimized.<sup>41,42,8,13</sup> However, there exists non-decomposable queries which require all the relations that they access to be present at a common location. A large number of relation transfers may be needed if these relations are geographically distributed. In order to avoid these extra relation transfers, a technique utilizing redundant information is proposed here. Instead of decomposing queries that access multiple files, it may be sufficient to provide redundant information in each relation so that multiple relations do not need to reside at a single location before the query can be processed. This will be illustrated later in this section. We begin by first examining the different types of queries on a relational data base.

A query on a relational data base consists of two parts: the part specifying the domains of the relation to be retrieved and the part specifying the predicate which is a quantification representing the defining properties of the set to be accessed. Let  $S$  be a relation of domains  $s\#$ ,  $sname$ ,  $status$ ,  $city$ ; and  $SP$  be a relation of domains  $s\#$ ,  $p\#$ ,  $qty$ . The queries on a relational data base can be classified into the following categories:<sup>6</sup>

- *Retrieval Operations*

- a. *Single Relation Retrieval*—The predicate representing the defining property of the set to be retrieved is defined on the same relation as the set.

E.g. GET (S.sname): S.city="Paris" AND S.status>10

- b. *Multiple Relation Retrieval*—The predicate, as well as the set to be retrieved, may be defined over multiple relations.

E.g. GET (S.sname): (SP.s#=S.s# AND SP.p#="P<sub>2</sub>")

Relation SP and S must be available simultaneously before the query can be processed.

- *Storage Operations*

- a. Single Relation Update
- b. Multiple Relation Update
- c. Insertion
- d. Deletion

- *Library Functions*

These represent more complicated operations on the predicate than the equality operations, e.g. counting the number of occurrences, selecting the maximum/minimum etc.

A query which is defined over multiple relations is not decomposable into single relation sub-queries when it has a

logical relation defined over a common domain of these multiple relations. For example, the query:

GET (S.sname): (SP.s#=S.s# AND SP.p#='P<sub>2</sub>')

is not decomposable into single relation retrievals because there is a logical relation "=" which is defined over a common domain s# of the relations S and SP. These relations must be available simultaneously at a common location before the retrieval or update operations can be performed. It is noted that the common domains of these multiple relations actually represent multiple copies of the same domain on these relations (although the information they contain may not be identical). A lot of transfers can be eliminated if their common information is represented in both relations. For example, in processing the query:

GET (S.sname): (SP.s#=S.s# AND SP.p#='P<sub>2</sub>')

on two geographically separated relations, S and SP (Figure 3a), it may be necessary to transfer relation S to the node where SP resides and then process the query there or vice versa. However, if the information SP.s#=S.s# are compiled beforehand into the two relations (Figure 3b), then it is only necessary to send the query to the location where S or SP resides and the query can be processed there.

This technique poses several problems. First, it is necessary to take one extra bit for each tuple in order to compile this piece of information. If the amount of information to be added is large, (e.g. when the number of different predicates defined on a common domain of two relations is large), the size of the extra storage space may be significant. Second, when the common domain of one relation is modified, it is necessary to "multiple update" all the common domains of the other relations in the data base. Referring to Figure 3b, if an extra tuple with s#=2 and sname="Boston" is added to relation S, then it is necessary to update the SP.s#=S.s# information in relation SP because relation SP contains a tuple with s#=2. If updating activity is frequent, then the "multiple update" cost is large. Third, this technique requires that the data base designer to be able to estimate the amount of additional information to be compiled into the relations. A possible technique is to pre-analyze the type of predicates used in retrievals and updates and to determine what are the essential information to be compiled into the relations. A compromise should be made between introduc-

					4		A2
					5	1	P2

Figure 3b—Relations S and SP with (S.s#=SP.s#) information compiled into the relations.

ing extra information with additional storage space and higher cost in multiple updates and reducing the amount of relation transfers. It would be advantageous for the more frequently used predicates and less advantageous for others.

DATA COMPRESSION

With the increase in the amount of information processing, it is important to keep the utilization of the memory high. The information content of data stored in large alphanumeric data bases is usually low. Further, as the processing becomes distributed, the communication overhead of transferring data from one location to another is usually substantial. In order to keep the utilization of the storage sub-system high, and to keep the amount of data transferred over communication links low, data compression is a natural solution to the problem. However, the use of compression codes which remove the redundancy of data seems to be in direct conflict with the use of redundant coding, e.g. parity check codes, which increase the reliability. What is needed then is an exploration of efficient error limiting codes which can be applied to compressed data and an analysis of the error rate of various compression schemes.

*Desirable properties of compression codes*

In designing a compression code, it should possess to some degree each of the following properties:

1. The technique should be reversible, i.e. the original data should be fully recoverable from the compressed form. This property can be relaxed in certain situations when the data is repeated elsewhere, e.g. the keys in a directory structure are usually repeated across levels.
2. The coding scheme should cause a measurable reduction in the size of the stored data. In comparing compression codes, a standard measure called percent compression is generally used.

$$\text{percent compression} = \frac{[\text{size of input data}] - [\text{size of output data}]}{[\text{size of input data}]} \times 100\%$$

3. The technique should be reasonably efficient to implement.

4. The technique should be general enough to be equally applicable to all alphanumeric data files.

Two other properties which are often desirable in compression schemes are:

5. The prefix property, i.e. no code is the prefix of another code. This assures that the decoder never has to backup on any portion of the text.
6. Lexicographic ordering property, i.e. if the input data is in a sorted order, then after encoding, the output data is still in sorted order. This property is useful for indexes.

Existing compression techniques, which possess part or all of the above properties, can be classified into the following board categories: (1) Run length encoding; (2) Differencing; (3) Statistical encoding; (4) Value set schemes.

**Run Length Encoding**—In a data base, there are frequent occurrences in which the data occur in a continuous sequence of identical characters, e.g. sequence of zeroes. This sequence can be replaced by the character followed by a count. Run length encoding is a technique by which a string of continuous characters or a "clump" are replaced by a repeat flag for the character followed by the size of the "clump" or run length. In practice, however, since very long clumps are highly improbable, one can limit the run length encoded and combine the flag and length in a single byte. This is the technique used in WYLBUR.<sup>10</sup> Run length encoding of a single character type is potentially the most successful, with diminishing returns for more characters. Huang has discovered an upper bound for the entropy of run length encoding.<sup>19</sup>

**Differencing**—Differencing refers to techniques which compare a current record to a pattern record and retain only the differences between them. It is particularly successful with large files of records with fixed length alphanumeric fields where most corresponding fields are the same or are blanks and zeroes. This is the approach normally used for sequential files, where the pattern record is taken by the previous record in the file. When differencing is applied to direct access files, however, the first record of each block is left uncompressed and used as a pattern for the remaining records in the block. The unit of information on which differencing is performed can be the bit, the byte, the field or some logical data in the record. Byte-level differencing is the most common case since byte access is convenient and cheap. In field-level differencing, bit maps are often used to indicate the presence or absence of a field when identical to the previous. Two examples of the use of differencing in relational data base systems are Titman's experimental system<sup>38</sup> and the Peterlee Relational Test Vehicle.<sup>39</sup>

**Statistical Encoding**—Statistical encoding is a transformation of an input alphabet so that it is assigned a code bit string whose length is inversely proportional to the frequency of its occurrences in the text. Since different characters occur with different frequencies, a statistical encoding scheme will usually compress the text. Huffman coding

scheme<sup>20</sup> is an optimum, elegant and simple algorithm to assign variable length bit codes with the prefix property to characters, given their frequencies of occurrence in a text. There are other techniques such as the Hu-Tucker Algorithm,<sup>18</sup> which has both the prefix and the lexicographic ordering property. The major drawbacks of statistical encoding are that it does not exploit the natural radix of the computer (e.g. byte, word, etc.), and it does not take into account some special characteristics of the data, e.g. strings of repeating characters, and the distinction between numeric and character data. A solution to this is the use of fixed length encoding which manipulate data in units of byte.<sup>32,2</sup> Further, the fact that the size of each character is variable also causes problems when the data are modified and the reliability of the data is difficult to assure because the character stream would not be recognizable once a bit is destroyed.

**Value Set Schemes**—A value set scheme in a data base system is a coding scheme in which repeated storage of data elements in their full character representation is avoided. Instead, each data element is stored once in the system and all subsequent occurrences of the same data element are referred to the first stored occurrence. An example of this technique is shown in the MacAIMs Data Management (MADAM) System<sup>14</sup> in which a reference number is assigned to a new entering data element and all subsequent operations on the data element use the reference number. However, the fact that reference numbers are unique only within a relation could lead to problems in the reliability of the data management system and the integrity of the data. The MADAM System also uses a binary tree scheme for maintaining reference numbers which is inefficient for insertion and costly in storage space for large sets of data. There are other schemes which represent a better tradeoff between storage efficiency and processing efficiency.<sup>24</sup>

The decision of which code to use is highly dependent on the applications. For example, in a data base where the order of data is not important, the lexicographic ordering property is not important. The required properties of the applications must therefore be identified by the designers before the code is selected.

#### *Future directions of research*

While there are many reported results on data compression, the future directions of research are seen to be concentrated in the following areas:

**Identify and characterize data redundancy**—In a data base, there are many levels of data. For example, there are the file level, the record level, the field level and the byte level. The type of data redundancy at each level must be identified. This would aid in selecting data compression schemes best suited to the particular type of redundancy. Further, it leads us to the possibility of multi-level compression schemes, wherein data is compressed through a set of cascaded stages. Each level of the data is possibly compressed using a different technique. The compression code must be selected so that it minimizes the effects on other levels of the data.

**Develop a comparison model for various compression schemes**—The comparison model must be able to measure the amount of storage reduction and the computation cost for encoding and decoding. A simple measure is the percent compression defined earlier. The computation cost can be broken down into the CPU cost, the memory usage cost and the input/output cost. In order to calculate the storage reduction for a given compression scheme, the number of encodable units of tokens in a record or file must be predicted. This can be obtained from an assumed input distribution such as uniform distribution, normal distribution or Zipf's distribution at the given level of data.

**Study adaptive Huffman coding techniques which respond to update activity**—As the data base gets updated, the initial Huffman code assignment based on the a priori character frequency distribution may no longer be optimal. A threshold for the expected compression ratio has to be determined which can dynamically reassign the variable length codes for the new frequency distribution. Further, the threshold selected should not cause excessive re-coding. The problem of updates which change the size of the data, and the reliability problems should also be studied.

**Investigate the feasibility of implementing, in a microprocessor, a simple self-measuring self-adjusting encoder/decoder**—Experience has shown that the current implementation of data base systems are I/O bound within a node and communication bound on the DCS. A microprocessor encoder/decoder, by performing compression and decompression, would cause communications to be done more efficiently, at the same time distributing or relieving this function from the processor sub-systems. Such a device would perform the following functions: (a) encode and decode data; (b) measure and adjust the code assignments; (c) detect errors and automatically re-initiate the operation; and (d) control concurrent accesses. The advantage of this design is that it would make data compression transparent to the rest of the system.

In conclusion, the use of data compression allows data to be stored more efficiently and data communication to be done with shorter messages. However, many issues relating to the feasibility, the design of coding techniques, the reliability of the resultant codes, the implementation issues, etc., must be solved. It is contended that such solutions do not exist now and future study is necessary.

## PROGRAM/DATA PLACEMENT AND MIGRATION

### *Definition of the problem*

The problem is defined as follows: given a number of computers that process common information files, how can one allocate the files so that the allocation yields minimum overall operating costs. This problem has been called the *File Allocation Problem (FAP)*.<sup>9</sup> A more general problem is the *Dynamic File Allocation Problem (DFAP)* in which the files are allowed to migrate over time so as to adapt to changing access requirements. The solution to this problem

is affected directly by the query decomposition strategies and rather lightly by the data compression techniques. If the query is always decomposable into single file sub-queries, then the placement of each file may be optimized independently. Otherwise, the distribution of the files on the DCS must be optimized jointly and this increases the complexity of the problem significantly. On the other hand, data compression techniques generally affect the amount of data requested at a node and therefore the cost of an access is governed by the type of compression techniques used. By making certain assumptions on the query decomposition strategy and the compression technique, the FAP can be studied independently.

### *Motivations for file placement and migration*

The major reason for allocating multiple copies of a file to certain parts of the system at certain times and the unnecessaryness of keeping a copy of every file at every node all the time is because users have localities of access in any time interval. At any particular time, a file may be used by a group of users and it will continue to be used by the same group for a certain length of time. For a particular user, the file that he wants to access may be available locally, in which case, he can access the file with very little cost. If the file is not available locally, he would have to pay a cost in terms of delay in accessing the file and also introducing traffic in the network before he can make the access. It is under this situation that we should consider moving a copy of the file to his node. Introducing a new copy would also increase the cost in terms of storage space and the additional overhead in locking and concurrency control. Therefore, the decision of whether to introduce a new copy of a file involves a balance of the cost between the two cases. The costs, e.g. communication costs, are a function of the topology of the system, the type of communication protocols used and most importantly, the extensiveness of usage at a particular node. Further, as the request frequencies change, the file allocation on the system must also change accordingly. However, in this case, the cost in migrating the file from one node to another must also be taken into account in the file placement algorithm.

### *Previous work*

Most of the previous studies on optimization are based on static distribution, that is, the allocation does not change with time. Some variation of dynamic distribution involves the application of static algorithms whenever need arises. A summary of the previous researches in this area is shown in Table I. These algorithms are very expensive to run in real time. A particular solution to this problem involving a 30 site network required about an hour on an IBM 360/91 computer.<sup>16</sup> The difficulty in optimization is also exemplified in Reference 33. Moreover, most of the algorithms are shown

TABLE I.—A Survey of Previous Researches in File Placement/Migration

	Network Flow Techniques		Mathematical Programming & Exhaustive Searches					Heuristic	
	Stone <sup>34-37</sup>	Jenny <sup>21,17</sup>	Chu <sup>3</sup>	Casey <sup>1</sup>	Levin & Morgan <sup>25,29</sup>	Ghosh <sup>13</sup>	Foster et. al. <sup>11</sup>	Loomis & Popek <sup>26,27</sup>	Mahmoud & Riordon <sup>28</sup>
Assumption	Complete relations among objects: No redundant copies of objects.	Complete relations among objects.	Complete relations among objects: File access is poisson.	All objects independent.	Only Program-data relation exists between objects.	All objects independent.	Star network: All objects independent.	Complete probabilistic relation among objects.	Indep. obj's: Query & ret'n traffic divided equally among alloc. nodes.
Parameters	Avg. amount of comm. traffic among obj.: Execution cost on a computer: Overhead in migration.	Functional equations represents constraints on which process placements depend; Communication demands between processes.	Storage cost: Transmission cost: File length: Request rate between files: Update rate between files: Maximum allowable access time: Storage capacity.	Storage cost: Query trans. cost: Update trans. cost: Query rate between nodes: Update rate between nodes.	Communication cost for query: Communication cost for update: Traffic rate for query/update from a node to a file via a program.	Data base with multiple target segment types: Queries with multiple target segment types	Queuing time & service time for transactions: Storage capacity: Avg. no. of messages in network: Avg. local processing: Average file length: Access frequency: H/W, S/W characteristics.	Inter-node trans. cost: Node capability: File length: Processing needs of file: Prob. of a request acc. an object: Prob. of a request/update is incident on a node: Prob. of 2 objects processed in parallel.	Communication cost: File storage cost: Query/update traffic & corresponding return traffic for each file at each node: Availability requirements.
Algorithm used	Network flow	Network flow & predicate calculus.	Integer programming	Path search on cost graph	Path search on cost graph	Combinatorial search thru. possible sol.	Queueing network alg.: Integer prog.	Clustering	Int. prog. or add-drop heuristic
Remarks	Static: Optimal for 2 processors: Sub-optimal for 3 processor system: Can calculate critical load factor for 2 processor system.	Do not consider multiple copy allocation: Min-cut alg. produces optimal subprocess groupings: Minimize communication overhead.	Algorithm very complex: Consider delay from network queuing approach.	Algorithm efficient: Independence of objects reduces allocation of multiple file to single file.	Algorithm efficient: Definite access relations among objects reduces the allocation of multiple file to single file.	Maximize no. of segments that query can retrieve in parallel from different nodes: Do not model communication delays.	Minimize difference from optimal branching probabilities: Algorithm complex.	Dynamic network behavior ignored: Maximize potential for parallelism.	Obtain both capacity assignment for links & file placements: Should consider query to be routed to nearest node & not distributed equally among all nodes.

to be NP-complete.\*\*<sup>9</sup> Although polynomial algorithms could exist for some special cases of the problem, e.g. the allocation of files in a two-processor system,<sup>34</sup> their use in practical applications is very limited. This result suggests that the distributed system designer should focus his attention to efficient heuristics.

Heuristics for file distribution on a DDB are usually interactive algorithms. A feasible solution can be generated. Users of some decision algorithms then have to decide whether to improve the solution or not and how to improve it. The disadvantages of these types of algorithms are that they usually find a local optimum instead of a global optimum and the validation of the algorithm is very difficult. For most cases, the heuristics can be shown to perform

satisfactorily for some example values, but the algorithm is so complex that its worst case behavior is very difficult to determine. We first classify the three most commonly used heuristics, then we will discuss the application of a file assignment algorithm on this problem.

### Hierarchical designs

This is a heuristic procedure in which attention is first restricted to the more important features of a system. In a file allocation problem, attention can first be restricted to geographical regions. After analysis has been performed and the files have been distributed to different geographical regions, attention can be directed to the less important details such as allocating files within a geographical region. This stepwise refinement procedure can continue down many levels. At each level of optimization, it is hoped that the effects on the optimization of the current level from the levels above and the levels below are very small. Neverthe-

\*\* NP-complete problems<sup>22</sup> is a class of problems for which there are no known optimal algorithms with a computation time which increases polynomially with the size of the problem. The computation times for all known optimal algorithms for this class of problem increase exponentially with problem size, i.e., if  $n$  represents the size of the problem, then the computation time goes up as  $k^n$  where  $k > 1$ .

less, iterations and design cycles may exist to refine the solution.

### Clustering algorithms

Clustering algorithms are horizontal design processes which have a similar objective as hierarchical algorithms, namely, to reduce the complexity of the analysis in a large system. In a DDB, clusters can be formed on geographical distribution of access frequencies. The files are then allocated to clusters. The file allocation within a cluster may further be refined as in hierarchical algorithms.<sup>26,27</sup>

### Add-drop algorithms

In applying this algorithm, a feasible distribution of files is first found. The total cost of the system can be improved by successive addition or deletion of file copies. When a feasible solution with a lower cost is found, it is adopted as a new starting solution and the process continues. Eventually, a local optimum is reached in which addition or deletion does not reduce the cost. The whole procedure can be repeated with a different starting feasible solution and several local optima can be obtained. By taking the minimum of all the local minima obtained, it is hoped that we can get very close to the global optimum.<sup>28</sup>

The above techniques are by no means complete. A combination of these techniques may be chosen by the designer. In the next section, we introduce a file assignment heuristic which utilizes some of the principles of add-drop algorithms.

### File assignment algorithm

In this section, we present an algorithm which can be used to optimize the file placements on a DCS. The assumptions that we use in developing the model are:

1. **File accesses are independent**—By this, it is meant that there are no interactions among the files and all the accesses on the system are single file accesses. The placements of each file can therefore be optimized independently.
2. **It is assumed that all the constraints on the system can be represented in the form of costs.** For instance, paths linking two nodes in the network which violate some constraints such as the response time constraint, have a high inter-communication cost induced on them.
3. **It is assumed that for a certain time interval considered, it is divided into periods.** The file access behavior for a period are assumed to be estimated at the beginning of the period and the access behavior for the subsequent periods cannot be estimated at that point. With this assumption, it is possible to optimize the file allocations of each period independently and is not necessary to use dynamic programming to optimize the allocations for all the periods as done in Reference 25.

No assumption is made on the length of each period. Their lengths need not be identical and may be determined dynamically. The algorithm described in this section determines the file placements for each period, but no provision is made for determining the length of each period.

The symbols used in the model are:

$n$	number of nodes in the distributed system
$a, b, c$	indices for files
$t$	length of the current period of consideration, T
$q_i^a$	a random variable indicating the total amount of query accesses (including updates) at node $i$ to file $a$ (since we are optimizing each file independently, we will not write the superscript $a$ in the remaining part of the discussion)
$\alpha_i$	a random variable indicating the fraction of queries at node $i$ that are updates to file $a$
$S_{i,j}$	per unit cost of accessing file $a$ from node $i$ to node $j$
$M_{i,j}$	per unit cost of multiple updating file $a$ from node $i$ to node $j$
$N_{i,j}$	per unit cost of moving file $a$ from node $i$ to node $j$
$f_i$	per unit cost of storing file $a$ at node $i$
$l_a$	length of file $a$ in bits
$Y_i =$	$\begin{cases} 0 & \text{if file } a \text{ does not exist at node } i \text{ during period } T \\ 1 & \text{otherwise} \end{cases}$
$X_i =$	$\begin{cases} 0 & \text{if file } a \text{ does not exist at node } i \text{ during period } T-1 \\ 1 & \text{otherwise} \end{cases}$
$K_0 =$	$\{j: Y_j=0\}$ —set of nodes without a copy assigned
$K_1 =$	$\{j: Y_j=1\}$ —set of nodes with a copy assigned
$K_2 =$	$\{j: J_j=\text{unassigned}\}$ —set of nodes unassigned
$K =$	$K_0 \cup K_1 \cup K_2,  K =n$ (cardinality of $K$ )

Consider the problem of allocating file  $a$  on the system at the beginning of period  $T$  of length  $t$ , the total amount of the retrievals and updates in this interval are estimated to be  $q_i(1-\alpha_i)$  and  $\alpha_i q_i$ . The per unit cost of assessing, updating and transferring file  $a$  from node  $i$  to node  $j$  are  $S_{i,j}$ ,  $M_{i,j}$ , and  $N_{i,j}$  respectively. We assume that whenever a user at node  $i$  makes a request to a file not residing at node  $i$ , he will make the access at a node which has a copy of the file and with the lowest cost of access from node  $i$ . Our objective is to minimize the cost in the system. Our objective function is:

$$Z = \sum_{i=1}^n q_i(1-\alpha_i) \min_{j, Y_j=1} S_{i,j} + \sum_{j=1}^n Y_j(f_j + \min_{i, X_i=1} N_{i,j})l_a + \sum_{j=1}^n \sum_{i=1}^n Y_j \alpha_i q_i M_{i,j}$$

The first term in the above equation represents the query access cost; the second term represents the fixed cost of the period (cost of storage+cost of file transfers at beginning of

period); while the third term represents the multiple update cost of the system. We can rewrite the integer program as follows:

$$Z = \sum_{i=1}^n Q_i \min_{j, Y_j=1} S_{i,j} + \sum_{j=1}^n Y_j F_j \quad (1)$$

where

$$Q_i = q_i(1 - \alpha_i) \quad (2)$$

$$F_j = (f_j + \min_{i, X_i=1} N_{i,j})l_a + \sum_{i=1}^n \alpha_i q_i M_{i,j} \quad (3)$$

subject to

$$Y_i = 0, 1 \quad (4)$$

The file assignment algorithm proposed here consists of the following basic parts:

1. Property or condition to assign or not to assign a copy of the file to a node.
2. Computation of a representative value for a candidate problem. (The state of a candidate problem is made up of the states of allocation to the  $n$  different nodes of the DCS. In general, the  $n$  nodes of the DCS can be partitioned into three sets,  $K_0$ ,  $K_1$  and  $K_2$ .) The function of the representative value is to illustrate the minimum of the candidate problem without actually enumerating all the allocations for the unassigned nodes.
3. Stopping the criterion.

The general steps of the algorithm are shown in Figure 4. We discuss each of these steps briefly here.

**M-1.** This is to initialize the candidate problem—all nodes are unassigned at this point. The candidate list, which is a list of states where an extra node from  $K_2$  is added to  $K_0$  or  $K_1$  and its corresponding representative value, is assigned the empty set.

**M-2 to M-5.** These four steps essentially achieve the following: a node is selected from the un-assigned set,  $K_2$ , and is assigned a copy or not assigned a copy of the file. A representative value, which is chosen to be a lower bound estimated by solving the integer program (Equation 1) without the integrality constraints (Equation 4), is calculated for each of the corresponding candidate problems. The derivation of the linear programming lower bound for a candidate problem is shown in the appendix. The computed lower bound and the corresponding assignments are attached to the candidate list. These steps are then repeated for each of the nodes in  $K_2$ .

**M-6.** This step selects, from the candidate list, the candidate problem with the minimum lower bound and the corresponding assignment of nodes and use it for the next iteration. Steps M-2 to M-6 therefore have selected a node and have decided whether a copy should be placed at that node. This node is removed from the  $K_2$  list.

**M-7.** The steps M-2 to M-6 are repeated until the  $K_2$  list is empty. The overall computational complexity of the

algorithm is  $O(n^4)$ . To further illustrate the steps of the algorithm, it is applied on the following example.

Suppose the following matrix represents the query cost  $S_{i,j}$  for a five-node system.<sup>1</sup>

$$S = \begin{bmatrix} 0 & 6 & 12 & 9 & 6 \\ 6 & 0 & 6 & 12 & 9 \\ 12 & 6 & 0 & 6 & 12 \\ 9 & 12 & 6 & 0 & 6 \\ 6 & 9 & 12 & 6 & 0 \end{bmatrix}$$

Let

$$Q = [Q_i] = [ \quad 24 \quad 24 \quad 24 \quad 24 \quad 24 \quad ]$$

and

$$F = [F_i] = [ \quad 168 \quad 180 \quad 174 \quad 126 \quad 123 \quad ].$$

By enumerating the  $2^5 - 1$  possible allocations, it is found that a copy of the file should be allocated to nodes 1, 4 and 5 giving a cost of 705. The detailed application of the heuristic is shown in Figure 5, giving a solution of 717. In general, this method will give a solution very close to the optimal solution and the computation complexity is very low when compared with that of generating the optimal solution. The five examples on a 19-node problem solved by Casey<sup>4</sup> are compared with the solutions using the proposed heuristic and is shown in Table II. It is seen that the results do not deviate substantially from the optimum solutions. The results indicated here are somewhat preliminary. For the sake of simplicity, a more complicated algorithm is not presented. This algorithm, together with the analytical results and the theoretical studies will be presented in a future paper.

## TASK SCHEDULING

### Definition of the problem

This problem is related very strongly to the problem of query decomposition. After the query has been decomposed, the *Query Scheduling Problem (QSP)* is to sequence the processing of the sub-queries on the DDB for a given distribution of the files on the DCS defined by the FAP. Depending on the ways in which the sub-queries are processed, QSP can further be classified into *Sequential Query Scheduling Problem (SQSP)* and *Parallel Query Scheduling Problem (PQSP)*. In SQSP, the sub-queries are processed

TABLE II.—Comparison between Casey's Solutions on a 19-node Problem and the Solutions of the Proposed Algorithm

Problem	Update/Query Percent	Casey's Optimum Cost	Cost using Proposed Algorithm	Time on CDC6400 (sec.)
1	10	117596	123073	7.7
2	20	188738	200971	7.7
3	30	242581	246107	7.7
4	40	291790	298690	7.7
5	100	431720	615342	7.7

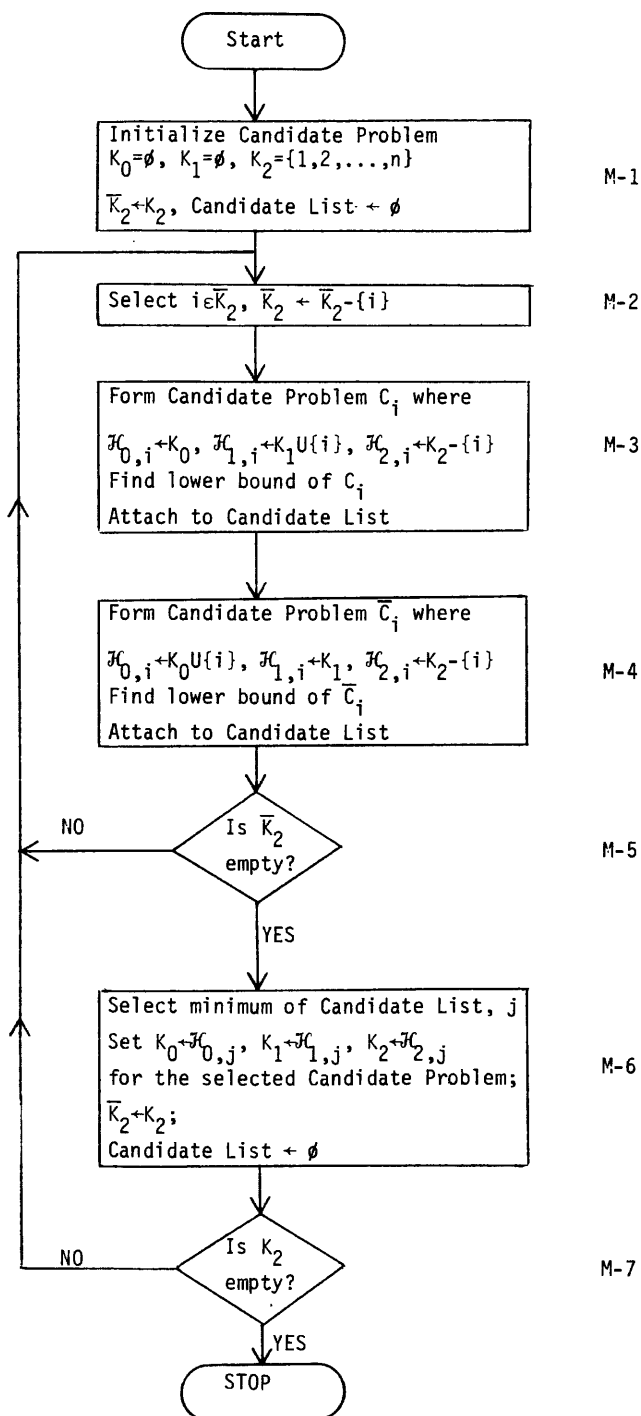

Figure 4—File assignment algorithm.

in sequential order. Using the results produced by the processing of the previous sub-query, the processing of the present sub-query will produce some results to be used by the next sub-query in sequence. If the files used by the sub-queries are separated geographically, intermediate results have to be transferred over communication lines. The objective is to minimize the amount of communications re-

quired. In PQSP, multiple queries are sent to different nodes and they are processed in parallel. The results after the processing are sent back to the requesting location. In this case, the response time may be smaller because all the communications are done in parallel (it is assumed that the major overhead is in communications and not in processing). For a compromise between the amount of communications and the response time, a combination of sequential and parallel query processing may be used. The QSP is a very similar problem which has been studied in other areas, e.g. the deterministic scheduling of multi-processors, the scheduling of requests in a computer system, etc. The results obtained there may therefore be extended to this study.

In order to solve the QSP, the notion of task must be defined. A *task* is defined to be a simple request which uses a resource for a finite amount of time. A request is said to be simple if no other resource is needed during the processing of this request. A complex request can always be broken down into a sequence of simple requests. A resource on a DDB can be physical, such as a communication channel, a processor, etc., or it can be logical, such as a file. The tasks are usually governed by a precedence graph so that a task cannot be processed until its predecessor has finished processing. The task scheduling problem is to sequence the processing of the tasks, subject to precedence constraints, so that some overall optimization criterion is satisfied. The criterion can be the maximum completion time of all the tasks if the objective is to maximize the throughput of the system; or it can be the sum of the completion times of all the tasks if the objective is to minimize the average response time.

To schedule the processing of queries, they are first decomposed into multiple tasks and the tasks are subsequently scheduled. The general task precedence graph for the processing of a query in the PQSP which requires the use of geographically distributed files is shown in Figure 6. On a DCS, the communication overhead, which includes time to set up the communication path and the queuing delay to transmit the messages, is usually much larger than the processing overhead for a query. Therefore, the time required to process a task at a node in Figure 6 is usually negligible as compared to the time to pass the results over the communication sub-system. The communication overhead on a DCS is dictated by the configuration of the interconnection mechanism. Many models have been designed to study the behavior of these delays, e.g. in Reference 23.

The QSP is usually solved with distributed control, that is, there does not exist a primary node which schedules all the processing of the queries on the DCS. Further, complete information for optimal scheduling are usually not available due to the high overhead in distributing them. The tasks are usually scheduled at each node sub-optimally without assembling all the necessary information before the scheduling.

#### Assumptions used to simplify the problem

Certain assumptions are often used so that the problem can be simplified.

Figure 5—Application of file assignment on Casey's 5 node example.

### Communication overhead

The processing overhead is usually much smaller than the communication overhead and they are usually ignored. This assumption will eliminate many tasks in the precedence graph.

### Static versus dynamic algorithms

Static algorithms schedule a set of tasks available at the time of scheduling and a set of tasks that are known to arrive at fixed future times. The schedule does not change during the duration of the processing of these tasks. On the other hand, dynamic algorithms are more flexible and they re-schedule all the available tasks whenever a new task comes in. The advantage of dynamic algorithms is that they allow task initiations to be dynamic and do not restrict the schedule to the order determined initially, but they have the disadvantage of larger overhead. With the use of dynamic algorithms, the assumption that there are precedence constraints among the tasks can also be relaxed. Whenever

a task enters the system, all the tasks in the system are re-scheduled dynamically. The choice between the use of static and dynamic algorithms is system dependent. If the arrivals of requests are indeterminate, then dynamic algorithms are usually better. On the other hand, if the arrivals of requests can be determined precisely, then static algorithms should be used. The choice between static and dynamic may also be dictated by the overhead in each type of algorithm, and a judicious choice must be made by the designer.

### Deterministic versus probabilistic processing time

The processing time for a task can be assumed to be deterministic or probabilistic. In the deterministic case, it is possible to determine which order can best satisfy the optimization criterion and therefore all the tasks can be scheduled in a specific order. However, in a probabilistic case, it is difficult to do so when the processing times of all the tasks are governed by a common distribution. Certain assumptions, e.g. the distribution of job size, have to be made before an analytical evaluation is possible.<sup>5</sup> The theory of

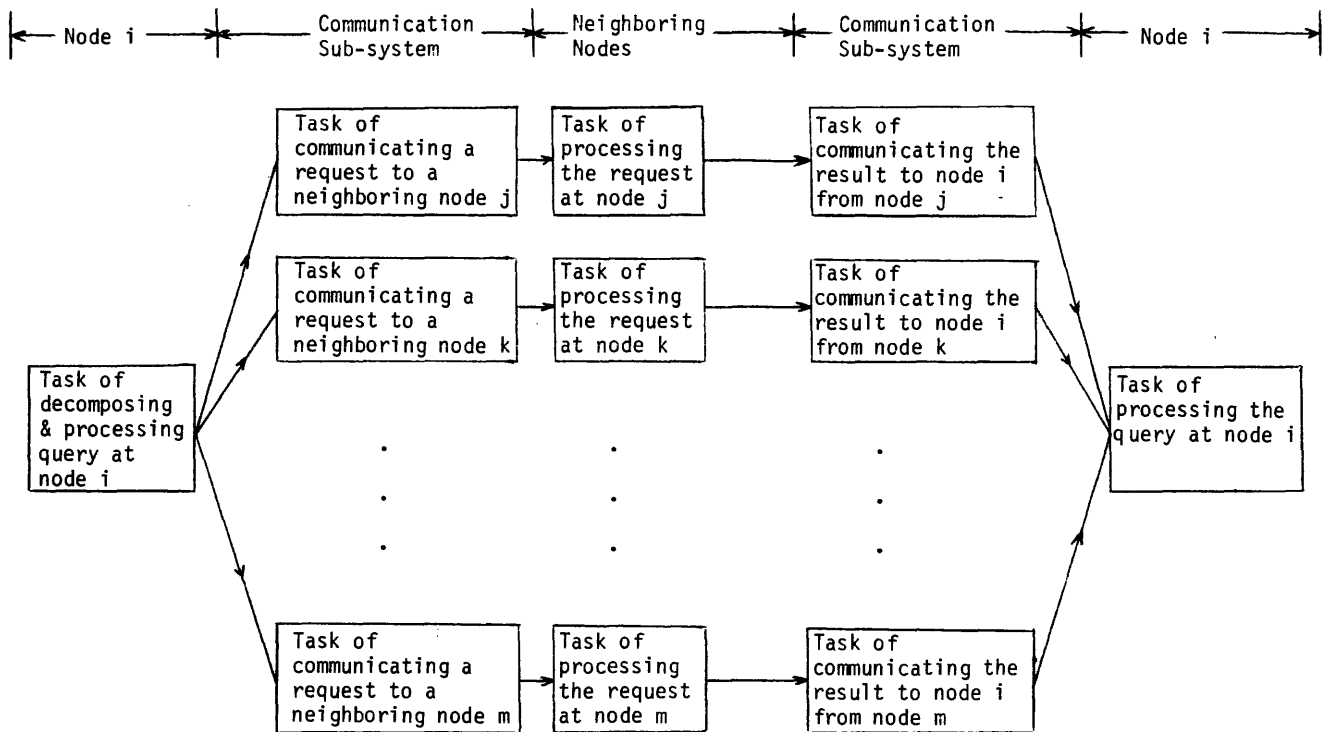

Figure 6—Task precedence graph for the processing of a query in the PQSP which requires the use of geographically distributed files.

scheduling developed now are mostly applicable to the deterministic case.<sup>15</sup> They can be used to approximate the probabilistic case when the average or the worst case processing times are used. Lastly, the difficulty of the scheduling problem can be assessed easily in most cases under the deterministic assumption. NP-completeness of the problem can usually be shown or a polynomial algorithm can be found. The QSP under the independent query assumption, can be shown to be NP-complete. Under this situation, the designer has to look for good heuristics which can be executed within the real time constraints. However, the evaluation of these heuristics is usually difficult. Evaluation methods and techniques are usually of three kinds, analytical techniques, simulations and approximation algorithms. Analytical techniques generally have to make some simplifying assumptions about the system parameters in order for the solution to be tractable and the results obtained are usually not accurate. On the other hand, simulations are almost always expensive to run, and it is difficult to exhaust all the possible cases of the system. A third type of evaluation algorithms are approximation algorithms.<sup>40</sup> There are two classes of these approximations, one guaranteeing a near-optimal solution always, and the other producing an optimal or near-optimal solution "almost everywhere." These types of algorithms are still in the research stage and a unifying approach in designing algorithms of this type is still lacking. The future trend is in the direction of investigating good approximation algorithms for scheduling queries.

## CONCLUSION

In this paper, we have studied in detail the issues of resource management of data on a distributed data base. These issues are divided into three related levels, namely, the query level, the file level and the task level.

On the query level, the major issue is the decomposition of user queries so that parallelism in processing can be maximized and the amount of communications on the system can be minimized. It is shown that the approach using decomposition is deficient when the query is non-decomposable. In this case, the files needed to process the query must be moved to a common location before the query can be processed. An algorithm is proposed in this paper which preanalyzes the type of accesses on the system and introduces redundant information onto the files so that file transfers can be reduced.

On the file level, the issues are the compression of data for efficient storage and communication and the placement and migration of files for efficient accesses. In data compression, the existing techniques has been classified into four areas—run length encoding, differencing, statistical encoding and value set schemes. A multi-level compression scheme is proposed so that data is compressed through a set of cascaded stages. In the area of file placement and migration, a file assignment algorithm has been proposed. In general, this algorithm gives a solution very close to the optimal solution and the computation complexity is very low when compared with that of generating the optimal solution.

On the task level, the problem is to sequence the processing of the sub-queries for a given distribution of the files on the distributed system so that overlap in processing can be maximized. It is shown that the problem of query scheduling on a distributed data base is NP-complete. The future directions of research are therefore in the search of effective approximation algorithms.

The issues we have discussed in this paper encompasses the spectrum from the processing of the query to the scheduling of the requests. However, many other issues may arise in the design of the data base. These include other issues in operational control, such as directory management, concurrency control, security and privacy, etc. and they may affect the strategies used in data management. The study of these issues, however, are beyond the scope of this paper.

#### APPENDIX—DERIVATION OF THE LOWER BOUND OF A CANDIDATE PROBLEM

We derive in the appendix the lower bound of a candidate problem given the state of it. We can rewrite the objective function (Equation 1) on condition on  $K_0$ ,  $K_1$  and  $K_2$ .

$$Z = \sum_{i \in K_1} F_i + \sum_{i \in K_0} Q_i^* \min_{j, Y_j=1} S_{i,j} + \sum_{i \in K_2} Q_i^* \min_{j, Y_j=1} S_{i,j} + \sum_{i \in K_2} F_i Y_i$$

We have

$$\min Z = \sum_{i \in K_1} F_i + \sum_{i \in K_0 \cup K_2} Q_i^* \min_{j, Y_j=1} S_{i,j} + \sum_{i \in K_2} F_i Y_i \quad (A-1)$$

subject to  $Y_i=0,1$

where  $Q_i$  is defined in Equation 2, and  $F_i$  is defined in Equation 3.

Equation A-1 is a non-linear integer program, we can rewrite it in the form of a linear program. Let

$U_{i,j}$  = fraction of accesses made from node  $i$  to node  $j$ ;

$P_i$  = set of indexes of those nodes that can access node  $i$ ;

$n_i$  = cardinality of  $P_i$ .

$$\min Z = \sum_{i=1}^n \sum_{j=1}^n Q_i S_{i,j} U_{i,j} + \sum_{i=1}^n F_i Y_i \quad (A-2)$$

$$\text{s.t. } \sum_{j=1}^n U_{i,j} = 1 \quad i = 1, \dots, n \quad (A-3)$$

$$0 \leq \sum_{i \in P_j} U_{i,j} \leq n_j Y_j \quad j = 1, \dots, n \quad (A-4)$$

$$Y_i = 0, 1 \quad (A-5)$$

Equation A-3 is true because the total amount of fractions must be summed to 1. Equation A-4 is derived by summing over all  $i \in P_j$ , the inequality  $0 \leq X_{i,j} \leq Y_i$  which says that only nodes with a copy of the file can supply users' demands. By relaxing constraint A-5, it becomes a linear program and the

value of  $Z$  obtained will provide a lower bound to the original integer program. The solution to the linear program (Equation A-2 to Equation A-4) has been solved in Reference 7. The solution is:

$$Y_j = \frac{1}{n_j} \sum_{i \in P_j} U_{i,j} \quad (A-6)$$

$$Z_{i,j} = \begin{cases} 1 & \text{if } S_{i,j} + \frac{g_i}{n_j} = \min_{k \in K_1 \cup K_2} \left( S_{i,k} + \frac{g_k}{n_k} \right) \\ 0 & \text{otherwise} \end{cases} \quad (A-7)$$

$$g_k = \begin{cases} F_k & k \in K_2 \\ 0 & k \in K_1 \end{cases}$$

The complexity of the solution is  $O(n^2)$ .

# A unified architecture for data and message management\*

by GEORGES GARDARIN\*

*Institut de Programmation*  
Paris, France

## INTRODUCTION

The ANSI/X3/SPARC study group on data bases has proposed a general architecture for a data base management system.<sup>2</sup> The keystone of this architecture is the conceptual schema which is an explicit description of the enterprise informations modelled in the data base. It portrays the entities, properties and relationships of interest in the enterprise and constitutes a stable platform in order to map the external schemas which describe the data, as seen by the programmers, onto the internal one which defines the data as seen by the system. Finally the ANSI/X3/SPARC DBMS study group envisions a three-level organization which induces three levels of administration functions, three levels of schema processors and three levels of data manipulation modules. This architecture is partially represented Figure 1. It should be noted that only functions are specified, not their implementation.<sup>24</sup>

The ANSI/X3/SPARC study group on distributed systems has proposed a reference model.<sup>3</sup> This model allows application processes possibly located on different systems to exchange messages through sessions which logically join them. The major contribution is the structuration of the cooperating systems into layers. Each layer can be seen as a distributed sub-system. Cooperation between the distributed parts of a layer is governed by a set of protocols specific to the layer. Six, and now seven,<sup>11</sup> layers have been identified. The first three, and now four, layers provide a universal transport service. The next layer supports interaction between cooperating application processes—it performs their binding and unbinding by sessions and controls the exchange of data through these sessions. The presentation layer enables the application processes to interpret the meaning of the data exchanged by transforming them into the desirable representation, format or model. The major concepts of this reference model are represented in Figure 2.

In this paper, the architecture of a distributed data base management system integrating the two proposals is presented. The basic assumption which guarantees the feasibility is that the geographical localization of data has a con-

ceptual meaning. Consequently, the conceptual schema can be distributed, each part representing an enterprise department's description as modeled in a local data base. Obviously, an external schema is entirely situated on a site. The mapping of a user request which refers to an external object into one or several conceptual requests is performed by an external presentation module which can be seen either as an external to conceptual transformer<sup>2</sup> or as a presentation control service.<sup>3</sup> The conceptual requests which result are then taken in charge by a communication kernel which performs at first the session control functions of the ANSI/X3/SPARC distributed system reference model. In addition, it also performs the data base concurrency,<sup>20,5,9</sup> recovery<sup>6,13</sup> and security<sup>12</sup> controls. After possible transmission through the transport management layers, the requests are submitted to conceptual data base managers which execute them. The answers follow symmetric paths in the distributed system. Finally, the external presentation module is responsible for constructing the concluding unique user answer.

This paper is organized as follows: In the first section, it is argued that, at least for a large class of applications, the distribution of objects is performed at the conceptual level. Consequently, an implementation of the conceptual schema in a distributed system is suggested. In the second section, the ANSI/X3/SPARC DBMS architecture is distributed in a computer network. That entails the development of a communication kernel allowing the interchange of the conceptual data manipulations through the transport network. Moreover, each local metabase which contains the local part of the conceptual schema must be accessible from remote computers; this feature permits the binding of an external schema with the distributed conceptual schema. In the third section, the communication kernel is presented using several concepts proposed in the ANSI/X3/SPARC distributed system contribution, mainly at the session control level. In the last section, a reference model for a distributed data base system is proposed. Data base and message management are integrated—(a) The external-to-conceptual transformer of the DBMS architecture is coalesced with the presentation controller of the distributed system architecture. (b) The read/write data base commands and the send/receive message commands appear as two different presentations of data interchange basic actions. (c) The integrity controls of

\* Sponsored by IRIA, Le Chesnay, France.

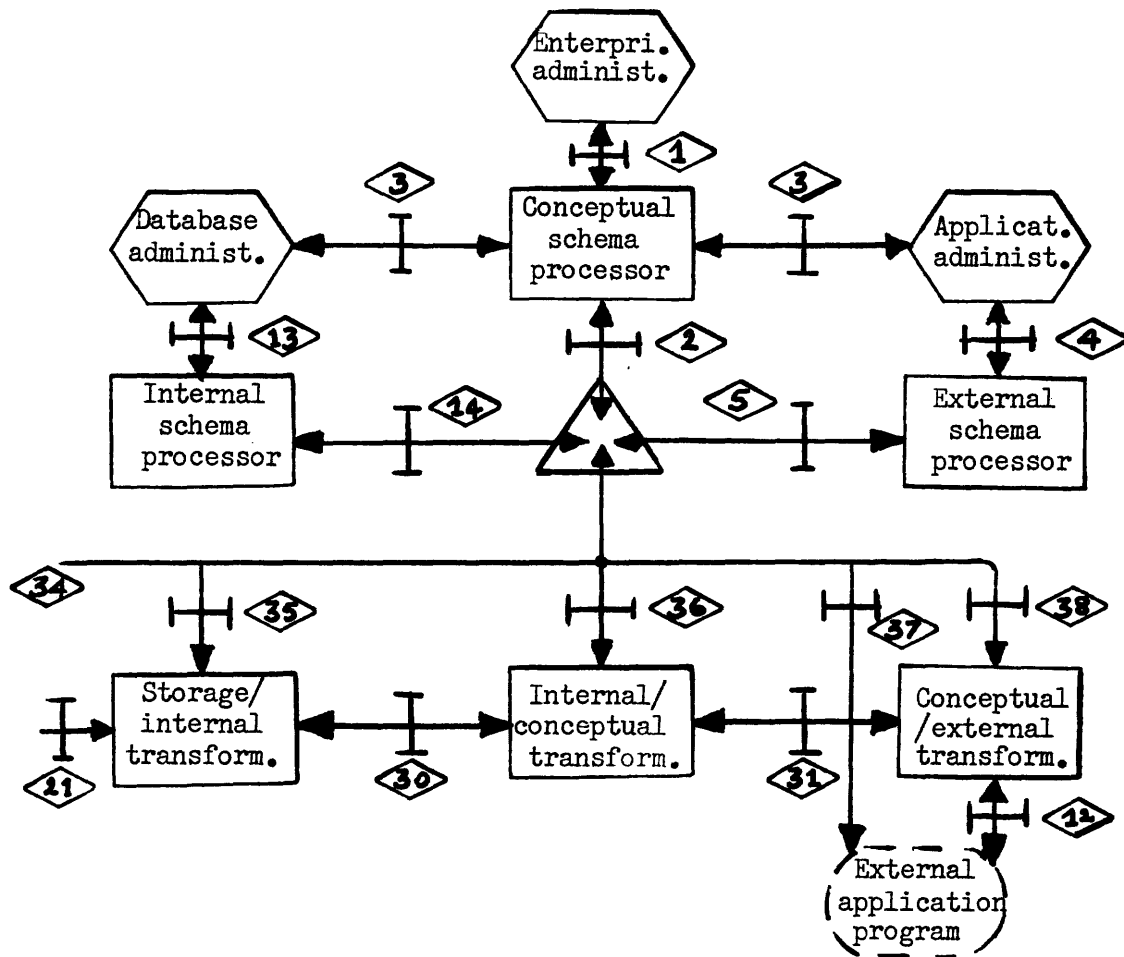

Figure 1—DBMS partial schematic.<sup>2</sup>

the data bases and of the communications between processes are executed by the communication kernel which appears as the heart of the proposed architecture.

CONCEPTUAL DATA DISTRIBUTION

*Conceptual realm of data distribution*

Several papers<sup>16,18,8</sup> dealing with distributed data base management system architecture assume that only the internal schema is geographically split and that localization of data concerns the conceptual to internal level mapping. Other papers<sup>17,1</sup> are quite ambiguous on this topic. Our opinion is that at least for a large family of applications, the distribution of data is connected with the view of the enterprise. This opinion seems to be in agreement with the SDD.1 architecture.<sup>21</sup>

Such an opinion has been verified on real application—first, the ordering, manufacturing and delivery of vehicles at the French motor car company Renault.<sup>7</sup> For example, the fact that Renault model R30 is manufactured in Flins and that all the entities concerning a car of this model must be stored on the Flins site belongs to the enterprise descrip-

tion and should be explicated at the conceptual level. For this application, the localization criterion of an entity is the place of the modeled object in the real world. This is not directly connected with efficient use of computing facilities. On the other hand, the transfer of R30 entities from Flins to Paris in the distributed system would doubtless be of interest for the life of the enterprise—it would mean that the manufacturing of R30 model is moved from Flins to Paris.

The conceptual meaning of object localization has also been verified on other applications, like the management of spare parts. In the Renault real world, spare parts are distributed to two stores. Consequently, in the Renault computer world, they will be distributed in two local data bases managed by two interconnected computers. The localization criterion of objects is the modeling of the distribution of spare parts in the real world which is a conceptual property.

*Conceptual schema design and implementation*

The conceptual schema contains the definition of conceptual objects and the expression of their properties. In distributed data bases, the first property of conceptual objects is to be distributed. Therefore, this property can direct the

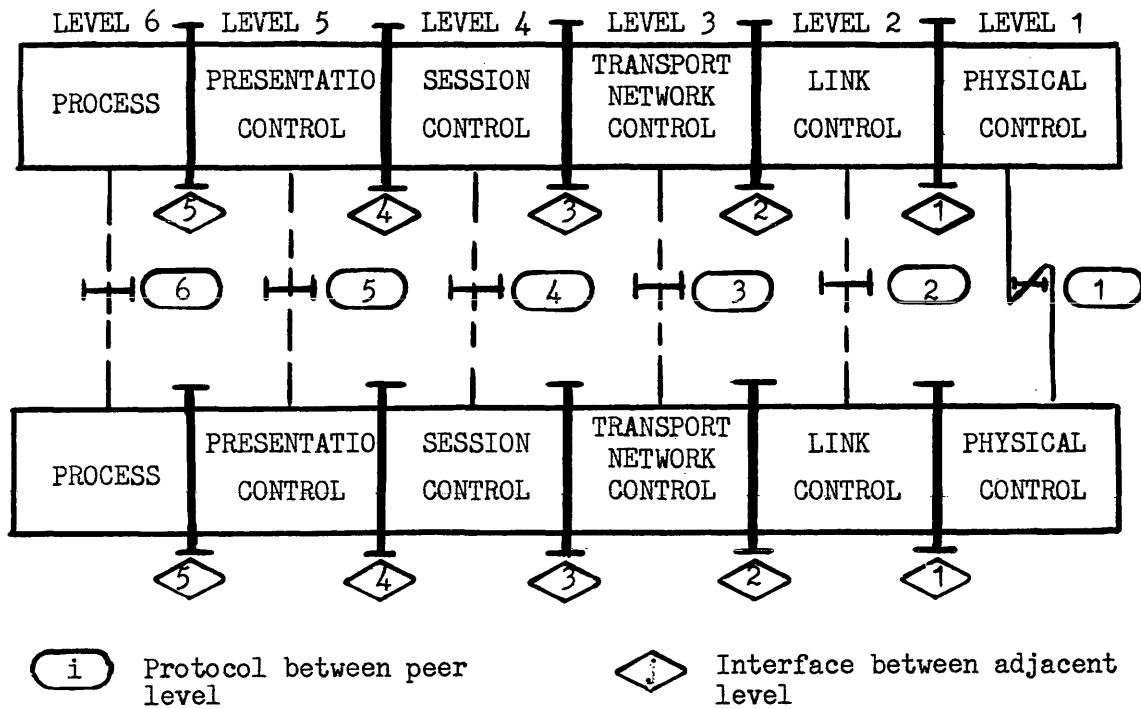

Figure 2—Distributed system levels.<sup>3</sup>

design of the conceptual schema in agreement with the geographical distribution of sites. Thence, it is proposed to divide the conceptual schema in parts, each part corresponding to a local site. Obviously, it may be argued that some properties involve objects localized on different sites, such as distributed integrity constraints.<sup>19</sup> They must be known in each concerned part; that means that when the conceptual schema is divided, the distributed properties must be integrated to each interested part.

It is emphasized that only one conceptual schema must be designed—to provide a coherent conceptual view of the distributed enterprise couched on a unique booklet using the conceptual model should enhance significantly the interest of the system. The implementation of each part of the unique conceptual schema is performed on each site which must present conceptual objects to other sites in agreement with the conceptual schema. Thus, it should provide a distributed stable platform to which local internal schema and global external ones may be bound (see Figure 3). The design process of the conceptual schema may be distributed (each site designing its part) or centralized (designed by some enterprise administrators), but the existence of such a platform is very important in distributed enterprises because it defines the objects which may be interchanged between the departments.

ANSI/X3/SPARC DBMS ARCHITECTURE DISTRIBUTION

Assuming that the conceptual schema can be divided in local parts, the ANSI/X3/SPARC DBMS architecture can

be easily distributed in a computer network. In order to simplify the presentation, host computers of the network are classified in two types:

- *Data computers*, which contain a set of data stored in a local data base.
- *Processing computers*, which execute external data base application programs.

In the last section, an integration will be presented where

Figure 3—Schema binding and division. (1) External schema (several external models). (2) Conceptual schema divided in local parts (one model). (3) Internal schema (one internal model for each computer type).

each host is simultaneously a data computer and a processing computer.

#### *Data dictionary directory*

A key point of the ANSI/X3/SPARC DBMS architecture is the data dictionary directory. It can be seen as a meta-data base where every DBMS processor fetches the parameters required by its execution. In order to implement the ANSI/X3/SPARC DBMS architecture with data computers and processing computers, it is necessary to distribute the elements of this data dictionary directory. The main elements of interest are

- The user program descriptions
- The external data base schema object type descriptions
- The mapping structures relating external and conceptual objects
- The conceptual data base schema object type descriptions
- The mapping structures relating internal data base and conceptual one
- The internal data base schema object type description

A large part of these elements is now easy to distribute. By hypothesis, a user program description and an external schema are located on a processing computer. In the same way, each data computer needs at least an internal schema to describe the internal structure of its local data base. Then, as the conceptual schema is divided in local parts, it is desirable to implement each part on the corresponding data computer, particularly in order to avoid duplication of the whole conceptual schema on each processing computer. Consequently, mapping structures relating internal and conceptual level are situated on data computers.

The only point to discuss is the place of the mapping structures relating external and conceptual objects. As they are strongly dependent on the model seen by external application programs, localization on each computer which uses them improves the independence between computers. Let us point out that an external schema can be mapped on the whole conceptual schema; thence, an external object can be mapped into many conceptual objects of different localization. Consequently, the mapping structures relating external and conceptual objects must include the distribution rules of the external objects.

#### *Functional processors*

Once the data dictionary directory is distributed, each DBMS processor can be located using the simplest criterion of setting it on the computer which manages the parameters most frequently required by its executions. Consequently a processing computer is equipped with an external data base schema processor (one for each external model) and a conceptual/external data base transformer (one for each external model). A data computer is endowed with an internal data

base schema processor, a conceptual data base schema processor, an internal data base/conceptual transformer and an internal storage/internal data base transformer. Let us point out that the transformation of external objects into conceptual ones includes the distribution of external objects on data, that is to say, the decomposition of global queries and updates into local ones.<sup>25,21</sup>

#### *Interfaces*

The distribution of ANSI/X3/SPARC DBMS interfaces is straightforward. However, two interfaces must be transformed into a protocol.

- a. The conceptual data manipulation language (system format) must be exchanged on the network between a pair processing computer—data computer. This includes conceptual objects requests and receipts with associated control. For this purpose, it is proposed to develop a standardized *data manipulation protocol*. Such a protocol must be derived from a data manipulation language with a high degree of functionality in order to take care of the network slow rate of communication. A good example of such a language is QUEL<sup>22</sup> as used in SDD.1<sup>21</sup> and in progress in the SIRIUS project.<sup>9</sup>
- b. The external data bases schema processor needs have access to the distributed conceptual schema in order to bind the external objects to objects declared in the conceptual schema. It can be performed by consulting the meta- data base which contains on each data computer the conceptual schema. For this purpose, the previous data manipulation protocol can be utilized. It allows documentation on the conceptual schema from a processing computer if a facility is provided to manipulate the meta- data bases which contain the local parts of the conceptual schema.

Finally, only one data manipulation protocol must be added. This protocol is implemented as the first level of the communication kernel which is described in the next section. Figure 4 gives the schematic of the system on a processing computer and Figure 5 gives the schematic on a data computer. Let us point out that Interface 3 must stay accessible through the network for the application system administrator; this interface can be implemented with the data manipulation protocol.

## THE COMMUNICATION KERNEL

### *An overview*

The communication kernel performs and controls the communications of data manipulations and resulting entities. It includes the transport management which carries out the transfer of data between endpoints and which corresponds to Levels 1, 2 and 3 of the ANSI/X3/SPARC distributed

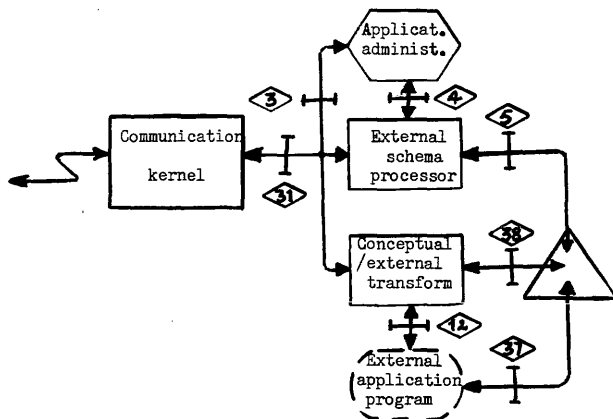

Figure 4—Partial schematic on a processing computer.

reference model (1, 2, 3 and 4 in (ISO 78), see Figure 2) when the endpoints are located on different computers. When they are located on the same computer, the transport management corresponds only to a buffer movement. In addition, the communication kernel includes two layers:

- The session control which controls the correct interaction of processes (transaction and possibly batch processes) with the conceptual data base.

- The data manipulation control which controls requests and receipts of conceptual object occurrences.

The functions of these two levels are specified in the following. Each of them requires a specific protocol between pairs of controllers. The different layers implemented on every computer are summarized in Figure 6. Figure 7 illustrates the different levels of protocols between two sites.

*Data manipulation controller functions*

The different functions of the data manipulation controller are the following:

- Communication of conceptual data manipulations, i.e. coding/decoding into/from messages and sending/receipt of these messages.
- Communication of status, i.e. coding/decoding into/from messages and sending/receipt of these messages.
- Communication of conceptual object occurrences, i.e. packing/unpacking into/from messages with possibly ciphering/deciphering and sending/receipt of these messages.
- Fatal error control and occasional abortion of conceptual data manipulations.

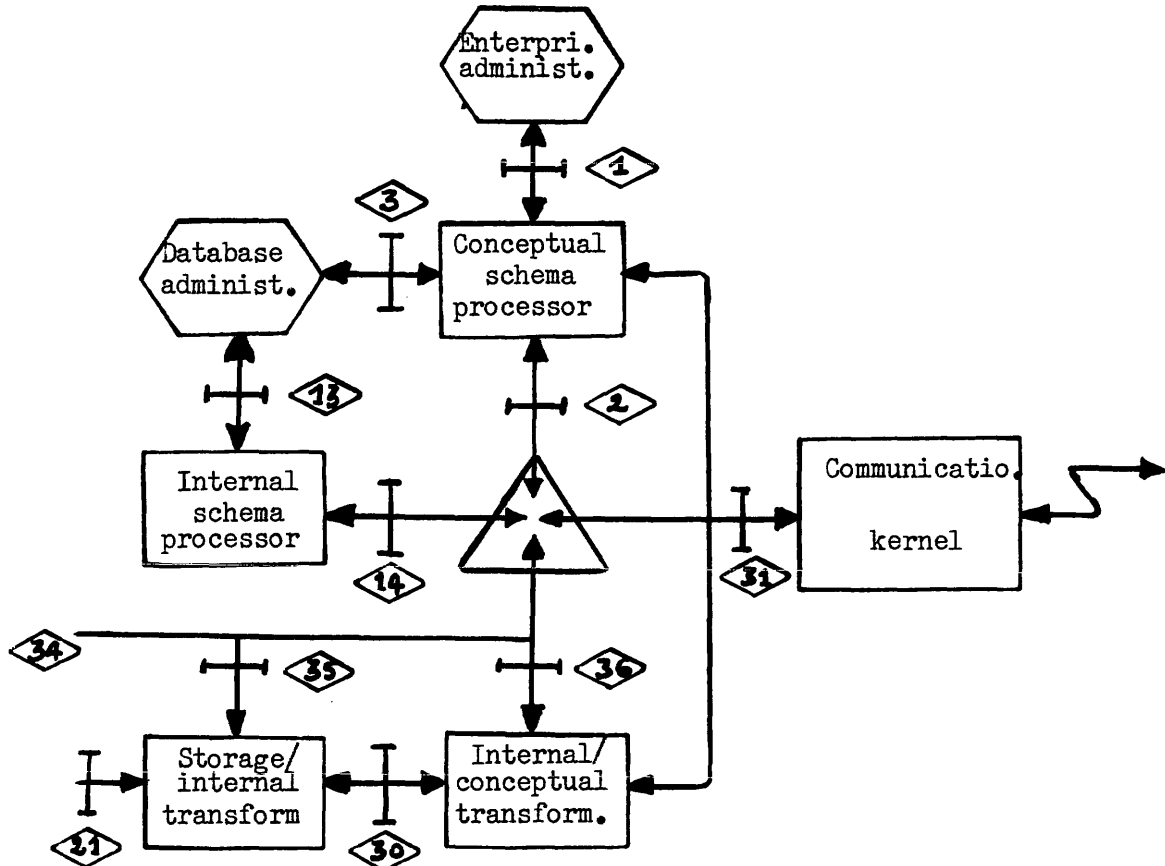

Figure 5—Partial schematic on a data computer.

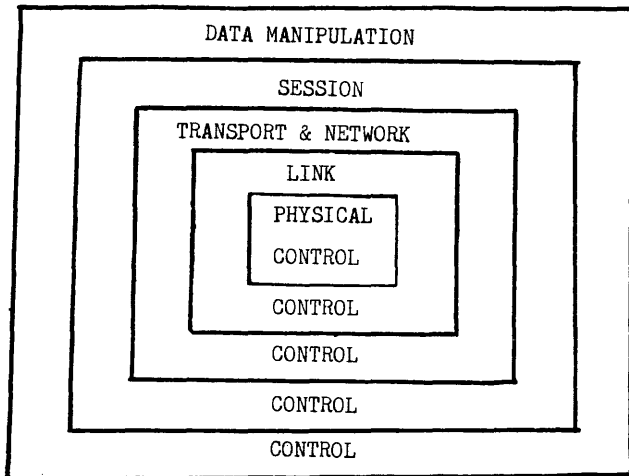

Figure 6—An overview of the communication kernel.

- Global flow control of the number of objects generated by each conceptual data manipulation.

The data manipulation protocol specifications define the format of messages which contain data manipulations, status and conceptual objects.

*Session controller functions*

The session controllers coordinate the distributed processing. The main functions of this layer are the following:

- Initiation and termination of processes.
- Start/stop of process steps (transaction commitment unit or job step).
- Journalizing of updates.
- Commitment of updates and step back-up and recoveries.
- Resolution of concurrency conflicts.

The session control protocol specifications define the format of messages requesting initiation and termination of processes, start/stop of steps, commitment of updates,<sup>4</sup> locking and unlocking of objects,<sup>15</sup> collection of locking status for deadlock detection,<sup>10</sup> step back-up and recoveries.<sup>14</sup>

**THE UNIFIED ARCHITECTURE**

The unified architecture is now straightforward. Two general-purpose computers are represented Figure 8.

The external presentation box summarizes the processors and interfaces represented in Figure 4, except the external application programs and the communication kernel. It includes the external schema processors whose roles are the validation of the external schema declarations, their binding to the conceptual schema and the insertion of the resulting structures in the local part of the data dictionary directory.

It also includes the conceptual/external transformers which receive the user primitives and translate them into standardized conceptual data manipulations. For this purpose, the structure describing the external schemas and their binding to the conceptual one are utilized. Of course, several external models and external data manipulation languages should be offered to the users.

The data base management box summarizes the processors and interfaces represented in Figure 5, except the communication kernel. It includes the conceptual schema processor which interacts with the enterprise administrator for the declaration of the local part of the conceptual schema. After compilation, the structures resulting from this local part of the conceptual schema are stored in the local part of the data dictionary directory. This box also includes the internal/conceptual transformer which receives the conceptual data manipulation from the communication kernel and transform them into internal data manipulations using the structures resulting from the conceptual schema and the mapping structures relating conceptual schema and internal one. Of course, the data base management box also includes all the internal and storage facilities.<sup>2</sup>

Let us point out that there is no direct path to interchange a message between two application programs located on the same computer or on different ones. This can be performed through data bases. However, in order to simplify such a path, objects can be defined in the internal to conceptual mapping description as stored in main memory—only buffering will be performed.

**CONCLUSION**

The proposed architecture requires the definition of every interchangeable object in the conceptual schema. That is, in the mind of the author, a key-point to ensure the success of distributed systems. Indeed, it is alarming to see in some distributed enterprises the development of distributed applications without control over the application-level communications—each application programmer is allowed to specify his own application protocol.

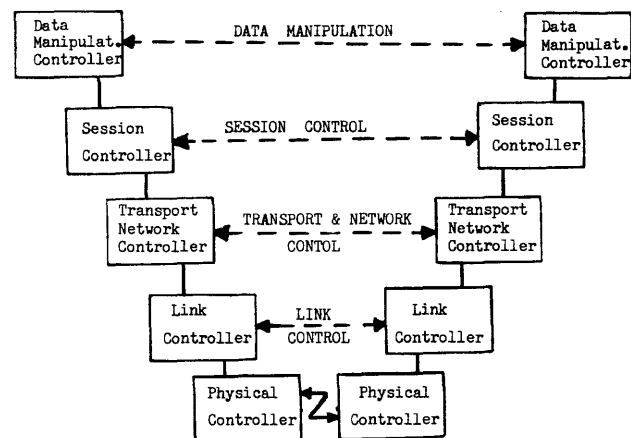

Figure 7—The different levels of protocols.

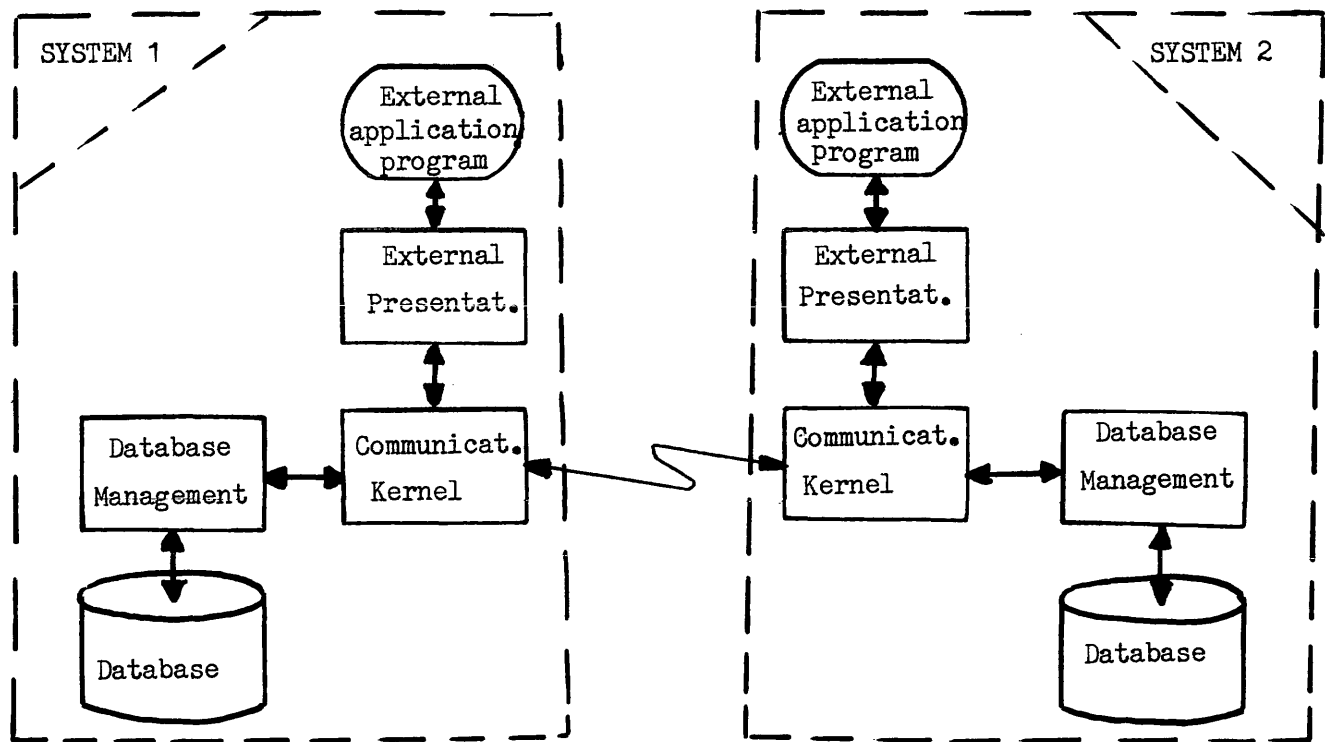

Figure 8—An overview of the unified architecture.

At the present time, the question of great importance is to control and standardize the high-level communications between computerized workstations. The conceptual description of objects which are modeled and consequently can be interchanged is a necessary tool towards the ultimate goals: "To make every process in the world addressable to one another such that they can exchange information when such exchange appears useful. . . ." But also, to make every set of data accessible to every process when such accesses are useful and authorized.

#### ACKNOWLEDGMENTS

The proposed unified architecture has been improved by helpful discussions with R. Gomez, M. Jouve, with the SIR-IUS project members and with C. W. Bachman.

# Design of a prototype ANSI/SPARC three-schema data base system\*

by ERIC K. CLEMONS

University of Pennsylvania  
Philadelphia, Pennsylvania

## INTRODUCTION TO THE THREE-SCHEMA ARCHITECTURE

This paper has three objectives. First, it describes briefly how an ANSI/SPARC three-schema data base system prototype could be constructed, using wherever possible available data models, system software, and research results. Second, it lists data models selected for each of the three levels; it also explains these selections. We find no existing proposal for an external schema facility to be adequate; therefore, our third objective is to develop specifications for the external level. A user interface based upon simple hierarchical user records is proposed, the necessary theory is described and a mapping language for the definition of external schemata is proposed.

The first three sections treat the first and second objective, describing and justifying design decisions for each level. The next three sections introduce specifications for the external level. The final section presents conclusions.

### *Need for multiple data models*

Data structures employed in an integrated data base management system must address three goals: enterprise support, user support, and machine access for retrieval and storage. Enterprise support requires logical completeness: if data have been gathered and maintained at considerable cost, then it is essential that it be possible to use this data to respond to any logically meaningful query. User support requires logical simplicity: regardless of the complexity of the structures needed to support the enterprise's data processing, it is essential that the structures with which an individual user must interact be both simple and well suited to his programming needs. And, for machine access to the stored data, data description must be provided at a level low enough to permit efficient operation by the physical devices.

Unfortunately, these requirements usually appear to be incompatible. A structure that is logically complete enough

for the enterprise is not sufficiently simple for convenient use by most programmers. Likewise, as is shown by example in the following section, a structure that is well designed for one application may not be suitable for another.

A promising mechanism for resolving these difficulties is the three schema model offered by ANSI/SPARC.<sup>1</sup> Rather than attempt to define a single class of data structures of universal applicability, ANSI/SPARC proposes three levels of structures, one each for the enterprise, the users and the machine itself.

Such a model requires not only the ability to declare data structures of different classes, but to define maps between these structures. In this paper we propose choices for data models appropriate to each of the three levels. In particular, we develop an original model for the user level and a language for mapping to it from the enterprise level.

### *ANSI/SPARC Architecture*

In the proposed ANSI/SPARC architecture there are three separate but related levels of data base schema: conceptual schema, external schema, and internal schema. The conceptual schema must be complete; it supports the enterprise and its view of the data required for its operations. The external level includes many external schemata; each external schema supports one or more applications programmers and provides a set of data structures required by and designed for their applications. The internal schema is needed for data access at the device level.

The following terms will prove useful. We define the *stored data base* as the actual data described in the internal schema, and a *user data base* as the collection of *user records* described by the user's external schema. Mappings between the stored data base and a user data base are, at least in theory, composed of maps from the internal to the conceptual level and from the conceptual to the external level. An external schema is often referred to as a user view of a data base or as a *user view*.

\* Research supported in part by National Science Foundation Grant MCS77-18108.

*Design of a prototype*

The following design is proposed for a three-schema data base prototype. Its construction can be facilitated by exploiting existing software. It supports necessary functions for both machine efficiency and applications programmer effectiveness. And the data models used at all three levels are well understood.

For the internal level we propose that a CODASYL data base management system<sup>9,10</sup> be employed. The conceptual level will be a relational system.<sup>2,11</sup> And the external level will be based upon a Virtual Information Object (VIO) interface, introduced in an earlier work<sup>6</sup> and summarized in a later section. These choices are defended in the third section. The remainder of the paper describes the proposed external schema facility.

The three schema prototype will have the structure shown in Figure 1. We shall examine in detail only Interface One.

AN ANSI/SPARC EXAMPLE

We consider a simple university data base including six entity types and the relationships among them: Departments offer courses, employ both students and faculty and have students taking a major concentration in the department's courses. Faculty members teach course sections and advise students. Students enroll in course sections, and for each course taken by each student there is a course grade. A conceptual schema can be presented in several different ways; the data structure diagram in Figure 2 is but one way of displaying this university data base.

Several interesting external schemata can be defined on this conceptual schema; we offer three:

1. A grade report for each student, listing all courses and grades for courses taken.
2. A course roster, listing for each course section the faculty member who taught it and a list of students in the section and their grades.
3. A departmental roster, listing all student majors of each department and their grade-point average.

These data structures are shown in Figure 3.

We note that the structures of Figures 3a and 3b appear to be incompatible; for the first we want the data base

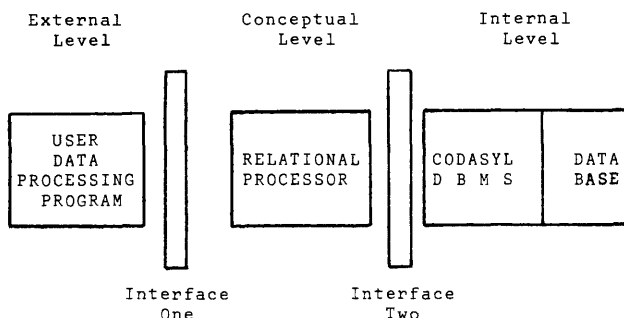

Figure 1—Form of the proposed three-schema data base system prototype.

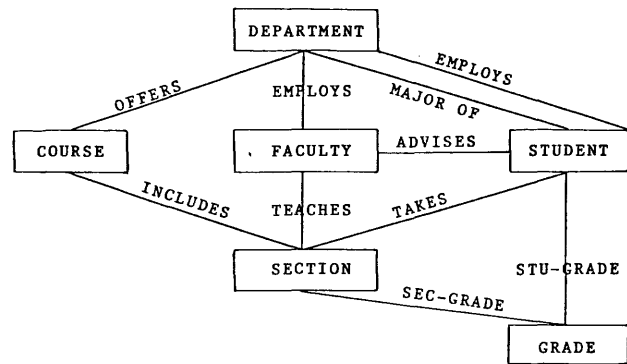

Figure 2—A university data base with six record types and the relationships among them.

organized as a hierarchy with courses listed for each student, while for the second an organization with the students listed for each course seems most appropriate. Also, the grade-point average data in Figure 3c, while derivable from data in Figure 2, is not explicitly stored in the university data base. These observations can be summarized:

1. None of the figures correspond exactly to the data structure of Figure 2 nor to a subset of this figure.
2. Each is a legitimate user view for a data processing application.
3. All are to be supported by the conceptual schema for the academic data base.
4. Each is to be supported by an appropriate external schema.

SELECTION OF DATA MODELS—INTERNAL, CONCEPTUAL AND EXTERNAL SCHEMATA

*CODASYL—Choice for internal level*

For a variety of reasons relating to efficiency of data access, we select the CODASYL model as the basis for the internal level.

Requirements at this level are control of record placement and definition of access paths for efficient selection of single records, subset queries and complex queries requiring data base navigation. The CODASYL model permits placement of records in areas, and supports indexed and hashed single record access, multi-list processing using pointer chains, inverted access using pointer arrays, and navigation using access through sets.

But we must reject the CODASYL model as too complex for the external level.<sup>7,13</sup> Likewise, we must reject it as too rigid and inflexible for the conceptual level:<sup>7</sup> while extensions to the functions to be supported by a data base can generally be encompassed by changes to the CODASYL schema, these changes are likely to result in dramatic restructuring of the schema, rather than mere extensions to it. For example, additional functions require replacing a hierarchical relationship between two record types with a confluency among three.

	.....	
	STUDENT-NAME	GRADE-POINT-AVE

(c) A Departmental Roster based upon the data base shown in Figure 2

Figure 3—Three user views defined upon the university data base of Figure 2.

### Relational—Choice for conceptual level

We select the relational model as the basis for the conceptual level.

The relational model is flexible, in that changes in use of the data base will rarely require changes in the structure of the conceptual schema. It is mathematically rigorous, in that its operators are defined in terms of the predicate calculus. And it is complete, in the sense that any retrieval request expressible in the first order predicate calculus may be performed.

But we must reject the relational model as too tedious for the external level:<sup>6</sup> overcoming normalization to recreate records with structured or repeating data items requires lengthy and unnatural queries. Likewise, we reject the relational model for the internal level, because we require more explicit control of record placement and of the specification of efficient access paths than the relational model provides.

There exist other possibilities for the conceptual level, e.g., Chen's Entity Relationship Model<sup>5</sup> or recent work by Bachman<sup>4</sup> or Gerritsen and Lee.<sup>14</sup> We prefer the relational model because it is more proven and more robust. The relational model has been subjected to considerable analysis and several implementations are currently operational.<sup>2,15</sup> The relational model's syntactic simplicity makes it unlikely that changes to the perceived relationships among entities will require changes to the schema.

### Choice for external—No model available

There is no model available that fully meets our requirements for an external schema facility. Requirements are summarized and a proposed model is presented in the following section.

## DESIGN OF AN EXTERNAL SCHEMA FACILITY

The external schema provides the basis for convenient use of the data base by individual applications programmers. It supports the definition of user views, that is, virtual data bases constructed from the common stored data base. These virtual data bases may differ dramatically in format and content from the stored data base; ideally this would permit a close or exact match between the cognitive structures employed while analyzing the problem and the data structures employed while writing the program.

### Requirements

The external schema facility must support restructuring of data and definition of data items in user records that are not necessarily explicitly present in the stored data base or described in the conceptual schema. Data structures in user views need not support multiple and diverse users; a user view need not be flexible or complete in the sense of a schema designed to support the data processing of the enterprise. Rather, we want the simplest possible use: to obtain the description of a single entity, the user requests a single data access. Thus, to obtain grade-point averages for students majoring in decision sciences, we should be able to write a query of the form:

```
SELECT GRADE-POINT-AVE
FROM STUDENT
WHERE MAJOR = 'DEC SCI'
```

It should not be necessary to traverse a complex data base like the one depicted in Figure 2; it should not be necessary for the user to specify the full details of obtaining a student record, testing the major, then obtaining all grade records for this student for the course grade.

These requirements argue against supporting networks in the external schema. Networks are useful principally because data bases must support multiple users employing different access paths through the data; confluencies, for example, usually appear because different users require different and inconsistent hierarchies, not because any single application requires a network. Networks offer more power than a single user needs, but at a cost: they are too complex to be truly convenient. Similarly, these requirements argue against flat systems like the relational model; because of the simplicity of the supported structures these systems do not permit data structures that closely match the cognitive structures with which the programmer solves his problem, and thus they are too simple to be convenient. We believe that an external schema facility must support the greatest possible variety of virtual hierarchies.

We define a *virtual information object* (VIO) as the program structure corresponding to the programmer's cognitive structure employed during problem analysis and solution. VIOs are constructed as required from the stored data base to meet the needs of individual applications programmers. A *VIO instance* serves as a user record, and a *VIO decla-*

ration provides both the schema definition for a record type in the user view and the definition of the map needed to construct records of this type from the stored data base.

*Classification of hierarchies*

Hierarchies are either *basic* or *recursive*. A recursive hierarchy is one where subordinate entries are of the same type as their parent node and have all the same properties; thus they can have subordinate entries also of the same type. Such hierarchies can reach arbitrary depths and degrees of complexity. Discussion of recursive hierarchies is deferred until a later section.

In this section we introduce three dichotomies that permit the classification of all basic hierarchies:

1. Extent—"Single" or "all"
2. Entries—"Simple" or "grouped"
3. Content—"Complete" or "summary"

When entries are "simple," descendant nodes correspond to single entities (e.g., single treatments for a patient), and are constructed from single instances of entity descriptions (e.g., a single treatment record). When entries are "grouped" descendant nodes correspond to groups of entities (e.g., groups of all medical treatments or all surgical treatments for a patient), and are constructed from several instances of entity descriptions (e.g., the collection treatment records of the appropriate type).

When extent is "all," then all of a node's descendants are present in a single, wide, tree-structured record; when extent is "single" each node has one descendant and thus relationships between a node and its descendants are represented by a forest of narrow trees.

Combination of options for entries and extent provides power and flexibility in the definition of hierarchies. Grouped entries and single extent would provide a set of records, one for each type of treatment received by a patient. Grouped entries, all extent would provide a single record including data on all treatment types, while simple entries and all extent would provide data on all treatments but without aggregation by treatment type.

Finally, "summary" content indicates that only summary information such as counts, totals or averages are to be included in the hierarchies while "complete" content indicates that both the summaries and the complete data from which they are calculated are to be included.

These three dichotomies can be combined to form seven classes of hierarchies\*\* as shown in Figure 4. By forming hierarchies of greater depth, structures of arbitrary complexity can be formed.

\*\* Generally, three dichotomies would yield eight classifications. Since the combination single, simple, summary is not useful, it is not included. Thus there are only seven types of hierarchies.

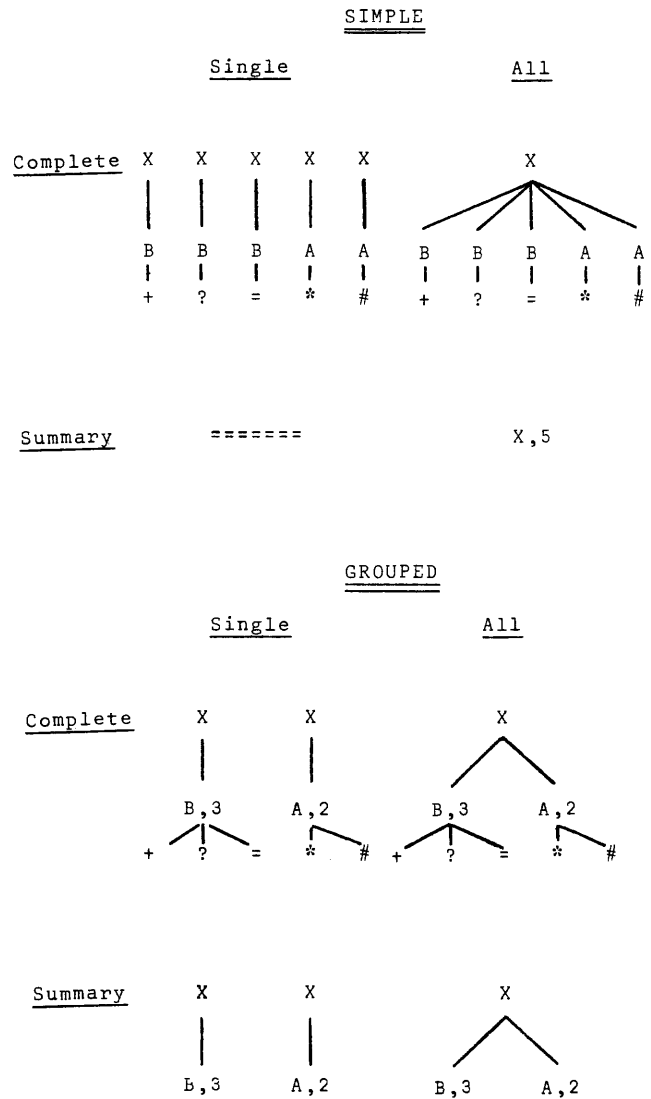

Figure 4—A general taxonomy of hierarchies.

LANGUAGE FOR DECLARATION OF USER VIEWS

*Information required by the external schema facility*

The external schema facility itself requires information, specifying how data from the physical data base are to be accessed and combined to produce records in the user view. This information is of three types:

1. Access information
2. Restructuring information
3. Data item declaration

Access information specifies which data are to be accessed. It names the relations in the conceptual schema that contain the desired information and gives conditions that determine which tuples are actually to be used.

Restructuring information controls the combination of data from normalized relations to produce the desired general hierarchical records. These hierarchies are of the forms presented in the fourth section; restructuring information must therefore be specified in terms of the three dichotomies that were introduced.

Data item declaration specifies what information is actually to be included in user records; this information may of course be different from the data accessed from the stored data base, as an average of course grades differs from the extensive list of grades and courses taken. Data items may be of three types: real elementary, virtual elementary or structured. A real elementary item is one present in the conceptual schema. A virtual elementary item is unstructured (i.e., a field or COBOL elementary item) and computed from items in the conceptual schema. A structured item itself contains one or more data items; since these in turn may possess structure, hierarchies of arbitrary complexity may be declared.

#### Introduction to the language

The language we developed for the declaration of user views is based upon SEQUEL.<sup>2</sup>

Access information is specified using the form:

```
FROM relation-name
WHERE condition
```

We have found that the condition that qualifies the tuples to be accessed is almost always of the same form: use in the descendant items those tuples whose keys are related "in the obvious way" to the keys of the parent items. As an example, in a personnel data base, keys of children contain the keys of a parent; in a customer-order data base, keys identifying details include the keys of orders to which they belong. We call this form of qualification *implication*; e.g., access those children implied by employee tuple, access those details implied by the order tuple. We represent implication by the symbol " $\leftarrow$ ".

Restructuring information is specified by placing an option list within parentheses. The default options are "single" extent, "simple" entries and "complete" content, and only non-standard options need be specified.

There are different formats for declaring each of the types of data items. Virtual elementary items have the form:

```
item-name: defining-expression
```

Real elementary items may be declared with either the form:

```
item-name: conceptual-schema-item-name
```

or, if the data item is to have the same name in both the conceptual schema and the user record, the equivalent form:

```
SELECT item-name
```

may be used. Finally, to declare structured data items, the

form is:

```
STRUCTURE structure-name: (option-list)
item declaration
. . . . .
END structure-name.
```

#### Comments on this language

We offer below an example of a declaration of a map to construct a user record. We present the language statements needed to map from the conceptual schema of the university data base presented in Figure 2 to a departmental roster. In this external schema for each department there is a record containing the department name and a list of all students and their grade-point averages.

```
STRUCTURE ROSTER:
SELECT DEPT-NAME FROM DEPARTMENT;
STRUCTURE STUDENT-ENTRY: (ALL)
SELECT STUDENT-NAME
FROM STUDENT  $\leftarrow$  DEPARTMENT;
STRUCTURE COMPUTE-AVERAGE:
(ALL, SUMMARY)
SELECT GRADE FROM
GRADE-REC  $\leftarrow$  STUDENT;
GRADE-POINT-AVE: (SUMMARY)
AVERAGE (GRADE);
END COMPUTE-AVERAGE.
END STUDENT-ENTRY.
END ROSTER.
```

That is, undeniably, an ugly language for schema declaration. We offer the following observations in its defense:

1. It is not solely a DDL, as the CODASYL subschema facility is. Its mapping function subsumes much that is DML and thus eases the writing of applications programs.
2. It is not solely a subschema facility. Its DML function subsumes many of the data access and restructuring tasks that would otherwise be performed by applications programmers to construct item descriptions from several data base sources.
3. The declaration of a single map, while prepared only once, will be of use in several programs associated with an application.

Thus, while this map may not be easy to code, it permits the easy retrieval of names and averages for students majoring in Decision Sciences:

```
SELECT STUDENT-NAME, GRADE-POINT-AVE
FROM ROSTER
WHERE DEPT-NAME = 'DEC SCI'
```

Likewise, it is now easy to perform several other tasks, e.g.,

comparing averages in the Finance and Marketing Departments:

```
SELECT AVERAGE (GRADE-POINT-AVE)
FROM ROSTER
WHERE DEPT-NAME = 'FIN'
```

```
SELECT AVERAGE (GPA)
FROM ROSTER
WHERE NAME = 'MARKET'
```

In the next section we offer a more advanced example of VIO declaration. Additional details of the language, its use and its implementation, can be found in an earlier work.<sup>6</sup>

*A more advanced example of VIO declaration*

The following example illustrates use of grouping and multiple levels of summary in VIO declaration. We examine a hospital data base, in which records are maintained on patients, physicians and treatments. In particular, patient records include patient identification number, patient name and identification number of attending physician; treatment records include patient identifier, identifier of the administering physician and associated data.

We wish to construct a patient history that lists all treatments of a single patient, grouped by treatment type and within type grouped by physician. We want only summary information: Counts of the number of treatments by physi-

END PATIENT-HISTORY.
```

Figure 6—An example of VIO declaration employing summaries and multiple levels of groupings.

cian within type, by physician, and total, as well as counts of the number of types of treatment and the number of physicians administering treatments to this patient.

An illustrative collection of conceptual level records and an associated VIO instance are depicted in Figure 5. The necessary VIO declaration is shown in Figure 6. We note that in the construction of this user record the interface performed both DML and DDL functions—data are accessed from several data base sources, grouping and ordering is performed and the necessary summaries are prepared. While the associated VIO declaration is somewhat lengthy, it is now possible for simple data processing tasks to be accomplished by the retrieval of the appropriate virtual records.

RECURSIVE HIERARCHIES

Finally, the external schema facility is extended to include declaration and processing of recursive hierarchical structures. Recursive structures are those where lower levels in the hierarchy are of the same type as higher levels, and may themselves have similar lower levels. Recursive hierarchies do arise (e.g., organizational chains of command, parts explosion diagrams) and may readily be encoded in a single relation. Unfortunately, even relationally-complete languages do not support retrieval from such structures.<sup>8</sup> For example, the ORG relation represents the relationship between a department and its subordinate departments:

```
ORG: (DEPT#, SUB#)
```

The query:

```
SELECT SUB# FROM ORG
WHERE DEPT# = 1
```

retrieves all sub-departments of Department 1.

```
SELECT SUB# FROM ORG
WHERE DEPT# =
  SELECT SUB# FROM ORG
WHERE DEPT# = 1
```

retrieves all sub-departments of sub-departments of Department 1. But there is no single query which will traverse the entire organizational structure, retrieving all subordinate departments regardless of their depth in the tree.

Three concepts are essential in an external schema facility that is to treat recursive structures:

- *Definition—Node specification* is the declaration of the individual nodes of a recursive structure, their format and data content.
- *Definition—Iteration control* is the control of which nodes are to be included in a recursive structure.
- *Definition—Tree traversal* is the processing of the nodes of a recursive structure.

Node specification has much in common with VIO declaration. The structure of the node may be specified using the three dichotomies introduced in the fourth section, data may be accessed from desired tuples of any combination of relations, and the data included in the node may be real or computed virtual items as appropriate. Thus, considerable generality in the format of individual nodes is provided.

Iteration control is used to prune the depth and breadth of the tree. It determines which nodes are to be included, based upon distance from the root, content or contents of subordinate nodes. By combining node specification, which determines the contents of nodes, with iteration control, which determines the shape of the tree, the necessary generality in definition of recursive hierarchies is attained.

Tree traversal is used to process recursive hierarchies. It is used for such things as determining manpower totals over an organization, or cost of components using a parts explosion diagram. A more detailed treatment of recursive structure definition and processing is not possible here, but is available elsewhere.<sup>8</sup>

## CONCLUSIONS

### *Summary of the proposed prototype*

For the conceptual schema we want generality, completeness and the ability to support unanticipated users of the data base. For this we employ the relational model.

For the internal schema we want control over storage, record placement and use of indices and access paths. Wherever possible, we want efficient operation; in particular, for common and anticipated requests, we require this efficiency. For this we employ the CODASYL network model.

For the external schema we want user orientation, ease of applications programming, close relationships between the cognitive structures of the programmer and the data structures of the program. For this we employ a hierarchical external schema facility, the details of which have been outlined previously.

### *Features that must be provided by an external schema facility*

A facility to treat adequately the declaration of external schemata must provide the following features:

1. *A set of hierarchies*—These hierarchies are virtual; that is, they are declared in the external schema but need not be stored in the data base in terms of set memberships, repeating groups or related record segments. Hence the set of hierarchies provided may be redundant or inconsistent; we feel this last point eliminates the need for the support of more general networks.<sup>6,7</sup>
2. *Full support of the classes of hierarchies presented in the fourth section*—Provision must be made for "simple" or "grouped" entries, "single" or "all" extent, "complete" or "summary" content. Additional features have also proved useful; e.g., sorting entries, limiting the number of entries included.
3. *Recursive hierarchies*—Provision must be made for node specification, iteration control, and tree traversal. We feel that node specification is best managed using the features of VIO declaration and that iteration control should be a simple extension to qualification.

### *Status of implementation*

We have completed both an analysis of the requirements for a hierarchical external schema facility and the design of a VIO-based interface to support this facility. A language processed by the interface, used for mapping between conceptual and external levels, has been presented. Two experimental tools have been constructed; a VIO-to-relational processor and a VIO-to-CODASYL processor. No serious conceptual difficulties have been encountered. Implementation of the three-schema prototype described here requires only acquisition of a relational-to-CODASYL mapping facility.

## INTRODUCTION

The ANSI/X3/SPARC study group on database management systems<sup>2</sup> as well as some independent researchers<sup>17,10</sup> have proposed a three-level "coexistence" architecture to database management systems. Under this approach (see Figure 1) a number of different users can be supported by means of different External Schemas, possibly with different data models and languages. It involves construction of a conceptual schema which completely represents the structure and semantics of a particular database. The underlying internal schema must provide a storage representation for the conceptual schema. Although the composition and scope of the conceptual schema is still a matter of controversy,<sup>1</sup> several data models, semantic models (e.g., References 7, 8, 9, 13, 16, 20, 21) etc. could be considered as candidates for defining conceptual schema. Given a particular model for the conceptual schema, a number of problems arise in its implementation into a three-level DBMS, particularly regarding the design of an internal schema specification language to specify the mapping of the model into storage.

This paper discusses the general issues involved in implementing one specific model due to Falkenberg<sup>9</sup> termed "the object-role model," as a conceptual schema model. Considerations in the design of a Conceptual Schema Language will be indicated. However, the emphasis will be on the issues of Internal Schema Language design. These languages are currently being developed and implemented at the Research Laboratories, Siemens AG, Munich, West Germany. Detailed analyses of these languages will be presented in forthcoming papers.<sup>4,15</sup> Rather than present detailed language syntax, mathematical definitions of terms, operations, etc., this paper will highlight the issues and design decisions deemed essential for implementing a conceptual model.

A database administrator (DBA) in an organization is en-

trusted with the task of defining a conceptual schema and an internal schema. In this paper wherever applicable, we point out that the DBA has to choose among alternatives or has to be aware of the implications of his decision.

### *The object-role (O-R) model*

For the sake of completeness we will summarize the concepts from the object-role (O-R) model. This model is an ideal candidate for conceptual schema modeling since it has only a few basic concepts, which make it simple to use. It also has been shown to be evolvable and transformable.<sup>9,10</sup> The model is used for modeling facts from a particular universe of discourse by means of objects, roles and associations. Objects are atomic, discrete elements in nature; the only information represented by them inherently is their existence. Facts concerning an object correspond to its association with one or more objects. An object performs a role in every association of which it is a part. Thus associations, which are n-ary in general, are composed of object-role pairs. Figure 2 gives an example of a model of a database in which the pairs (Doctor D, performs), (Surgical-procedure S, is-performed), (Patient P, is-operated) define the association "Surgical operation." An association may be "objectified" and may perform a role in another association. The latter is termed a *nested association*. In Figure 3 Miller's-salary is a binary association and (Miller's-salary, has-as-starting-date) is an object-role pair which is a component of the nested association "Miller's-salary-history."

The modeling concepts introduced thus far deal with modeling *instances* of objects, roles and associations. The *type* concept is introduced by which an *association type* refers to all associations with identical object-role pairs. Objects are pooled into *object types* such that objects under one type have at least one role in common. Figure 4 represents a database schema of which Figure 3 is an instance.

Objects and roles may be provided with *significations*.<sup>11</sup>

\* This work was done while the first author was at Siemens AG, Munich, West Germany.

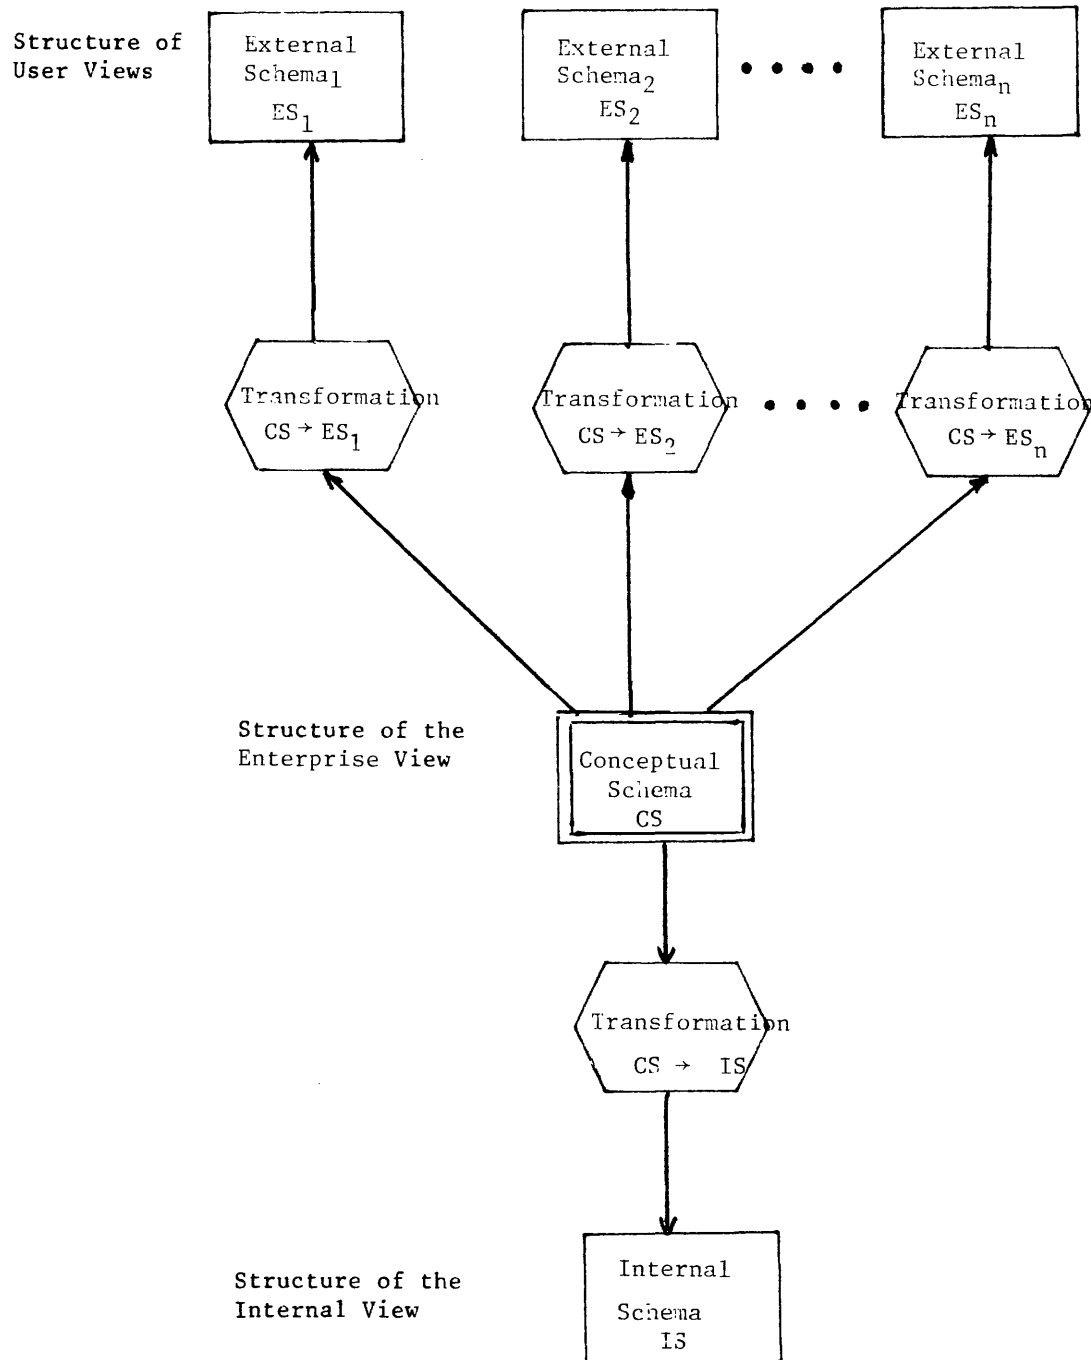

Figure 1—Three-level DBMS architecture.

An object-type named Person may be signified by the person's First-name. A number of significations may be provided, e.g. First-name, Last-name and Date-of-birth for the object-type Person to make the signification unique. Frequency of occurrence of roles may be supplied as an additional information. In Figure 4 they are shown in parentheses. E.g., (0,1000) indicates that a Date may be the starting date in 0 to 1000 Salary-history associations whereas (1,1) indicates that a particular salary association starts on one and only one Date.

#### A conceptual schema language (CSL)

A CSL is being designed<sup>4</sup> to define the conceptual schema of a database using the concepts from the object-role model. One of the early design decisions involved the definition of object-types.

As originally defined in the model, an object is atomic and has no information of its own. On principle, *identification* (=unique significance) of an object  $x$  must be possible by associating  $x$  with objects of a different type(s)—usually

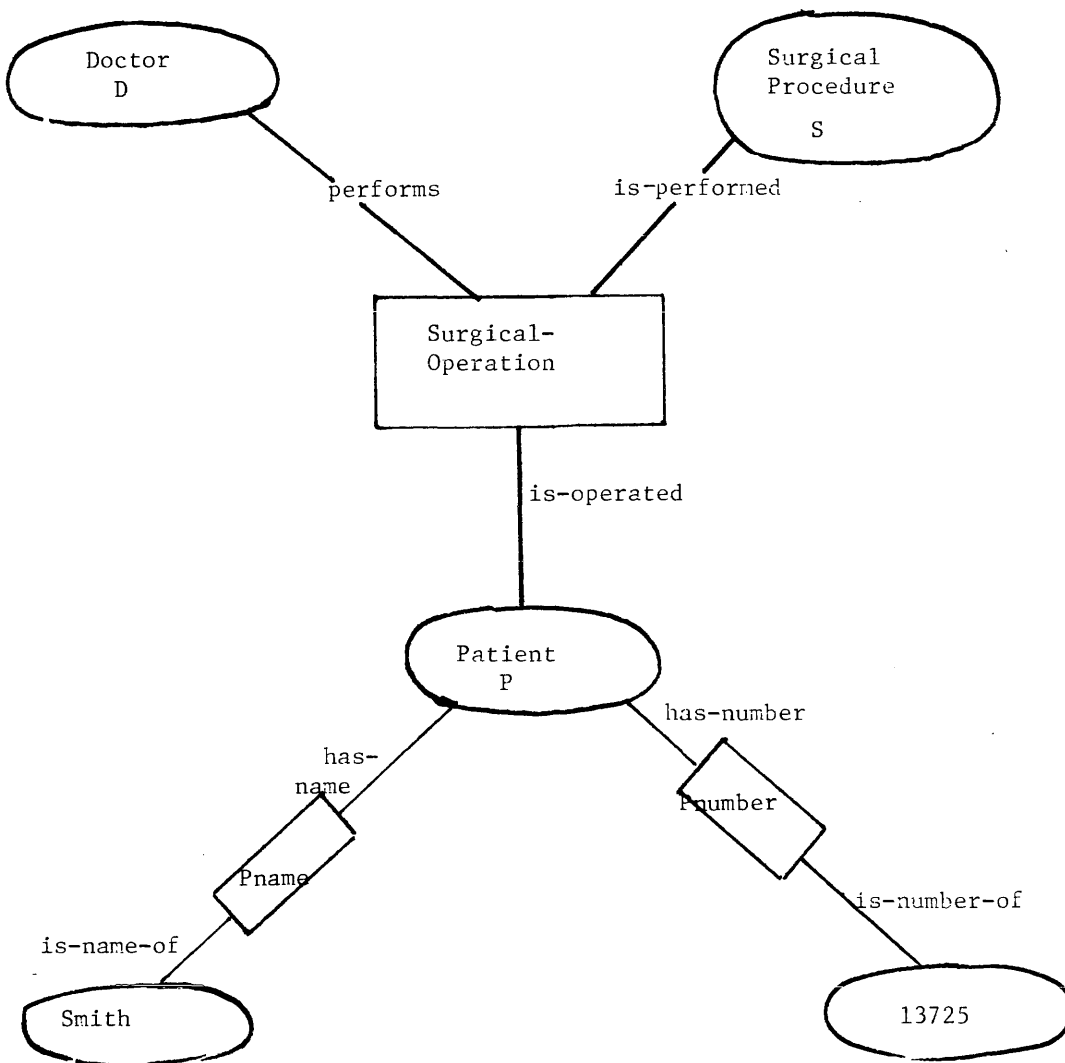

Figure 2—Objects and associations in a conceptual model<sup>9</sup> (instance diagram).

Figure 3—A nested association (instance diagram).

Figure 4—A database schema involving object-types and association-types (schema diagram).

strings over some alphabet. Associations serving this purpose are called *name associations* (also *identifying associations*) and an object ( $\neq x$ ) participating in a name association for  $x$  is called a *name object for  $x$* . E.g., in Figure 6 object type Dept is identified by association type Dnum, and Person by Pnum. In general, a hierarchy of associations may identify an object. However, if for each object  $x$  of a type  $X$  we know a string  $s_x$  that can serve as a never-changing identifier for  $x$ , CSL allows for defining  $X$  as a *self-identified object type*. This simplifies the conceptual schema. CSL deals with object types as follows:

1. An object type has a name (e.g. Person).
2. An object type is devoid of any inner structure. An association participating in a nested association is treated as an association rather than as an object.
3. A non-self-identified object type is distinguished from an object type which stands for the names of the former, (e.g. Person is different from Alpha). It is identified by a number of name associations. (E.g. each Person object is identified by an object of type Empl-number.) This concept is parallel with Navathe's identifying relations.<sup>14</sup>
4. For a self-identified object type the distinction mentioned above is not made. The name of an object of such a type is treated as if it were the object it stands for.

Roles, object types and even (object type, role) pairs may occur in more than one association type and also several times within one association type, if this is necessary to describe the semantics of a conceptual model. The latter is a means for expressing symmetric relationships between objects (see Figure 5). However, the DBA must realize that the choice of several identical (object type, role) pairs affects possible manipulations. E.g., a query like "List all persons associated with person  $x$  by role is-friend-of" implies investigation of *all* (not only one) roles is-friend-of. This is a typical example of implementing a conceptual model by selecting a proper implementation strategy rather than by changing the model itself.

Semantic rules were postulated<sup>9</sup> as a means of providing additional constraints for consistency and integrity among data instances. The syntax of CSL can be designed to incorporate such rules to any degree of complexity. E.g., a very high-level semantic rule: no two names in the database can be the same; a very low-level semantic rule:

Figure 5—An association-type with identical role names.

$10,000 \leq \text{Salary} \leq 50,000$ ; a 'complex semantic rule: salary raises do not apply to persons who earn more than their second-level managers. Another design consideration involves the setting up of triggering mechanisms to invoke procedures representing semantic rules. Currently CSL allows semantic rules like the following to be automatically invoked during the execution of corresponding update procedures:

1. Characteristics of association types, e.g. "An employee cannot work on more than two projects."
2. Characteristics of object types, e.g. " $10,000 \leq \text{salary-amount} \leq 50,000$ ."
3. Dependencies between associations, e.g. "Total salaries of employees on a project cannot exceed its budget."
4. Characteristics of events, e.g., "A person's marital status cannot change from 'divorced' to 'single'."

Most databases have transactions or updates which cause changes in the data instances over a period of time. Time is an important attribute of data and provides valuable information in any dynamic database. Incorporation of time in semantic models has not been addressed sufficiently, barring a few exceptions (References 3, 5 etc.). Objects with a time point as an attribute have been called events, while those with time interval as attributes have been called processes.<sup>24</sup> Incorporation of time into the above CSL is being investigated without classifying the object-type into subtypes.<sup>4</sup>

#### AN APPROACH TO THE DESIGN OF AN INTERNAL SCHEMA LANGUAGE

In the discussion above we highlighted the features of the O-R model and the requirements of a corresponding CSL. After a particular database conceptual schema is expressed using CSL, the database must be populated with instances which are mapped into storage according to an internal schema specification. Any retrieval or updating transactions operating on an external view are mapped into transactions on the conceptual view and further into transactions on the internal view. The internal schema language (ISL) must be capable of expressing all manipulation.

Our ISL design is based on the premise that databases will be stored in electronic cyclic memories using quasi-associative addressing techniques. Existing implementations<sup>12,18,19</sup> have shown that these storages and accompanying processors can store and manipulate relations very efficiently. The relational data model<sup>8</sup> has also been shown<sup>6</sup> to fit the bubble hardware well because of the intrinsic similarities between the two. A relational model-based ISL must allow for specifying the storage of relations corresponding to the conceptual schema in the CSL.

#### ISL structure

The language is divided into four levels along the logical to physical spectrum.

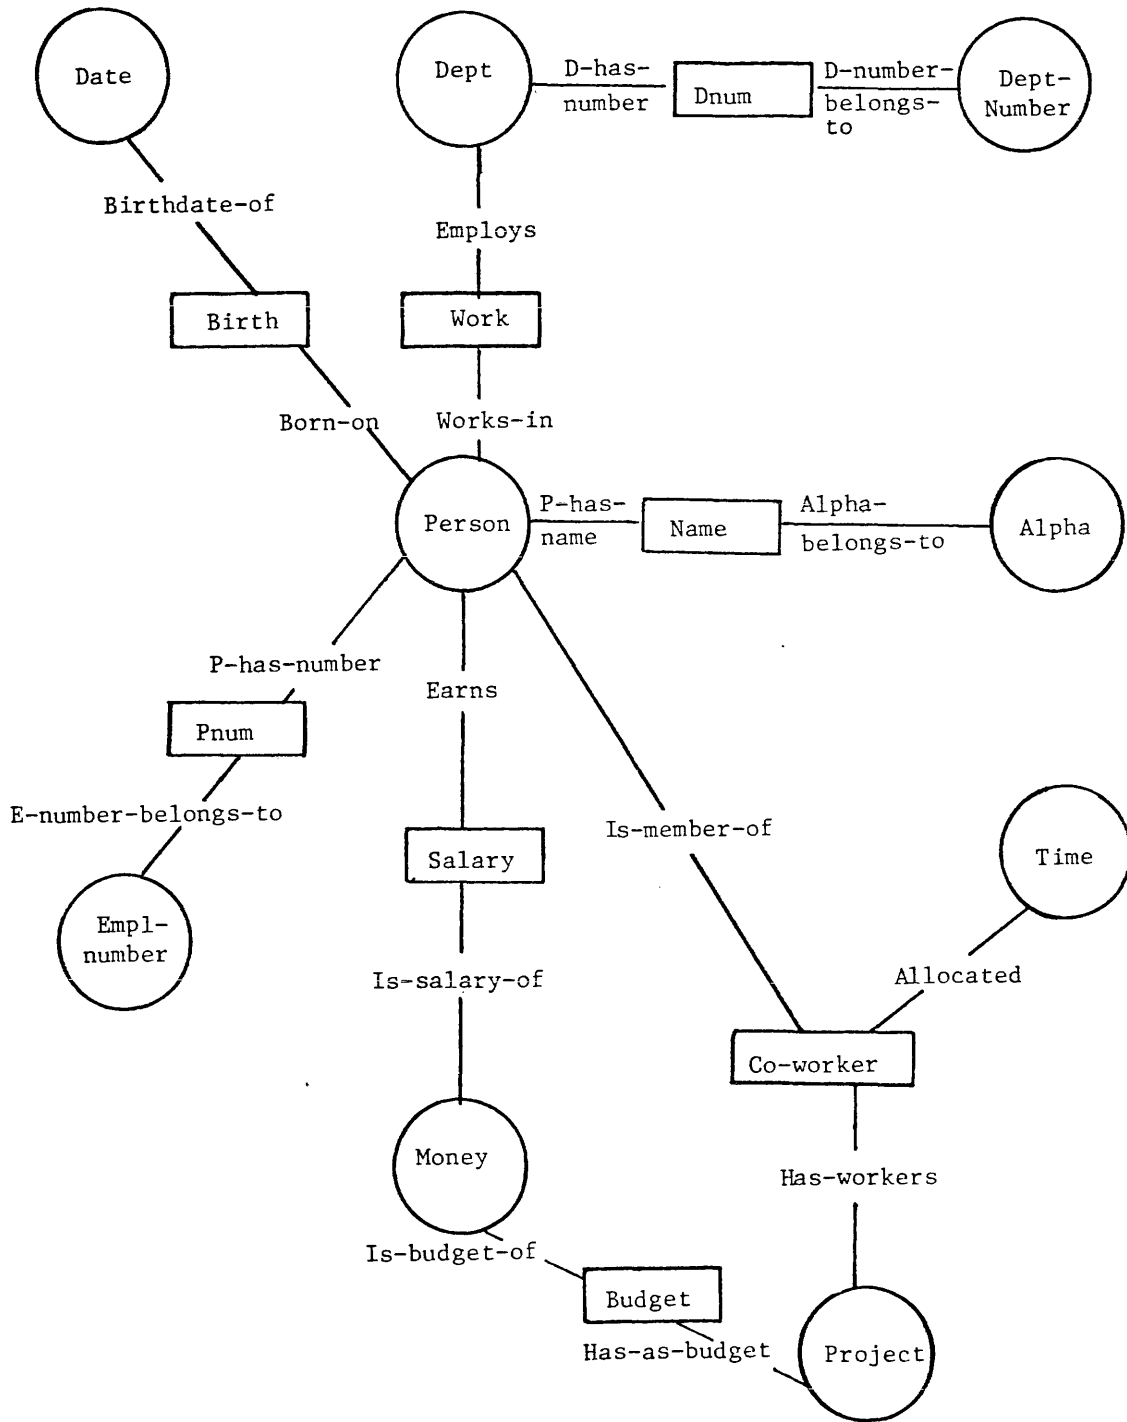

Figure 6—Conceptual model of a personnel database.

*Level 1*—At this level the logical structure of the stored data is specified. With the assumption that stored data is in the form of relations, one must specify *what* relations need to be stored and *how* they are populated. Two main operations termed aggregation and substitution are defined at this level.

*Level 2*—Provides for the specification of constraints on

relations whereby they can be organized to support efficient logical access structures. E.g., tuples may be ordered, a relation may be partitioned horizontally by clustering tuples or vertically by reordering and grouping of domains.

*Level 3*—At this level a lot of information is supplied to define the mapping of relations into storage. It consists

of: the division of the target address space into areas (extents) and the allocation of relations to them; definition of the type of encoding, formatting information at the domain level such as length, type (picture), padding, justification; definition of storage policies dealing with tuple insertion, overflow handling, free space management, space reclamation, relative placement of relations, etc.

*Level 4*—This level is used to characterize the structure of the storage itself. It defines what a unit of storage is, how these units are grouped into higher-level storage structures, what types of access is supported, whether data compression algorithms are used and so on.

Levels 2 through 4 include the detailed specifications that any Internal Schema Language should be able to express (see Reference 2). If a model other than the relational were used for stored data, relations and tuples would be replaced by corresponding constructs from that model.

In the rest of this paper we propose to focus on the ISL at Level 1 because it is at this level that the conceptual model of a database must be mapped into and specified in terms of a corresponding storage counterpart. The choice of the O-R model for conceptual modeling and the relational model for internal schema modeling presents some interesting problems.

*An internal schema "view"*

An Internal Schema View defines one particular way that a DBA might choose to map a given conceptual model into storage. Some of the previous work<sup>22</sup> on internal schema has dealt with the problem of coming up with optimal solutions to mapping, i.e. defining optimal views when the target storage model is known. We assume that by doing an analysis of the processing requirements and given the knowledge of occurrence frequencies in associations, the DBA would decide to aggregate associations in a particular way; the opposite possibility where the DBA would like to split associations does not exist since in the O-R conceptual model associations represent semantically-irreducible facts.

We first describe the IS structure as it is implied by the CS definition. This is the structure we store in case no structuring specification is given.

*Representation of references to objects*—Whenever an ob-

ject of a self-identified object type is referred to, we store its name. For each instance  $y$  of a non-self identified object type or of an objectified association type we create an internal identifier  $i_y$  and store  $i_y$  wherever  $y$  is referred to.

*Representation of associations*—An association type  $A = ((O_1, r_1), (O_2, r_2), \dots, (O_n, r_n))$ , where  $O_i$  is an object type or an (objectified) association type and  $r_i$  is a role, is represented by an elementary relation

$$R_A \subset O_1 \times O_2 \times \dots \times O_n$$

with domain names  $O_1 \cdot r_1, O_2 \cdot r_2, \dots, O_n \cdot r_n$ . The term "elementary" was chosen because these relations may be used to build larger relations, but cannot be split. Given an instance of type  $A$  that associates object instances  $x_1, x_2, \dots, x_n$  such that for  $1 \leq i \leq n$ ,  $x_i$  is of type  $O_i$  and plays role  $r_i$ , we store the tuple  $(y_1, y_2, \dots, y_n)$  in relation  $R_A$ , where, according to (i), for  $1 \leq i \leq n$ ,

$$y_i = \begin{cases} \text{name of } x_i, & \text{if } O_i \text{ is a self-identified object type} \\ i_{x_i}, & \text{the internal identifier of instance } x_i, \text{ which we} \\ & \text{create, if } O_i \text{ is a non-self-identified object type or} \\ & \text{an objectified association type.} \end{cases}$$

A key of relation  $R_A$  comprises a sublist of the domain list of  $R_A$ .

E.g. the Birth association is represented by elementary relation  $R_{\text{Birth}} \subset \text{Date} \times \text{Person}$  with domain names

$$\text{Date} \cdot \text{Birthdate-of}, \text{ Person} \cdot \text{Born-on}$$

Let us consider Figure 4 as an example of a nested association:

We create elementary relations  $R_{\text{Salary-History}}$  and  $R_{\text{Salary}}$  with domain names  $\text{Salary} \cdot \text{Starts}$ ,  $\text{Date} \cdot \text{Is-the-starting-date-of}$ ,  $\text{Person} \cdot \text{Earns}$  and  $\text{Salary} \cdot \text{Amount-Is-earned-by}$ . The instance of Figure 3 will be treated as follows:

1. Assuming  $\text{Person}$ ,  $\text{Salary-Amount}$  are self-identified object types, the tuple (Miller, 20000) is stored in  $R_{\text{Salary}}$ .
2. Since  $\text{Salary}$  is an objectified association type, we create an internal identifier, e.g. S1, for the tuple (Miller, 20000).
3. Assuming  $\text{Date}$  is a self-identified object type, the tuple (S1, 1-1-78) is stored in  $R_{\text{Salary-History}}$ .

*Aggregation*

An IS View is defined by specifying an aggregation. E.g., to aggregate all associations in Figure 6, the following statements are used (An assumption could be made that each role name occurs in one and only one association type. However, for the sake of generality, we use role names qualified by association type names.):

V1=Name	[(Person · P-has-name)	AGGR	(Person · Born-on)]
Birth	[(Person · Born-on)	AGGR	(Person · Works-in)]
Work	[(Person · Works-in)	AGGR	(Person · Earns)]
Salary	[(Person · Earns)	AGGR	(Person · Is-member-of)]
Co-worker	[(Project · Has-workers)	AGGR	(Project · Has-as-Budget)] Budget

The philosophy of the AGGR statement is to specify a relational join<sup>8</sup> by selecting a joinable domain from a number of different associations. Two relations are joinable if they are coherent, i.e. if they share at least one object type. In V1, the domains on which join is performed are either Person-ids or Project-ids. Figure 7(a) shows the elementary relations and Figure 7(b) the result of aggregation which is a relation with domains containing identifiers, either internal identifiers or name values.

In aggregating associations we had to use a "modified join" as follows: "A *modified join* takes the union (as opposed to intersection) of values in the join-domain from the relations being joined. Null values are created under appropriate domains corresponding to relations where a domain value may be absent." This is necessary because no elementary facts may be lost in mapping from the conceptual to internal schema. Figure 8 shows a conceptual schema and corresponding elementary relations. Relation BIBLIO is the result of aggregation of the two associations by joining on the Book-ids. The tuples <B3,A2,-> and <B4,-,P1> would be absent under conventional join. However, in relation BIBLIO we must preserve the fact that book B3 has author A2 and book B4 has publisher P1.

*Substitution*

As shown in Figure 7(b) aggregation results in the definition of an aggregated relation where certain domain values are internal identifiers. A DBA is allowed to define relations by substituting some or all of the internal identifiers by name values

Elementary relations for identifying associations

$R_{pnum}$	Person • P-has-number	Empl-number • E-number-belongs-to
	P1	100
	P2	110
	P3	200

$R_{dnum}$	Dept • D-has-number	Dept-number • D-number-belongs-to

	B4	--	P1

Figure 8—A modified join operation.

*Manipulation of IS*

Additional ISL statements have been defined for a further manipulation of the stored relations by the DBA. A DROP statement has the following syntax:

`<dropstatement> ::= DROP <typename>{,<typename>}n  
 <typename> ::= <objecttypename> | <associationtypename>`

If the DBA visualizes that all the processing against a conceptual schema can be supported by the defined aggregations, he may proceed to drop certain object types and/or association types. The corresponding elementary relations would be

Given relation R with one:many relationships;

R	<u>A</u>	B	C
	a1	b1	c1
	a1	b1	c2
	a1	b1	c3
-----			
	a1	b2	c1
	a1	b2	c3
-----			
	a1	b3	c6
-----			
	a2	b1	c2
	a2	b1	c4
	a2	b1	c6
-----			
	a1	b2	c1
	a1	b2	c2
	a1	b2	c3

R takes up 36 elements of storage

S = R REPEAT C 3 TIMES; gives

S	<u>A</u>	B	C(1)	C(2)	C(3)
	a1	b1	c1	c2	c3
	a1	b2	c1	c3	-
	a1	b3	c6	-	-
	a2	b1	c2	c4	c6
	a1	b2	c1	c2	c3

S takes up 25 elements of storage

T = S REPEAT B 2 TIMES; gives

T	<u>A</u>	B(1)	B(2)	C(1)	C(2)	C(3)
	a1	b1	b2	c1	c2	c3
	a1	b2	-	c1	c3	-
	a1	b3	-	c6	-	-
	a2	b1	-	c2	c4	c6

T takes up 24 elements of storage

Figure 9—Use of REPEAT by DBA to adjust the breadth of relations.

automatically scratched. To scratch a specific relation from internal-schema storage, the DBA uses a SCRATCH statement.

$\langle \text{scratchstatement} \rangle ::= \text{SCRATCH}(\text{relationname})\{, \langle \text{relationname} \rangle\}^{\infty}$

When there is an association type which associates an object type with two or more object types in a one:many fashion, multiple values occur in certain domains for a given value in one domain. Figure 9 shows an example relation which results from one:many associations between A:B and A:C. To fit the storage-characteristics a DBA may want to adjust the "breadth" of a relation by allowing domains to be subscripted as shown in Figure 9. A REPEAT statement is used toward that purpose (see Figure 9). This idea is related to multi-valued dependencies.<sup>23</sup>

$\langle \text{repeatstatement} \rangle ::= \langle \text{relationname} \rangle \text{REPEAT}(\text{domainlist}) \text{ n TIMES}$

To revert back from the use of SUBSTITUTE, DROP, SCRATCH and REPEAT commands, a DBA can use RESUBST, KEEP, CREATE and COLLAPSE commands.

One of the advantages of choosing a relational structure for the internal schema is that the manipulation operations can be derived from the relational algebra. Queries in external schemas will be mapped into a set of relational operations like Projection, Restriction, Natural join on the elementary and aggregate relations. The implementation will account for repeating domains with subscripts and null values.

### Reorganization of IS

According to the procedure outlined previously, a given conceptual schema produces a set of relations in the internal schema. The composition of this set can be controlled to some extent by the DBA by using the manipulation operations. If relations need to be normalized, rearranged, decomposed or synthesized, the relational operators will be available to the DBA. It is conceivable in the future that certain sequences of operations will be made available in the form of IS reorganization verbs.

### SUMMARY

This paper has highlighted some of the typical issues that arise during the implementation of a particular semantic model in a three-level DBMS architecture. The model chosen is the object-role model due to Falkenberg.<sup>9</sup> With a given design decision to organize the internal schema using relations, considerations for the design of an internal schema language were discussed. A systematic approach to defining relations and populating them so that they are equivalent to a conceptual model was outlined. Of particular importance is the concept of aggregation using a modified join operation. IS manipulation verbs for the DBA were also indicated. The Conceptual and Internal Schema Languages are currently being implemented at the Research Laboratories, Siemens AG, Munich, West Germany.

### ACKNOWLEDGMENTS

The authors would like to acknowledge the cooperation of and valuable discussions with Mr. Breutmann, Dr. Falkenberg, Mr. Hahne and Mrs. Mauer in the development of the paper. The research contribution of Mr. Breutmann and Mrs. Mauer in the development of the Conceptual Schema Language is particularly recognized.

# The practice of data base administration

by JAY-LOUISE WELDON

New York University  
New York, New York

The position or role of data base administrator has been described and discussed since the earliest specifications for data base management systems.<sup>1,2,4</sup> Most of the literature on DBA is normative—describing in detail what the DBA function *should* include. Different authors have focused on the DBA's role in introducing the data base concept to organizations,<sup>8</sup> the functions that the DBA should perform,<sup>7</sup> the specification of tools and DBMS features needed by DBAs,<sup>3</sup> and how to establish and perform the DBA's responsibilities within an organization.<sup>5,6</sup> In practice, however, the organization and content of the DBA function may be quite different from the ideal. Other factors related to the DBA's technical and organizational environment may influence the DBA's role. This paper summarizes the results of an exploratory survey on data base administration<sup>9</sup> which was undertaken as a first step toward identifying and understanding these factors.

## METHODOLOGY

The survey included 25 DBA groups within firms located in the New York metropolitan area. Individual interviews were arranged with the manager of each DBA group. The interviews were unstructured and the questions generally open-ended. However, the interviewer did follow an interview outline that included questions on three topic areas: 1) basic characteristics of the firm, 2) organizational characteristics of the firm and of the DBA group, and 3) the tasks performed by the DBA group. The interviews were summarized immediately after they occurred and the responses were later coded according to previously-defined classification schemes.

Based on existing literature on DBA, seven characteristics were defined as independent variables, i.e. factors that were thought to influence DBA organization and content:

Age of the DBA organization	The number of years that the DBA organization/position had existed.
Origin relative to DBMS	Was DBA instituted before, with, or after the DBMS?
DBMS	Which DBMS package was used?

Industry	The industry most descriptive of the firm's business operations.
Installation size	An index combining the size of the hardware and the number of bytes stored in data bases.
EDP organization	The degree of centralization of the EDP organization.
Data base scope	An index based on the number of different application areas with current or planned data base support.

Five factors descriptive of the DBA function were also defined for use as dependent variables:

Size	Size of DBA staff with respect to total EDP staff.
Organizational position of DBA	Described by the number of levels between the DBA and the head of EDP, the position of DBA with respect to its primary users, and an indicator of organizational change since DBA's inception (higher, lower, no change).
Orientation of DBA staff	Ratings of the DBA staff on a technical-administrative scale and an application-systems scale.
DBA organizational structure	DBA's span of control and the number of organizational levels below DBA.
DBA tasks	A vector of yes-no indicators for 48 representative DBA tasks.

Responses were tabulated for each of the variables above to obtain descriptive statistics (frequency distributions, means or medians, etc.) on each. The task indicators were summed for the sample and used to rank order the DBA tasks with respect to frequency of mention.

To explore possible relationships among the independent and dependent variables, comparative statistics (Chi-square tests, t-tests, and rank-order correlations) were used. The sample was partitioned by each of the seven independent variables and values of the dependent variables for the sub-samples were compared.

## RESULTS\*

The nature of the survey respondents can be determined from the descriptive statistics on the independent variables. The sample was largely self-selected, and therefore not demonstrably random. However, the characteristics show a reasonably diverse group, representing a spectrum of age (one to five years), industry, installation size, and data base scope. One DBMS (IMS) dominates the sample (used by 65 percent of the respondents) as does one mode of EDP organization (75 percent were centralized).

The characteristics of the DBA groups can be summarized as follows:

- *Size*—The size of the DBA group relative to EDP staff size ranged from 0.4 percent to 12.5 percent with a mean of 3.34 percent and a standard deviation of 3.01 (actual staff sizes ranged from one to 28). If projected staff increases are included, the mean increases to 3.86 percent.
- *Organizational position*—Organizational position was of interest since most authorities claim that DBA requires a high management level for success. Most of the groups surveyed were two or more levels below the top EDP manager. The range for this variable was one to four, with only 25 percent reporting directly to the top EDP manager. Most of the DBA groups had changed their organizational position since their inception, most for the better. This suggests that DBA might start low in the organization and gain in position as the function matures. Over half of the groups, however, were placed on a lower organizational level than their primary users (e.g. applications programmers). This suggests that DBA is still considered a support function by most EDP groups. Only 10 percent of the DBA managers were on a higher level than the manager of their primary user group.
- *Staff Orientation*—Each DBA group was assigned a rating on two five-point scales according to the job titles or descriptions provided for their staff members. (Scale 1: 1=All administrative, no technical; 2; 3=Mixed; 4; 5=All technical. Scale 2: 1=Applications-oriented; 2; 3=Mixed; 4; 5=Systems-oriented.) The tabulation of the first scale showed a clear dichotomy, with twice as many groups rated technical as rated administrative (mean rating=3.55, standard deviation=1.5). Responses on Scale 2 showed that most groups were applications-oriented (45 percent) or mixed

(40 percent), and none were entirely systems-oriented. (Mean ratings=2.4, standard deviation=1.1).

- *Organizational Structure*—Almost all of the respondents (89 percent) had either one level (42 percent) or two levels (47 percent) of staff reporting to the DBA manager. For both flat and pyramid structures, the most common span of control was three (the range was zero to six). The most common functional designations associated with these three subgroups were: Support for data base design and maintenance, data standards (including data dictionary), and DBMS support.
- *Tasks*—The tasks performed by each DBA group were recorded on a menu of 48 representative tasks culled from the literature.\*\* By summing across the sample for each task, the proportion of DBA groups performing each task was determined and the tasks were ranked accordingly. Table I shows the tasks most, and least, frequently mentioned.

## FACTORS INFLUENCING DBA CHARACTERISTICS

Relationships were detected between each of the independent variables and one or more DBA characteristics. While some of the other cross-classifications suggested possible relationships, due to the small sample size (N=20, five responses being unacceptable for various reasons), they were not statistically significant. Except where noted, the following discussion will be limited to significant relationships ( $p < .05$ ).

The length of time that a DBA had been in existence was found to be related to four of the five DBA characteristics. Only relative staff size was not significantly related. Inspection of the data shows, however, that the younger groups (three years or less) show more variation in size and a higher proportion of small staff sizes than the older groups.

As might be expected, the older groups show more internal structure and have experienced more organizational change than the younger groups. Younger groups also tend to be more applications-oriented, while older groups are more systems-oriented. This might be associated with the development cycle of the data base applications (i.e. younger—design, older—operational).

DBA appears to start as a technical support group for one or more applications areas (and below them in the organization). Over time DBA moves to a higher level (equal to the primary user group) functioning then in a more consultative fashion.

One interesting, though non-significant, result suggests that a change may have occurred in this pattern over the past two years. The youngest DBA groups (two years or less) reported a broad range of applications supported, similar to the oldest groups (greater than four years). This, coupled with the fact that none of the young groups supported only one application area, suggests that DBA may now be avoiding the project approach, i.e. supporting only one application area, which was common in the past.

\* An extended discussion of the survey results and supporting data can be found in another paper by the author.<sup>9</sup>

\*\* The full list of tasks is shown in the Appendix.

TABLE I—DBA Tasks Mentioned by Survey Respondents

<i>Most Frequently Performed</i>		<i>Least Frequently Performed</i>	
<i>Task</i>	<i>%</i>	<i>Task</i>	<i>%</i>
Maintain Data Dictionary System	75	Select DB-related hardware	0
Evaluate DB software	60	Enforce DB retention policies	0
Maintain DB descriptions	60	Requirement analysis for DB applications	5
Reorganize DBs	60	Schedule computer time	5
Recover DBs	60	Determine program structure	10
Select DB software	55	Evaluate DB-related hardware	15
Forecast DB growth	55	Design forms/procedures for DB applications	15
Generate DB descriptions	55	Enforce standards for application coding	15
Monitor DB performance	55	Maintain DC monitor	15
Develop standards for data element names	55	Enforce standards for documentation	20
Determine physical structures	50	Educate DB users	20
Specify DB access policies	50	Set application priorities	20
Load DBs	50		
Set policies on DB backup and recovery	50		

DBA groups established before a DBMS was installed tend to be larger (in relative size) than those instituted with or after the DBMS. This, however, may be indirectly related to age, since groups started before the DBMS are older than most of the groups started with or after the DBMS.

Installation size was found to be related to the level of the DBA with respect to the top EDP manager and also to the amount of organization change experienced by the DBA. DBAs in organizations with large installations (large model hardware and large data bases) tend to be lower in the EDP organization than those in smaller installations. These DBAs also reported more organizational change (both positive and negative) in the DBA group than did DBAs at smaller installations.

The relationship between the DBMS package used and DBA characteristics was significant for only two variables: DBA's span of control and DBA tasks. Both of these results compared IMS DBAs with DBAs using other DBMS packages. IMS DBAs were found to have larger span of control, i.e. more persons reporting to them, than the other DBAs. Further, the ranks assigned to DBA tasks by the IMS DBAs were found to be inversely correlated with those assigned by the other DBAs. The IMS DBAs emphasize tasks related to planning and control (forecast growth, data dictionary, data name standards) while the others emphasize operational support tasks (e.g. data base load, troubleshooting).

In contrast with the sparse relationships detected between DBA organizational characteristics and the independent variables, the content of the DBA function was related to all but one. Differences in the rank order of tasks performed were detected among groups partitioned by every independent variable, except installation size. For a fuller discussion, see Reference 9.

## CONCLUSIONS

The results of this survey support two major conclusions. First, the organizational aspects of data base administration groups are affected primarily by the length of time that the

group has existed. This suggests a maturation process for DBA, perhaps similar to Nolan's stages of EDP growth. To formulate such a hypothesis, criteria defining each stage in the process must be specified and characteristics of DBA organization and structure related to each stage.

Second, it appears that the tasks performed by DBA groups vary independently from organizational structure or position. The composition of a DBA's job and the rank ordering of tasks within it are influenced by several factors, including the DBMS package used, EDP organization type, and the scope of data base applications. Additional task data from stratified random samples for each of the related variables could be used to explore these relationships in greater detail. It may then be possible to develop task profiles for the several different types of data base administration functions that exist in practice.

## APPENDIX—CLASSIFICATION OF DBA TASKS

### *Planning and Management*

- Evaluate data base software (e.g. DBMS, DDDS)
- Select data base software
- Evaluate data base-related hardware (e.g. disks, terminals)
- Select data base-related hardware
- Define implementation strategy for data bases
- Forecast data base growth
- Set operational goals (performance, downtime)
- Set application priorities
- Hire, fire, promote data base personnel

### *Data Base Design*

- Requirement analysis for data base applications (data identification)
- Develop data definitions
- Determine data structures (views)
- Determine physical structures
- Generate data base descriptions (DDL)
- Design integrity controls for data base applications
- Design forms and procedures for data base applications

*Application Programming/Testing*

Determine program structures (processes)  
 Develop standards for application coding  
 Enforce standards for application coding  
 Application system testing

*Controls*

Generate data base descriptions (DDL)  
 Maintain data base descriptions  
 Design integrity controls for data base applications  
 Specify data base access policies  
 Record data base usage  
 Monitor data base controls  
 Develop standards for data names  
 Develop standards for application coding  
 Develop standards for documentation  
 Maintain DDDS  
 Set data base retention policies  
 Select/design security techniques (passwords, locks, etc.)

*Operational Support*

Monitor data base controls  
 Load data bases  
 Reorganize data bases  
 Recover data bases  
 Monitor data base performance  
 Tune data base to meet operational goals  
 Troubleshooting (i.e. track down problems)  
 Enforce standards for data element naming  
 Enforce standards for application coding  
 Enforce standards for documentation  
 Set policies on data base backup and recovery  
 Schedule computer time (e.g. when data base is up)  
 Develop data base utilities (data compression, encryption, query languages)  
 Enforce data base retention policies

*DBMS Support*

Install new DBMS features  
 Modify or fix DBMS  
 Maintain data communications monitor  
 Develop data base utilities (data compression, encryption, query languages)

*User Support*

Prepare data base documentation  
 Disseminate data base documentation  
 Educate data base users  
 Maintain DDDS  
 Maintain query language(s)

# An approach to automatic maintenance of semantic integrity in large design data bases

by GILLES M. E. LAFUE

Carnegie-Mellon University  
Pittsburgh, Pennsylvania

## INTRODUCTION

One way a data base can cease retaining a meaningful relationship with the "real world" situation that it models is through violations of its *semantic integrity*, i.e., transgressions of the defining constraints of its data. These constraints state the legality of the data values and are defined by the creators of the data, e.g., a checking account cannot be negative, or the salary of an assistant professor cannot be greater than that of a full professor.

The variety of integrity constraints to be maintained can be extremely wide. It can range from general low-level management such as dangling references to complex knowledge specific to the "real world" situation, e.g., in the case of a building, detection of spatial conflicts or even statics and mechanics.

Many of the debates about the different data models proposed in the past few years center around the extent of the semantics that these various models hold. Whatever data model one can use nowadays, there will always be semantics which escape it. In daily practice, these semantics are often maintained by the application programs or the manual users. This forces them to maintain information about the data base in a form external to it (a data base about the data base) when in fact it is conceptually part of the data base itself. Incorporating this external information in the data base would be an extension of the effort which led in the first place to modeling a "real world" situation with a computer data base. Moreover, interaction with the data base would be improved by automating the maintenance of these semantics.

This need exists for any kind of data base but it is especially pressing for what I call *design data bases*.<sup>4</sup> A design data base not only stores a model of some artifact and provides primitive accesses to it (e.g., query processing) but also supports the design of this model with the hesitations and backtracking usually involved, e.g., the *schema* (the set of data types) is continuously modified. The design of, and the interaction with, such a system are greatly helped by the data and control abstraction features of a high-level programming language. GLIDE<sup>2</sup> is an example of a design data base. The integration of language and data base concepts for

design applications and its relationships with the principles presented here are discussed in Reference 4.

*Unary* integrity constraints apply to a single record and *n-ary* constraints apply to several records. The proposed approach starts by considering an *n-ary* integrity constraint as composed of one set of *dependent* variables and one set of *independent* variables. Variables can be both dependent and independent. The value of a dependent variable is partially or entirely determined by the values of the independent ones. Maintaining an *n-ary* integrity constraint consists in recomputing or checking the values of its dependent variables when the independent ones change.

The variables of an *intra-record* integrity constraint are *attributes* of the same record. A record is a collection of data logically related and stored together. The variables of an *inter-record* constraint are attributes of several records. These records can be instances of the same type or of different types.

The distinction of constraints according to the number of records they involve is important from two viewpoints. First, the record types and the operations performed on them determine the modularity of the data base schema and of the "contexts" in which the applications execute. Secondly, records belonging to the same integrity constraint are rarely in core at the same time and, in a traditional computer architecture, the cost of disk access is high. The emphasis of this approach is on inter-record constraints.

This paper presents three basic principles of an approach to automatic maintenance of semantic integrity in large design data bases. First, the maintenance of integrity is delayed until strictly necessary. Second, integrity violations are temporarily tolerated. Third, integrity constraints are procedures included in the record definitions and automatically activated by the system. These principles are generally not supported by the data base systems attempting elaborated automatic maintenance of integrity, in particular INGRES<sup>7</sup> and System R.<sup>1</sup> A mechanism based on these principles is currently under investigation.

## DELAYED MAINTENANCE OF INTEGRITY

An integrity constraint is to be maintained when one or more of its independents has been updated. This mainte-

nance consists of propagating the updates from the independents to the dependents. Scheduling this propagation requires knowing which records are the dependents, and also something of the ways these dependents use the independents in order to decide when to notify them and in what order. This propagation can be scheduled either by the records themselves or by the system.

The records are not the best qualified to schedule this propagation. As noted by Hammer,<sup>3</sup> the dependents of a record are often defined long after the record itself. Records should not have to anticipate their users and their uses. They should not even have to maintain the knowledge of their existing uses in order to confine their view of the world to themselves, thus reinforcing the modularity of the schema.

Making the system schedule the propagation of updates has important costs, too. The propagation must be scheduled relative to other tasks. The scheduling policy must be general enough to fit all applications or, at least, to fit most applications and offer the others a way to override it.

A simple and general policy is immediate propagation of updates, which consists of giving priority to propagation over everything else. It is the policy of INGRES. However, it often means that control leaves the context which introduced the update to wander through the data base. This happens when a record is used in different contexts. For instance, in a building, a post can be used for structural purposes as well as for running pipes and wires. When updating the post for structural reasons, it would be long and difficult to consider simultaneously the effects of this update on the piping and the wiring systems. Often, accesses of overlapping contexts must be serialized. Furthermore, the disk accesses to the remote dependent records can drastically slow down the operation of writing in records.

Other scheduling policies consisting of alternating propagation and other tasks would require well defined priorities between these tasks and propagation. They would require spreading some knowledge of record dependencies and uses out of the records. This knowledge should remain associated with the records, even if not necessarily with the independent ones.

The proposition, then, is to delay the propagation of updates until strictly necessary, i.e., when the dependents are accessed, for whatever reason, including checking their external integrity. The integrity of a record is more important when the record is about to be used than when it resides on disk.

## TOLERANCE OF INTEGRITY VIOLATIONS

A consequence of delayed maintenance of integrity is that the data base must be able to tolerate violations of its integrity, at least temporarily. Between the time an independent record is updated and the time a record depending on this record is accessed, the constraint that links these two records is left unenforced. Furthermore, the independent update may imply a dependent value which is illegal because of another constraint applying on the dependent. Violations

are tolerable only as long as they, or their causes, i.e., the updates, are recorded. In contrast, in System R and INGRES, updates leading to violations are immediately rejected.

Sometimes, tolerance of violations is not only an acceptable consequence but is desirable. Integrity constraints may apply at some moments and not at others. This is particularly true for design data bases. One advantage of using a model to design a complex artifact is that the constraints for making the model are different, and hopefully more manageable, than those for making the artifact. Some constraints pertaining to the artifact may be ignored for convenience, until the end of a design phase. Such a phase defines an *integrity transaction* for the constraints temporarily dropped and the records they concern.

In the current approach, integrity transactions are delimited by (dependent) record openings. Opening a record ends the transaction for the record and the constraints in which it is a dependent. If it is desired to open a record without maintaining one of its constraints, this constraint can be associated with another record. This other record is opened when the constraint needs to be checked. The purpose of some records may be to implement the external integrity of other records. Such records are typically *aggregation abstractions* as defined by Smith and Smith.<sup>6</sup> They are the dependents of the aggregations and the records whose integrity they implement are the independents. For instance, aggregations are useful for centralizing the management of circular dependencies.

In the cases described so far, violations are tolerated until they are detected. Now, tolerating and recording a violation may be the action to take when the violation is detected, in order to postpone its resolution. For instance, in a transaction during which an integrity constraint does not apply, it may be useful to record the violations of this constraint on the fly, so that they can be readily taken care of at the end of the transaction, instead of being recomputed. Recording violations is also useful when a constraint possesses several independent variables and is violated by the update of one of them. This violation can be notified to the other independent variables. Often, at least one can change its value in order to accommodate the requested update. For instance, if several persons share a checking account, one person can overdraw the account and another one compensate the overdraw.

Simultaneous alternative values for variables can be assimilated to violations of the data base integrity. They indicate some indecision as to what the unique values of the variables are. They are often useful to tolerate temporarily, especially in design activities, due to the hesitant nature of these activities.

Alternatives may be generated by the same process or by different ones. Regarding the latter case, the principles of resource protection and concurrency control, traditionally used in operating systems, are necessary but not sufficient for data bases. Locking mechanisms serialize concurrent accesses. However, since writing in a data base is to leave a more or less permanent mark, the question of whether the authorized processes write in a record serially or in parallel,

is immaterial. What is important is that overwriting each other may lead the processes into conflicts which cannot necessarily be solved as soon as they occur.

#### INTEGRITY CONSTRAINTS INCLUDED IN THE RECORDS AND AUTOMATICALLY MAINTAINED

Since all the semantics usually desired in a data base cannot be incorporated in the data structures, one has to resort to executable code. This code should be of a high level in order to maximize the power of integrity constraints.

The code implementing the integrity constraints of a record can be included in the record definition in the manner of abstract data types.<sup>5</sup> It participates in defining the record semantics, particularly, its behavior, as much as data structures. This code should be pre-compiled in order to avoid recompiling it every time it is executed. Integrity constraints can then be implemented by pre-compiled procedures called *integrity procedures*.

Clearly, including integrity constraints in the records is acceptable for intra-record constraints since it confines them to the concerned records. It also holds for inter-record constraints. While the records should not know their uses, they must know the records on which they depend or, rather, abstractions of these records. Consequently, integrity procedures are included in the dependent records. This inclusion respects abstraction boundaries. Integrity procedures write in the dependent records or check their values, and they simply read the independent ones.

While the usefulness of the notion of abstract record type in data bases has been acknowledged by several authors, e.g. Reference 6, others have objected to it. In particular, Hammer<sup>3</sup> rightly points out that the behavior and the uses of a record type evolve over time. The proposal to exclude the uses of a record from its definition reduces this evolution significantly.

This procedural approach is different from one which guarantees integrity by providing procedures for accessing the data base. Such procedures guarantee that the data base transits from one valid state to another. They implement *state transition* integrity. State transition procedures enforce immediate maintenance of integrity and do not tolerate violations.

The inclusion of integrity constraints not only in the data base but in the records, contrasts with other approaches. The separation of integrity constraints from the records, as in INGRES and System R, makes insertions and deletions of integrity constraints easier and it centralizes the detection

of conflicts between them. The cost of this separation, however, is to spread the definition of the records.

The mode of activating integrity checks, i.e., integrity procedures, remains to be examined. There are two kinds of integrity checks. Some are implicit. The user does not want to have to activate them explicitly all the time. They can be activated automatically whenever necessary, i.e., when the records are accessed. The others are explicit. They take place at the end of a user-defined transaction which can span several record accesses. A unified scheme is proposed which satisfies both sorts of integrity checks.

Integrity procedures should be written by the user and compiled in relation with record declarations (either types or instances), but automatically invoked by the system upon well defined conditions. These conditions are data base operations, e.g., record reads and writes. System R possesses a similar triggering mechanism which activates the execution of statements of a query language.

For implicit checks, integrity procedures are automatically activated every time their records, supposedly the dependent records of the constraints, are accessed. As for explicit checks, opening a record which implements integrity constraints of other records marks the end of a user-programmed transaction.

# On query-answering in relational data bases

by E. L. LOZINSKII\*

Rutgers University  
New Brunswick, New Jersey

## INTRODUCTION

In recent years the relational model has been widely adopted for data base description. According to this model a data base, DB, describes certain objects of the world having certain attributes, and the relationships among them. Thus, DB is characterized by a set of *attributes*,  $D$ , a set of *domains* associated with the attributes, and a set of *dependencies*,  $F$ , corresponding to the relationships among the attributes (all the terms and concepts not defined here are those of References 1-3). A data base is a collection of *relations*,  $R = \{R_i\}$ . Each relation  $R_i$  is characterized by a set of attributes  $S_i = \{D_j | D_j \in D\}$  called its *scheme*, and consists of a set of *tuples*. Each tuple is a map from the attributes of the relation scheme to their domains that satisfies all the dependencies of  $F$  (we shall consider functional dependencies).

We shall consider the following model of a data base operation. A data base represented by a collection of relations  $R$  is accessed by a set of jobs submitted by users in order to retrieve, delete, insert or modify any subset of the data. In general, retrieval is an essential part of these processes. Thus, each job accessing a data base requires retrieval of some information from it. Users submit their requests for information in the form of queries, specifying the data which must be retrieved and the conditions that must be satisfied by the desired data. The task of query processing is to determine the set of data to be checked and retrieved from the data base, the proper order in which the data should be accessed and the types of manipulations that must be performed on the data.<sup>4</sup> This processing is referred to by different authors as query translation<sup>5</sup> or access path finding.<sup>4,6,7</sup>

Let a query require a retrieval of data which belong to a set of attributes  $D'$ . It can be shown that such a query may be answered in a certain relational data base only if from the same data base a relation can be derived which contains all the attributes of  $D'$  specified by the query. Let us call *R-query* a query that requires a creation of relation with a given scheme. *R-queries* originate not only from users' requests but can also be initiated by a data base management system (a data base administrator) as a means of relations

transformation in the process of data base evolution and restructuring.

Let a query be answerable by means of a procedure which contains a sequence of relational operations project, join, divide and restrict.<sup>8</sup> Among these operations, the join operation is subject to a number of strong constraints. Specifically, an execution of a join operation on two relations  $R_1$  and  $R_2$  with the purpose of creating a new relation  $R_3 = R_1 * R_2$  can produce invalid data in the sense that  $R_3$  can contain a tuple which does not satisfy the original set of dependencies  $F$ . In order to avoid the appearance of invalid data, the condition of a *lossless join*<sup>9-12</sup> must be satisfied. Thus, we shall concentrate upon join operations of a query-answering procedure, assuming that all the relations produced by joins are properly projected and restricted.

So, considering a collection of relations,  $R$ , and a  $R$ -query that requires a relation  $R_k$  with a scheme  $S_k$ , the following questions arise:

1. Can  $R_k$  be derived from  $R$ ?
2. Which relations should be joined to produce  $R_k$  from  $R$ ?
3. What is the sequence of join operations (optimal according to the accepted criteria) that produces  $R_k$ ?

The algorithm described in the fourth section answers these questions.

## LOSSLESS JOINS

As was shown by J. Rissanen,<sup>10</sup> a relation  $R_k$  with a scheme  $S_k$  can be produced by means of join and project operations from a set of relations  $R = \{R_i\}$  (such that  $S_k \subseteq \cup S_i | R_i \in R$ ) if these relations satisfy the following *conditions for lossless join* given in References 9-12.

Let us say that a set of attributes  $B$  functionally depends on a set of attributes  $A$  (abbr.  $A \rightarrow B$ ) if there is a functional dependency  $f \in F$  such that  $f: A \rightarrow B$ . We shall use the concept of *closure*,  $CL(X)$ , of a set of attributes  $X$  defined in Reference 11 as follows:

1.  $X \subseteq CL(X)$
2. If  $Y \subseteq CL(X)$  and there is  $f \in F$  such that  $f: Y \rightarrow Z$ , then  $Z \subseteq CL(X)$

\* On leave from the Department of Computer Science, Hebrew University, Jerusalem, Israel.

- No attribute is in  $CL(X)$  unless it so follows from (1) and (2).  $X \xrightarrow{*} Y$  denotes the fact that  $Y \subseteq CL(X)$ .

It can be shown that if  $X \xrightarrow{*} Y$ , then the functional dependency  $X \rightarrow Y$  is in  $F$  or can be derived from  $F$  using a set of inference rules based on the axioms given by W. Armstrong.<sup>13</sup> So, the closure of  $X$  is the union of all the sets of attributes dependent on  $X$  according to the adopted inference rules.

A join of relations  $R_i$  and  $R_j$  is *lossless* (that is, it does not produce any invalid information) iff  $S_i \cap S_j \xrightarrow{*} S_i$  or  $S_i \cap S_j \xrightarrow{*} S_j$ .

As an example (taken from Reference 11), let us consider a data base characterized by the attributes NAME ( $N$ ), ADDRESS ( $A$ ), PHONE NUMBER ( $P$ ), DISTRICT ( $D$ ), under the given set of dependencies  $F = \{N \rightarrow A, N \rightarrow P, A \rightarrow D, P \rightarrow D\}$ , and represented by the following set of relations (the primary keys of relations are underlined):  $R = \{R_1 = (\underline{N}A), R_2 = (\underline{N}P), R_3 = (\underline{A}D), R_4 = (\underline{P}D)\}$ .

By the definition of join operation,<sup>1,2,8</sup> two relations,  $R_i$  and  $R_j$ , may be joined if they contain common or comparable sets of attributes,  $A$  and  $B$ , such that  $A \subseteq S_i$  and  $B \subseteq S_j$ . So, four different joins can be executed on the sample relations of  $R$  (common attributes are indicated in parentheses):  $R_{12} = R_1 * R_2 (N)$ ,  $R_{13} = R_1 * R_3 (A)$ ,  $R_{24} = R_2 * R_4 (P)$ ,  $R_{34} = R_3 * R_4 (D)$ . The three former joins satisfy the condition for losslessness, but the latter one does not, because  $CL(N) = \{N, A, P, D\}$ ,  $CL(A) = \{A, D\}$ ,  $CL(P) = \{P, D\}$ ,  $CL(D) = \{D\}$ , so neither  $\{A, D\}$  nor  $\{P, D\}$  belongs to  $CL(D)$ . Relation  $R_{34}$ , indeed, can contain invalid data, because within a district it relates each phone number to arbitrary addresses not considering that the related phone number and address must belong to the same person name.

Suppose that a relation  $R'$  with a scheme  $S'$  required by a  $R$ -query can be produced losslessly by a sequence of join operations on a set of relations  $\{R_i\}$ . Let us denote the operands of a join operation  $R_l$  (*left relation*) and  $R_r$  (*right relation*), such that if the join is lossless, then without any loss of generality  $S_l \cap S_r \xrightarrow{*} S_r$ . A join  $R_l * R_r$  produces a relation  $R_{lr}$  with a scheme  $S_{lr} = S_l \cup S_r$ . There is a subset of attributes  $K_l \subseteq S_l$  (called a key of  $R_l$ ), such that

$$K_l \xrightarrow{*} S_l \tag{1}$$

By Armstrong's axioms,<sup>13</sup>  $K_l \xrightarrow{*} S_{lr}$ , i.e. a key of the left relation is also a key of the product. This implies the following property of sequences of lossless join operations:

If a relation  $R'$  with a scheme  $S'$  is produced losslessly by a sequence of join operations from a set of initial relations  $\{R_i\}$  such that  $S' \subseteq \cup S_i$ , then there is a relation  $R_j \in \{R_i\}$ , called a *source relation* of  $R'$ , such that  $S'$  functionally depends on each key,  $K$ , of  $R_j$ . (Proofs are omitted here for brevity).

GRAPH REPRESENTATION

A given set of functional dependencies,  $F$ , can be represented by an AND/OR graph<sup>14</sup> in the following way. Let  $G = (V, W, E_1, E_2)$  denote an AND/OR graph, where  $V$  is

a set of AND-nodes and terminal nodes,  $W$  is a set of OR-nodes,  $E_1$  is a set of AND-arcs (the arcs going out of AND-nodes),  $E_2$  is a set of OR-arcs (the arcs going out of OR-nodes). We shall say that an AND/OR graph  $G$ , called an  $F$ -graph, displays a given set of dependencies  $F = \{f_i\}$  iff for each  $f_i \in F$  such that  $f_i: A_i \rightarrow B_i$  ( $A_i$  and  $B_i$  are sets of attributes) all of the following hold:

- $V \supset \{v_j \mid D_j \in (A_i \cup B_i)\}$ , where  $v_j$  denotes the node displaying  $D_j$
- $w_i \in W$
- $E_1 \supset \{(v_k, w_i) \mid D_k \in A_i\}$
- $E_2 \supset \{(w_i, v_m) \mid D_m \in B_i\}$
- There are neither other nodes nor other arcs in  $G$ .

In words,  $V$  contains nodes, called  $v$ -nodes, corresponding to all the attributes appearing in  $F$  ( $D(v_i)$  denotes the attribute displayed by  $v_i$ ,  $D(v_i) = D_i$ );  $W$  contains nodes, called  $w$ -nodes, corresponding to all the dependencies appearing in  $F$  ( $f(w_j)$  denotes the dependency displayed by  $w_j$ ,  $f(w_j) = f_j$ ); for each distinct left-side set of attributes  $A_i$  (of a dependency  $f_i$ ) there is a  $w$ -node,  $w_i \in W$ , which accepts incoming arcs from all the  $v$ -nodes corresponding to  $A_i$  and emits outgoing arcs to all the  $v$ -nodes corresponding to  $B_i$ .

For example, Figure 1 shows a  $F$ -graph which displays the following set of dependencies:  $F = \{D_1 D_2 D_3 \rightarrow D_6 D_7, D_4 D_5 \rightarrow D_7, D_6 \rightarrow D_9, D_7 \rightarrow D_9, D_7 D_8 \rightarrow D_{10}\}$ . The AND-arcs going to the same  $w$ -node are linked by a bow,  $w$ -nodes are marked by a double circle.

Let a collection of relations  $R = \{R_i\}$  represent a DB with a given  $F$ . Because our aim is to construct a requested relation from  $\{R_i\}$  we supplement the  $F$ -graph  $G = (V, W, E_1, E_2)$  with the following information corresponding to the relations of  $\{R_i\}$ : for each  $R_i$  add to  $G$  a node  $u_i$ , called a  $u$ -node, such that if  $K$  is one of the keys of  $R_i$ , then  $u_i$

Figure 1

emits outgoing arcs to all the nodes of  $G$  displaying attributes of  $K$ .  $R_i$  is displayed by  $u_i$ ;  $K$  is said to be tied by  $u_i$ .

We shall say that an AND/OR graph  $H=(U, V, W, E_1, E_2, E_3)$ , called an  $R$ -graph, displays a given representation  $R$  of a DB with a given  $F$ , iff all of the following hold:

1.  $V, W, E_1$  and  $E_2$  are those of the  $F$ -graph  $G$
2.  $U=\{u_i | R_i \in R\}$ ,  $u_i$  denotes the node displaying  $R_i$
3.  $E_3 \supset \{(u_i, v_k) | D_k \in K_i\}$ ,  $K_i$  denotes a key of  $R_i$
4. There are neither other nodes nor other arcs in  $H$ .

As an example, Figure 2 shows a  $R$ -graph displaying the following representation of a DB having the  $F$ -graph of Figure 1:  $R_1=(D_1D_2D_3D_6D_7D_9)$ ,  $R_2=(D_4D_5D_7)$ ,  $R_3=(D_7D_8D_9D_{10})$ .

Let us say that a node  $v_i \in V$  in  $H=(U, V, W, E_1, E_2, E_3)$  is reachable from a set of nodes  $\tilde{V} \subseteq V$  (abbr.  $\tilde{V} \xrightarrow{*} v_i$ ) if the following holds:

- a.  $v_i \in \tilde{V}$ , or
- b. There is a node  $w_j$  preceding  $v_i$ ,  $(w_j, v_i) \in E_2$ , s.t. all the nodes preceding  $w_j$ ,  $\{v_k | (v_k, w_j) \in E_1\}$ , are reachable from  $\tilde{V}$ .

Because each dependency of  $F$  is displayed by the corresponding  $w$ -node of  $H$ , reachability is equivalent to belonging to a closure in the same sense as  $H$  is equivalent to  $F$ . This implies the following:

- (i) A node  $v_i \in V$  is reachable from a set of nodes  $\tilde{V} \subseteq V$  iff  $D(\tilde{V}) \xrightarrow{*} D(v_i)$ .
- (ii) A node  $v_i \in V$  is reachable from a node  $u_j \in U$  if  $u_j$  ties a set of nodes  $\tilde{V} \subseteq V$  such that  $\tilde{V} \xrightarrow{*} v_i$ .
- (iii) If a relation  $R'$  with a scheme  $S'$  can be produced losslessly from a set of relations  $\{R_i\}$ , then a  $R$ -graph  $H$  which displays  $\{R_i\}$  contains a  $u$ -node,  $u_s$ , called a source node of  $S'$ , from which all nodes  $\{v_i | D_i \in S'\}$  displaying the attributes of  $S'$  are reachable. Indeed, let  $R_m$  be a source relation of  $R'$ , then the node  $u_m$  displaying  $R_m$  in  $H$  is a source node of  $S'$ .

Figure 2

JOIN PROCEDURE FOR  $R$ -QUERY

If a relation  $R'$  can be produced from a set of relations  $R=\{R_i\}$  there is, in general, a number of different sequences of join operations producing  $R'$ . For example, if a data base having the  $F$ -graph shown in Figure 3 is represented by the relations  $R_1=(D_1D_2)$ ,  $R_2=(D_1D_3)$ ,  $R_3=(D_2D_4)$ , then a relation  $R'=(D_1D_3D_4)$  can be produced by the following join sequences:

- a.  $J_1: R'_1=R_1 * R_2(D_1), R'_1=(D_1D_2D_3);$   
 $J_2: R'=R'_1 * R_3(D_2), R'=(D_1D_3D_4).$
- b.  $J_1: R'_1=R_1 * R_3(D_2), R'_1=(D_1D_2D_4);$   
 $J_2: R'=R'_1 * R_2(D_1), R'=(D_1D_3D_4).$

In these sequences we do not care about project operations which should appear in practical procedures. For instance, in Sequence b the relation  $R'_1$  probably should be projected in  $(D_1D_4)$  before  $J_2$ . We assume that relations  $R'_i$  produced by joins are properly projected.

One of the join sequences producing  $R'$  should be preferred to others according to certain criteria, one of which, in particular, is the total processing cost,  $CJ=\sum c(J_i)$ , where  $c(J_i)$  is the processing cost of  $J_i$ . The processing cost of a join operation depends on the structure, composition and location of the joined relations and of the product as well. We assume that each relation  $R_i$  is assigned an access cost  $c(R_i)$  (say, proportional to its physical size).

Our goal is to construct an efficient sequence of joins  $J(R')=\{J_1, J_2, \dots\}$  which produces a relation  $R'$  (with a scheme  $S'$ , required by a  $R$ -query) from a given set of relations  $R$  representing a data base with a  $R$ -graph  $H$ . The features of lossless joins of relations and the graph representation described in the second and third sections provide a basis for an algorithm which performs this task in a number of stages as follows.

- A. Let  $X$  be a target set, that is a set of nodes displaying the attributes required by a given  $R$ -query, such that  $X=\{x | D(x) \in S'\}$ . At this stage all the source nodes of  $X$  (from which all the nodes of  $X$  are reachable) are found in  $H$ , constituting a set  $U_s$ . If  $U_s$  is empty then, by (iii), the requested relation cannot be constructed according to the given data. The algorithm used at this stage is a graph equivalent of the Membership algorithm presented in Reference 15.

Figure 3

- B. Let us consider a  $u$ -node  $u_i$ , a  $v$ -node  $y$  and a set of relations  $P(u_i, y)$  such that a relation  $R'$  with a scheme  $S' = D(K_i) \cup \{D(y)\}$  can be produced from  $P(u_i, y)$  but cannot be produced from a subset of  $P(u_i, y)$ . We shall call  $P(u_i, y)$  a *join path* from  $u_i$  to  $y$ .  $CP(u_i, y)$  stands for the cost of  $P(u_i, y)$  such that  $CP(u_i, y) = \sum c(R_j) | R_j \in P(u_i, y)$ .  $P(u_i, Y)$  denotes a join path from  $u_i$  to a set of nodes  $Y$ , such that  $P(u_i, Y) = \cup P(u_i, y) | y \in Y$ . Stage *B* finds a join path from  $u_i \in U_s$  to a given target set  $X$  which has the minimum join path cost among all the join paths from  $u_i$  to  $X$  found by the algorithm. This stage is based on Dijkstra's algorithm for the shortest path in a graph.<sup>16</sup>
- C. As was mentioned previously, there is, in general, a number of different *join procedures* (i.e. sequences of join operations),  $J(u_i, X)$  producing  $R'$  from  $P(u_i, X)$ . Let  $J^o(u_i, X)$  denote the *optimal join procedure* that has the minimum total processing cost,  $CJ^o(u_i, X) = \min CJ(u_i, X)$ . At Stage *C* for all the source nodes  $u_i \in U_s$ , an optimal join procedure  $J^o(u_i, X)$  is built. This stage is based on Huffman's algorithm<sup>17</sup> for finding a tree with minimum weighted path length. Then among all these join procedures the algorithm chooses the one,  $J(R')$ , with the lowest processing cost, such that  $CJ(R') = \min CJ^o(u_i, X) | u_i \in U_s$ . If  $R'$  cannot be produced from the given data, the algorithm returns  $J(R') = \phi$ .

## COMPLEXITY ESTIMATION

Let  $\tau$  stand for a *measure of complexity* (say, the running time) of an algorithm, and let  $\bar{F}$  denote the number of all appearances of attributes in all the dependencies of  $F$  (if all the dependencies belonging to  $F$  are written down as a sequence of names of attributes appearing in them, then  $\bar{F}$  is the length of this sequence). Let  $|R|$  denote the cardinality of  $R$ .

The analysis of the algorithm of the fourth section gives the following estimation of the complexity of its stages:

$$\tau(A) = 0(|R| \cdot \bar{F}),$$

$$\tau(B) = 0(|R|^3 \bar{F}),$$

$$\tau(C) = 0(|R|^3).$$

Thus, the complexity of the algorithm finding an efficient

join procedure for a given query is polynomial,

$$\tau = 0(|R|^3 \bar{F})$$

(cf. an exponential-time algorithm given in Reference 12).

# ASTROL—An associative structure-oriented language

by JAMES F. WIRTH

East Carolina University  
Greenville, North Carolina

## INTRODUCTION

The language ASTROL resulted from the search for a "small" language somewhat like LISP 1.5 which could be easily implemented on a minicomputer with about 32K bytes of store. The LISP cell was considered to be an example of the record—an object whose structure is specified by a set of field descriptors. However, the set of descriptors is often allocated at compile time, whereas it would be useful to be able to add descriptors to a record dynamically.

The essential information requirement for a record is the ability to associate values to certain combinations of record and descriptor—a task for an associative memory. Consequently, the author determined to create a conversational language whose structure was implicitly bound to the facilities provided by an associative memory—an Associative Structure-Oriented Language. This was a conceptual experiment to discover what ideas would arise in the attempt to adapt traditional programming constructs to such an environment.

## FUNDAMENTAL CONSTRUCTS

The kind of memory envisioned for ASTROL was one that could associate a value  $z$  to a pair  $x, y$  where  $x, y$  and  $z$  were any members of some set  $A$ . Perhaps a content addressable memory (CAM) could be used—where each word of the memory is divided into three fields  $x, y$  and  $z$ . Instead of being addressed, a word  $(x, y, z)$  would be accessed by specifying its  $x$  and  $y$  field contents. The storage of the word  $(x, y, z)$  would represent the association of  $z$  to the pair  $(x, y)$ . In ASTROL the instruction  $xy \leftarrow z$  expresses the storage of such an association in the memory while the expression  $(xy)$  denotes the retrieval of the value  $z$  last associated to  $x$  and  $y$ . The association is deterministic in that a subsequent storage operation  $xy \leftarrow w$  will erase the previous association. The operation  $(xy)$  can be thought of as meaning "the  $y$ th element of array  $x$ ," "field  $y$  of record  $x$ ," or "subject  $x$ 's  $y$ -attribute." It is left associative with maximum precedence so that  $xyz$  is the same as  $(xy)z$  while  $xy \leftarrow w$  means  $(xy)z \leftarrow w$ .

The objects  $x, y$  and  $z$  from the set  $A$  are called atoms and include the signed integers, symbols à la LISP such as BIRZWP, and two other categories—the code atom and

anonymous atom—to be described later. A special anonymous atom, *nil*, is included as the default value for an undefined association  $(xy)$ .

Beyond the simple notations given above, the evolution of ASTROL was guided by the principle of simplicity, and so the language has only one data type—the atom from  $A$ . The subcategories of  $A$  are mostly irrelevant to the language so that no expression is restricted to using a special kind of atom.

Simplicity also required that there be a single statement type and so ASTROL is an "expression" language. Each instruction is an expression with a value and so can appear elsewhere within a larger expression. The value of the association  $xy \leftarrow z$  is  $z$ , whereas the expression  $x(y \leftarrow z)$  causes the same association but has the value  $x$ . The latter form is useful in assigning multiple attributes to the same subject. Thus

$$x(y_1 \leftarrow z_1)(y_2 \leftarrow z_2) \dots (y_n \leftarrow z_n)$$

can be thought of as defining a "record"  $x$  whose  $y_i$ th field has the value  $z_i$ . As in ALGOL 60, the operation  $\leftarrow$  is right associative so that  $xy \leftarrow zw \leftarrow u$  means  $xy \leftarrow (zw \leftarrow u)$  and results in two associations  $zw \leftarrow u$  and  $xy \leftarrow u$ . For a general example suppose that the memory has already stored the associations:

MARY SON ← BILLY      JOHN WIFE ← MARY  
JOHN DOG ← SPOT      REL I ← WIFE

Then the expression:

JOHN (REL I) SON (DOG ← MARY DOG  
    ← JOHN DOG) BUDDY ← JOE,

has the value *JOE* and causes the associations *MARY DOG ← SPOT*, *BILLY DOG ← SPOT*, and *BILLY BUDDY ← JOE* to be placed in memory.

In addition to the  $(xy)$  and  $xy \leftarrow z$  operations, there are seven binary infix operators  $+$ ,  $-$ ,  $*$ ,  $/$ ,  $<$ ,  $\leq$ , and  $=$  with the usual meanings. These all have the same precedence as  $\leftarrow$  and are all right-associative. The relational operators yield 1 for true and the nil atom for false; and a missing left operand for  $-$  is presumed to be 0.

## CONTROL STRUCTURES

Formally speaking ASTROL does not support the concept of a program. However, a series of expression  $e_i$  can be

combined into a new expression ( $e_1; e_2; \dots e_n$ ) by the operator  $;$  which is left-associative, has minimum precedence and operates by deleting its left operand after evaluating both. Clearly this is a thinly-disguised program block.

Conversational languages such as BASIC provide editing flexibility by labeling every instruction in a program. This process can be seen as the association of an instruction code segment to each label. It is natural to adapt the associative mechanism in ASTROL to this purpose, and to that end code segments are allowed to be atoms in  $A$ . The series of instructions which evaluate an expression ( $e_1; e_2; \dots e_n$ ) can be organized into a single object called a code atom and will then be a member of  $A$ . This data object is denoted by  $[e_1; e_2; \dots e_n]$ . The operator  $DO$  is used to evaluate the instructions in such a code atom. For example the value of  $[2+3]$  is the code atom which can add 2 and 3, but the value of  $DO [2+3]$  is 5. The operator  $DO$  has a precedence just above that of the semicolon. When  $DO$  is applied to a non-code atom, it leaves that atom unchanged. Consequently, the value of  $DO MARY$  is just  $MARY$ . However if the association:

$STEP 1 \leftarrow [MARY DOG \leftarrow SPOT; JOHN HAIR \leftarrow BROWN]$

were placed in memory, then the value of  $(STEP 1)$  would be a single code atom while the expression  $DO STEP 1$  would have the value  $BROWN$  and would cause the two indicated associations.

The code atom is the only device for controlling program flow. It is unnecessary to have a "case" construction, because what might have been written:

```
case X(1) of begin
A: MARY DOG ← SPOT;
B: JOHN DOG ← SPOT;
Y: MARY HAIR ← BLOND
end case
```

can instead be rendered as  $DO CS (X 1)$ , provided that the associations:

```
CS A ← [MARY DOG ← SPOT]
CS B ← [JOHN DOG ← SPOT]
CS Y ← [MARY HAIR ← BLOND]
```

are present in memory.

Because the "if-then-else" construction is a special version of the "case" statement, it too becomes unnecessary. However, the resulting ASTROL formulation is awkward and so an *IF-ELSE* operator was included in the language:

$$\text{value}\{x \text{ IF } y \text{ ELSE } z\} = \begin{cases} \text{value } \{x\} & \text{when value } \{y\} \text{ is not nil} \\ \text{value } \{z\} & \text{when value } \{y\} \text{ is nil} \end{cases}$$

This operator does not control program flow as in ALGOL because each operand of the *IF-ELSE* is evaluated before the result is selected. Thus the code atom remains the sole vehicle for program control and the ALGOL version of "if  $x$  then  $y$  else  $z$ " must be expressed as  $DO ([y] \text{ IF } x \text{ ELSE } [z])$ , where the parentheses could be omitted since the  $DO$  and *IF-ELSE* operators have the same precedence and are associated to the right.

The traditional loop construction can be implemented by recursion, but it was felt that this would be an expensive solution in practice. Consequently the language supports an operator, *REPEAT*, with the same precedence as  $DO$ . Its operand will be repeatedly activated by  $DO$  until it yields a non-nil value, which will then be the result of the *REPEAT* operator. Several loop flowcharts are given in Figure 1 along with equivalent expressions in ASTROL.

It should be emphasized that *REPEAT*  $x$  is an expression and does have a value. For example if  $A$  were an array of 20 elements, then the instruction:

```
STEP FIND ←
[POS I ← 0; REPEAT [DO NONE IF (20 < POS I ← POS
I + 1) ELSE [POS I IF A(POS I) = 3 ELSE NIL]]];
```

will create a code atom  $STEP FIND$  whose activation gives the value of the first position in  $A$  whose element is 3, or the value *NONE* in case none are.

## SYSTEM SYMBOLS

Although generally speaking there are no variables in ASTROL, it does support six operandless operators  $\#, \$, @, ?, ??,$  and *NIL* which are like read-only variables. The result of executing each of these system symbols is described below:

- $\#$  Results in a new anonymous atom for each execution.
- $\$$  Results in an anonymous atom, called the procedural context, which represents the procedure call depth.
- $@$  Results in the atom representing the function procedure currently executing.
- $?$  Results in the next atom from the input data stream each time that it is executed.
- $??$  Results in the atom previously read by the  $?$  operator.
- NIL* Results in the nil atom.

The operator  $\#$  introduces the fourth category of atom—the anonymous atom—which is a data object not in one of the other three categories: integer, spelled symbol or code segment. An anonymous atom is an internal object created by the system when the user needs a new object but does not want to name it. Each occurrence of the operator  $\#$  in an expression will represent a new such object. As an example consider the expression:

```
THE ROOT ← # (OP ← ADD)
(LEFT ← # (OP ← ADD)(LEFT ← 3)(RIGHT ← 7))
(RIGHT ← # (OP ← SQR)(RIGHT ← 9))
```

which creates the labeled ordered tree shown in Figure 2. The first occurrence of  $\#$  creates the root node of the tree, while the second and third occurrences create the left and right daughters of the root. The root node is associated to the pair *THE ROOT*. The node labels are considered to be OP-attributes of the anonymous nodes.

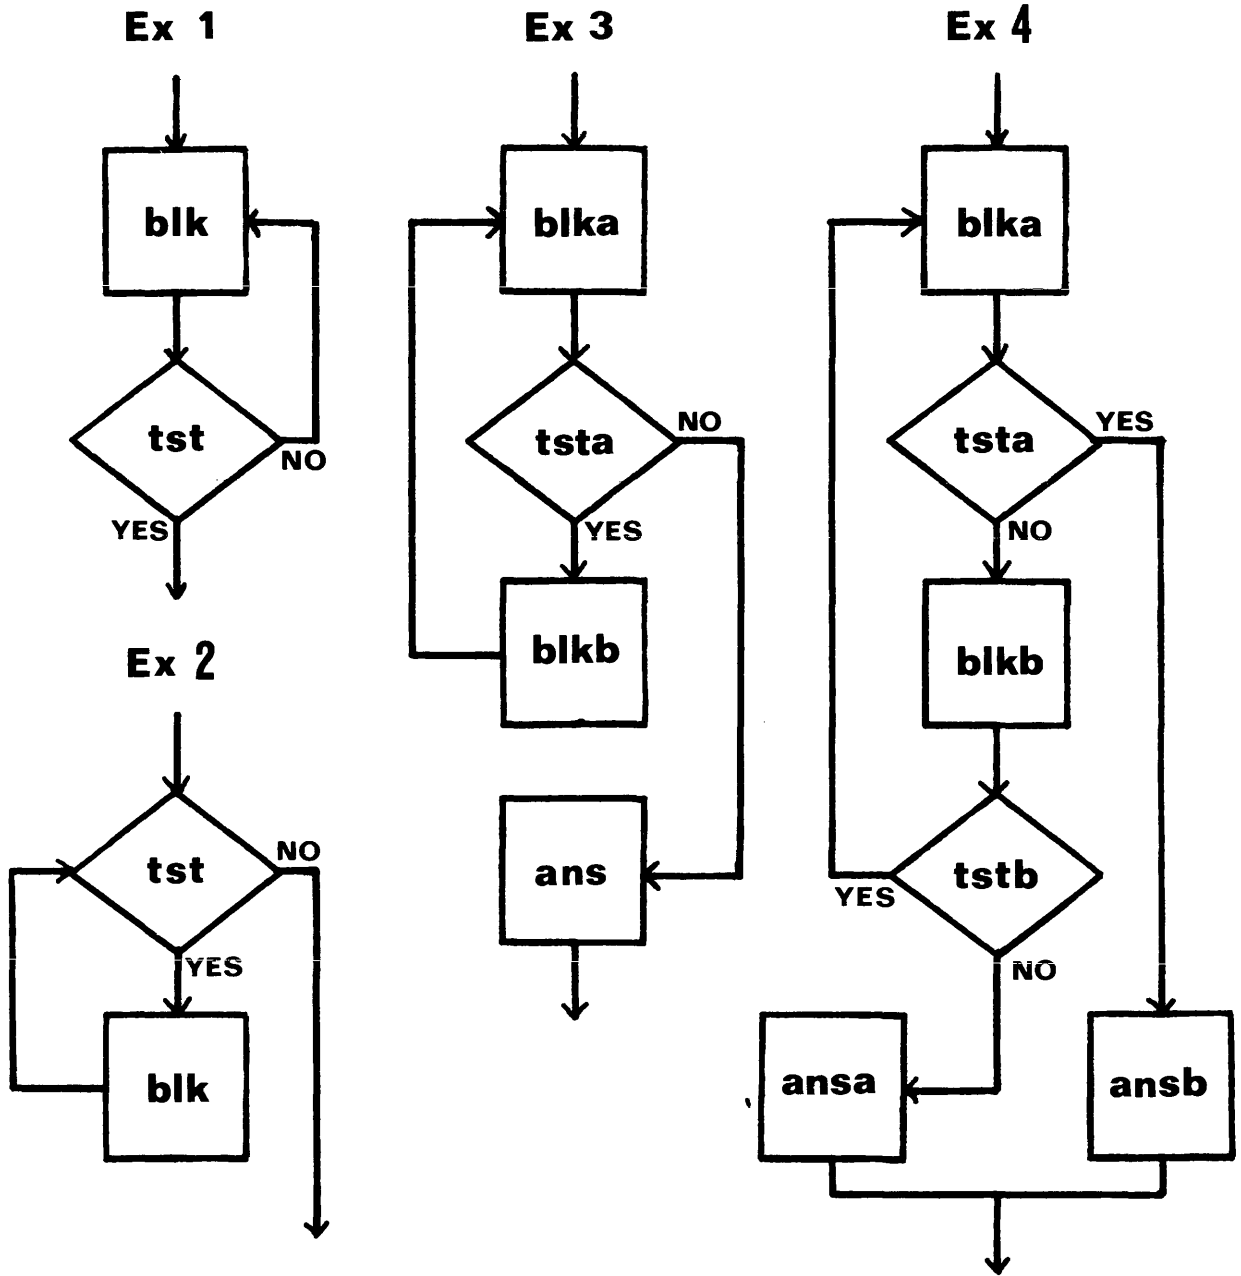

Figure 1

The operator \$ is related to the procedural treatment of identifiers. In a sense no procedural language has explicit variables but rather uses an identifier to represent a variable in that specific context which is the scope of the variable. Hence the value of the variable is associated with the context/scope and the identifier. This association is explicit in ASTROL so that the context/scope is a concrete atom in A represented by \$ and not an abstraction of the form of a program. Hence \$x represents the value associated to the identifier x in the current context \$ without need of a special mechanism. When a procedure is invoked, \$ acquires a new value to represent the context of that copy of the procedure,

while return from the procedure reinstates the previous value of \$. Hence the action of \$ simulates the pushing and popping of procedure stack "frames." In ASTROL the only means of changing context is the procedure call and so contexts can be stacked dynamically (even recursively) but cannot be statically nested as in ALGOL. The use of \$ is discussed further in the next section.

**FUNCTIONS**

Since ASTROL is an expression language, the only procedures are functions. There is no special syntax for the

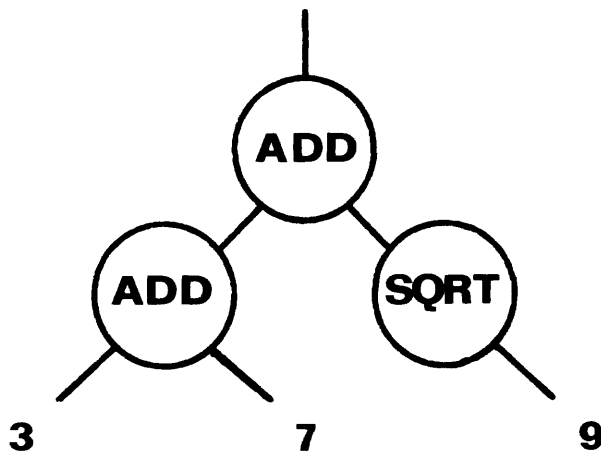

Figure 2

definition of a function and *any* atom can represent a function. A function invocation has the form:

$$x[y_1, y_2, \dots, y_n]$$

where  $x$  is the function name and the  $y_i$  are the actual parameters and are passed by value. The  $[ ]$  operation has the same precedence as the elided operator  $(xy)$  so that  $xy[z, w]p(q \leftarrow r)$  means the same as  $((xy)[z, w])p(q \leftarrow r)$ .

The actual parameter  $y_i$  is passed to the function  $x$  as follows. The expression  $(xi)$  should be the corresponding parameter name and so the association  $\$(xi) \leftarrow y_i$  is used to pass  $y_i$  under the name  $(xi)$ . After the parameters have been passed, the system performs a  $DO(x \text{ VAL})$  to execute the code body  $(x \text{ VAL})$  associated to the function. As mentioned in the last section, the value of  $\$$  is changed just before initiating the function call and is restored when the code atom  $(x \text{ VAL})$  has finished execution. Even if  $x$  is not a function, or  $(x \text{ VAL})$  is nil, all these operations are still legal, although the function value may be nil.

Since a local variable  $n$  used in a function can be referred to as  $(\$n)$ , the associative mechanism and the explicit context atom  $\$$  make it unnecessary to allocate local variables to the function in any special way.

As one example, consider the expression:

$$F(1 \leftarrow X)(2 \leftarrow Y) \text{VAL} \leftarrow [(2 * \$X) - \$Y],$$

which creates the function  $F(x, y) = 2x - y$ . A more elaborate example is given by the definition of the function composition operator *COMPOS* which creates a function dynamically. This created function is represented by an anonymous atom and its composition factors are stored as the  $F$  and  $G$  attributes of that atom. Since the created function is anonymous, its name is accessed by the operator  $@$  within its code body:

$$\text{COMPOS}(1 \leftarrow F)(2 \leftarrow G) \text{VAL} \leftarrow \\ \#[(1 \leftarrow X)(F \leftarrow \$F)(G \leftarrow \$G) \text{VAL} \leftarrow [ @ F [ @ G [ \$X ] ] ] ]]$$

Although parameters are passed by value in ASTROL, the existence of the code atom allows a parameter to be effectively passed by name.

## USER INTERACTION

User input is handled by the  $?$  and  $??$  operators covered earlier, while output is done with the operators  $!$  and  $:$  which have a precedence slightly higher than the semicolon and are left-associative. Both operators tabulate to the position given in the left operand. The  $!$  then outputs the print record and begins a new one. Finally both operators enter the right operand into the print record and yield the next available record position as their value. For example the expression  $!A:B:C!D$  would produce:

```

ABC
D {no carriage return},

```

and have 3 as its value. Output of anonymous atoms and *NIL* is omitted, while output of a code atom will print it out in source form. This eliminates the need for a program listing command.

There are no special editing or command instructions. The user types an expression followed by  $a .$  and the system evaluates it. For example the instruction  $: 1+2.$  would print out 3.

Liberal use of the *DO* operator will allow simple instruction editing via the  $\leftarrow$  operator. This also facilitates debugging since individual steps in a task can be tested in isolation.

Creating user program files presents a problem, since a task in ASTROL is performed by a loosely organized system of code segments and there is no program as such for the user to save. Dumping *all* the associations in memory would be awkward because of the anonymous atoms. Consequently, the primitive function  $\text{SAVE}[file-name, n]$  includes a parameter  $n$  to determine the class of associations  $xy \leftarrow z$  to save. When  $n$  is 0, then  $z$  must be a code atom and  $x$  and  $y$  must be integers or symbols. When  $n$  is 1, then  $z$  may also be an integer or symbol. The associations are dumped in source-readable format so that the primitive function  $\text{READ}[file-name]$  can simply substitute the specified text file for the normal teletype input stream.

Actual implementation of the language required simulation of the associative memory. This was done by hash-coding the subject-attribute pairs. For efficiency in execution, code atoms were translated into a postfix polish notation, although this requires de-translation in order to list such an atom. The only garbage collection is to delete unreferenced code atoms. Currently, ASTROL runs on a PDP11/20 with 32K bytes of store under the RT11 operating system.

## CONCLUSION

A potential technological advance such as the associative memory might be expected to have some impact on programming concepts. ASTROL was created in anticipation of this advance and illustrates some of its consequences for programming. Although it is goto-less and programs should be carefully organized in a top-down fashion—the code segmentation and automatic data structure allocation impart an unstructured flavor to the language. The use of data associations to control program flow allows easy extension of

conversational programs—often without requiring *any* alteration of existing code segments.

Currently the language is being used to implement CAI programs for mathematics and computer science and to investigate an alternative to transformational English grammar.

# An associative search language for data management

by AMAR MUKHOPADHYAY and ALIREZA HURSON

*The University of Iowa*  
Iowa City, Iowa

## INTRODUCTION

Recent years have witnessed a widespread and intensive effort to develop systems to store, maintain and access data bases of varied size. Such systems are referred to as DBMS—Data Base Management Systems. In different areas, such as artificial intelligence, management information systems, military and corporate logistics and medical diagnosis, a wide variety of DBMS exist. All these systems have generally been implemented on conventional computers, which are based on the von Neumann design. In this design, operations will be performed on the information in the memory by means of their addresses. Because of the size of typical data bases and costs of memory, we cannot hold all information in the main memory and swapping converts the search problem to a transportation problem. Present-day systems have to transfer large sets of data from their mass storage to the CPU, where simple compare-functions are performed in order to separate relevant data from irrelevant data. The transfer channels with their limited capacity form the main bottleneck of this system and as a result, great efforts have been made to reduce the necessary data flow by means of sophisticated software systems and additional redundancy such as index tables and inverted files. By these techniques, address of information will be obtained from a directory. Although directory partially solved the bottleneck problem, it nevertheless created some problems. The directory should logically be kept in the main memory. If we are dealing with large data bases, naturally we are dealing also with large directories, and large directories occupy a large portion of the memory. Also, the use of directories will create some complexity in the search, update and delete algorithms. Conventional computers are all based on numerical operations. The necessity of designing new hardware based on non-numerical operations has been discussed in detail by one of the authors.<sup>1</sup> In contrast, use of associative or content addressable memories and hardware design based on non-numerical operations as well as numerical operations causes information stored at unknown locations to be processed efficiently on the basis of some knowledge of its content.

In developing new architectures for future machines some of the most important trends in hardware and software technology must be brought into focus. On the hardware side,

the significant trends are the development of LSI and VLSI technology which allow increased functionality of hardware components coupled with a drastic reduction in cost per function. This implies that new architectures must exploit this trend to incorporate more software functions by hardware. The second important trend in hardware is the development of serial access secondary storage devices such as CCD or magnetic bubble memory (MBM). It is forecast that by 1980/81 a 1Mbit memory will be available for both CCD and MBM, which will emerge as powerful competitors for disks and tapes.<sup>2</sup> We could make the assumption that a major part of future data base systems will reside in such shift-register type memories. The proposed architectures in this paper will, of course, work for other kinds of rotating secondary devices such as disks. A common feature of all these secondary devices is that they are block-oriented, that is, access to a block is slow but data flow rate is high. If the processing of information has to be done by CPU, blocks of information need to be transferred back and forth from the CPU to secondary devices. The new machine architectures, therefore, should attempt to provide processing capabilities outside of CPU and along with secondary devices in the form of associative hardware which will operate on information on the fly. This idea was originally suggested by Slotnik,<sup>3</sup> and in recent years a significant amount of effort has been expended in the development of similar architectures in data base applications.<sup>8-17</sup>

There are, however, several disadvantages to an associative approach—first, hardware for associative processing still has to prove its cost-effectiveness compared to the existing software implementations; second, future innovations in computer systems design and architecture have to confront inertia and large investments on the existing systems. Although the principles of associative processing are as old as second generation computers (and there is an extensive body of literature dealing with many aspects of this phenomenon in computer design), the major bottleneck for the development of associative systems has been the degradation of speed (the memory cycle time) for the required size of the memory. The demand on the size of the memory can be reduced by intelligent design of the architecture. For example, the design of the Lee machine is impractical because the design assumes the main memory system to be associative. In an earlier paper one of the authors<sup>1</sup> showed that a small associative memory could em-

ulate the functions of the Lee machine if information could be passed over it. In the data base context, we are looking for similar architecture and therefore the size of the associative memory will be reduced. This, coupled with the development of VSLI technologies, shows good promise for the use of associative hardware for future machines. A relatively recent associative processor ALAP<sup>19</sup> demonstrates the feasibility of making large associative processors practical.

This paper will introduce a high-level data base language, ASL—Associative Search Language—which is suitable for direct hardware implementation by associative hardware. The architecture for ASL and its proposed hardware implementation will be described in future papers. This paper is concerned with a preliminary definition and specification of ASL.

On the software side, as far as the data base management systems are concerned, an overall recent trend is characterized by the phrase *data independence*. Data independence means that the user is able to perform retrieval and storage operations on the data base depending on the *information content* without having to deal with representational details. Codd<sup>4,5</sup> proposed an important data model, the now-famous relational model, which provides the user with a model of data based on content or data value only. Based on Codd's model, a number of families of data sub-languages and query languages have been proposed—one class based on relational calculus (viz., DSL ALPHA, INGRES, DAMAS), another class based on relational algebra (PRTV, SQUIRAL), and a third class which adopts a "mapping" approach based on the relational algebra (SQUARE, SEQUEL, Query-by-example). The reader is referred to the text by Date<sup>6</sup> or the review article by Chamberlin<sup>7</sup> for more details. In the late 60s, an associative language, ASP,<sup>20</sup> was developed in the context of list and language processing.

The conceptual framework of ASL is very similar to that of SQUARE,<sup>18</sup> a data sub-language which formed the basis for the development of SEQUEL. The similarities of these two languages are reflected in the definition of the basic operations which brings forth explicitly the associative nature of processing, and also in avoiding the use of quantifiers required by languages based on relational calculus. Both ASL and SQUARE are relationally complete, provide facilities for query, insertion, deletion and update operations, and are meant for non-professional programmers who do not possess a high degree of mathematical sophistication. However, the originators of SQUARE did not emphasize the associative nature of the primitive operations since the language was not considered for hardware implementation. The authors are of the opinion that for hardware implementations of data base operators, development of a language like SQUARE or ASL is essential. The relationship between a high-level user language such as SEQUEL or Query-by-example with SQUARE or ASL is similar to the relationship between FORTRAN or PL/1 and assembly language except that the definition of ASL is independent of actual hardware implementation. We also claim that ASL has several advantages over SQUARE, as follows: the structure of the language is more precise and the expressions in the language

can be handled by parsing algorithms that are available for well formed arithmetic expressions in programming languages which, in the hardware context, define a precise sequence of controlling operations by the hardware; ASL allows parallel computations of a set of relations and is based on variable size information fields with complete independence; ASL is also easily extendable to multi-dimensional as well as non-relational data bases; and finally, ASL provides potential for the development of a FORTRAN-like language for data base applications.

#### ASL—AN ASSOCIATIVE SEARCH LANGUAGE FOR DATA BASE MANAGEMENT

The language ASL—Associative Search Language—is a high-level data base language designed for information retrieval and storage operation on data bases using associative principles for basic operations. The language has been defined based on the relational model of data presented by Codd, although extensions to non-relational models are possible. A partially complete syntax for ASL is included in the Appendix.

The fundamental operation in ASL is a search on a data base with respect to criteria (search arguments). The result is a relation yielding the retrieved information. This operation can be thought of as an assignment statement  $W:=X$ , where  $W$  is a relation and  $X$  is composed of three parts,

*HOW WHERE WHAT*,

where "HOW" specifies the search arguments (search criteria), "WHERE" specifies the relation name and "WHAT" specifies the output domains of the relation. If  $R$ ,  $C$ ,  $D$  stand for *WHERE*, *HOW* and *WHAT* respectively, we can say  $R$  is a binary transformation operation whose operands are  $C$  and  $D$ , and can be expressed as

$$C \textcircled{R} D.$$

$C$  is a set of sets ( $C=(c_0, \dots, c_k)$ ) where each element in this set ( $c_i, 0 \leq i \leq k$ ) is an unordered list of search arguments; for  $i=0$ ,  $c_i=\phi$ , denotes an empty set of search.  $D$  is also a set of sets ( $D=(d_0, \dots, d_n)$ ) where each  $d_i(0 \leq i \leq n)$  is a non-empty unordered list of domains over  $R$ . When  $d_i$  includes all the domains of  $R$ , it will be denoted by  $\delta$ . The result of operation  $\textcircled{R}$  on  $C$  and  $D$  is a set of relations ( $W_0, \dots, W_n$ ) where the domains of  $W_i(0 \leq i \leq n)$  are the same as those of  $d_i(0 \leq i \leq n)$ . In our implementation we assume  $C$  and  $D$  as well as  $W$  are singleton sets.

The informal presentation of ASL will be with respect to the employee-department data base as follows:

```
E(ENO, ENAME, DEGREE, LOCATION)
D(DNO, DNAME, DHEAD, LOCATION)
ED(ENO, DNO, HOUR)
```

where *ENO*, *DNO* stand for Employee and Department number, *ENAME*, *DNAME* stand for Employee and Department name, and *HOUR* shows how many hours each

employee works in each department. Each query will be expressed in two forms, first as assignment statements  $W:=X$ , where  $X$  is specified using conventional notations in data base literature,<sup>6</sup> and then in the form of ASL statements.

## RETRIEVAL OPERATIONS

### Simple retrieval

- Get department number of all departments

$$W:=\phi \textcircled{D} DNO$$

According to our current implementation of ASL, this query will be presented as below in ASL language:

$$D, \\ W=[D]DNO;$$

where  $D$ . declares the name of the relation. Note the set of rules in the appendix shows that each program will be started with the declaration of all relations used in that program. Henceforth, in all the examples, we will omit the declarative statement.

- Get all the information of all employees:

$$W:=\phi \textcircled{E} \delta$$

which in fact is equivalent to  $W:=E$ . This query in ASL will be written as

$$W=[E];$$

### Qualified retrieval

- Get employee numbers for all employees in LOCATION L1 with DEGREE>3:

$$W:=(LOCATION='L1'\wedge DEGREE>'3')\textcircled{E} ENO$$

In ASL it is  $W=((LOCATION \text{ EQ } 'L1')\wedge DEGREE \text{ GT } '3')[E]ENO;$ .

This example illustrates that  $C$  could be specified by a predicate. The output  $W$  is a relation whose tuples are  $ENO$  of relation  $E$ .

### Complex retrieval

Up to now, retrieval operations with simple search arguments and over one relation which yields a sub-relation of the original relation have been discussed. A sub-relation is a relation derived from a given relation by the selection of a row, the projection on columns, and then removing the redundant tuples. We will now consider more complex retrieval operations.

Retrievals that yield sub-relations by using more than one

relation:

- Get employee names for employees who work in department D1:

$$W:=((DNO='D1')\textcircled{ED} ENO)\textcircled{E} ENAME$$

The nested nature of operations has been illustrated by this example—first, the relation  $ED$  will be searched for all department numbers equal to  $D1$  yielding a subrelation of  $ENO$ . This sub-relation will then be used as an argument to obtain  $ENAME$ . In fact, this sub-relation will be searched in associative fashion. The operation can be seen as:

$$X:=(DNO='D1')\textcircled{ED} ENO$$

$$W:=\forall_{(ENO\in X)}\textcircled{E} ENAME$$

In ASL we have  $W=((DNO \text{ EQ } 'D1')[ED]ENO)[E]ENAME;$ .

The right-hand side of an assignment statement will be called a *set expression*. A set expression, like arithmetic expressions, can be written in infix notation, as previously, or in postfix notation as

$$W:=(DNO='D1')ENO \textcircled{ED} ENAME E$$

defining the same relation  $W$ . The use of postfix notation avoids redundant use of parentheses and also has the advantage with respect to compilation and the design of hardware controller that implements the language. We will write the set expressions in infix notation. The predicate expressions will always be parenthesized.

- Get employee numbers for employees who work in department managed by 'SMITH':

$$W:=(DHEAD='SMITH')\textcircled{D} DNO \textcircled{ED} ENO$$

and in ASL:

$$W:=(DHEAD \text{ EQ } 'SMITH')[D]DNO[ED]ENO;$$

- Get employee names for employees who work in department managed by 'SMITH':

$$W:=(((DHEAD='SMITH')\textcircled{D} DNO)\textcircled{ED} ENO)\textcircled{E} ENAME$$

and in ASL:

$$W:= \\ (((DHEAD \text{ EQ } 'SMITH)[D]DNO)[ED]ENO)[E]ENAME;$$

A complicated set expression like the previous one could be parsed starting from the postfix equivalent expression using dynamic relation variables such as  $A$  and  $B$ :

$$W:=(DHEAD='SMITH')DNO \textcircled{D} ENO \textcircled{ED} ENAME \textcircled{E}$$

The parsing will proceed from left to right and the computation will proceed as

$$A:=(DHEAD='SMITH')\textcircled{D} DNO$$

$$B:=A \textcircled{ED} ENO$$

$$W:=B \textcircled{E} ENAME$$

We will now consider retrievals that do not necessarily

yield sub-relations and use several construction operators like tuple-compatible union ( $\cup$ ), intersection ( $\cap$ ), complementation ( $\bar{\phantom{x}}$ ), cartesian product ( $\otimes$ ), join, division ( $\div$ ) and restriction ( $\downarrow$ ), along with Boolean operations AND ( $\wedge$ ), OR ( $\vee$ ), NOT ( $\neg$ ), and predicates using these and relational binary operators  $<$ ,  $>$ ,  $=$ ,  $\leq$ ,  $\geq$ ,  $< >$ . The normal set of arithmetic functions and 'library' functions of counting and averaging, etc. could be super-imposed on these. In many of the expressions written that follow, more than one statement, sometimes with implicit loops, will be used. Although our language is relationally complete, it does not satisfy the single statement requirement. The data sub-languages using relational calculus that satisfy the single sentence constraint but use existential and universal quantifiers do not seem to be so easily understood by even reasonably sophisticated users. Furthermore, our motivation also has roots in the hardware implementation and provides us with a simple interface design for translating queries into hardware control signals. Only the first forms of the queries (viz.,  $W:=X$ ) are specified; ASL statements are omitted.

- Get a list of all employees with the amount of hours they work for each department:

$$X := \phi ED$$

$$W := \bigcup_{x \in X} [x \otimes ((ENO = x(ENO)) \textcircled{E} ENAME)]$$

where  $x(ENO)$  denotes the  $ENO$  field of  $x \in X$ .

- Get employee names for employees who do not work in department  $D1$ :

$$W := [(\phi \textcircled{ED} DNO)$$

$$-((DNO = 'D1') \textcircled{ED} DNO)] \textcircled{E} ENAME$$

- Get all employee and department names. Pair so that the indicated employee and department are located in the same place:

$$X := \phi E \text{ LOCATION}$$

$$W := \bigcup_{x \in X} [(LOCATION = x) \textcircled{E} ENAME]$$

$$\otimes (LOCATION = x) \textcircled{D} DNAME]$$

- Get employee names for employees who work in all departments:

$$X := \phi \textcircled{ED} ENO$$

$$Y := \phi \textcircled{D} DNO$$

$$W := ((X \textcircled{ED} DNO) = Y) \textcircled{E} ENAME$$

## JOIN OPERATION

Let  $\theta$  be any relation  $=, <, >, < \leq, > \geq$ . Then the  $\theta$  join of a relation  $R$  on domain  $D_r$  with relation  $S$  on domain

$D_s$  is defined (using Codd's notation) as:

$$R[D_r, \theta D_s] S = \{(rs) \mid r \in R \wedge s \in S \wedge (r(D_r) \theta s(D_s))\}$$

where  $r(D_r)$  and  $s(D_s)$  are assumed to be  $\theta$ -comparable. The quantity  $(rs)$  denotes a concatenation of tuples. It is possible to specify a subset of domains to be concatenated without repeating the comparand domains. Let us denote these domains by  $D_r^*$  and  $D_s^*$ . Then we can define our set expression equivalent of  $\theta$ -join as:

$$Y := \phi \textcircled{R} D_r$$

$$Z := \phi \textcircled{S} D_s$$

$$X := \{(y, z) \mid y \in Y, z \in Z \text{ and } y \theta z\}$$

$$W := \bigcup_{a \in X} \{y \textcircled{R} D_r^*\} \otimes t \otimes \{z \textcircled{S} D_s^*\}$$

where  $t$  could be either  $y$  or  $z$  or  $(y, z)$ .

## Example

Let

	<i>A</i>	<i>B</i>	<i>C</i>
<i>R</i>	<i>a</i>	1	1
	<i>a</i>	2	1
	<i>b</i>	1	2
	<i>c</i>	2	5
	<i>c</i>	3	3

	<i>C</i>	<i>D</i>
<i>S</i>	2	<i>u</i>
	3	<i>u</i>
	4	<i>u</i>

and let  $D_r = D_s = C$ ,  $D_r^* = (A, B)$ ,  $D_s^* = (D)$ ,  $t = y$  and  $\theta$  be equality ( $=$ ) so that we are computing equijoin. Then

$$Y := \phi \textcircled{R} C = (1, 2, 3, 5)$$

$$Z := \phi \textcircled{S} C = (2, 3, 4)$$

$$X := ((2, 2), (3, 3))$$

$$W := \bigcup_{a \in X} [y \textcircled{R} (A, B)] \otimes y \otimes [z \textcircled{S} (D)] = \begin{bmatrix} b & 1 & 2 & u \\ c & 3 & 3 & u \end{bmatrix}.$$

The computations of the set  $X$  do not follow the format of a set expression although it is a well defined set. Similar well defined set computation procedures must be part of ASL facilities.

## DIVISION OPERATION

Let  $D_r, D_0$  denote domains in relation  $R$  such that  $D_r \cap D_0 = \phi$ . Let  $D_s$  be a domain in relation  $S$  such that it is comparable with  $D_r$ . Then the division operator

$$R[D_r \div D_s] \textcircled{S} (D_0)$$

is defined by the set expressions

$$X := \phi \textcircled{S} D_s$$

$$W := \bigcap_{x \in X} x \textcircled{R} D_0$$

Example

	A	B	C
R	1	11	x
	2	11	y
	3	11	x
	4	12	x

	D	F
S	x	1
	x	2
	y	1

Let  $D_r=C$  and  $D_s=D$ . Let  $D_0=(B)$ . Then

$$X := \phi(S) D = (x, y)$$

$$W := (x(R)(B)) \cap (y(R)(B)) = (11, 12) \cap (11) = (11)$$

RESTRICTION OPERATION

The restriction operation is simple to model in our scheme. The search arguments are defined in terms of a binary relation  $\theta$  between comparable subsets of domains  $D_1$  and  $D_2$  of the relation  $R$ , and an output domain  $D_3$  is specified. Thus

$$W := ((D_1 \theta D_2) (R) D_3)$$

Example

	A	B	C
R	p	2	1
	q	2	3
	q	5	4
	r	3	3

Let  $D_1=B$ ,  $D_2=C$ ,  $D_3=(A,B,C)$ ,  $\theta=>$ . Then

$$W := ((B > C) (R) (A,B,C)) = \begin{bmatrix} p & 2 & 1 \\ q & 5 & 4 \end{bmatrix}$$

STORAGE OPERATIONS

Storage operations such as "update," "insert," and "delete" can be performed easily by accessing appropriate tuple(s) from the appropriate relation followed by modification of information. They can be specified in two forms:

1. Set Expression := new-data.

This is a simple store operation that changes the existing information to new values without regard to previous value and does not alter the relation otherwise.

2.  $W := a$  modified relation expressed by appropriate transformation of the set expression.

We give some examples below:

- Update change the location of department D1 to "NEW YORK"

$$(DNO = 'D1') (D) LOCATION := 'NEW YORK'$$

- Delete all employees whose degree is less than 4.

$$E := E - (DEGREE < 4) (E) \delta$$

In ASL it is  $E = E - (DEGREE LE '4')[E]$ .

- Delete relation E.

$$E := E - E$$

In ASL it is simply  $E -$ .

- Add a new employee to EMPLOYEE relation.

$$E := EU(ENO = '123'; ENAME = 'JOE', DEGREE = 'S', LOCATION = 'ROME')$$

and in ASL we have

$$EU(ENO = '123'; ENAME = 'JOE'; DEGREE = 'S'; LOCATION = 'ROME');$$

- Add 5 to Hour for employee number N:

$$x := N (ED) HOUR$$

$$x := x + 5$$

$$(ENO = N) (ED) HOUR := x$$

In ASL it is given by

$$(ENO = N)[ED]HOUR = HOUR + 5$$

CONCLUSION

A preliminary definition of a data base management language based on associative primitive operations along with its BNF specification has been presented in this paper. Detailed implementation of ASL as a language processor and hardware architecture based on ASL will be reported in future papers. Because of the upsurge of recent interest in nonnumeric computation, development of specialized language processors will result in simplification of software systems and will lead to the development of specialized hardware processors which will exploit the current trends in technology.

# Updating defined relations

by I. M. OSMAN  
University of Khartoum  
Khartoum, Sudan

## INTRODUCTION

Some relational data base systems<sup>1</sup> such as PRTV<sup>2</sup> and SE-QUEL allow the user to create his own relations (logical files) as subsets of the main data. With such a facility the user may express his own view of the data in terms of the relations he creates. If a large number of such relations are created, disc storage space problems and other maintenance difficulties can arise.

A relation which is expressed in terms of other relations is called a defined (derived or implied) relation<sup>2</sup> or view.<sup>3</sup> The user submits to the system a definition of these relations expressed in terms of data base relations using relational operators. For example, consider relations MALE, FEMALE whose domains (fields) are name, age and income. The user may define the relation PEOPLE as the union of relations MALE and FEMALE. He may also define the relation OLD as a subset of relation PEOPLE where (age>50).

The data base system decodes the definition and stores it in a retrievable form. The defined relation is then available to the user at the same logical level as the other data base relations. The defined relation remains merely a stored definition (i.e. implicit) until it is requested by a query. The implicit form takes negligible disc space.

When the defined relation in its implicit form is referenced by a query, e.g. list the people whose income is greater than 5,000, it is then created, i.e. made explicit, by carrying out on the stored data the operations indicated in the definition. For example, to create relation OLD relation PEOPLE is assembled first. The tuples (records) of relation PEOPLE are then accessed and those matching the selection criterion are written back to disc as tuples of the relation OLD.

The explicit forms of relations PEOPLE and OLD may stay in the data base and they will not have to be recreated if they are requested by other queries. In this way defined relations may substantially improve the response time of recurring queries.

We may consider the data base storage space as made up of two parts. One part is for storing the base relations (e.g. MALE and FEMALE) and another part whose content changes dynamically with the needs of the users. The defined relations facility enables the system to make efficient use of the dynamic storage space. At some stage in the

process of creating and querying relations the dynamic storage space may be consumed. One or more explicit relations will then have to be made implicit in order to free space for other requested relations. The relations in the dynamic storage switch between being explicit and implicit. The replacement algorithm which picks the relations to be made implicit has been discussed in a previous paper.<sup>4</sup>

## Notation

In this paper the set notation is adopted for relations. This is explained in the following table:

SYMBOL	MEANING
$\cup$	union
$\cap$	intersection
:(filter)	selection, the filter is a boolean expression
%(list)	projection, the list is a string of selectors
*	join (cartesian product or equijoin).
-	difference
$\leftarrow$	is defined as
:=	assigned to

e.g. the definitions of relations PEOPLE and OLD are expressed as follows:

```
PEOPLE $\leftarrow$ MALE $\cup$ FEMALE  
OLD $\leftarrow$ PEOPLE: (age>50)
```

## The hierarchy of defined relations

In Figure 1 a data base having a hierarchy of defined relations is shown. In such a hierarchy the user may not be aware of the relationships and the dependencies that exist among the data base relations. It is therefore advantageous to provide the facilities by means of which the user can perform all the operations on a defined relation without restrictions. Ideally, the user will treat the defined relations in exactly the same way as any other base relations, without restrictions forcing him to be aware of the dependencies between relations. That is, the system should possess a higher degree of data independence. It is therefore desirable to have the user activities (queries, application programs,

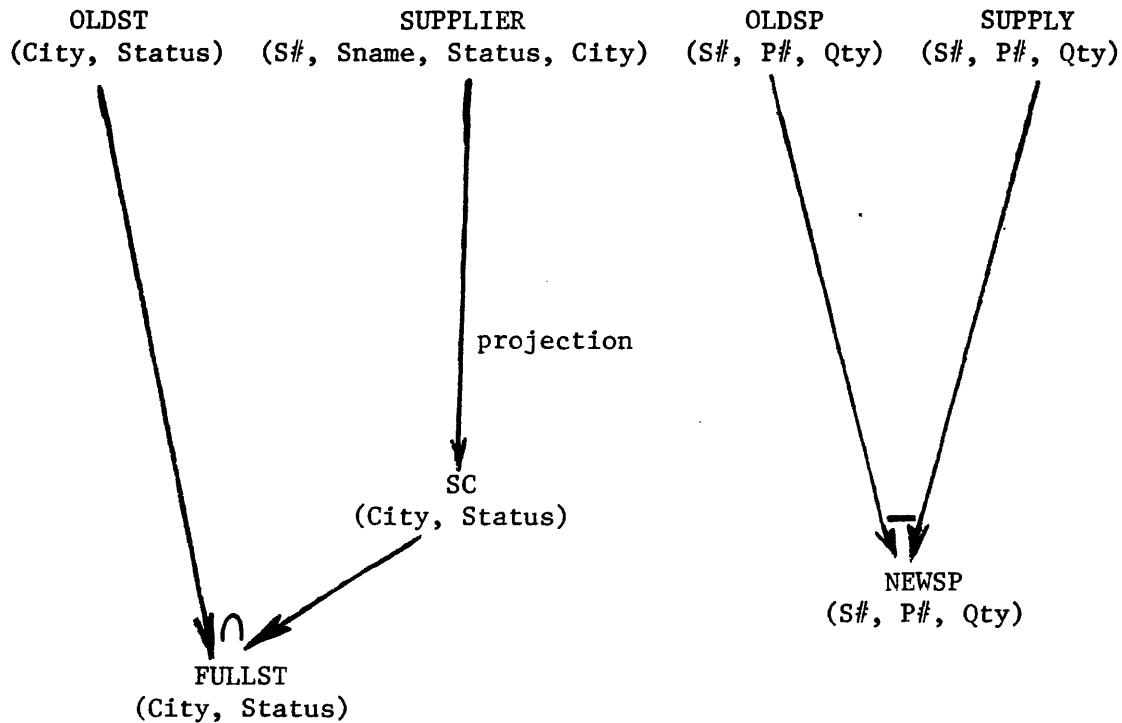

Figure 1—Supply data base. In these hierarchies of defined relations, OLDST, SUPPLIER, OLDSP and SUPPLY are base relations. SC is defined on SUPPLIER: FULLST is defined on SC and OLDST.

Definitions:  $SC \leftarrow SUPPLIER \% (City, Status)$   
 $FULLST \leftarrow OLDST \cup SC$   
 $NEWSP \leftarrow OLDSP \cup SUPPLY$

updates, etc.) independent of the logical representation, the access path and the level in the hierarchy of the data. The user need not know where a relation is a base or a defined relation, is implicit or explicit, nor will he need to know whether it is stored as a file or a mere collection of pointers to some other files. However, giving all this freedom to the user is desirable only as long as the consistency of the definitions and the defined relations is preserved.

#### *The problems of the management of defined relations*

In a data base with a defined relations capability such as the one shown in Figure 1, some of the system operators (e.g. updates, removal of relations from the data base and the redefinition of relations) may lead to logical problems. These operators must be adapted to take care of the hierarchical structure and the dependencies that exist among the relations. This paper is concerned only with the update problems.

Examples of these problems are:

- In Figure 1, if relation SUPPLIER is updated and relation SC is implicit, how can we update an explicit copy of relation FULLST? This is an efficiency problem.
- If relation FULLST is updated, how can we update SUPPLIER and OLDST? This is a logic problem.

#### *Objectives*

This paper explains the update problems and offers solutions for some of these problems. Examples are given to illustrate these solutions. The paper also identifies the unsolved problems which require further research and investigation.

Some update algorithms are suggested. They aim at preserving the consistency of the information in a data base having a high degree of data independence. These update algorithms deal with the logical part of the problem and hence pave the way for other algorithms to care for the particular details in particular implementations.

#### UPDATES

Updates may be divided into:

- Insertions
- Deletions
- Changes in object values.

In the following discussions, the tuples which will update a relation are termed the updating relation. The insertion is seen as a union of the updating relation and the relation to be updated. The deletion is seen as the difference of the relation to be updated and the updating relation. The

changes in object values are taken conceptually as deletions followed by insertions.

*The update algorithms*

Let us divide the updates into two:

1. Update at higher levels of the hierarchy.
2. Update at lower levels of the hierarchy.

Referring to Figure 1, updating relation SUPPLY or SUPPLIER is an update at a higher level of the hierarchy with respect to NEWSP and SC, FULLST respectively. Updating FULLST or NEWSP is an update at a lower level. Updating SC is an update at a higher level with respect to FULLST and an update at a lower level with respect to SUPPLIER.

**Update at a higher level**

In this type the update is filtered down the hierarchy and reflected on all the relations defined on the updated relation. The corresponding definition is applied to the updating relation successively at each level of the hierarchy. The problem here is how to pass updates down efficiently and in particular when intermediate levels are implicit.

**Insertions**

Given relations A and R, let RUI be the updated value of R. Let  $X=f(A,R)$  be a defined relation. Relation IN is sought such that  $X \cup IN$  is the updated value for X which corresponds to the update of R. Such IN can be found for all operators (f) in case of insertions at high levels. This is shown in table CHANGE (Figure 2).

When f is union, intersection, projection or selection  $IN=f(A,I)$  i.e. X need not be present in order to evaluate IN.

The mechanism of the insertion is essentially carried out at each level as follows:

- a. Given the updating relation (I) and a definition, relation IN is found from table CHANGE. Relation IN is now the updating relation which will be passed to the following levels down the hierarchy. (i.e. IN will be I of the lower level).
- b. If the relation to be updated (X) is explicit, the updated value will be  $X \cup IN$ . This applies to all relations at lower levels. If X is implicit, updates are passed down the hierarchy without materializing X.

Examples 1 and 3 in the Appendix illustrate this type of insertion.

The exception to Rules a and b is the definition containing the difference operator when the second relation is to be

	DEFINITION	PROOF	IN
INSERT	$X \leftarrow A \cup R$	$A \cup (R \cup I) = (A \cup R) \cup I = (A \cup R) \cup (A \cup I)$	I or $A \cup I$
	$X \leftarrow A \cap R$	$A \cap (R \cup I) = (A \cap R) \cup (A \cap I)$	$A \cap I$
	$X \leftarrow R - A$	$(R \cup I) - A = (R - A) \cup (I - A)$	$I - A$
	$X \leftarrow A - R$	$A - (R \cup I) = (A - R) - I = (A - R) - (I \cap A)$	I or $I \cap A$
	$X \leftarrow R\%(list)$	$(R \cup I)\%(list) = R\%(list) \cup I\%(list)$	$I\%(list)$
	$X \leftarrow A * R$	$A * (R \cup I) = (A * R) \cup (A * I)$	$A * I$
	$X \leftarrow R:(filter)$	$(R \cup I) : (filter) = (R:(filter) \cup I:(filter))$	$I : (filter)$
DELETE	$X \leftarrow A \cup R$	$A \cup (R - I) = (A \cup R) - (I - A)$	$I - A$
	$X \leftarrow A \cap R$	$A \cap (R - I) = (A \cap R) - I = (A \cap R) - (A \cap I)$	I or $A \cap I$
	$X \leftarrow R - A$	$(R - I) - A = (R - A) - I = (R - A) - (I - A)$	I or $I - A$
	$X \leftarrow A - R$	$A - (R - I) = (A - R) \cup (I \cap A)$	$I \cap A$
	$X \leftarrow R\%(list)$	$(R - I)\%(list) \neq R\%(list) - I\%(list)$	R must be made explicit
	$X \leftarrow A * R$	$A * (R - I) = (A * R) - (A * I)$	$A * I$
	$X \leftarrow R:(filter)$	$(R - I) : (filter) = R:(filter) - I:(filter) = R:(filter) - I$	I or $I : (filter)$

Figure 2—Table CHANGE for procedure alter. A is a relation; R is the relation to be updated; I is the relation of tuples to be inserted or deleted; RUI is the process of update by insertion; R-I is the process of update by deletion; IN is the resulting updating relation to be passed to lower levels. Given the definition, the updating relation IN is found. If a complex expression defines X in terms of R, the expression is broken down into simple forms.

updated i.e. definitions of the type  $X \leftarrow A - R$ , where  $R$  is the relation to be updated. In this type the insertion is carried out as follows:

1. Either:  
 $IN = I$  is passed to lower levels.  
 Or:  
 Alternatively,  $IN = I \cap A$  will be passed to lower levels (as in table CHANGE).  
 The updating relation ( $IN$ ) is passed to the lower levels as a deletion and the process continues as a deletion operation.
2. If the relation to be updated ( $X$ ) is explicit, the updated value will be  $X - IN$ . This applies to all the relations at lower levels. If  $X$  is implicit, updates are passed down the hierarchy without materializing  $X$ .

Example 2 in the Appendix illustrates this type of definition.

### Deletions

In this case the update may be specified by providing either a relation ( $I$ ) containing the tuples to be deleted or boolean filter which selects the tuples to be deleted from the relation to be updated. These extracted tuples constitute the updating relation ( $I$ ).

In a fashion similar to the previous section's, given relations  $A$  and  $R$ , let  $R - I$  be the updated value of  $R$ . Let  $X = f(A, R)$  be a defined relation. Relation  $IN$  is sought such that  $X - IN$  is the updated value for  $X$  which corresponds to the update of  $R$ . Such  $IN$  can be found for all operators,  $f$ , as in table CHANGE (Figure 2).

When  $f$  is intersection, join or projection  $IN = f(A, I)$ , i.e.  $X$  need not be present in order to evaluate  $IN$ . The mechanism of the deletion is the same as that of the insertion (described in the previous section) except for the following:

- In (b) the union is replaced by the difference.
- In (1) only the alternative method is applicable. The updating relation is passed to lower levels as an insertion.
- In (2) the difference is replaced by the union.

### Change in object value

A change in object value (modification) can be conceptually considered as deletion followed by insertions.

### The algorithm

The algorithm for insertions and deletions from higher levels follows:

```
procedure alter (R,I, DELT) recursive;
  boolean DELT, DELN: relations R,I,IN;
  comment R is the relation to be altered
```

```
I is the relation of tuples to be inserted or
  deleted from R
n is the number of relations defined on R
Dj is the jth definition on R
Xj is the subject of Dj, i.e. the jth relation
  defined.
DELT, DELN true if deletions are to be
  made from R false if insertions
  are to be made to R.
DELj is true if an insertion to R
  implies a deletion from Xj
CHANGE is a procedure which calls
  table CHANGE. Given the
  definition Dj, the updating
  relation I and DELT, the
  procedure returns the tuples to
  be inserted or deleted;
```

```
if R is explicit then begin
  if DELT then R: =R-I
  else R: =RUI
  end;
for j:=1 step 1 until n do
begin
  DELN: =DELT#DELj
  IN: =CHANGE (Dj,I,DELT);
  if IN#null
  then alter (Xj,IN, DELN)
  end
end alter;
```

The algorithm for changes in object value follows from the previous algorithm.

### Discussion

The great advantage of the approach described above is that only the explicit forms are updated. Implicit relations will not be recreated just for the purpose of having them updated. This saves the cost of creating all the relations down the hierarchy. Hence, in very large data bases the advantages of defined relations will not be outweighed by the substantial cost of recreating implicit relations whenever an update occurs. In such an environment, the overhead of storing table CHANGE and executing the update algorithm is negligible.

It is noteworthy that table CHANGE will have entries for all the user-defined operators. One problem, however, is to find rules for dealing with the complex definitions. No attempt has been made to explore this subject in the present paper.

### Update at a lower level

Here the problem is how to pass the update up the hierarchy without introducing inconsistency. It is a logic problem. In addition to the conditions imposed on ordinary updates, e.g. the compatibility of the updating relation and the

relation to be updated, the following conditions should be satisfied for updating relations at lower levels:

1. The update should not result in incomplete information at upper levels.<sup>6,7</sup>

Consider the following example:

Given relations X, Y and R.

	Y	X	R
2	C 5	3 A 8	3 A
3	A 8	6 B 8	6 B
6	B 8		

Definitions:

$X \leftarrow Y: (\text{field}(1) > 2)$   
 $R \leftarrow X\% (\text{fields } 1 \text{ and } 2)$

To update R by I

4 M  
5 T

and X by I'

9 K 3

When relation R is updated, the union of the updating tuples (I) and relation X cannot be formed because these tuples supply information for only two of the components of X. In such cases the update will provide incomplete information and should therefore be prohibited. Updating X, however, does not lead to missing information in upper levels. The system should prompt the user to update the relation at the lowest level whose update does not violate Conditions 1 and 2.

2. No ambiguity should result at higher levels due to the update.

S	Q	Z	I
1	4	1	9
6	5	6	3
2	2	2	
		4	
		5	

Definition:  $Z \leftarrow \text{SUQ}$

e.g. if a relation Z is defined as the union of relation S and Q.

When Z is updated the data base system cannot readily know which of the updating tuples should update each of S and Q and which should update both relations. Whenever such an ambiguity exists, the update operation must be prohibited.

3. The updating tuples must satisfy the definition of the relation to be updated. In the example in (1) above, if

relation X is updated by relation P,

P		
9	K	3
1	T	6

the system must reject the last tuple because it contradicts the definition of the relation to which it will belong. Similarly, if a tuple is to be deleted from such a relation, an equivalent tuple must exist in the relation; otherwise the deletion is meaningless.

With these constraints, more weight is attached to the consistency of the data base information at the expense of the user convenience. Indeed, inconsistency in itself, regardless of any other repercussions, may perhaps lead to more inconvenience to the user. With updating at a lower level, almost every operator in the definition requires different updating algorithms as will be explained in Figure 4. In all cases the update can be passed up without explicit values of the relations involved. For joins, the upper level relations must be implicit if side effects of updates are to be avoided.

A more formal but less complete discussion of these problems, based in part on an earlier version of this paper, is given by Todd.<sup>5</sup> The relational operators may be divided into regular and irregular operators according to their performance when relations having these operators in their definitions are updated. Regularity is a property of the type of update as well as of the form of operation.

#### The regular and irregular operators

Regular operators have two major properties when they appear in the definition of the relation to be updated:

- a. They do not lead to ambiguity.
- b. The updating information can be passed to higher levels.

When the operator is regular we will have the advantages of the updates at higher levels. When a definition contains an irregular operator, the problem of ambiguity arises. It is interesting to note (Figure 3) that with the exception of the selection operator, those operators that are irregular with insertion are regular with deletion and vice versa.

#### Validity of updates

In certain cases of join and selection, even regular updates can make the data base invalid or have undesirable side effects. These can only be checked given particular data values.

Consider a relation I inserted into relation X,  $X \leftarrow A: (\text{filter})$ . If the tuples of I do not satisfy the filter an inconsistency will be introduced. If such a set I is deleted

Insert:		
DEFINITION	PROOF	
$X \leftarrow A \cup B$	$X \cup I = (A \cup I) \cup B = A \cup (B \cup I)$	irregular
$X \leftarrow A \cap B$	$X \cup I = (A \cup I) \cap (B \cup I)$	regular
$X \leftarrow A - B$	$X \cup I = (A \cup I) - (B - I)$	regular
$X \leftarrow A\%(list)$	$X \cup I = A \cup (Q\%(list)), \text{ many } Q$	irregular
$X \leftarrow A * B$	$X \cup I \subseteq (A \cup I\%(fields(A))) * (B \cup I\%(fields(B)))$	regular
$X \leftarrow A:(filter)$	$X \cup I \supseteq A \cup I:(filter)$	regular
Delete:		
$X \leftarrow A \cup B$	$X - I = (A - I) \cup (B - I)$	regular
$X \leftarrow A \cap B$	$X - I = (A - I) \cap (B - I)$	irregular
$X \leftarrow A - B$	$X - I = (A - I) - B = A - (B \cup I)$	irregular
$X \leftarrow A\%(list)$	$X - I = (A - I)\%(list)^\dagger$	regular
$X \leftarrow A * B$	$X - I \subseteq (A - I\%(fields(A))) * B$	irregular
	$X - I \subseteq A * (B - I\%(fields(B)))$	
$X \leftarrow A:(filter)$	$X - I = (A - I):(filter)$	regular

Figure 3—Regular and irregular operators for updates at a lower level.  
 $\dagger$  A-I, generalized difference, those tuples of A that do not project into I.

from X, only tuples satisfying the filter must be deleted from A (the remainder cannot be deleted from X in any case, as they could not have been X to start with).

If a relation I is inserted into a relation X,  $X \leftarrow A * B$ , tuples are inserted into A and B. This may have the side effect of inserting tuples (E) into X. ( $E = I\%(fields(A)) * B \cup A * I\%(fields(B))$ .) Whether or not this is desirable depends on the application. It can be checked by reference to A and B without materializing X.

Other cases of regular updates cannot directly cause validity or side effect problems.

### Discussion

The table in Figure 4 shows the update form of the defining relations. Each defining relation has its own form of update. Updates from lower levels of the hierarchy should be care-

DEFINITION	NEW FORM AFTER UPDATE
Insertion:	
1. $X \leftarrow A \cap B$	$\begin{cases} A \cup I \\ B \cup I \end{cases}$
2. $X \leftarrow A - B$	$\begin{cases} A \cup I \\ B - I \end{cases}$
3. $X \leftarrow A * B$	$\begin{cases} A \cup I\%(fields(A)) \\ B \cup I\%(fields(B)) \end{cases}$
4. $X \leftarrow A:(filter)$	A $\cup$ I
Deletion:	
1. $X \leftarrow A \cup B$	$\begin{cases} A - I \\ B - I \end{cases}$
2. $X \leftarrow A\%(list)$	A - I (a generalized difference; those tuples of A which do not project into I).
3. $X \leftarrow A:(filter)$	A - I

Figure 4—CHANGE table for updates at a lower level. Only the regular operators are shown.

fully checked to ensure that the operators in the definitions involved are regular and that the updating information is logically valid. With large data bases such overheads are tolerable because of the probable avoidance of recreating intermediate implicit relations. However, with small sized data bases it may be sensible to prohibit updates from lower levels.

### CONCLUSIONS

This paper has attempted to investigate the major aspects of the update problem for data bases with defined relations capabilities. It has been shown that in the majority of the cases implicit relations can be updated at higher levels of the hierarchy without the need to create their explicit forms. No ambiguity or inconsistency will arise from updates at higher levels.

However, updates at lower levels may lead to ambiguity in some situations. Checks are also needed to establish the validity of the updating information. In very large data bases updating the defined relations in the manner described in this paper will lead to substantial saving in the computer system resources. It is hoped that this paper will initiate some research in this interesting and practical problem. Thorough investigation is needed for the whole problem of lower level updates. Algorithms for handling complex definitions are also required.

# Performance enhancement for relational systems through query compilation\*

by RANDY H. KATZ

University of California, Berkeley  
Berkeley, California

## INTRODUCTION

In recent years, considerable research has been directed toward the relational model of data first proposed in Reference 5. The advantages of this approach have been discussed elsewhere, however they can be summarized as follows: (1) the user is presented with a very simple view of his data (i.e., organized as tables of information), (2) the user is freed from explicitly knowing the underlying implementation structure of his data (i.e., data independence) and (3) very powerful non-procedural, set-oriented query languages can be defined for the relational model because of its simple conceptual structure.

While commercial versions of data base systems based upon hierarchical<sup>18</sup> and network<sup>17</sup> models have existed for several years and are used widely,<sup>9,8</sup> at this time there exist few commercially available relational systems. Two relational prototype systems currently in operation are the INGRES system<sup>7</sup> and System-R.<sup>3</sup>

A major criticism of the relational approach is that the model does not lend itself to efficient processing because there is no provision for the user to explicitly "navigate" through access paths in his data. Until recently, the experimental systems previously mentioned were not overly concerned with efficiency. However, efficiency has now become an important goal.

Hence, from direction of relational data base efficiency, motivation is provided for compilation of data base queries. The goal is to move as much query processing to compile-time as possible, thereby reducing the overhead of query execution at run-time. However, there are several problems. Some query processing algorithms are data-dependent. For example, the decomposition algorithm of Reference 19 makes use of the cardinalities of relations, rather than statistical information, in selecting among alternative plans to implement a query. Such algorithms may actually suffer in performance if the processing strategy is determined at compile-time rather than with the more perfect information available at run-time. Further, any change in the data base schema will invalidate some compiled queries. These include

changes to the authorization rights of a given user, changes to views of the data base one is allowed to see and changes to the physical structure of the data. Note that in many data base applications, the structure of the data is relatively static over time. Compilation can be most effective in these cases. Even given these problems, compilation techniques should improve relational system performance.

The goal of this paper is to analyze the problems of query compilation in the specific environment of the INGRES data base system. A proposal was implemented and its space and time efficiency is analyzed.

## PREVIOUS WORK

In the early work on relational systems, high level non-procedural query languages were provided to process ad-hoc queries presented interactively by non-programmers.<sup>5,6</sup> Current work is directed towards applications-oriented languages for programmers, which integrate relational query capabilities into programming languages. These languages are meant to complement conversational query languages. In this situation, it is possible to take advantage of the more static non-interactive environment to improve the efficiency of query processing.

In order to classify and to compare the work which will be summarized, it is useful to define "levels of compilation." Query processing consists of the following steps:

1. The query string is analyzed (i.e., parsing).
2. Object names are converted to an internal form via System Catalogs (i.e., lookup).
3. A processing plan is built.
4. The processing plan is executed by calls to the access methods.

Using this, five levels of compilation can be defined:

- 0—The query is completely interpreted at run-time (i.e., Steps 1-4 are performed at run-time).
- 1—The internal form of the query is built at compile-time (i.e., the query is converted from a string to a parse tree at compile-time).

\* Research supported by the Army Research Office under Grant DAAG29-76-G-0245.

- 2—The internal form is built at compile-time, with name resolution taking place if possible. Otherwise, Step 2 will have to be executed when the information is available at run-time.
- 3—The internal processing plan is determined at compile-time and translated into an internal form suitable for run-time interpretation.
- 4—The internal processing plan is represented within the user program by calls to the underlying access methods.

Level 0 represents the least amount work done at compile-time, namely complete interpretive execution of the query at run-time. Level 4, on the other hand, represents the movement of the most amount of processing to compile-time.

In the remainder of this section, we describe several existing or proposed data base programming languages and describe what level of compilation they support or propose to support.

*ASTRA*<sup>12</sup>

ASTRA is a relational system built on a hierarchical system at the University of Trondheim, in Norway. It supports a high-level applications-oriented language called ASTRAL (A STRUCTURED Relational Applications Language), based upon SIMULA. The compiler maps an ASTRAL program into a SIMULA program augmented by subroutine calls to the underlying data base system. It is the job of the compiler to choose the best access paths when translating relational expressions into sequences of host language statements and subroutine calls. The functions of query parsing and of determining a query processing plan are moved to compile-time. The plan, represented by calls to the underlying system, is interpretively executed at run-time. Hence, the ASTRAL compiler supports Level 3 compilation. No mention is made of the recompilation problems associated with changes to the data base schema.

*Extended PL/1*<sup>16,10</sup>

Reference 16 describes extensions to PL/1 which allow an applications programmer to access data from a relational data base. The language is extended by introducing the notion of a template, which is a PL/1 structure containing data base relation names and attribute names, along with a SELECT statement, that qualifies those tuples which are to be retrieved. In Reference 10 the problems of recompilation under a changing schema are explored. The authors point out that the performance advantages for a compilation approach are somewhat offset by the increased sensitivity of a compiled program to schema changes. They propose that the program be separated into three modules—one for applications-oriented processing, one for data base interactions and one for authorization and integrity enforcement. If there is a change in some aspect of the schema, only the relatively

small module of code which is effected by that change will have to be recompiled. This approach has actually been used in a system to support Extended PL/1. An architecture similar to this proposal will be necessary for any system which attempts to provide Level 3 or Level 4 compilation, because the internal processing plan will become invalid if the schema changes. Note, however, that the proposed architecture implies many inter-module communications. This overhead may outweigh the advantages of compilation.

*System-R*<sup>1-4</sup>

System-R is an interesting system from the standpoint of compilation because it originally supported only interpretive query execution, but now supports both compiled and interpretive queries. The origin of System-R can be found in SEQUEL-XRM,<sup>1,2</sup> a single-user relational system designed to support the SEQUEL query language.<sup>4</sup> The system interpretively mapped the non-procedural statements of the query language into tuple at a time commands to the underlying relational memory system, XRM (extended n-ary relational memory). The interpreter was organized into three modules—parser, optimizer and scanner. The parser translated a SEQUEL query into a corresponding parse tree. The optimizer, when given a query tree, selected a processing plan which would minimize the number of tuples retrieved based upon the available access paths. The scanner actually executed this plan by judiciously scanning the underlying relations.

Note that the parsing step is independent of whether the query is being interpreted or compiled. Furthermore, if the optimization step is independent of the actual data in the data base then the optimized processing plan can be determined at compile-time as well. It then becomes a simple matter to compile the scanner into a query specific data access routine. This approach was taken in System-R.<sup>11</sup> Because the data access routines consist essentially of access method calls, System-R supports Level 4 compilation.

All data access routines are separated from the user program to facilitate recompilation when the data base schema changes. A routine is marked invalid by the system if it depends on the schema change and is recompiled the next time it is called. The recompilation process is simplified if the query tree is saved along with the data access routine. This is because only the optimization and code generation phases need to be re-executed.

COMPILATION FOR INGRES

In this section, a scheme for the compilation of QUEL, the data sub-language of the INGRES Data Base System,<sup>7</sup> is presented. Complications due to the compilation approach are then examined.

The INGRES system consists of five concurrently executing processes:

These are the user program, the parser, the one-variable query processor, decomposition and the data base utilities. The parser converts query strings into trees. OVQP interpretively executes one-variable queries, i.e., those involving a single relation. Decomp controls the decomposition of multivariable queries into a sequence of one-variable queries. The DBUs provide utility support. Communication between the processes is accomplished by "pipes," which are essentially message buffers.

Borrowing from System-R terminology, there are three phases in the lifetime of a program—preprocess-time, compile-time and run-time. Preprocess-time refers to the time when data manipulation statements of a program are first analyzed and translated. Compile-time refers to the time when the actual host language program, with associated data base calls, is compiled. Run-time refers to the time when the program is in execution. Compilation of data base queries is most advantageous if it can be performed at preprocess-time. However, flexibility considerations may make it necessary to defer compilation of the data base portion of a program until run-time, when complete information is specified.

It is possible to describe the various levels of compilation presented in the previous section in terms of the INGRES system:

*Level 0*—INGRES interpretively executes all queries. The QUEL preprocessor translates a user program into a sequence of host language statements and calls on the underlying data base system. These calls pass the queries in the form of character strings to INGRES for run-time execution.

*Level 1*—INGRES translates the query string into a tree at run-time. The structure of the query tree can always be determined from the string. Thus, it is possible to parse the query and build the tree at preprocess-time. If the data base, relation, and attribute names are known then information associated with those names can be placed into the tree. If we make the restriction that this information must be known at preprocess-time, Level 1 compilation can be achieved.

*Level 2*—If the restriction that all names must be known at preprocess-time is lifted, then it is necessary to fill in missing information at run-time when all names must become known. Thus Level 2 compilation can be accomplished. Note that the form of the tree is unaffected by the lack of information at preprocess-time. The information in the nodes of the tree, on the other hand, depends upon information associated with unresolved names. These names must be looked up in the system catalogs at run-time.

*Level 3*—INGRES constructs an execution plan by decomposing a complex query into a sequence of one-variable queries. This is accomplished by alternatively applying tuple substitution and reduction.<sup>19</sup> Once a collection of decomposed query trees is available, it is possible to generate code at preprocess-time which will perform the decomposition at run-time. Because tuple substitution can not be performed until run-time, the generated code will have to be parameterized in order to allow actual values from the data base to be substituted. It is useful to think of the generated code as query procedures which can be invoked by other query procedures, with the lowest level of invocation representing

parameterized one-variable queries. These queries can then be passed to the OVQP for interpretive execution. Note that the invocation of the compiler to build these query procedures will have to be postponed until run-time unless complete information is available at preprocess-time.

*Level 4*—Based upon the physical structure of the underlying relations, OVQP determines the efficient access paths for the processing of a one-variable query. Once the query procedures are constructed, it is possible to generate access method calls for the query procedures. Thus, Level 4 compilation is easily achieved once Level 3 compilation is operative.

At this point, we will give an example of Level 4 compilation. Consider the following QUEL query:

```
range of E,M is employee
range of D is department
retrieve (E.name) where E.salary>M.salary
                        and E.manager=M.name
                        and E.dept=D.dept
                        and D.floor#=1
                        and E.age>40
```

The query requests the names of all employees over 40 years old who make more than their managers and work in a department which is situated on the first floor. The following two queries can be detached from the original:

```
range of D is department
retrieve into T1 (D.dept) where D.floor#=1
range of E is employee
retrieve into T2 (E.name, E.salary, E.manager, E.dept)
                        where E.age>40
```

The original query becomes:

```
range of D is T1
range of E is T2
range of M is employee
retrieve (E.name) where E.salary>M.salary
                        and E.manager=M.name
                        and E.dept=D.dept
```

The decomposition algorithm chooses a variable for substitution. If D is chosen, D.dept is replaced by actual values from the data base. A parameterized query of the above form is decomposed further, with the value of D.dept being the parameter. Continuing, the following query is detached:

```
range of E is T2
retrieve into T3 (E.name, E.salary, E.manager)
                        where E.dept=value
```

The above query now becomes:

```
range of E is T3
range of M is employee
retrieve (E.name) where E.salary>M.salary
                        and E.manager=M.name
```

At this point, another tuple substitution is necessary. Suppose the variable E is chosen. The resulting queries have one variable and can be executed directly by OVQP.

The compiled version of this query would look something like this:

```

Q(:)
  access method code for "retrieve into T1 (D.dept)
    where D.floor#=1"
  access method code for "retrieve into T2 (E.name,
    E.salary, E.manager, E.dept) where
    E.age>40"
  for each tuple in T1, call Q'(dept)
Q'(d):
  access method code for "retrieve into T3 (E.name,
    E.salary, E.manager) where E.dept=d"
  for each tuple in T3, call Q''(name, salary, manager)
Q''(n,s,m):
  access method code for "retrieve (n) where
    s>M.salary and m=M.name"
    
```

The compilation approach for INGRES just described causes several problems. Data bases are potentially dynamic objects. A system based upon compilation must be able to deal with changes to the logical and physical schema. Also, the architecture of the system must ensure security for user data.

Due to protection considerations, (e.g., only processes owned by INGRES are allowed to execute access method calls), the query portion of a program will have to reside in a separate process from the rest of the program. Requests for the execution of a query can be passed down the pipe from the user program to the query process, with results being returned in the opposite direction. The process structure would be as follows:

The five-process system has been replaced with a three-process system. Note, however, that the query process is unique to each program, whereas the processes of the current INGRES system can be shared among concurrent users.

Because the access method code is dependent upon the physical structure of the relations, the query process can become invalid if there is a change to the physical schema. A scheme similar to that used in System-R can be used to recompile those query processes that have become invalid. A system catalog, in the form of a relation, associates query processes with data base objects they depend on. A process can be marked invalid if an object it depends upon has changed. When a program uses an invalid query process,

the compiler can be invoked to recompile the program. If the query trees are maintained in the data base, only the query process itself need be recompiled. Otherwise, the original program will have to be reprocessed for the regeneration of the query parse trees.

Because authorization and views are implemented by query modification,<sup>14,13</sup> the techniques described above can be used to recompile a program if authorization privileges or views are changed. In this case however, the query tree will have to be reconstructed. To avoid reprocessing the user program, it may be useful to maintain the query string in the data base and to perform all four steps of query processing on this string.

### RESULTS

Four versions of the INGRES system were configured for comparison. These were:

1. The standard five-process system, available through the EQUQL preprocessor (the EQUQL system).
2. A modified five-process "parse at compile-time" system, with the parser process copying pipe input to pipe output (the C-EQUQL (5) system).
3. The four-process "parse at compile-time" system, available through the C-EQUQL preprocessor (the C-EQUQL (4) system)
4. A C program augmented with hand-coded access method calls (called AM code).

Three test programs were selected as benchmarks, called Test Programs 1, 2, and 3. The structure of the programs is essentially the same. Each program consists of a single retrieve statement which is executed one thousand times. The retrieve statement in Test Program 1 has no qualification, hence the entire relation must be scanned. Test Program 2 contains a relatively complex qualification. However, the entire relation must be scanned, because the qualification is true for every tuple. The only difference between Test Programs 1 and 2 is the complexity of the qualification. Similarly, Test Program 3 contains a relatively complex qualification for which no tuples of the relation will qualify.

The first comparison made between the configurations was in user program size. Table I summarizes the results. Basically, as the level of compilation increased (e.g. approached complete compilation), the user program size increased. This result can be misleading. The total size of an INGRES program is actually the sum of the sizes of the processes which make up the system. Table II contains the

TABLE I.—Relative Program Sizes (bytes)

Compiler Used	Test Program 1	Test Program 2	Test Program 3
EQUQL	10694	10756	10758
C-EQUQL (5)	16180	16306	16306
C-EQUQL (4)	16192	16318	16318
AM Code	24400	24418	24418

TABLE II.—Relative Sizes of INGRES Processes

Process	Size (K=1024 bytes)
Parser	54K
OVQP	60K
Decomp	57K
DBUs	58K

relative sizes of the major INGRES processes. Using this measure of program size, the QUEL programs required 224K bytes, the C-QUEL programs required 181K bytes, and AM programs required 24K bytes.

INGRES processes are actually shared among concurrently executing INGRES programs, since the processes are re-entrant. Thus, the storage requirements for QUEL and C-QUEL programs should be distributed among the concurrent users of the system. This would require approximately ten concurrent users of INGRES for an QUEL program to match the storage requirements of the AM program. The results indicate that for certain kinds of programs, the compilation approach may actually decrease the overall storage requirements for data base programs. This will depend upon the complexity of the program as well as the number of concurrent users. In any case, the storage requirements for compiled programs do not appear to be prohibitive.

The second comparison made was in speed of query processing. For each of the four systems, five different tests were run. These tests differed mainly on the test program used and the number of tuples scanned during the test. The first three tests consisted of the three test programs run on a relation with a single tuple. The remaining tests consisted of Test Programs 1 and 2 run with the same relation, but this time with 25 tuples. The timing results are listed in Table III.

TABLE III.—Test Run Elapsed Times

Program # (tuples scanned)	Compiler Used	Mean (sec)	Standard Deviation
1 (1 tuple)	QUEL	235.0	.7
	C-QUEL (5)	201.9	.9
	C-QUEL (4)	183.0	.5
	AM Code	4.5	.5
2 (1 tuple)	QUEL½	310.8	1.2
	C-QUEL (5)	224.6	.5
	C-QUEL (4)	205.1	.3
	AM Code	4.4	.5
3 (1 tuple)	QUEL	308.4	.9
	C-QUEL (5)	223.1	.6
	C-QUEL (4)	203.4	2.0
	AM Code	4.4	.5
1 (25 tuples)	QUEL	489.8	.5
	C-QUEL (5)	459.2	.7
	C-QUEL (4)	440.5	.7
	AM Code	28.8	.4
2 (25 tuples)	QUEL	641.3	1.4
	C-QUEL (5)	553.8	1.1
	C-QUEL (4)	532.9	1.8
	AM Code	28.8	.5

For each experiment, the four versions of the same program were run 20 times while there was no activity on the system. Elapsed time was used for the measurements because it is relatively easy to measure and because it is a good indicator of combined CPU and I/O time when there is little other activity on the system. The mean and standard deviation of the readings were computed and are reproduced in Table III. For easy comparison, bar graphs of these results can be found in Figure 1. Because the standard deviations are typically quite small (i.e. less than one percent), the mean run-times are a good basis for comparing the benchmarks.

Table IV is a compilation of the percentage improvements between two given configurations. The improvement due to parsing at compile-time is presented in Line 1. The improvement due to eliminating the parser process is listed in Line 2. The total improvement of C-QUEL over QUEL is available as Line 3. The improvement of complete compilation over interpretation is recorded in Line 4.

The advantages of parsing at compile-time are obvious from Table IV. The more complex the query is, in terms of the time it takes to parse the query string, the greater the improvement possible with C-QUEL. This is illustrated in the percentage improvement for Run 1 and Runs 2 and 3. However, because parsing represents a fixed overhead, as the total time to process the query increases, the improvement due to compile-time parsing decreases. This is evident from the improvements for Run 1 and Run 4.

The major difference between C-QUEL (5) and C-QUEL (4) is the inclusion of a dummy parser process that copies data from input to output. The improvement represents the benefits gained by reducing the size of the system by one process. As can be seen from the results of Runs 1, 2 and 3 and Runs 4 and 5, the overhead associated with the existence of an extra process is essentially fixed. As the

TABLE IV.—Percent Improvements

Program # (tuples scanned)	Compiler 1	Compiler 2	Percent Change
1 (1 tuple)	QUEL	C-QUEL (5)	14
	C-QUEL (5)	C-QUEL (4)	9
	QUEL	C-QUEL (4)	22

	QUEL	C-QUEL (4)	17
	QUEL	AM Code	96

Figure 1—Comparison of program execution times.

total processing time increases, the associated overhead becomes less significant, as shown in Runs 4 and 5.

The improvement of C-EQUEL over EQUEL is represented by the percentage improvement of C-EQUEL (4) over EQUEL. In the case of a complex query with little associated processing, the improvement is over one-third. In the case of simple queries which require much processing, however, this improvement is considerably less.

The most striking result is the improvement of compiled programs over interpreted ones. The result that compiled programs will run faster than interpreted ones is not surprising; the magnitude of this improvement is. It indicates that there is considerable overhead associated with a multiple process interpretive system that has little to do with performing the actual functions necessary for query processing.

## CONCLUSIONS

The compilation approach to query processing has the potential of greatly reducing the overhead associated with execution of queries. An actual parse at compile-time system was implemented and was shown empirically to reduce

query processing time, at a modest increase in storage requirements. This is only one possible point in a continuum of possible levels of compilation, each with its own time/space tradeoffs. Complete compilation was shown to produce substantial time savings, with possible space savings as well.

A general notion of compilation level was presented and it was shown how to describe an interpretation-based system such as INGRES in terms of different levels of compilation. On the basis of experience with C-EQUEL, some conclusions about the ease of implementing other proposed levels of compilation are possible. The extension of Level 1 to Level 2 would require little additional work. All that is needed is to look up names in the INGRES system catalogs. The extension of Level 2 to Level 3 would entail a considerable implementation effort. Programs would become sensitive to changes in the physical schema. Decomposition would have to be executed at preprocess-time in order to generate the query procedures. Further, the compiler would have to be invocable at run-time, because data base, relation and attribute names may not be known until then. Once these implementation obstacles have been surmounted, Level 4 is relatively easy to implement. All necessary information is known when the Level 3 program is created.

Essentially, code is generated directly, as opposed to being generated with conditional statements to control execution.

# System considerations for predicting mass storage subsystem behavior

by E. J. McBRIDE, A. B. TONIK and G. R. FINNIN

*Sperry Univac*  
Blue Bell, Pennsylvania

## INTRODUCTION

We are always interested in predicting the performance of systems and/or subsystems. A "typical" question is: "Is the most important component of system performance the way mass storage subsystems behave?" The answer is yes, most of the time.

Assume a solitary program is running on a system. The running of the program is broken into two major parts: the loading and the running. Loading usually takes between  $\frac{1}{4}$  to  $\frac{1}{10}$  of the total run time. The exceptions are programs that run for an hour or more during which the load time is insignificant. During load time there is little CPU-time and during the total run time there is usually little overlap between CPU-time and I/O-time. The amount of CPU-time will usually range anywhere from  $\frac{1}{6}$  to slightly more than  $\frac{1}{2}$  of the I/O-time. The exceptions are programs that will load the data and just sit there and grind away on it. These time periods, shown in Figure 1, are actually pieces of unequal duration that are intermixed. This is true of a transaction program as well as a batch program.

Another consideration of performance is multiprogramming, i.e., the way one program multiplexes with many others. In this case, when a program wants to use one of the facilities of the system, that program may find it busy. In fact there may be several of the programs waiting for the use of that facility. The waiting time until a program gets to use that facility has to be added to the run-time of that program. The average queue waiting for service depends upon the average utilization of that facility and the mix of programs. The higher the utilization, the longer the queue. Since mass storage already takes a majority of the running time, we do not want to multiply the I/O-time by more than three or four because of long queues. On the other hand since CPU-time is relatively short, we do not mind multiplying that time by a large factor. Therefore, we can afford multiprogramming up to the point of using the CPU for 80 to 90 percent of the time while we try to keep disk utilization down to 50 percent.

Disk performance is important to system performance, but trying to predict its performance is very complicated. The control unit is used for a short period of time to get a

disk started toward a location. During disk seek time, the control unit can start seeks to many other disks or perform data transfers to/from them. At the end of a seek, the disk enters latency time. At this point, the disk will either attempt to interrupt the control unit (non-RPS case) or wait until it arrives at a rotational position. At RPS time (rotational positioning sensing), the disk tries to request service from the control unit. If the control unit is busy and the disk is using RPS, the disk may have to wait a revolution or more. This is caused by the disk not gaining access to the control unit within a given RPS time. The number of missed revolutions depends on the number of disks on a subsystem, the request rate of I/O commands to the subsystem, the RPS timing constraints and the amount of the data to be transferred. These are related in very complex ways.

This paper is written to document some of the findings from our studies of Mass Storage Subsystem behavior. It is not intended to be an analytical treatise of Mass Storage behavior. It is written more as an attempt to describe some of the techniques we are using. GPSS models and analytical models were constructed. The study of these models yielded some interesting observations into subsystem behavior. A typical question is how many missed revolutions will an "average" disk have when attached to a system. Since each missed revolution costs 16.6 milliseconds on conventional disks, the answer to such a question can have a significant impact on system performance.

Figure 2 shows an example of the complex set of events which occur during normal disk accessing. The times shown are not necessarily to scale. Note that access completions need not be in the same order as initiations. Some disks may complete without missing revolutions while others may miss many. The remainder of this paper describes a method of studying this type of subsystem plus the effects of some of the critical parameters.

From a systems level the interesting parameters of a subsystem are its response time and its throughput. Response time as measured from the time an I/O is requested at the user level (not the control unit level) until the time the data is in memory. Throughput is the maximum number of requests per second which can be sent to a subsystem without having the queue build up beyond bounds.

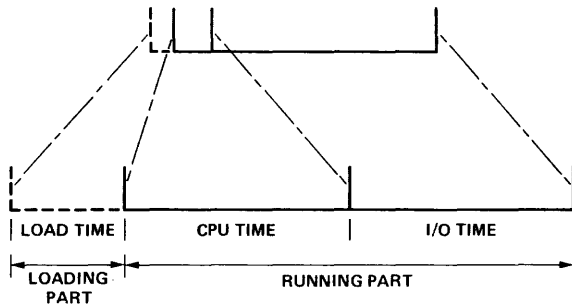

Figure 1—Typical distribution of time for a program.

**MASS STORAGE SUBSYSTEMS**

The term Mass Storage is used to refer to input-output (I/O) subsystems consisting of the rotating magnetic disk media or the new solid state technologies such as Bubble and Charge Coupled devices. The disk drives may have movable data recording and read back mechanisms (R/W Head) or fixed head mechanisms. The solid state devices are equivalent to the fixed head disks in that no physical positioning (seek) of the R/W Head is required prior to a data read or write operation.

The data are stored on these Mass Storage devices in what are called tracks. Figure 3a illustrates, in a simplified manner, the concept of data tracks on a movable head disk device. Each track contains a set of data blocks (four shown

in the figure) which are units of information read from or written to the device per operation. Each data block may contain one or more file records as specified by the application software. The number of blocks per track and the number of tracks per device are determined by the storage density of the device. The tracks are in continuous motion at a speed dictated by the design of the device. Now, in order to read or write a data block, the read/write head must be positioned over the desired track and the intended block must move under this head.

In Figure 3a, a seek (head positioning) has occurred from Track 1 to Track 200. Since this is mechanical motion, it tends to be very time-consuming; the time element is represented as  $S_{sk}$  (seek time). When the seek completes, the read/write head must wait for the particular data blocks. This also involves physical motion and is represented as  $S_l$  (latency time). In Figure 3a, the head is waiting for data block 3. When the data block reaches the head, time must be spent transferring the data to or from the block (provided the control facilities that connect the disk to system main storage are available for use). The data transfer time ( $S_d$ ) is determined by the track speed, the density of storage on the track (i.e. bits per inch) and the size of the block. When the block transfer is completed, the operation is finished and the disk is free to accept a new operation.

In Figure 3b, the track concept is illustrated for the solid state technologies. There is no seek time, instead, the track is switched to a single read/write head. However, there is a latency time in moving the desired data block under the

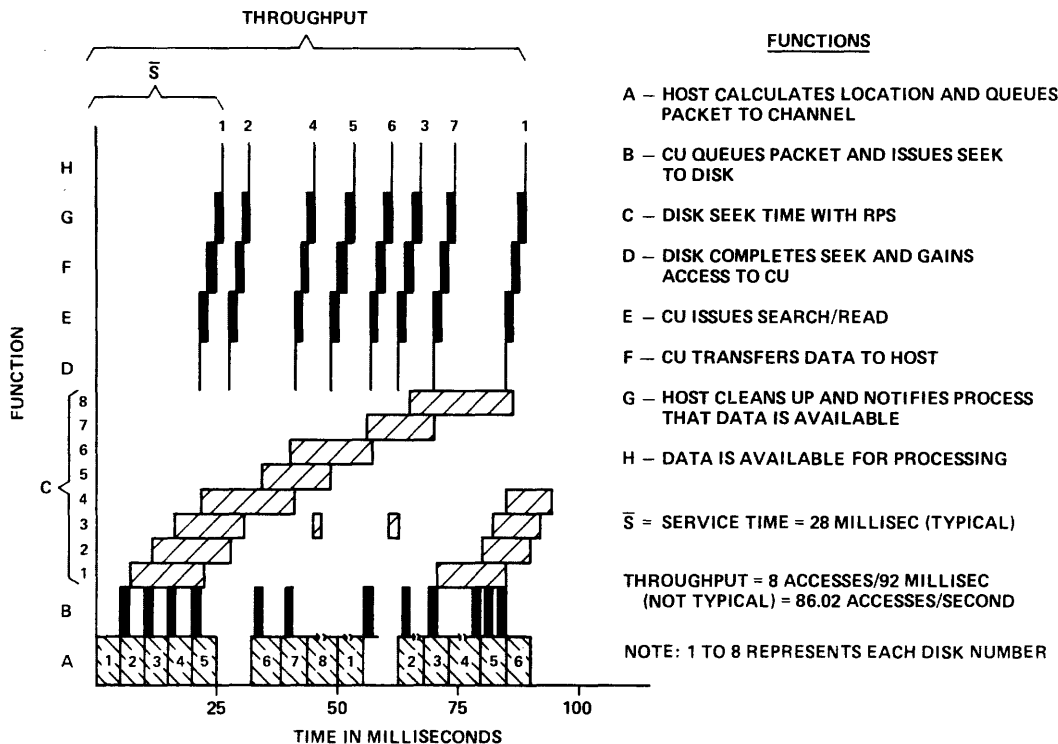

Figure 2—Performance factors.

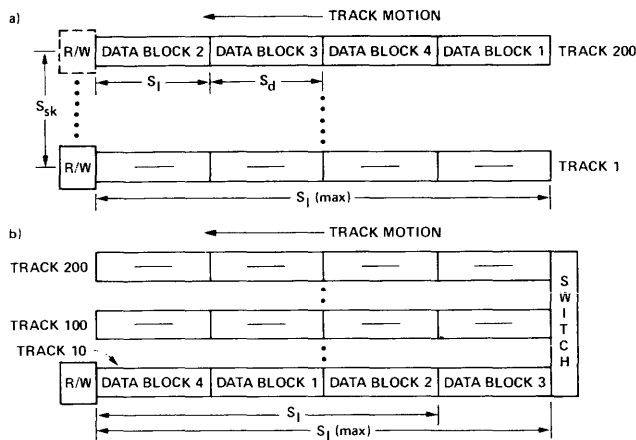

Figure 3—Logical representation of latency.

head. The maximum latency time ( $S_1 \text{ max}$ ) for these devices ranges in the one to five milli-second time interval, whereas disks are typically in the 16 milli-second range. This shorter latency time, zero seek time and higher track speed and density give the solid state devices a definite performance advantage.

Storage devices are only one constituent of the subsystem. Each subsystem has at least one control unit. The control unit usually services more than one storage device and also connects to the system facility called a channel. The channel services the software queues requesting input or output (I/O), issues commands to the subsystem control unit to start I/O operations and controls the flow of data blocks to or from main storage. Channels may also share facilities among more than one subsystem. However, the real burden is placed on the control unit. It must service requests from the channel to start I/O and it must service requests from the storage devices to transfer data blocks. To obtain efficiency, control units are designed to overlap certain I/O operations (i.e. time multiplex its resource) but once it connects to a storage device for data block transfer, it remains connected until the transfer completes. The utilization of the control and channel facilities plays an important role in determining the performance of the subsystem. This aspect will be discussed later in the paper.

ROTATIONAL POSITION SENSING (RPS)

A storage device after completing its seek or track select operation must then attempt to gain use of the control unit and channel facilities. A device without RPS will attempt to obtain the control unit immediately at the end of its seek or track select. On the average, the read/write head will be one-half the maximum latency time from the desired data block. Nothing can happen until the data block moves under the head. In the non-RPS case the control unit like the device is used during this waiting period. This tends to increase the control unit utilization during each data transfer operation and tends to limit the number of requests the subsystem can handle.

To keep from wasting control unit time by forcing it to wait out latency, RPS can be used. Figure 4 illustrates the concept of RPS. The tracks are divided into sectors (the figure shows eight sectors, typically there are 128) and the storage device does not become a candidate for control unit service until a specific sector is reached. This allows the control unit to service other requests from the channel or other storage devices during RPS time. In the illustration, the read/write head is shown within Sector 3 when the seek or track select completes.

The storage device will not become a candidate for control unit use until Sector 3 is sensed. Since Sector 3 is under the read/write head the device attempts to obtain the control and channel facilities. If these facilities are free and have set up for the data transfer before Sector 4 is sensed, the device and control facilities stay connected through Sector 4 and transfer at data block 14 in Sector 5. Otherwise, the device must wait until its track rotates almost one full latency time (to Sector 3) and try again to obtain the control facilities.

CONFIGURATIONS

The term configuration refers to how the subsystem connects to the system. This is very important to performance evaluation. This paper will deal to two basic configurations: 1) the single access and 2) the dual access. Figure 5a illustrates single access. Shown is one channel facility servicing two single access mass storage subsystems. Single access means that the storage devices connect to only one control unit. It will be shown that this configuration significantly limits the number I/O requests a subsystem can handle per unit time.

In the illustration, the channel is shown interfacing a software facility and main storage. The software is shown servicing the subsystem queues which hold requests for I/O. The software processes the termination of each I/O operation, removes requests from queues and starts I/O operations on the channel facility. This software process is not considered

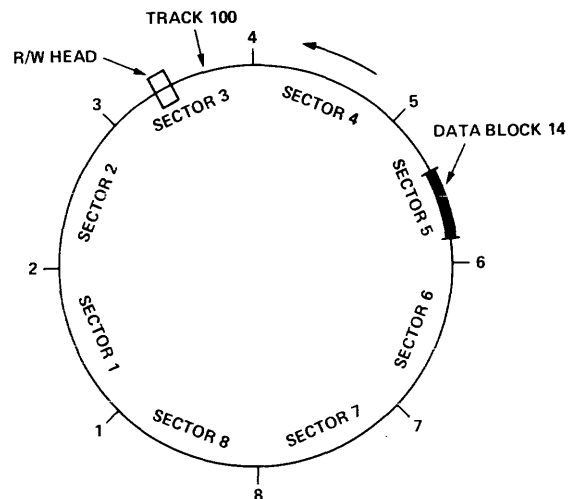

Figure 4—Sector positioning.

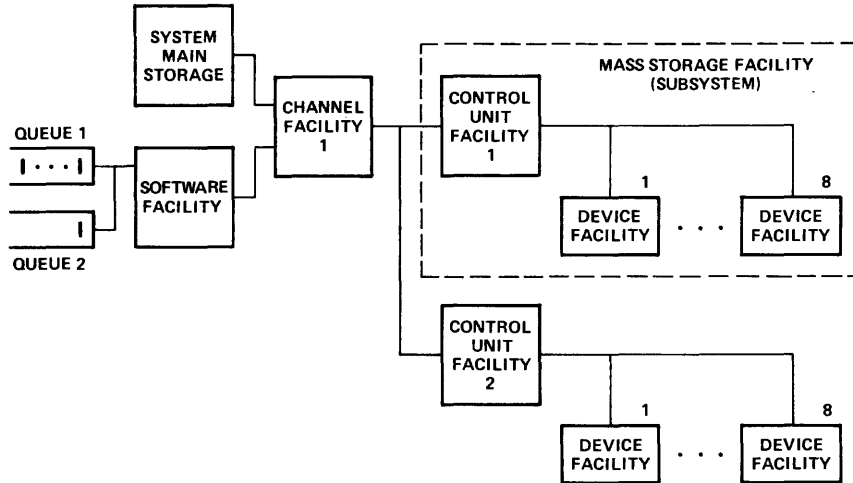

Figure 5a—Single-access subsystems configurations.

in this paper. The channel to main storage interface is shown to indicate the path for data block transfers. It too affects performance but will not be considered in this paper.

The control units are shown connecting up to eight device facilities. This value, typically, represents an efficient load on the control unit. However, cost-effective configurations with 16 or more devices per control unit are possible.

The second type of configuration (dual access) is illustrated in Figure 5b. Two channel facilities are shown connecting to two control units which share the eight storage devices. This connection, at the expense of hardware, enhances performance by effectively lessening the load on a single control unit. In general, the performance limitation is now predominately shifted to the service capabilities of the storage devices.

SUBSYSTEM ANALYTIC MODEL

When viewing subsystems performance, the concern is with individual storage devices and their software device queues. That is: 1) How long, on the average, must a request

sit on the device queue before being serviced by its device? 2) What is the average time for a request to pass through the subsystem? 3) What is the average size of the device queue? 4) How do the service time elements of the channel, control unit and device affect performance?

It is desirable to structure a model that is simple but takes account of the important parameters affecting performance. The model described in this paper views a single device queue and its storage device. The interference of other storage devices sharing the control unit and other subsystems sharing the channel are also included in the model.

Figure 6 represents a queuing model flow diagram for a subsystem storage device using RPS. The device queue resides in the system and holds requests for I/Os issued by the software. The queue is nothing more than a waiting line and obviously we would like the number of requests waiting in line to be small. Average time spent waiting on the queue for service is designated  $\bar{t}_w$ , and is dependent upon the rate at which requests enter the queue and the average time the subsystem takes to service the queue. The arrival rate to the group of device queues associated with a specific control unit is  $\lambda_r$ . This value is a random arrival and the device queues are not skewed. Each device queue receives on the average an equal fraction of  $\lambda_r$ . The arrival rate per device

Figure 5b—Dual-access subsystems configurations.

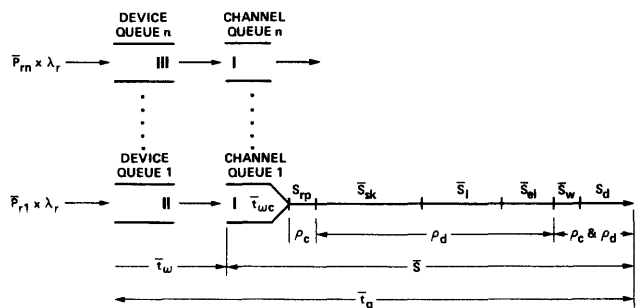

Figure 6—Time sequence for RPS model.

is  $\lambda_r P_n$ , where:

$$P_n = \frac{1}{N_d} \text{ where } N_d = \# \text{ of devices per control unit.} \quad (1)$$

The wait time ( $\bar{t}_w$ ) can, under heavy load, exceed the time to service a request ( $\bar{S}$ ). Service time ( $\bar{S}$ ), as Figure 6 indicates, is comprised of seven time elements. The first time element is the mean wait time that a request, taken from the device queue, must experience before gaining access to the control unit ( $\bar{t}_{wc}$ ). That is, when a request leaves the device queue, it enters a queue in the channel. This queue can hold only one request; however, the channel has a large number of such queues to handle many devices on one or more subsystems.  $\bar{t}_{wc}$  depends on the effective control unit utilization and the mean time the control takes to service requests. The effective control unit utilization ( $\rho_{ce}$ ) is a measure of the average time the control unit appears to be busy to a request on the channel queue. If only one control unit is connected to the channel,  $\rho_{ce}$  equals  $\rho_c$  (the real control unit utilization). However, if other control units are also using the channel,  $\rho_{ce}$  is larger than  $\rho_c$ . This is a method used to factor in interference due to other subsystems sharing the channel facility. The service time of the control unit is the average of the time to process a command from the channel ( $\bar{S}_{rp}$ ) and to transfer a data block to or from the device ( $\bar{S}_w + S_d$ ).

When the control unit becomes available it processes the request ( $\bar{S}_{rn}$ ). This action consumes some control unit time as indicated in Figure 6 by  $\rho_c$  under the  $\bar{S}_{rn}$  increment. The control unit then signals the storage device to seek to the track specified in the channel command. At this point, the control unit is free to service other requests and the storage device is now busy in its seek time interval. When the seek completes, the read/write head must wait for the track sector to position. This is the mean latency time ( $\bar{S}_l$ ) and is equal to one-half the maximum latency time. The device now attempts to gain use of the control unit. If the control unit is busy and if the track sector slips past a given point, the track must reposition again to the specified sector. This requires one full latency time interval and is sometimes referred to as missed revolutions. The average of these missed revolutions serves to increase or extend the mean latency by an additional time interval depicted as  $\bar{S}_{el}$ . It is desirable to keep this time as small as possible.

When the device finally obtains the control unit, both the control and device must wait out any sector time preceding the data block to be transferred. This time is determined by the sector window time and has a mean value depicted by  $\bar{S}_w$ . In Figure 4 the maximum window time would be Sector 3 and 4 plus Sector 5 up to the start of Data Block 14. Window time should be small if RPS is to provide a performance advantage over non-RPS.

When the data block is reached, both control unit and device take part in the block transfer during period  $S_d$ . At block transfer completion, the I/O request leaves the model and the next request on the device queue can enter the channel queue. Figure 7 is a flow diagram for a non-RPS device. The model is the same as RPS up to the end of  $\bar{S}_{sk}$ . The device then attempts to gain use of the control unit and

Figure 7—Time sequence for non-RPS model.

like the channel request, a mean wait time for the control unit is encountered ( $\bar{t}_{wc}$ ).

Finally, when the control unit is obtained, both the control unit and device must wait out the mean latency time ( $\bar{S}_l$ ). Here lies the disadvantage, the value of  $\rho_c$  increases because of device latency. This increases  $\bar{t}_{wc}$  and thus the service time. The increased  $\bar{S}$  and subsystem utilization causes an increase in the device queue waiting time.

### MATHEMATICAL EXERCISE

Now that we have walked through the flow diagrams and have defined the terms relating performance, we are ready to handle the equations of the model. The main time element of interest is the average response time ( $\bar{t}_q$ ) in performing an I/O request to a specific device. This measures the time waiting on the device queue and time being serviced by the subsystem device:

$$\bar{t}_q = \bar{S} + \bar{t}_w, \quad (2)$$

$\bar{t}_q$  is referenced to the independent variable  $\lambda_r$ . That is, we are interested in examining how  $\bar{t}_q$  varies as the load to the subsystem is changed.

Service time ( $\bar{S}$ ) as indicated in the flow diagrams is composed of subsystem-dependent parameters. The degree of control that can be exercised over these time elements will dictate the control over subsystem performance. Ultimately, performance relates to throughput which is  $\lambda_r$  times the size of the data blocks transferred per unit time. This throughput may be constrained by response time requirements and buffer requirements for the queues in main storage. If a system can tolerate large response times in I/O and the resulting variance in  $\bar{t}_q$ , then high throughput can be obtained. Otherwise, response time must be restricted which results in lower throughput:

$$\bar{S} = \bar{t}_{wc} + S_{rp} + \bar{S}_{sk} + \bar{S}_l + \bar{S}_{el} + \bar{S}_w + S_d \quad \text{RPS} \quad (3)$$

$$\bar{S} = 2\bar{t}_{wc} + S_{rp} + \bar{S}_{sk} + \bar{S}_l + S_d \quad \text{non-RPS} \quad (4)$$

- $\bar{t}_{wc}$  (Mean control unit wait time)—See Equation 12
- $S_{rp}$  (Control unit processing time)—Fixed by control unit design. Values may range from 0.2 milliseconds to 1.0 millisecond.
- $\bar{S}_{sk}$  (Mean seek time)—Determined, to some degree, by device design and system factors. Refer to Appendix I and Reference 1. For the model, specific values are assumed and the variance from the mean is assumed to be uniformly distributed.
- $\bar{S}_l$  (Mean latency time)—Fixed by device design.  $\bar{S}_l$  equals one half time maximum latency time which assumes a variance that is uniformly distributed.

$\bar{S}_{el}$  (Mean extended latency)—See Equation 20

$\bar{S}_w$  (Mean window time)—See Equation 11

$S_d$  (Data block transfer time)—Determined by the design of the device and the software application's need for certain data block sizes.  $S_d$  is the block size in bytes divided by the data transfer rate of the device.

Each time interval with a bar has a variance. Variance is a measure of the spread or dispersion from the mean value. Our intent is to obtain a reasonable estimate of variance which will be used in evaluating mean wait time on the device queue:

$$\sigma^2(\bar{S}) = \sigma^2(\bar{t}_{oc}) + \sigma^2(\bar{S}_{sk}) + \sigma^2(\bar{S}_1) + \sigma^2(\bar{S}_{el}) + \sigma^2(\bar{S}_w) \quad (5)$$

$$\sigma^2(\bar{t}_{oc}) = (\bar{t}_{oc})^2 \quad \text{exponential distribution}$$

$$\sigma^2(\bar{S}_{sk}) = (S_{sk} \text{ max})^2/12 \quad \text{uniform distribution}$$

$$\sigma^2(\bar{S}_1) = (S_1 \text{ max})^2/12 \quad \text{uniform distribution}$$

$$\sigma^2(\bar{S}_{el}) = \text{See Equation 21}$$

$$\sigma^2(\bar{S}_w) = (S_w \text{ max})^2/12 \quad \text{uniform distribution}$$

Before device queue wait time ( $\bar{t}_o$ ) can be evaluated, the subsystem utilization ( $\rho_s$ ) must be specified:

$$\rho_s = \bar{P}_{rn} \times \lambda_r \times \bar{S} \quad (6)$$

Now,  $\bar{t}_o$  can be determined and when added to  $\bar{S}$ , we have the mean response time. The equation for  $\bar{t}_o$  is a basic equation from the field of queueing theory (see Reference 1):

$$\bar{t}_o = [\bar{S} \times \rho_s / 2(1 - \rho_s)] \times [1 + \sigma^2(\bar{S})/\bar{S}^2] \quad (7)$$

The mean wait time for the control unit ( $t_{oc}$ ), the extended latency time ( $\bar{S}_{el}$ ), and the sector window time ( $\bar{S}_w$ ) must still be evaluated before service time ( $\bar{S}$ ) can be known.

In the section on RPS, the concept of sectors was discussed. The data block to be transferred starts in a specific sector. The starting point can be located anywhere within the sector (i.e. between beginning and end). Now, it takes time for the control unit and channel to prepare for the transfer. Therefore, all resources must be ready at least one sector prior to the sector containing the data. We will call this portion of the sector window the fixed portion ( $\bar{S}_{wf}$ ). A specific number of sectors prior to  $\bar{S}_{wf}$  is allotted to the device to obtain use of the control and channel facility. This is called the window connect time ( $S_{wc}$ ). Obviously for the sector RPS device to have a performance advantage over non-RPS devices, the window connect time must be small in comparison to the maximum latency time. Only a few sectors per track are normally required. Typical disk devices have 128 sectors per track at about 0.130 milli-seconds per sector.

$T_{sec}$  equals the time interval of one sector:

$$T_{sec} = S_1 \text{ max} / \# \text{ of sectors per track} \quad (8)$$

$\bar{S}_{wc}$  equals mean window connect time:

$$\bar{S}_{wc} = N \times T_{sec} / 2 \quad N = 0, 1, 2, \dots \text{ etc.} \quad (9)$$

$\bar{S}_{wf}$  equals mean fixed window time:

$$\bar{S}_{wf} = 1.5 \times T_{sec} \quad (10)$$

The mean window time is now available:

$$\bar{S}_w = \bar{S}_{wc} + \bar{S}_{wf} \quad (11)$$

The next step is to determine the control unit wait ( $\bar{t}_{oc}$ ). This time element is dependent on how busy the control unit and channel are and on the average time the control unit takes to service a channel command or transfer data. A modification of the Equation 7 used to evaluate the wait time on the device queue is used to calculate  $\bar{t}_{oc}$ . The adjustment to the equation is necessary because the queues in the subsystem are finite. That is the number of requests at any given time for control unit service can not exceed the number of devices connected to the control unit. A very good discussion on this subject can be found in Reference 1, p. 451. The adjustment factor (A) used in this model was developed by trial and error to force fit the wait time results to the graph on p. 453 of Reference 1.

$$\bar{t}_{oc} = \frac{\bar{S}_c \times \rho_{ce} \times A}{(1 - \rho_{ce})} \quad (12)$$

$\bar{S}_c$  is the control unit service time:

$$\bar{S}_c = [S_{rp} + (\bar{S}_w + S_d)]/2 \quad \text{for RPS} \quad (13)$$

$$\bar{S}_c = [S_{rp} + (\bar{S}_1 + S_d)]/2 \quad \text{for non-RPS} \quad (14)$$

$\rho_{ce}$  is the effective control unit utilization. It factors in the real control unit utilization  $\rho_c$  with the channel utilization ( $\rho_{ch}$ ) that may result due to other subsystems sharing the channel:

$$\rho_{ce} = 1 - (1 - \rho_{ch}) \times (1 - \rho_c) \quad (15)$$

If only one subsystem is connected to the channel,  $\rho_{ch}$  equals zero. Therefore,  $\rho_{ce}$  equals  $\rho_c$ . Under this condition the channel and control unit can be viewed as one single facility:

$$\rho_c = 2\lambda_r \times \bar{S}_c \quad (16)$$

A is the adjustment factor to compensate for a limited queue:

$$A = (1 - \rho_{ce}^{(N_d - 1)}) \times \exp [(-10) \times (N_d - 1)] \times \rho_{ce} / [(N_d \times [N_d + 1])] \quad (17)$$

$N_d$  equals the number of devices connected to the control unit.

The last equation to be evaluated is for the extended latency time ( $\bar{S}_{el}$ ). To do this, we need to determine what the probability is that the control unit will be available during the sector window connect time. The time the control unit is free is  $1 - \rho_{ce}$ . If the control unit is busy when the connect sector is sensed, the probability that it will become free within  $S_{wc}$  (window connect time) is:

$$P_{wc} = \rho_{ce} \times [1 - \exp(-\bar{S}_{wc}/\bar{t}_{oc})] \quad (18)$$

Therefore, the probability the control unit is available is:

$$P_{ca} = 1 - \rho_{ce} + \rho_{ce} \times [1 - \exp(-\bar{S}_{wc}/\bar{t}_{oc})] \quad (19)$$

The extended latency ( $\bar{S}_{el}$ ) is:

$$\bar{S}_{el} = \bar{S}_1 \max \times (1/P_{ca} - 1) \tag{20}$$

The variance of  $\bar{S}_{el}$  is:

$$\sigma^2(\bar{S}_{el}) = \frac{\bar{S}_{el}^2(1-P_{ca})}{P_{ca}^2} \tag{21}$$

The set of equations are now complete and response time as a function of request rate can be evaluated. The supplementary equations above also provide additional insight into what is going on in the subsystem.

SUBSYSTEM EVALUATION

The first configuration that will be looked at is the single-access, non-RPS disk subsystem with one control unit connected to the channel. The components of service time assumed for this configuration are:

- $S_d = 0.5$  milli-seconds
- $\bar{S}_1 = 8.33$  milli-seconds
- $S_{rp} = 1$  milli-second
- $\bar{S}_{sk} = 15$  milli-seconds
- $\bar{t}_{wc}$  = varies with the load
- $\bar{S} = 24.8$  milli-seconds +  $2\bar{t}_{wc}$

Figure 8 is a plot of response time ( $\bar{t}_q$ ) as a function of requests ( $\lambda_r$ ). Figure 8a shows three curves: (1) two disks per control unit; (2) four disks per control unit; and (3) eight disks per control unit. Each disk services an equal percentage of  $\lambda_r$ . The arrows indicate the point on the curves where the probability that a request to the subsystem must wait because a previous request has not been completed is 0.5.

Figure 8a—Single control unit with non-RPS.

This will be called subsystem queue=1. If the service time is assumed to be exponentially distributed (worse case), the variance of response time when subsystem queue=1 can be very large. This means that it is possible for approximately 10 percent of the requests to the device to exceed response times that are three to five times the mean. Note that as the device queue approaches one, the wait time on the queue ( $\bar{t}_w$ ) almost equals the service time. This is due to the increase in control unit and device utilization. The two-disk curves show that the disk devices are the limiting resource at about 20 requests per disk per second. The four-disk curve indicates that both control unit and devices limit the performance at about 17 requests per disk per second. The eight-disk curves show the control unit limiting the performance at about 11 requests per disk per second. It appears that in the area of the four-disk curve, the subsystem is most cost effectively utilized. The reason that control unit utilization increases rapidly is due to waiting out the disk latency time since the devices are not using RPS. A point of concern is how the subsystem performance behaves as  $\lambda_r$  is increased beyond a device queue of one. For the eight-disk curve, the subsystem would bog down with large queues and long response times.

The next configuration is a single-access disk subsystem using RPS. The service time elements assumed are those specified for the non-RPS configuration. However, two additional elements are required for RPS:

- $\bar{S}_c = 0.5$  milli-seconds (~4 sector times)
- $\bar{S}_{wr} = 0.19$  milli-seconds (~1.5 sector times)

A plot for a four-, eight-, and 16-disk configuration is shown in Figure 8b. It's easy to see that a definite performance increase has resulted by not tying up the control unit during latency time. The disk devices are now the major limiting resources in performance. The gain in performance over the

Figure 8b—Single control unit with RPS.

non-RPS for the four-disk configuration isn't too drastic (i.e. 20 requests per disk per second with respect to 17). However, the control unit utilization for RPS is very low and this implies that additional devices can be cost-effectively added to the subsystem. Note the gain in performance for the eight-disk curve over the non-RPS. The devices are capable of servicing 19 requests per disk per second as opposed to 11 for the non-RPS and with a response time in the area of 50 milli-seconds instead of 90 milli-seconds. Additionally, the curve beyond the subsystem queue=1 is more gradual, implying a greater tolerance to variation in the request rate. The RPS control unit is even capable of handling up to 16 disk devices in an efficient manner.

Beyond this point cost-effective gains in performance become questionable. The magnitude of the extended latency time at a subsystem queue=1 increases as disks are added and  $\lambda_r$  is increased. This is due to the increase in control unit utilization and reduces the device's capability to handle requests. The situation isn't too bad because the time to transfer data chosen for this configuration was small. This implies that the device either has a fast data transfer rate or a small data block size (e.g. 500-1000 bytes per block). If a larger  $S_{el}$  is assumed the control unit utilization would increase and with it the extended latency. The only way to reduce extended latency is to reduce control unit utilization. A good way to do this is to add a second control unit and channel and configure it as a dual access subsystem. This cuts the control unit utilization because the two units share the request load.

Figure 8c illustrates a dual-access configuration using RPS. Again, four-, eight-, and 16-disk curves are shown. The service time elements are specified for the single access RPS configuration. For the reason stated above, the gain in performance is not dramatic for the four- and eight-disk curve. For the 16-disk curve, a respectable improvement in  $\lambda_r$  is indicated. In addition, the low control unit utilization

Figure 8c—Dual control unit with RPS.

indicates that disks in excess of 16 can provide a cost-effective increase in performance.

SUPPLEMENTAL EVALUATION

Channel utilization impact

If the channel is being used by more than one subsystem, each subsystem interferes with the other. The effect of this interference is felt in increased response times at a given load on the subsystem. This in turn forces the system to drive the subsystem at fewer requests per second to obtain reasonable response times and more stable queues. A reasonable approximation of the degree of impact channel utilization has on a subsystem is listed in Table I.

Latency time

The role that maximum latency time plays in limiting the throughput of a subsystem depends on the magnitude of the maximum latency time with respect to the service time ( $S$ ) of the subsystem. Reducing latency will improve performance. Table II lists the gain in performance when maximum latency time is reduced by 25 percent, 50 percent and 100 percent. Column 1 indicates that if maximum latency time has a value in the area of 80 percent of the service time, a significant increase in throughput is gained if it can be reduced by 50 to 100 percent. For disk units there is little chance to reduce latency but for bubble and charge coupled devices some latitude of control exists. Furthermore, these solid state technologies have performance characteristics such that latency time may be in the area of 80 percent  $S$ .

Seek time

Seek time, like latency time, has a major affect on throughput. For disk subsystems, some control can be exercised over seek time. The degree of performance improvement, again, depends on the initial value of seek time with respect to the service time ( $S$ ). Table III lists the percentage of increase in throughput by reducing seek time by 25 percent, 50 percent and 100 percent. Column 1 shows that significant gains are realized if the initial value of  $S_{sk}$  is 80 percent of  $S$ .

TABLE I—Performance Impact Due to Channel Utilization

CHANNEL UTILIZATION	APPROXIMATE LOSS IN THROUGHPUT
0.1	6%
0.2	15%
0.3	25%
0.4	36%
0.5	48%

TABLE II—Predicted Improvement Due to Reduced Latency

	$S_l \text{ max} = .8 \bar{S}$ PERFORMANCE INCREASE	$S_l \text{ max} = .5 \bar{S}$ PERFORMANCE INCREASE	$S_l \text{ max} = .2 \bar{S}$ PERFORMANCE INCREASE
25%	12%	6%	3%
50%	25%	14%	5%
100%	75%	34%	12%

*Data transfer time*

Typically,  $S_d$  is small compared to service time. However, it not only consumes device time, it also consumes control and channel time. These latter two facilities are shared and time consumption must be well managed. Table IV shows the impact of reducing  $S_d$  when it is 10 percent, 5 percent, and 2 percent of the service time ( $\bar{S}$ ). Disks typically have  $S_d$  in the 5 percent, to 2 percent of  $\bar{S}$  range. A change in  $S_d$  can be the result of a change in data block size or data transfer rate.

*Control unit processing time*

This time is small compared to  $\bar{S}$  for disk subsystems, but may become significant for solid-state devices. It impacts throughput in a manner similar to data transfer time. Like  $S_d$ , it consumes control unit time and if the control unit is to service a large number of requests for high-performance solid-state devices, it must be held to a small percentage of  $\bar{S}$ . Table V lists the impact on performance of  $S_{rp}$  when its value is 10 percent, 5 percent and 2 percent of  $\bar{S}$ .

CONCLUSION

The mathematical model defined in this paper can be used to give a system designer a good deal of insight into what parameters can be most effectively changed to yield the desired performance. Given parameters such as seek time, latency time, control unit processing time, sector time, and channel loading, these parameters can be used to predict subsystem performance. The model described here was checked against an internal GPSS model simulating overlapped seeks on disks. The results of our mathematical model agreed within 10 percent of the GPSS model.

APPENDIX I

*Seek time*

There are a number of ways to compute seek time. Some of them are analytic, some are heuristic. There are a number of ways to shorten seek time. This appendix will talk about shortening seek time by restricting the number of cylinders that contain data.

On the assumption that the requests to a disk are to random locations, then the average movement of the head mechanism is across  $\frac{1}{3}$  of the cylinders. Many people have suggested that the average seek time could be shortened by taking the contents of the queue of requests for this disk and moving to one of the closer positions.

Two techniques have emerged called Scan and C-Scan. In both, the list of commands are arranged in cylinder position sequence. Any new command is inserted in the list in the proper numerical position. Scan says to start at one end of the list and always go to the next position as you go through the list in one direction. When there are no more in the list for that direction, turn around and go through the list in the opposite direction. The head mechanism will take a number of steps in one direction and then a number in the other. The C-Scan (circular scan) will do the same, except that at the end of the list, it will jump back to the beginning of the list and start over.

Intuitively, C-Scan seems more efficient. In Scan, when a new position is deposited in the list after the scan has just passed that point, the command has to sit there until the scan reaches the end and comes back through the list once again. In C-Scan, such a command only has to wait through one scan (not two). Also, in Scan, when the end of the list is reached and it turns around, there is small probability that there is anything in the list at a close cylinder position. Therefore, at the beginning of each scan, the distances to

TABLE V—Predicted Improvement Due to Reduced Processing Time

	$S_{rp} \text{ max} = .1 \bar{S}$ PERFORMANCE INCREASE	$S_{rp} \text{ max} = .05 \bar{S}$ PERFORMANCE INCREASE	$S_{rp} \text{ max} = .02 \bar{S}$ PERFORMANCE INCREASE
25%	13%	3%	0.5%
50%	30%	5%	1%
100%	69%	9%	2%

the next cylinder will be relatively large. Surprisingly, intuition does not work. Simulations<sup>2</sup> show that for small queues, Scan is better than C-Scan. The large seek distance to the beginning of the list seems to hurt. For example, if there are two commands in the list, C-Scan has one large seek and one small seek, while Scan has two small seeks. Teorey<sup>3</sup> says that C-Scan does not begin to pay off until the queue length goes over 100. But we cannot allow the queue length to ever reach such lengths because of the prohibitively long response times.

Croteau states that whenever the average queue length exceeds 0.2 per disk, Scan begins to give better results than random. She also states that when the average queue length is two or three (response time is two or three times service time), then the average positioning time has been reduced about 10 percent.

#### *Restriction to part of disk*

The only way to radically shorten the seek time on a disk is to keep the head from moving long distances. To do this, take the group of files or databases that are accessed by a set of programs. Record part of these files on all the non-removable disk packs. The part of any disk should be confined to contiguous cylinders. Then when running those programs, seek time is confined and shortened and as many disks as possible are operated in an overlapped way. Multiprogramming has to be restricted to one set of programs at a time. If multiprogramming cannot be restricted, then the only way to shorten seek time is to use only a fraction of the cylinders to record data. This costs more, because more disks are needed. In addition, it could mean more throughput because more disks are operating in parallel.

The average positioning distance, if requests are random, is one-third of the occupied cylinders. The average positioning time is not the time to move one-third of the cylinder positions. You have to add all the times to move from any possible position to any other position (including the zero time to stay on the same cylinder position) and then divide by the number of moves. The average positioning time is usually less than the positioning time to move an average number of cylinder positions. Waters<sup>4</sup> gives the formula for computing average seek time.

The average seek time is reduced if the requests are not randomly distributed over all cylinder positions, but are bunched. Waters shows how to compute the average positioning distance if the high activity records are all grouped together. He shows that the minimum seek distance occurs when the high activity records are recorded in the middle group of cylinders while the maximum seek distance occurs when they are in the lowest numbered cylinders. Waters then gives two examples. In one case 80 percent of the requests go to 20 percent of the disk. When the 20 percent are in the beginning cylinders, then the average seek distance is about one-fifth the number of cylinder positions. When the 20 percent are in the middle cylinders, the average

seek distance is about one-seventh of the cylinder positions. Both are better than the one-third for random requests.

The other case is for 60 percent of the requests to go to 5 percent of the disk. When the cylinders are in the beginning, the average number of positions moved is about 0.3 of the cylinder positions. When the 5 percent are in the middle cylinders, the average number of cylinder positions moved is less than 0.2 of them.

If you confine 100 percent of the requests to a smaller number of cylinders, then you get even better average seek times. In fact, if you only used 40 percent of the cylinder positions for data, then you get a small average number of cylinders moved than any of the previous cases.

## APPENDIX II

### *Wait times with RPS*

The following derivation is due to John Marsden of our Sperry Univac group in London sometime in the middle or early 1970s. Usually, wait time is a function of queue length. He has come up with an ingenious scheme where wait time is a function of the utilization of the control unit. Ordinarily, with only one command waiting for service, the wait time is latency time with an average of  $R/2$  (half a rotation time). With more than one command waiting for service, some of the commands will have extra rotation times added to their wait time because the control unit is busy when it is time to acquire it. The average wait time is:

$$\text{Avg. wait time} = \frac{R}{2} + \frac{R \cdot \rho_{ce}}{1 - \rho_{ce}}$$

where  $\rho_{ce}$  = utilization of the control unit caused by all other disks and channel contention.

$R$  = Time for 1 revolution of the data or media.

The extra wait time begins to be noticeable when the control unit is busy more than 20 percent of the time.

The derivation goes like this. The average latency on the first rotation is  $R/2$ . This will be true if the control unit is not busy at the RPS time. The other disks keep the control unit busy with a utilization of  $\rho_{ce}$ . The probability that it will not be busy is  $(1 - \rho_{ce})$ . The probability it will be busy on the first revolution is  $\rho_{ce}$ , and not busy on the second is  $(1 - \rho_{ce})$ . The average wait time in this case is one-and-a-half rotations.

$$\text{Prob. of first rev.} = 1 - \rho_{ce}; \quad \text{avg. time} = \frac{R}{2}$$

$$\text{Prob. of second rev.} = \rho_{ce}(1 - \rho_{ce}); \quad \text{avg. time} = \frac{3R}{2}$$

$$\text{Prob. of third rev.} = \rho_{ce}^2(1 - \rho_{ce}); \quad \text{avg. time} = \frac{5R}{2}$$

Weighted Avg. Time:  $W_{at}$

$$\begin{aligned} &= \frac{R}{2}(1-\rho_{ce}) + \frac{3R}{2}\rho_{ce}(1-\rho_{ce}) + \frac{5R}{2}\rho_{ce}^2(1-\rho_{ce}) + \dots \\ &= \frac{R}{2} [1 + 3\rho_{ce} + 5\rho_{ce}^2 + \dots (1-\rho_{ce})] \\ &= \frac{R}{2}(1-\rho_{ce}) \frac{1}{1-\rho_{ce}} + \frac{2\rho_{ce}}{(1-\rho_{ce})} \cdot 2 \\ &= \frac{R}{2} + \frac{R \cdot \rho_{ce}}{1-\rho_{ce}} \end{aligned}$$

If  $P_{ca} = 1 - \rho_{ce}$

Then

$$W_{at} = \frac{R}{2} + R \left( \frac{1}{P} - 1 \right)$$

Variance of latency

The variance of the extra missed revolutions has been computed by Antony Jenkins. It is derived as follows:

$$\begin{aligned} \sigma^2 &= (1-\rho_{ce}) \left( 0 - \frac{R \cdot \rho_{ce}}{1-\rho_{ce}} \right)^2 + \rho_{ce}(1-\rho_{ce}) \left( R - \frac{R \cdot \rho_{ce}}{1-\rho_{ce}} \right)^2 \\ &\quad + \rho_{ce}^2(1-\rho_{ce}) \left( 2R - \frac{R \cdot \rho_{ce}}{1-\rho_{ce}} \right)^2 + \dots \\ &= (1-\rho_{ce}) \frac{R^2}{(1-\rho_{ce})^2} [\rho_{ce}^2 + \rho_{ce}(1-2\rho_{ce})^2 + \rho_{ce}^2(2-3\rho_{ce})^2 + \dots] \\ &= \frac{R^2}{1-\rho_{ce}} (\rho_{ce} + \rho_{ce}^2 + \rho_{ce}^3 + \rho_{ce}^4 + \dots) \\ &= \frac{R^2 \cdot \rho_{ce}}{(1-\rho_{ce})^2} \end{aligned}$$

# A software reliability study using a complexity measure

by THOMAS J. WALSH

*Control Data Corporation*  
Shrewsbury, New Jersey

## INTRODUCTION

Software engineers face a real problem in guaranteeing that their computer programming systems under development will be able to function in a reliable manner and be easily understood, maintained and extended. A major impediment of this problem is coping with the inherent complexity of the software system in an effective way. The complexity of the computer system will defeat the designer's efforts unless a relatively simple way is found to break the problem down in order that the resulting programs are testable and maintainable. Complex problems must be factored into smaller units to be treated by the human intelligence because man's capacity for logically precise invention is limited. The consequence of ignoring these bounds to man's cognitive and creative capacity was well stated by Harlan Mills of IBM:<sup>1</sup>

We often ignore the complexity of a planned program or sub-program. But when the complexity exceeds certain unknown limits, frustration ensues. Computer programs capsize under their own logical weight, or become so crippled that maintenance is impossible.

Complexity is an attribute of a computer program much like storage and speed of execution, the difference being a measurement stick of a program's complexity has not been available. Thus, this important quantitative attribute has been generally ignored.

To appreciate the impact of ignoring a program complexity measure, let us take a brief look at the phases constituting the life-cycle of a typical software system. These phases encompass the process of design, implementation, testing and maintenance.

Scientific studies have validated the facts that at least half of the systems development time is spent in testing<sup>2</sup> and most dollars are spent on maintaining systems.<sup>3</sup> Figure 1 illustrates the typical break-down of software costs.<sup>4</sup>

The high cost of software is primarily due to software not being reliable enough. The key to software reliability is in the degree of precision and accuracy achieved during the design process, which has the greatest effect on the overall efficiency of the system and consequently the overall cost. This point cannot be over-emphasized. Frequently, programming systems have not been designed to facilitate testing efforts nor to constrain the impact of change. What is

needed is a methodology for software system development which makes a concern for reliability an integral part of the development process, especially in the design phase. Such a methodology would consist of various tools and techniques distributed over the four previously-mentioned phases.

In recent years, what I will refer to here as "structured programming ideas" have emerged as a foundation for programming to become a science. This set of ideas has been referred to as "improved programming technologies" by IBM and as "programmer productivity techniques" by Yourdon.<sup>5</sup>

Regardless of the label, they represent several interrelated disciplines which have a natural affinity and yield noticeable benefits to the software system builder when used together in a systematic fashion.<sup>5-8</sup>

Each time a new idea is added to this evolving programming methodology, the opportunity for greater precision and reliability in programming practices increases. The analytical complexity measurement of McCabe is a new idea and deserves both recognition and membership in the promising methodology.<sup>9</sup> The complexity measurement represents an attractive and powerful concept because of its relatively simple applicability, its direct impact on the process of design, and its mathematical origin.

Complexity can usually be calculated for computer programs by simply counting the number of decision statements and adding one. The complexity measurement focuses attention on the process of design so the function specified for the software can be intellectually gripped and performed in the simplest possible manner. This advanced design technique allows for comparing alternate designs in search of the true order that the best solution really called for. It strives to eliminate obscure structures, cumbersome decision-making processes, and overly complicated control paths. This design capability is language-independent. The mathematical origin accounts for the measure being highly correlated with the expected amount of testing work. It facilitates a more thorough and methodical testing process by yielding a minimum number of paths through a program that must be exercised in order to make testing meaningful (Structured Testing). Furthermore, it simplifies maintenance activities by the strengthening of testing and limiting the complexity of the program to be fixed. It identifies software programs that will be difficult to test and maintain and encourages the creation of a more testable and maintainable

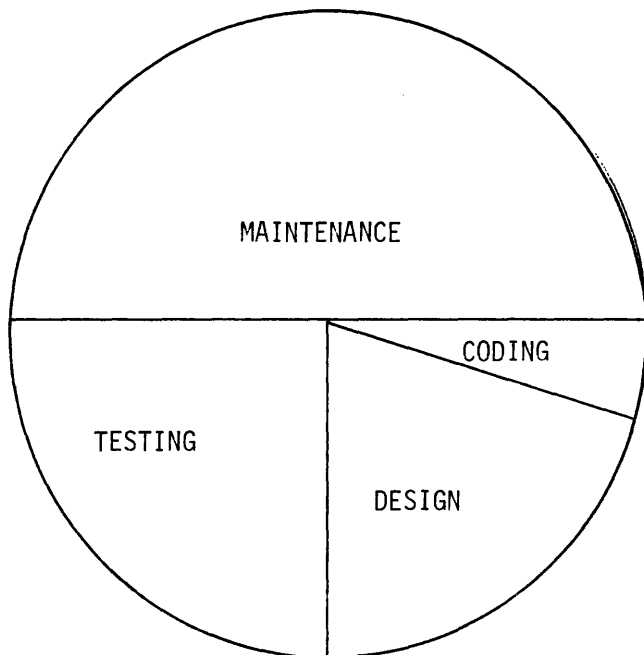

Figure 1—Typical breakdown of software costs.

system. Overall, this mathematically-based measurement permits management and control of program complexity via a quantitative basis.

Figure 2 illustrates the hierarchical relationship and utilization order between top-down design, the complexity measure and structured programming. Top-down design is concerned with the "divide-and-rule" principle. It recognizes that complex problems must be factored into a combination of many small solvable problems. The complexity measure then weighs the individual module's complexity to facilitate proper design, testing and maintenance. This may indicate the need for further top-down design. Finally, structured programming tackles the problem of program logic design. Figure 3 represents a survey of structured programming ideas distributed over the four phases of software development. This chart is not complete, but it is intended to be illustrative. Definitions for these techniques and related documentation techniques may be found in the Glossary.

## BACKGROUND

This section's purpose is to sketch some significant historical developments in the evolution of structured programming ideas in order to properly view McCabe's complexity measure. The first major result was a paper by Bohm and Jacopini.<sup>10</sup> This classic manuscript introduced organization and discipline by showing that any program, no matter how complex, can be composed in a structured manner with only three relatively simple control structures which are popularly known as "SEQUENCE," "IF THEN ELSE" and "DOWHILE" (Figure 4). An analogy of this powerful development is often made to engineering where any logic

circuit can be constructed from "AND," "OR" and "NOT" gates. The importance of this result was that it mathematically dealt with the problem of complexity in control logic. The proof for the "structure theorem" is grounded firmly in mathematics. Solidly grounding viable techniques in mathematics not only increases the confidence level of present users of these techniques, but it facilitates the future development of even more powerful techniques. Although this paper was published in English in 1966, the proper recognition it deserved did not materialize until the 1970s. A major driving force in its recognition was Edsger W. Dijkstra who strongly endorsed structured programming by a famous letter in the *Communications of the ACM* and numerous articles.<sup>11,12</sup>

Professor Dijkstra, historically, is a man ahead of his time whose clear thinking and proper design of programs have earned him a most influential and respected position in the computer programming profession.<sup>13</sup> An underlying theme to much of his work has been the view of software as a creative branch of mathematics. Therefore, he sees the mathematical method as the most effective way for the human mind to come to grips with complexity.<sup>14</sup>

Many individuals have contributed to the methodology referred to here as structured programming ideas—especially Harlan Mills, who also was an early advocate of structured programming.<sup>15</sup> He provided mathematical assurance for structured programming ideas in his "Mathematical Foundations for Structured Programming."<sup>11</sup> It should be noted that Mills' paper also contains the mathematical seeds that McCabe will use to simplify his theory of cyclomatic complexity. Mills has been very concerned about the problem of complexity. He views<sup>16</sup> complexity as the "principal barrier to the application of computers to intelligent problem-solving." In a more recent article,<sup>17</sup> he reiterates the call of Dijkstra for a mathematical basis for the practical control of computers in complex applications.

Recently, endorsements of McCabe's method as being both reasonable and intuitive have come from various sources.<sup>18,19</sup> Glenford J. Myers of the IBM Systems Research Institute concludes his manuscript by stating:

Although it is an extremely simple concept,  $V(G)$  appears to be a practical complexity measure because it is easy to calculate, it confirms subjective opinions about complexity, and it is consistent with studies showing a high correlation between the number of decisions in a module and the modules' complexity and error proneness.

## McCABE'S COMPLEXITY MEASURE

McCabe's complexity measure is a mathematical technique for calculating the logical complexity of a computer program. The complexity of a computer program is an attribute which may be assigned a number representing its logical weight. The quantitative complexity number generated is independent of the program's size, but dependent on a program's decision structure or the number of basic paths

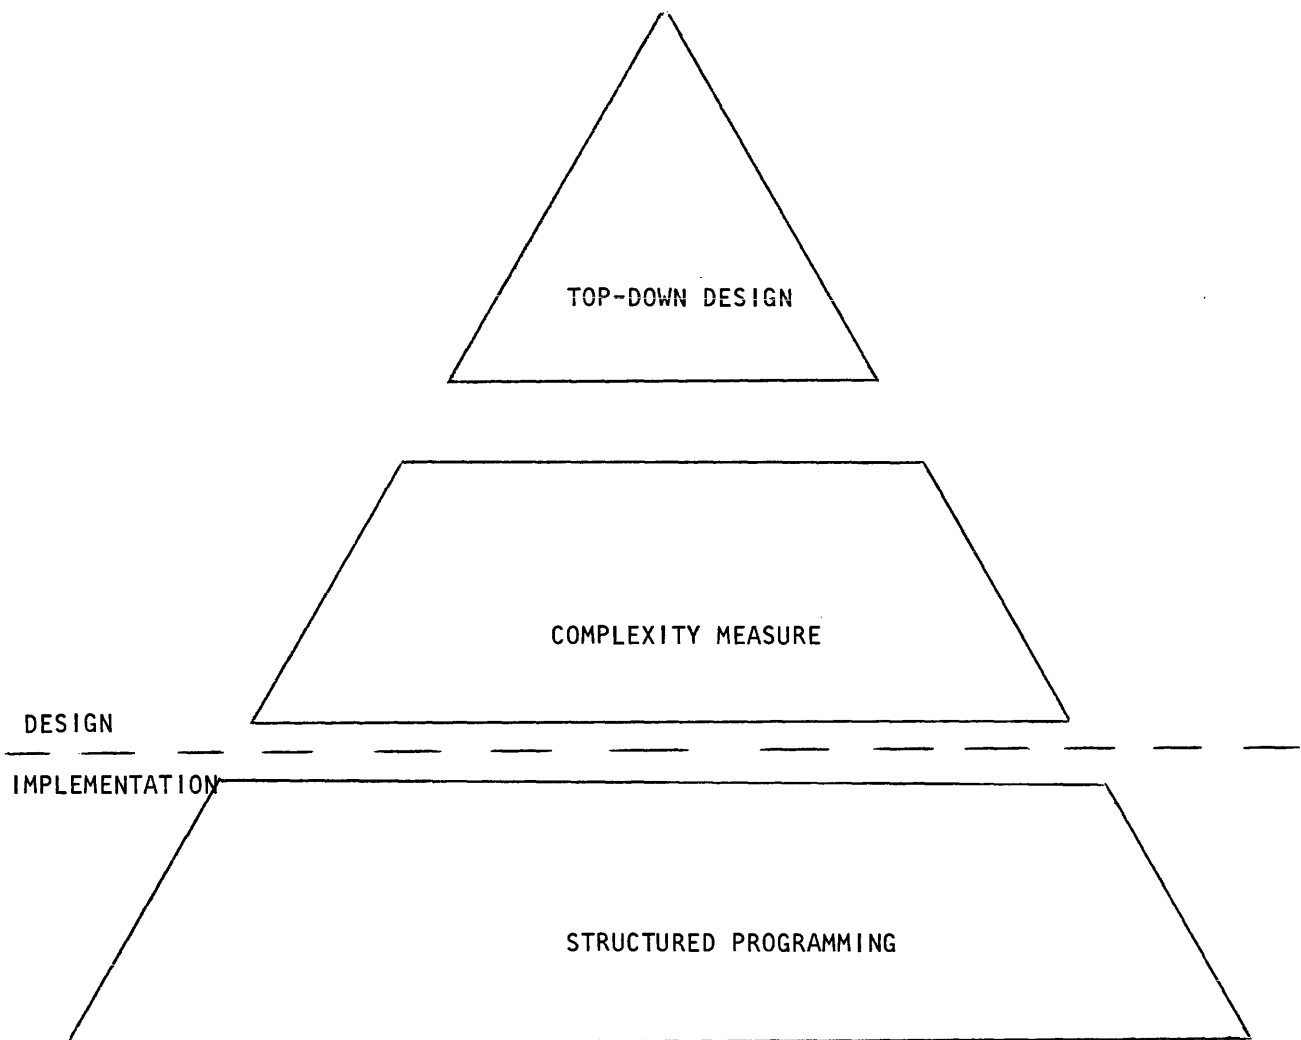

Figure 2—Hierarchies of system development reliability tools.

through a program. It provides a quantitative means for modularization and allows for identification of programs that will be difficult to test and maintain. Although complexity can assume a value of one to infinity, a reasonable upper limit of intellectual manageability has been placed by McCabe at ten. This number is only slightly higher than the upper bound that psychological studies confirm as the number of issues man can consider simultaneously.<sup>20</sup>

McCabe recommends that designers be required to calculate complexity as they create software programs and when complexity exceeds ten, sub-functions should be given their own procedure or the software should be redone.

In the interests of communication, this section has suppressed much of the technical mathematics which forms a solid foundation for this advanced methodology to come to grips with complexity. This would include the works of many people, including Bohm, Jacopini, and Mills.<sup>10,1</sup> It would require a highly technical type of discussion outside the scope of this paper. I am very much aware of these

shortcomings and can only trust this approach will not diminish the serious respect this body of knowledge so well deserves.

The following material represents some of the highlights. The theoretical basis for McCabe's complexity measure is graph theory. The following connection exists between graph theory and computer programs. Each node in the graph corresponds to a block of code in the program where the flow is sequential and the arcs correspond to branches taken in the program. Thus, all computer programs may be expressed as graphs or to be precise "program control graphs." This is an important concept because it represents a gateway through which the power of mathematical analysis may be applied to computer programs. Graph theory allows for such a graph to yield a quantitative cyclomatic complexity number via the formula:

$$v(g) = e - n + 2 \quad (1)$$

For example, in Figure 5  $e$  (arcs) has a value of nine,  $n$

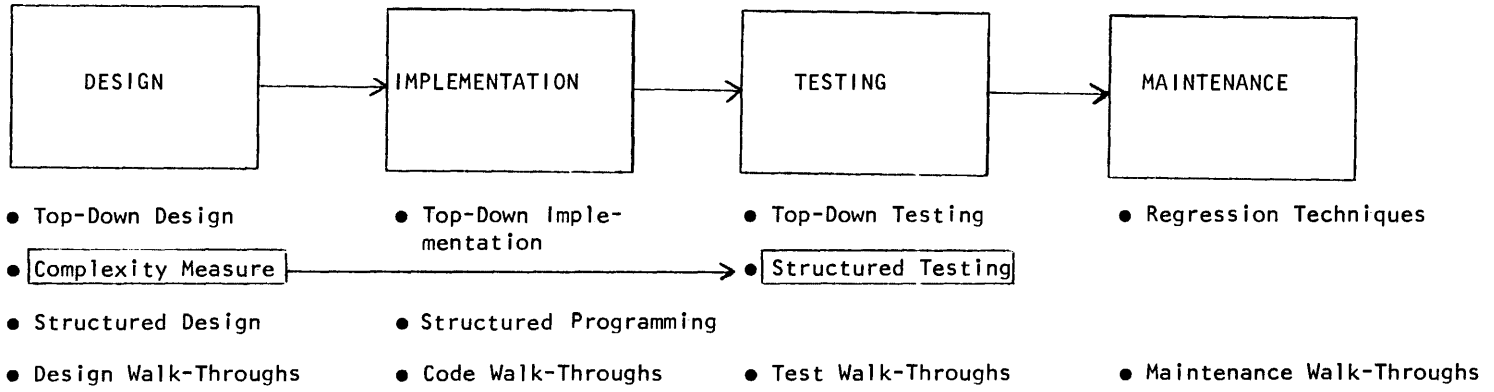

Figure 3—Partial list of structured programming ideas.

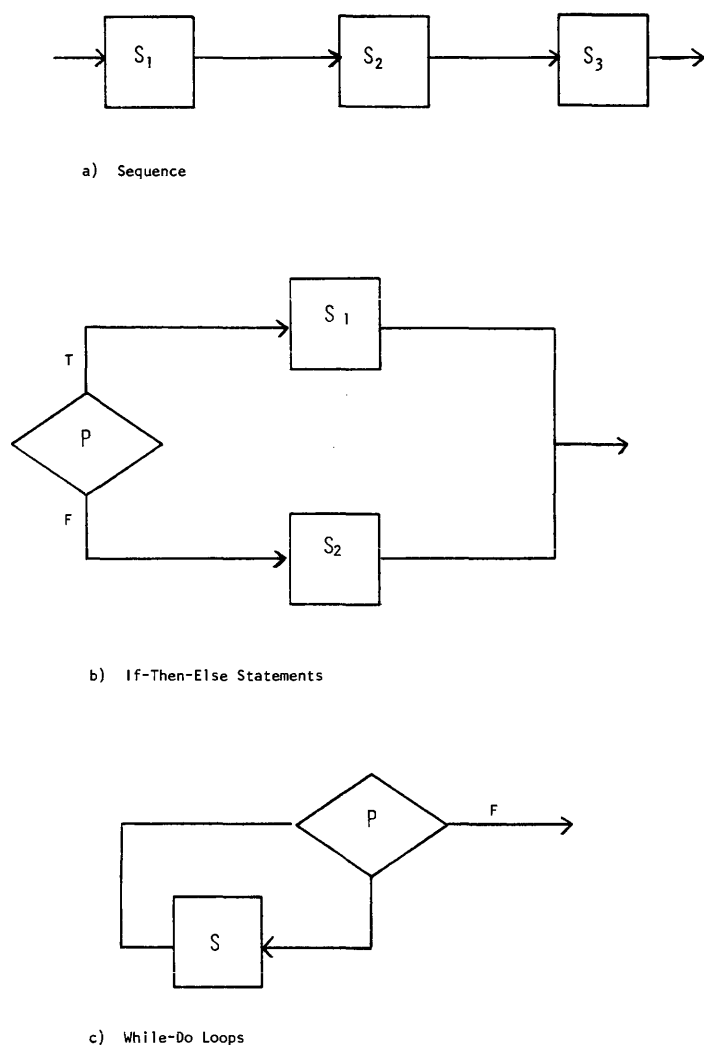

Figure 4—Control structures of structured programming.

(nodes) has a value of eight, and the complexity of the program is three.

A simple but powerful key to McCabe's proposal is brought about by a mathematical simplification that shows the complexity for a structured program to be equal to the number of decision statements plus one. Mills<sup>1</sup> showed that with the number of function, predicate and collecting nodes represented by  $\theta$ ,  $\pi$ , and  $\gamma$ , respectively, and the number of control lines (edges) represented by  $e$  in a structured program, that the following holds true:

$$e = 1 + \theta + 3\pi. \tag{2}$$

Furthermore, the number of collecting nodes is always equal to the number of predicates as in:

$$\pi = \gamma. \tag{3}$$

Therefore, it follows that (1) can be transformed,

$$V(G) = (1 + \theta = 3\pi) - (\theta + 2\pi + 2) + 2 = \tag{4}$$

$$\pi + 1. \tag{5}$$

$v(6) = 3$

Figure 5—Example of complexity graph.

It should be noted that McCabe has recently proved that the structure of all programs (structured and unstructured) is equal to the number of conditions plus one. The preceding grants us the mathematical assurance to calculate the complexity of a given program either by counting the predicate nodes in the flowchart or by inspecting the source code. This allows for simplicity in the application of the complexity measure by suspending the task of drawing time consuming graphs. In addition, the measurement process can be easily automated. In fact, McCabe has built a control structure complexity tool to run on a PDP-10 that analyzes the structure of FORTRAN programs.

### AEGIS CASE STUDY

The AEGIS Naval Weapon System is an advanced ship-board combat system which is tasked with shielding the U.S. fleet.<sup>21</sup> System control is governed by three high-speed general purpose AN/UYK-7 computers. An individual computer is assigned to the Radar system, the Weapons and Control System and the Command and Decision system. The heart of this large computerized system is the AN/SPY-1A three-dimensional phased array radar. The reliability study focused on eight functionally-related computer modules which constituted what is known as the software control loop and display processing of the radar. Each module was assigned with a primary function of the radar control soft-

ware. This included radar scheduling, search management, track processing, radar return processing, etc. A module itself is further divided into procedures to perform specific tasks within the module. These eight modules were composed of 276 procedures or programs which were the actual subjects of the complexity study. These procedures were written in a high-level language (CMS-2Y) and run on a 4-bay AN/UYK-7 high-speed computer. The AEGIS project utilized the software engineering techniques of top-down design and structured programming.

The methodology called for the calculation of a number of quantitative parameters for each procedure. These parameters included the number of software errors experienced, the number of source statements, the number of machine words, and a complexity number. The first parameter called for the collection and analysis of software errors detected during the development phase of these modules. The number of software errors were distilled from an existing program trouble report system. A serious effort was made to obtain only those problem reports related to software errors rather than design changes. Interviews with the programmers responsible for the code facilitated this end. The procurement of a complexity number was through McCabe's complexity measurement recommendation.

A correlation was found between a high complexity value and the occurrence of bugs for a procedure. Those procedures with a complexity greater than or equal to ten accounted for a disproportionate share of the bugs. Overall, 23 percent of the procedures accounted for 53 percent of the bugs. This fact alone is not conclusive. In general, the procedures with a complexity measurement greater than or equal to ten were also the largest users of source statements.

This meant that a correlation also existed between a high number of source statements and the occurrence of bugs for a procedure. Recognition of this phenomenon, most notably described in the *New York Times* project by IBM,<sup>7</sup> has led to attempts to limit the physical size of procedures, e.g., 50 lines of source code. An obvious flaw with limiting programs solely by physical size is that it ignores the density of control structures in those 50 lines.

The principal result of the study into logical complexity occurs when the 276 procedures are divided into two groups and their respective error rates are compared. These groups are defined as those procedures with a complexity measurement less than ten and those procedures with a complexity measurement greater than or equal to ten (Figure 6). Approximately half of the actual source code is in each of these groups. Yet, those procedures with complexity greater than or equal to ten experienced over 21 percent more errors. The error rate for the group of procedures with complexity measured below ten was 4.59 errors per 100 source statements. The error rate for the group of procedures with complexity greater than or equal to ten was 5.60 errors per 100 source statements. Clearly, the effect of these error rate differences in a large software system is significant.

Now, Figure 7 illustrates what empirical studies have shown concerning the relationship between detected and undetected errors. As the number of detected errors in a piece of software increases, the probability of the existence of more undetected errors also increases.<sup>4</sup> Put simply, errors come in clusters. Thus, it can be confidently predicted that when the procedures in the study enter the maintenance phase of their existence, the procedures with a complexity greater than or equal to ten will continue to experience

Figure 6—Complexity measurement.

Figure 7—Relationship between discovered and undiscovered errors.

higher error rates than those procedures with complexity below ten. A far more reliable radar computer system could be achieved by reducing the software logical complexity of all procedures below ten. In fact, this suspicion can be extended to all large systems that were developed without a complexity measure.

## SUMMARY AND RECOMMENDATIONS

Reliable software is no accident. It is the residue of a collection of software engineering techniques which have a natural affinity and are distributed over the four phases of software development. The key phase is design because its effects propagate through all the other phases. A new software engineering design technique is McCabe's quantitative complexity measure which is mathematically linked to the works of Bohm, Jacopini and Mills. The following recommendations are made as a result of my study utilizing McCabe's complexity measure to software system builders:

1. The complexity measure should be viewed as a structured programming technique and employed with the other structured programming techniques to enhance software reliability.
2. The complexity measure should be used to create a more testable and maintainable system by warning designers when a program has become too complex.
3. The complexity measure should be used to evaluate alternate designs with the goal of finding the simplest possible solution to the problem specifications.
4. The complexity measure should be used as a more

thorough and methodical testing process which quantifies the amount of work necessary for reliable testing.

5. The complexity measure should be viewed as an aid to the maintenance process via its strengthening of testing and the limiting of the complexity of the program to be fixed.
6. The complexity measure should be used on existing software to identify programs that will be difficult to maintain and extend. These programs are prime candidates for redesign.

## STRUCTURED PROGRAMMING IDEAS GLOSSARY

1. *Chief Programmer Team*—A group of computer specialists organized into a team much like a surgical team.
2. *Code Walk-Throughs*—A walk-through of the actual code to guarantee that it reflects the design document.

3. *Complexity Measure*—A quantitative attribute of a computer program which measures its logical weight. Mathematically expressed via formula  $v(g) = e - n + 2$ .
4. *Hipo Hierarchy Chart*—A documentation technique based on function.
5. *Design Walk-Throughs*—A walk-through of the design document checking for errors or omissions in the architecture of the design.
6. *Maintenance Walk-Throughs*—A walk-through of the proposed changes to guarantee the "fix" is not going to unintentionally impact other parts of the system.
7. *Nassi-Shneiderman Charts (Chapin Charts)*—A chart detailing the internal logic of a module.
8. *Programmer Librarian*—A designated person who handles the clerical activities of programming.
9. *Pseudocode*—An informal documentation method representing structured programming logic.
10. *Regression Techniques*—Analytical techniques which are capable of comparing different versions of the system and indicating differences.
11. *Structured Design*—A set of design guidelines to be used at the modular level.
12. *Structured Programming*—A programming technique based on the combination of three basic forms resulting in programs which can be easily read, modified and maintained.
13. *Structured Testing*—Testing guidelines which require that the number of tests not be less than the cyclomatic complexity.
14. *Top-Down Design*—A design strategy which constantly seeks to factor a problem into its smallest parts.
15. *Top-Down Implementation*—Coding in a top-down fashion or the higher level modules first.
16. *Top-Down Testing*—Testing the higher-level modules of a system before the lower-level modules.

# A Markovian model for reliability and other performance measures of software systems\*

by AMRIT L. GOEL and KAZU OKUMOTO

Syracuse University  
Syracuse, New York

## INTRODUCTION

Several studies have been undertaken in recent years to investigate the software failure phenomenon, with the objective of developing analytical models for quantitative assessment of software performance. Most of these studies assume that the times between software failures follow an exponential distribution with a failure rate that depends on the number of errors in the system (see, for example, Jelinski and Moranda,<sup>5</sup> Littlewood and Verrall<sup>6</sup> and Shooman<sup>11</sup>). A key assumption made in most of these studies is that the errors are removed with certainty when detected. However, as pointed out in Miyamoto<sup>7</sup> and Thayer *et al.*,<sup>12</sup> errors are not always corrected when detected. The existing models do not provide a solution for such situations.

In this paper we develop a Markovian model, which we call an Imperfect Debugging Model (IDM), for studying software failures when errors are not removed/corrected with certainty, i.e., for the case of imperfect debugging. Also, expressions are derived for the following probabilistic performance measures:

- Time to a completely debugged system.
- Time to a specified number of remaining errors.
- Number of remaining errors at time  $t$ .
- Number of errors detected by time  $t$ .
- Reliability function.

Actual failure data from a large Department of Defense (DoD) software project are analyzed and the results compared with the observed values.

## MODEL DEVELOPMENT

The following assumptions are made for developing the model:

1. An error causing a software failure, when detected, is corrected with probability  $p$ , while with probability

$q(p+q=1)$  we fail to completely remove it. Thus,  $q$  is the probability of imperfect debugging.

2. The time,  $T_i$  to a software failure, when  $i$  errors remain in the system, follows an exponential distribution with parameter  $i\lambda$ . The parameter  $\lambda$  represents the mean error occurrence rate per unit time.
3. The time to remove an error will be neglected in this model.
4. No new errors are introduced during the debugging process.
5. At most, one error is removed at correction time.

Let  $X(t)$  denote the number of errors remaining in a software system at time  $t$ . We will use this random variable to describe the behavior of the error removal process as a function of time. Further, let  $N$  be the number of errors at the beginning of the debugging phase, i.e.,  $X(0)=N$ .

Suppose that there are  $i$  errors in the package at some time. Then from Assumption 1, we note that after the occurrence of the next failure

$$X(t) = \begin{cases} i-1 & \text{with probability } p \\ i & \text{with probability } q \end{cases} \quad (1)$$

In other words, if we were to observe the  $X(t)$  process at times of software failures, then its behavior is governed by Equation 1. The transition probabilities  $P_{ij}$  from state  $i$  to state  $j$  are given by

$$P_{ij} = \begin{cases} p & j=i-1 \\ q & j=i \\ 1 & i=j=0 \\ 0 & \text{otherwise} \end{cases} \quad i, j=0, 1, 2, \dots, N. \quad (2)$$

A diagrammatic representation of transitions between states corresponding to Equation 2 is given in Figure 1.

Assumption 2 implies that the Probability Density Function (PDF) and the Cumulative Distribution Function (CDF) of the random variable  $T_i$  are, respectively given by

$$f_i(t) = i\lambda \cdot e^{-i\lambda t} \quad (3)$$

and

$$F_i(t) = 1 - e^{-i\lambda t}. \quad (4)$$

We note that even though the stochastic process  $X(t)$

\* This work was supported by the Air Force Systems Command's Rome Air Development Center, Griffiss Air Force Base, NY.

Figure 1—A diagrammatic representation of transitions between states of  $X(t)$ .

makes transitions from state to state in accordance with Equation 2, the times spent in various states are random and are given by Equation 3. Hence, the process  $\{X(t), t \geq 0\}$  forms a semi-Markov process (see, for example, Ross<sup>9</sup>). A typical realization of this process is shown in Figure 2. It should be pointed out that in our formulation the process  $X(t)$  undergoes both real and virtual transitions. This means that after an attempt to remove an error the state of  $X(t)$  may change or may remain unchanged. In Figure 2, real transitions occur at states  $N, N-2$  and  $i$  while a virtual transition occurs at state  $N-1$ .

Figure 2—A typical realization of the  $X(t)$  process.

Let  $Q_{ij}(t)$  denote the one-step transition probability that, after making a transition into state  $i$ , the process  $X(t)$  next makes a transition into state  $j$  by time  $t$ . In other words, if a software package has  $i$  remaining errors at time zero, then  $Q_{ij}(t)$  represents the probability that the next failure, resulting in  $j$  remaining errors, will be by time  $t$ . Then, we can show that

$$Q_{ij}(t) = P_{ij} \cdot F_i(t) \tag{5}$$

for  $i, j=0, 1, 2, \dots, N$ . Substituting (2) in (5) yields

$$Q_{ij}(t) = \begin{cases} pF_i(t) & j=i-1 \\ qF_i(t) & j=i \\ 1 & j=i=0 \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

For known parameters  $N, p$  and  $\lambda$ , the probabilities  $Q_{ij}(t)$  are obtained from Equation 6. This equation represents the basic model that will be used in the following sections for obtaining the various performance measures for software systems.

### EXPRESSIONS FOR PERFORMANCE MEASURES

#### *Distribution of time to a completely debugged software system*

Suppose  $i$  is the number of errors remaining in a software system at some time during the debugging process and let  $G_{i,0}(t)$  represent the probability that the time required to go from  $i$  to 0 errors is less than or equal to  $t$ . In other words,  $G_{i,0}(t)$  represents the CDF of the time required to get a completely debugged system when the current number of remaining errors is  $i$ .

Recall that at time zero,  $X(0)=N$  and at the time of the first failure

$$X(t) = \begin{cases} N-1 & \text{with probability } p \\ N & \text{with probability } q \end{cases} \tag{7}$$

as shown in Figure 1. Suppose that the debugging at the first error occurrence is perfect. Then the probability of going from  $N$  to  $N-1$  errors in time  $[u, u+du]$  is given by  $dQ_{N,N-1}(u)$ . If the system clears an error at time  $u$ , then the process  $X(t)$  restarts with  $(N-1)$  remaining errors at time  $u$  and the probability of going from  $N-1$  to 0 in time  $t-u$  is  $G_{N-1,0}(t-u)$ . Hence the probability of going from  $N$  to 0 in time  $t$  is

$$\int_0^t G_{N-1,0}(t-u) \cdot dQ_{N,N-1}(u) = Q_{N,N-1} * G_{N-1,0}(t), \tag{8}$$

where  $*$  denotes convolution.

Similarly, if the debugging at the first error occurrence is imperfect, the probability of going from  $N$  to 0 in time  $t$  is

$$\int_0^t G_{N,0}(t-u) \cdot dQ_{N,N}(u) = Q_{N,N} * G_{N,0}(t). \tag{9}$$

Since the events depicted in Equations 8 and 9 are mutually exclusive, we get the renewal equation

$$G_{N,0}(t) = Q_{N,N-1} * G_{N-1,0}(t) + Q_{N,N} * G_{N,0}(t). \tag{10}$$

In general, we get the renewal equation

$$G_{i,0}(t) = Q_{i,i-1} * G_{i-1,0}(t) + Q_{i,i} * G_{i,0}(t) \tag{11}$$

for  $i=1, 2, \dots, N$

where  $G_{0,0}(t)=1$ .

Using the Laplace-Stieltjes (L-S) transform technique (see Ross,<sup>9</sup> for example) to solve the renewal Equation 11, we obtain the probability that the software system will be completely debugged by time  $t$  as

$$G_{N,0}(t) = \sum_{j=1}^N C_{N,j} (1 - e^{-jp\lambda t}). \tag{12}$$

where

$$C_{N,j} = \binom{N}{j} (-1)^{j-1}.$$

*Distribution of time to a specified number of remaining errors*

In many instances a completely debugged software is not cost-effective and we may be willing to tolerate a certain number of remaining errors, say  $n_0$ , which will ensure some desired reliability. The distribution of time to  $n_0$  is then of interest.

Using an approach similar to the one above, we get the renewal equation

$$G_{i,n_0}(t) = Q_{i,i-1} * G_{i-1,n_0}(t) + Q_{i,i} * G_{i,n_0}(t), \tag{13}$$

for  $i=n_0+1, \dots, N$

where  $G_{n_0,n_0}(t)=1$ . Then the probability that the software system will have  $n_0$  errors by time  $t$ , starting with  $N$  errors at time 0, is obtained by

$$G_{N,n_0}(t) = \sum_{j=1}^{N-n_0} B_{N,j,n_0} \{1 - e^{-(n_0+j)p\lambda t}\}, \tag{14}$$

where

$$B_{N,j,n_0} = \frac{N!}{n_0! j! (N-n_0-j)!} (-1)^{j-1} \frac{j}{n_0+j}.$$

*Distribution of number of remaining errors*

Let  $P_{N,n_0}(t)$  represent the probability that there are  $n_0$  errors remaining in a software package at time  $t$ , given that there are  $N$  errors at the beginning of debugging, i.e.,

$$P_{N,n_0}(t) = P\{X(t) = n_0 | X(0) = N\}$$

which is the so-called state occupancy probability. Conditioning on the next failure and following an approach similar to the above, we get the following renewal equations:

$$P_{n_0,n_0}(t) = e^{-n_0\lambda t} + Q_{n_0,n_0} * P_{n_0,n_0}(t), \quad N \leq n_0, \tag{15}$$

$$P_{N,n_0}(t) = P_{n_0,n_0} * G_{N,n_0}(t), \quad n_0 < N. \tag{16}$$

The distribution of the number of remaining errors at time  $t$  is

$$P_{N,n_0}(t) = G_{N,n_0}(t) - G_{N,n_0-1}(t), \quad n_0 = 0, 1, 2, \dots, N \tag{17}$$

where

$$G_{N,N}(t) = 1,$$

$$G_{N,-1}(t) = 0.$$

Finally, the expected number of remaining errors in the software at time  $t$  is

$$E[X(t) | X(0) = N] = \sum_{n_0=0}^N n_0 P_{N,n_0}(t) = N e^{-p\lambda t}. \tag{18}$$

From Equation 18, we note that the number of errors remaining in the software system is expected to decrease exponentially over the debugging time.

*Expected number of errors detected by time t*

We introduce a new random variable  $N(t)$  which denotes the total number of errors detected by time  $t$ . The process  $\{N(t), t \geq 0\}$  is called a counting process. We are interested in obtaining the expression for the expected number of errors detected,  $M_N(t)$ , during the debugging period,  $t$ , when the initial number of errors is  $N$ , i.e.

$$M_N(t) = E[N(t) | X(0) = N]$$

which is called a Markov renewal function. By conditioning on the next software failure, we obtain the renewal equations

$$M_j(t) = F_j(t) + p M_{j-1} * F_j(t) + q M_j * F_j(t), \quad j=1, 2, \dots, N \tag{19}$$

where  $M_0(t)=0$ . From (19) we obtain

$$M_N(t) = \frac{N}{p} (1 - e^{-p\lambda t}). \tag{20}$$

By taking the derivative of (20) we can get the error detection rate at time  $t$ ,

$$M'_N(t) = N\lambda e^{-p\lambda t} \tag{21}$$

which is exponentially decreasing over time. This implies that more errors are detected during the early stages of debugging. Note that if we let  $t \rightarrow \infty$  we have

$$M_N(\infty) = \frac{N}{p}$$

which is the expected number of software errors detected by the end of debugging.

Let us now consider the case when the detected errors are separated as new errors and errors which were not corrected due to imperfect debugging. Let  $N_I(t)$  be a random variable which denotes the total number of imperfect debugging errors by time  $t$ . Then we can show that

$$D_N(t) = q M_N(t), \tag{22}$$

where

$$D_N(t) = E[N_I(t) | X(0) = N].$$

Note that  $D_N(\infty) = q \frac{N}{p}$ . Equation 22 implies that 100q percent of the software failures during debugging will be due to imperfect debugging.

*Software system reliability*

So far we have studied the stochastic behavior of the number of errors in the software system during the debugging period. Now we investigate the distribution of the time between software failures and study the problem of reliability growth. From the second section recall that the random variable  $T_i$  denotes the time to next failure when the number of remaining errors is  $i$  and  $F_i(t)$  is the CDF of  $T_i$ . Let  $X_k$  denote the time between the  $(k-1)$ st and  $k$ th software failures and  $\Phi_k(x)$  be the CDF of  $X_k$ . Note that  $X_k$  does depend on the number of remaining errors at the  $(k-1)$ st failure but this number is not explicitly known. Further, let  $\eta_k$  be a random variable which denotes the number of remaining errors between the  $(k-1)$ st and  $k$ th software failures. Then, from the second section we have

$$\begin{aligned} \eta_1 &= N \\ \Phi_1(x) &= F_N(x), \end{aligned}$$

and

$$\Phi_2(x) = pF_{N-1}(x) + qF_N(x).$$

In general, we have

$$\Phi_k(x) = p(X_k \leq x) = \sum_{i=N-(k-1)}^N p(X_k \leq x | \eta_k = i) p(\eta_k = i)$$

or

$$\Phi_k(x) = \sum_{j=0}^{k-1} p[X_k \leq x | \eta_k = N - k + j + 1] p(\eta_k = N - k + j + 1)$$

or

$$\Phi_k(x) = \sum_{j=0}^{k-1} \binom{k-1}{j} p^{k-j-1} q^j F_{N-(k-j-1)}(x). \tag{23}$$

This is called a mixture of exponential distributions with binomial mixing portions. It can be shown that  $\Phi_n(x)$  is a Decreasing Failure Rate (DFR) distribution. The reliability function at the  $k$ th stage, i.e., between  $(k-1)$ st and  $k$ th failure, is given by

$$\begin{aligned} R_k(x) &= p\{X_k > x\} \\ &= 1 - \Phi_k(x) \\ &= \sum_{j=0}^{k-1} \binom{k-1}{j} p^{k-j-1} q^j \bar{F}_{N-(k-j-1)}(x) \end{aligned} \tag{24}$$

where in general

$$\bar{F}_N(x) = 1 - F_N(x) = e^{-\lambda x}.$$

From a practical point of view the reliability obtained in (24) is not easy to work with. For computational purposes we use the following approximation.

$$R_k(x) \sim e^{-[N - p(k-1)]\lambda x}, \quad k=1, 2, \dots \tag{25}$$

For details of this approximation, see Goel and Okumoto.<sup>2</sup>

APPLICATION TO A LARGE SOFTWARE PROJECT

In this section we analyse the error data from a large software project and compute various performance measures using the results of the two preceding sections. The error data is taken from Fries,<sup>1</sup> and represents software errors from a large DoD systems development project. The project consisted of approximately 320,000 assembly language instructions. It included the operational software and the simulation software necessary to develop and test the former. Software Problem Reports (SPRs) were written in the time period from the beginning of configuration management (approximately start of integration testing) to delivery of the software. A total of 2036 SPRs were encountered during this period and they were categorized into 20 major groups. Data are also included about the source of errors, the type of correction made, and the time to find and fix the error.

For purposes of this analysis, we consider 1612 errors reported during the last 12 months of the software testing phase. For estimating the parameters  $N$ ,  $p$  and  $\lambda$  we use the method given in Goel and Okumoto.<sup>3</sup> The estimated values of these parameters are

$$\hat{N} = 2108, \quad \hat{p} = 0.936 \quad \text{and} \quad \hat{\lambda} = 0.1127.$$

Substituting  $\hat{N}$ ,  $\hat{p}$  and  $\hat{\lambda}$  for  $N$ ,  $p$  and  $\lambda$ , respectively, in Equation 18, the estimated value of the expected number of remaining errors over the testing period  $t$  is obtained as

$$\hat{E}[X(t) | X(0) = \hat{N}] = 2108 e^{-(.936)(.1127)t}.$$

A plot of this quantity is shown in Figure 3. Also shown in this figure are the observed values by month. The fitted curves for  $M_N(t)$  and  $D_N(t)$  from Equations 20 and 22 are shown in Figure 4 along with the actual values for these quantities. From Figures 3 and 4 we see that the model seems to describe the behavior of the software error phenomenon very well.

The reliability function for the system is obtained from Equation 25 as

$$\hat{R}_k(x) = e^{-[2108 - .936(k-1)](0.1127)x}.$$

Plots of reliability for  $k=1613(50)1863$ , i.e., for the cases when the number of errors removed is 1612(50)1862, are shown in Figure 5. From these plots the extent of reliability growth with  $k$  can be easily evaluated. For example,  $R_{1613}(0.1) = 0.24$  while  $R_{1863}(0.1) = 0.74$ , i.e., the value of  $R(0.1)$  increases by 200 percent when  $k$  goes from 1613 to 1863.

The plots in Figure 5 can also be used to determine the expected time required to achieve a desired reliability. Suppose our objective is to have a reliability of 0.3 at 0.2 weeks.

Figure 3—Plots of the number of remaining errors and the fitted curve.

Figure 5—Plots of the reliability function for various values of  $k$ .

We want to know the number of errors that must be removed to achieve this reliability. In other words we want to know the value of  $k$  that yields  $R_k(0.2)=0.3$ . From Figure 5, we see that  $R_{1813}(0.2)=0.3$  so that  $k=1813$  errors to achieve desired reliability for the software system. Then the number of remaining errors will be

$$\hat{n}_0 = 2108 - .936(1813 - 1)$$

or

$$\hat{n}_0 = 412.$$

Figure 4—Total and imperfect debugging errors by month.

The expected time required to remove  $(N - n_0)$  errors is

$$\mu_{N, n_0} = \frac{1}{p\lambda} \sum_{j=n_0+1}^N \frac{1}{j} = \frac{1}{p\lambda} \ln \frac{N-1}{n_0+1}.$$

For our case, we get

$$\hat{\mu}_{2108, 412} = \frac{1}{(0.936)(0.1127)} \cdot \ln \frac{2108+1}{412+1} = 15.46 \text{ months.}$$

In other words, to achieve the desired reliability, we will need to continue testing for  $15.46 - 12 = 3.46$  additional months.

### CONCLUSION

We have developed an imperfect debugging model (IDM) for software systems and derived expressions for various performance measures in terms of the first passage time distribution of the underlying semi-Markov process. The failure data from a large software project were analyzed using the model developed in this paper. A comparison of the fitted and the observed values indicates that the model provides a good description of the underlying failure phenomenon. Also, reliability curves were used to determine the debugging time required to achieve a desired level of software system performance.

# Partial match retrieval for non-uniform query distributions\*

by V. S. ALAGAR and C. SOOCHAN

Concordia University  
Montreal, Canada

## INTRODUCTION

A good file design and investigation of reasonably fast and efficient algorithms to perform a required task on the information stored in the file are important in data base studies. In a reasonably large class of problems one can devise and evaluate algorithms with respect to measures independent of the storage and structuring of data. But when the question is the investigation of a suitable data structure for retrieval of a specific kind, algorithms and their measures depend heavily on the proper file design. This paper addresses both file design and algorithm design when searches are to be made in a data base for queries of special type.

We are concerned with information retrieval based on secondary keys. In general the secondary keys form a subset of the attributes of a record and, thus, they can not uniquely identify a record. We view a secondary key as a  $k$ -tuple  $(i_1, \dots, i_k)$ , where  $i_1, \dots, i_k$  is a subset of the attributes. The standard methods of whole key comparisons cannot be done and hence the complexity measures for search problems involving secondary keys are different.

Several authors, notably Schkolnick,<sup>11</sup> have given methods to select an optimal or near optimal subset of attributes for indexing under suitable assumptions on the probability distributions of transactions to be done on the data base. Another approach to handle multi-attributed files is to design tries, originally proposed by de la Briandais<sup>7</sup> and Fredkin.<sup>8</sup>

A trie is essentially a  $k$ -ary tree whose leaves correspond to records and each internal node is a vector with components corresponding to attribute values. Each node on Level  $j$  specifies the set of all secondary keys that begin with a sequence of  $j$  characters and the node specifies a  $k$ -way branch depending on the  $(j+1)$ st attribute.

Recently, considerable interest has been shown in the design of good tries for handling partially-specified queries. Partial match retrieval is concerned with searching and accessing those records that satisfy the given query, although only fewer than  $k$  attribute positions are specified in the query. A survey of the software and hardware requirements for such associate retrieval problems is given in Minker.<sup>9</sup>

Rivest<sup>10</sup> is the first to propose and use tries for partial match searching on binary attributed files. He discusses the

average case behavior of tries for uniform data and uniform query patterns. One of his conclusions is the conjecture that if  $s$  out of  $k$  attributes are specified in a query and there are  $N$  buckets, the average number  $A$  of buckets examined must be at least  $N^{1-s/k}$ . This analysis for tries shows that the average  $A$  is close to  $N^{\log_2(2-s/k)}$ .

Burkhard<sup>3-5</sup> has investigated partial match file designs and in particular gives methods to construct tries with good-worst case performance. Bentley and Burkhard<sup>2</sup> have suggested several strong heuristics for the design of tries to handle partial match retrieval on real life files.

We report our preliminary results on the construction and performance of tries for non-uniform data and non-uniform query patterns. Rivest suggested this as an open problem. The methods to be discussed here have a strong bearing on the characteristics of the records in a file and assume a known probability distribution on the query patterns. The concept of non-uniformity is thus different from the one used in Reference 5. Our empirical results and statistics gathered on exhaustive testing are reported in the fifth section. These results convincingly indicate that the tries constructed handle partially specified queries better both in the average and in the worst case; the average case performance is better than the one reported by Rivest<sup>10</sup> and the worst case results are better than the one reported by Burkhard.<sup>4</sup>

## DEFINITIONS AND PRELIMINARY RESULTS

In this section we define the basic notions of record, file, query and trie. Some examples are also given. Let  $A_1, \dots, A_k$  be a finite set of attributes, where  $A_i$  takes values from a domain  $D_i$ ,  $1 \leq i \leq k$ . A record  $R$  is defined to be an ordered  $k$ -tuple  $(r_1, \dots, r_k)$ , where  $r_i$  is in  $D_i$ . A file  $F$  is a collection of records and thus a subset of  $D_1 \times D_2 \times \dots \times D_k$ . Thus every record has the same number of attributes and we do not consider records with variable number of attributes. A key is an ordered  $k$ -tuple and is an element of  $F$ . A fully specified query is an element of  $D_1 \times \dots \times D_k$ . A partially specified query is an element of  $(\prod_1^k (D_i U \{*\}))$ , where the  $*$  indicates the unspecified of a component. One can regard this special symbol to mean a 'don't care' condition. Any record which matches the specified  $q$  values is relevant for this query. We restrict ourselves to the special case when each  $D_i = \{0, 1\}$  and we say that  $F$  is a binary attributed file.

\* This research is supported by National Research Council Grant A 3552.

We let  $Q$  denote the set of all queries, i.e. the set of all sequences of length  $k$  over the alphabet  $(0, 1, *)$ . Thus, the cardinality  $|Q|=3^k$ . Let  $Q_s$  denote the set of all queries in each of which exactly  $s$  positions are specified (thus there are  $u=k-s$ 's). It is easy to see that  $|Q_s|=\binom{k}{s}2^s$ . For any query  $q_s$  in  $Q_s$ , we let  $q_s(f)$  denote the set of records each matching  $q_s$  in the  $s$  specified components. *Example 1*—Let  $k=3$  and

$$F=\{001, 011, 100, 101, 111\}$$

The query  $q_1=(0, *, 1)$  requests all records with  $r_1=0$  and  $r_3=1$  without any regard to  $r_2$  value. Thus  $q_1(F)=\{001, 011\}$ . The set of all queries for  $s=2$  is

$$Q_2: \begin{aligned} & (*, 0, 0), (*, 0, 1), (*, 1, 0), (*, 1, 1) \\ & (0, *, 0), (0, *, 1), (1, *, 0), (1, *, 1) \\ & (0, 0, *), (0, 1, *), (1, 0, *), (1, 1, *) \end{aligned}$$

One can verify that the total number of records which are retrieved from  $F$  to answer all queries in  $Q_2$  is 15. If we assume that the queries from  $Q_2$  occur with uniform distribution then the average number of records examined to answer a query from  $Q_2$  is 1.25.

We will define a binary search trie (to be referred to simply as a trie). Each leaf node of a trie stores one record or bucket. Each internal node at level  $i$  (the root is at level 1) specifies a 2-way branch based on the  $j$ th component of the record being stored. We insist that

1. Each internal node specifies an attribute position  $j$ ,  $1 \leq j \leq k$ , such that no other node from the root to that position specifies  $j$ .
2. If attribute  $j$  is tested in a node, then all nodes in the left subtree of that node have a 0 in attribute position  $j$  and all nodes in the right subtree of that node have a 1 in attribute position  $j$ .

The records in  $F$  of Example 1 may be stored as shown in Figure 1. We have stored a record in a leaf node as soon as we find that this is the only record in its subtree. Obviously this is not the only possible trie structure for  $F$ . The trie in Figure 2 is another mode of storage for  $F$ .

A trie such as the one in Figure 1 or Figure 2 is known as a pruned trie. More formally we have the following defini-

Figure 1

Figure 2

tions:<sup>6</sup> A full binary trie for a file  $F$  is a binary tree with all leaves at level  $(k+1)$ , where  $k$  is the number of attributes in a record. The skeleton of a full trie is completely specified by the order of testing of the attributes on the trie. A pruned or collapsed trie is obtained from a full trie by deleting all empty leaves and pruning upwards until each leaf node stores one record. The decision regarding the order of testing the attributes can be made either globally (in which case all paths have the same relative order of attributes) or such a decision can be localized at each node. In the latter case the attributes might be tested in different relative orders along different paths from the root to a leaf node. A trie in which the order of testing is explicit in each node is called an O-trie. The tries shown in Figures 1 and 2 are collapsed O-tries; they have the same depth but have different shapes. If queries from the set  $\{(1, *, 0), (*, *, 0), (*, 1, 0)\}$  come more often than queries from the set  $\{(0, *, 1), (*, *, 1), (*, 0, *)\}$  then fewer comparisons need be made in Trie 2 than in Trie 1. Moreover, the number of records examined in Trie 2 is smaller than the number of records examined in Trie 1 to answer a single query from the first set.

The methods that we describe in the fourth section will construct collapsed order containing tries. Thus a record is stored as a leaf as soon as it is the only record in the subtree; this reduces the average path length from the root to a record in a random binary trie from  $k$  to about  $\log_2 N$ , where  $N$  is the size of the file. We remark that the partial match file tries considered by Burkhard<sup>4</sup> differ slightly from ours in the sense that he considers full (complete) binary tries and we get full binary tries only for the case  $N=2^k$ .

Without any regard to specific implementations, we assume that the space taken for a trie is simply the number of internal nodes in the trie. If the size of the file is small then the entire trie can be maintained in the main memory and in this case the cost of a search (or search time) is the number of internal and leaf nodes visited during the search. If the file is large, which is usually the case in real-life situations, the internal nodes of the trie can be maintained in the main memory and the leaf nodes are stored in external storage such as disk. In this case each leaf node contains more than one record; we refer to this as a bucket or a page. The cost of a search in this situation is the number of distinct accesses to the secondary storage. Since the time to search the trie itself is relatively small compared to the time needed for several accesses to the secondary storage, the cost measured

in number of buckets examined is justified. In our analysis the following is true: All buckets examined by a search contain all of the records in the data base satisfying the given partially-specified query. However, all the records in the examined buckets are not necessarily relevant to the given query. This would happen especially when a certain unspecified attribute in the given query is not chosen for testing anywhere along the search path in the trie. For example, the query 01\* will examine two buckets in the trie shown in Figure 2, although the record 100 in one of the buckets is not relevant to this query; however the other bucket examined has the record 011 which is the only relevant record for this query in the data base.

## RECORD SPACE AND QUERY SPACE

All the previous researchers in this area assumed uniform distribution for record space as well as query space. This approach presupposes that all queries from the query space are equally likely to be queried when the data base contains a set  $N(\leq 2^k)$  of records and these  $N$ -subsets are once again equally likely. Such an assumption leads to closed form results for the average case and worst case behavior of search algorithm for a trie.

But in real-life situations it is more natural to encounter non-random data. For example, consider a data base consisting of records over non-binary alphabets. Each record can be suitably coded to obtain a binary coded data base. Trie methods can be applied to this coded data base and with suitable decoding procedures querying in the original data base can be handled. In such cases the strong characteristics of the original data base and the properties must be taken into account in trie designs. Clustering, sparsity and coding influence the distribution of the binary-coded data base.

As pointed out by Rivest,<sup>10</sup> for non-random data an interesting problem is the choice of bits in order to split the file in the best possible manner. Thus, it is natural to assume that certain attributes are more often queried than others. Such an assumption must clearly reflect the relative frequency of instances of query patterns in the query space. The sample of query instances actually appearing over a period of time must be estimated in an unbiased way and must be incorporated in the construction and performance of the tries.

It is also necessary for us to remark here that the concept of randomness or non-randomness must be clearly defined so that the results can be evaluated properly. Burkhard<sup>5</sup> has discussed non-uniform partial match file designs; he achieves non-uniformity of labels within the tries. One clear accomplishment of this non-uniform distribution of labelling has been to obtain inversions of certain recurrence relations and establishing bounds for the worst case behavior. Our concept of non-uniformity is different, although our methods of trie construction based on this concept might cause non-uniform distribution of labels within the constructed tries.

In the next section we discuss three methods for construction of tries. These methods seem immensely suited to the

following problem instances—non-uniform data and uniform query pattern; uniform data and non-uniform query pattern and non-uniform data and non-uniform query pattern. The basic approach in each method is to make use of the characteristics of the records and the distribution of queries to decide the order of testing the attributes and obtain a collapsed O-trie.

## TRIE DESIGNS

We discuss three methods for constructing tries; the first one is the one suggested by Bentley and Burkhard;<sup>2</sup> the second method is appropriate to non-uniform query distributions and the last method is suitable for non-uniform record and query spaces.

*Method A*—Rivest<sup>10</sup> observes that very unbalanced tries have good average case performance. Assuming that all partial match queries are equally likely (uniform), the probability that a query will examine a node at level  $l$  in the trie is  $(2/3)^l$ ; this is because there are  $2^{3^k-l}$  queries out of  $3^k$  queries that will visit this node. Hence, a query will less frequently visit the node that is farthest from the root. This suggests that one should try to maximize the unbalance at every level in the trie, hoping to achieve global unbalance. As suggested by Bentley and Burkhard,<sup>2</sup> it seems advantageous to look several levels down in the trie in choosing a bit position to be tested at a certain level; this look-ahead scheme tries to avoid those choices of bits that would optimize locally but not globally.

The notion of unbalance with respect to a bit position can be defined in more than one way. For example, consider the file as a table of  $N$  rows and  $k$  columns. Compute  $c_1, \dots, c_k$ , where  $c_j$  is the  $j$ th column sum. Then the ratio  $c_i/(N-c_i)$  is a measure of unbalance for bit position  $i$ ; another measure for the same bit position would be the absolute value of  $(N-2c_i)$ . Whatever the choice of measure, the main idea is to choose that bit position for a level in the trie that maximizes the measure and also maximizes the unbalance of the sub-trie at that level.

Thus, a brief description of the method will be as follows: For definiteness assume the measure  $c_i/(N-c_i)$  for every bit position that is not yet selected for testing in the trie. For the full file of  $N$  records, we compute the  $k$  ratios  $c_i/(N-c_i)$  and pick  $j, 1 \leq j \leq k$  for which the ratio is maximum. The attribute  $j$  is chosen to be tested at the root. Subdivide the file into two parts so that the left sub-trie will have records that have 0 in attribute position  $j$  and the right subtrie will have records that have 1 in attribute position  $j$ . We recursively construct the sub-tries for the partitioned files.

*Example 2*—Consider the file  $F=\{a, b, c, d, e, f\}$ ,  $a=1011, b=0001, c=0110, d=1101, e=1010$  and  $f=1111$ . The trie constructed by Method A is shown in Figure 3.

*Method B*—We assume that  $P$  is a given probability matrix having  $k$  rows (one for each attribute) and three columns (for the values \*, 0, 1). The entry  $P_{i,j}$  is the probability that the  $i$ th attribute will have the value  $j, 1 \leq i \leq k, j=*, 0, 1$ . The probability associated with any query can be computed

Figure 3

from  $P$ . In real situations the most probable queries are concentrated in a small subset of the query space and the matrix is assumed to reflect such a situation.

This method is mainly concerned with  $P$  and one may assume that the record space is uniform; i.e., the  $N$  records are equally likely to be chosen from  $2^k$  records. Since a search on the trie will visit both sub-tries of a node at Level  $l$  if the attribute tested there is unspecified in the query, and the probability of unspecified of that attribute is available in the matrix  $P$ , it is important to test that attribute in the lowest possible level in the trie; for this would decrease the number of buckets examined. Towards this we choose those attributes with high probability of unspecified and test them lower in the trie and choose those with low probability of being unspecified to be tested higher in the trie. Hence, we order the probabilities that the attributes may be unspecified. If  $(j_1, \dots, j_k)$  is the ordering of the attributes corresponding to the increasing order of the probabilities of unspecified, then this is the order in which the attributes would be tested along any path from the root to a leaf node. Without any regard to the file, the previous ordering establishes a full binary trie skeleton. At the root the attribute  $j_1$  is tested; in Level 2 the attribute  $j_2$  is tested and so on. The records are stored as leaf nodes in this trie and finally the trie is collapsed to minimize the internal path length. This collapsed order-containing and order-preserving trie will retain the same relative order of testing of the attributes, i.e.,  $j_i$  is tested higher in the trie than  $j_l$  if and only if  $j_i$  precedes  $j_l$  in the ordering obtained from  $P$ . Note that not all attributes would be tested along every path from the root to a leaf node. We have reason to believe from our results that the branching decisions made on the untested bit positions are favorable both in the average and worst case analysis. The trie constructed by this method for Example 2 is shown in Figure 4.

*Method C*—Here we propose to exploit both the query space and record space and record space non-uniformity. In some sense we correlate the structure of most probable queries with record structures to choose bit positions to be tested at various levels.

From the file  $F$  considered as a  $(0, 1)$  matrix and the probability distribution matrix  $P$ , we form the product  $F \cdot P$ , a matrix with  $N$  rows and three columns. The entries in this matrix can be looked upon as 'similarity measure' between

the record space and query space. The selection of attributes and their order of testing is done as follows:

Find the minimum in the first column of  $F \cdot P$  and the maximums in Columns 2 and 3. Consider the subset of  $F$  indicated by those row numbers wherein these extremums occur. Note that these extremums may not be unique. Apply Method A to this subset of  $F$  and select that attribute number that maximizes the unbalance at the root. Partition the file so that all records with 0 in the selected attribute position will be in the left sub-trie and those with 1 in that position will be in the right sub-trie. The partitioned files and the remaining attributes are used to compute the similarity measure matrix for the sub-tries and the procedure is repeated.

Some remarks are in order regarding the methods discussed here. Method A is one of the heuristics suggested in Reference 2, but we have tried several modifications. This method is easy to implement but requires several passes over the data. If the measure is properly normalized and the measure of skewness or unbalance of every node lies between  $p$  and  $q$ ,  $0 < p < q < 1$ ,  $q = 1 - p$ , it can be shown that the amount of work necessary to construct the trie with  $N$  leaf nodes is of the order  $O(kN \log_\alpha N)$ ,  $\alpha = p^{-p}q^{-q}$ . For very large files (large  $k$  and  $N$  close to  $2^k$ ), we have tried to reduce the amount of work by considering statistical sampling of subsets of records and estimating the attribute position that maximizes the unbalance. Our empirical results on the sampling technique are not conclusive; yet in several problem instances produce a good ordering of attributes in a small amount of time. We also remark that this method is very sensitive for update (insertion, deletion) operations; i.e., requires a total reorganization to produce a good trie for dynamically changing files.

The other two methods are suited for non-uniform query and record sets. The order of testing the attributes in Method

	*	0	1
1	1/3	1/2	1/6
2	1/4	1/3	5/12
3	1/5	3/10	1/2
4	1/2	1/5	3/10

$P =$

Figure 4

B is totally independent of the record space. Thus, it is well suited for all kinds of transactions i.e., retrieval, insertion and deletion. The cost of constructing the skeleton trie includes the cost of ordering the  $k$  probabilities of unspecifications and the insertion of  $N$  records; thus, it is of the order  $O(k \log_2 k) + O(hN)$ , where  $h$  is the average internal path length of the trie. These remarks do not apply to Method C.

CONCLUDING REMARKS AND TEST RESULTS

For a given trie, one can always find a partially specified query for which the cost of search is maximum. If this query occurs more often than others in practice, the constructed trie is far from optimal even in the average case. Keeping this in mind we have given methods, wherein near optimal number of buckets are examined for "almost all" query instances. We shall clarify this notion of "almost all."

Suppose  $B_s$ ,  $A_s$  and  $W_s$  denote the optimal, average and worst case costs for answering a query with  $s$  specified attributes. Let  $Q_1$  contain the set of queries for each of which the cost of searching the trie is either close to  $B_s$  or  $A_s$  and  $Q_2$  contain those queries for each of which the cost of searching the trie lie between  $A_s$  and  $W_s$ . We say that the performance of the trie is near optimal almost everywhere (in probabilistic sense) over the query space if the following conditions are met:

1.  $|\lceil A_s \rceil - B_s|$  remains small for all  $s=0, \dots, k$ . Here  $\lceil \cdot \rceil$  is the ceiling function.
2.  $\sum_{q \in Q_2} P_r[q]$  remains small.
3.  $\sum_{q \in Q_1} P_r[q]$  is large.

TABLE I.—Uniform Query Distribution (Method A)

	K=4	u	B	T <sub>B</sub>	W	T <sub>W</sub>	A	T <sub>A</sub>	N <sup>u/k</sup>

	0	1.0	32.0	1.0	32.0	1.0	0.0	0.0		
	1	1.0	8.26	2.0	71.74	1.80	0.0	0.0		
	2	1.74	4.78	4.0	53.44	3.33	0.0	0.0		
N=24	3	4.18	2.74	8.0	13.4	6.27	13.4	6.27		
	4	10.38	1.62	15.22	2.44	12.14	3.16	12.14		
	5	24.0	1.0	24.0	1.0	24.0	0.0	0.0		

Our extensive simulation for values  $k=3, 4$  and  $5$  and the collected statistics have shown that tries constructed by Methods B and C conform to this standard. See Tables I and II. The following explanation applies to the tables:

U—Number of unspecified attributes.

B—Best Case cost (averaged over all tries with  $N$  leaf nodes).

T<sub>B</sub>—Total number of queries that achieve B.

W—Worst case cost.

T<sub>W</sub>—Total number of queries that achieve W.

A—Average case cost.

T<sub>A</sub>—Total number of queries that exceed [A].

For Method A and uniform querying, the computed average  $A_s$  satisfies the inequality,

$$N^{u/k} < A_s < N^{\log(1+u/k)}, \quad u = k - s$$

$$u \neq 0, k$$

The right side of the previous inequality is the best average cost reported and the left side is the conjectured minimum cost. See Reference 10. So one conclusion is that Method A improves the average case performance. Our empirical studies show that for large values of  $k$ , and  $N$  close to  $2^k$ ,  $A_s$  approaches  $N^{u/k}$ . This only reaffirms the earlier conjecture on the lower bound. In the case of non-uniform querying, we have observed in several cases  $A_s$  lower than  $N^{u/k}$ ; in general  $A_s$  oscillates on either side of  $N^{u/k}$ . However, according to the 'almost everywhere' concept, the average case behavior prevails almost everywhere. This is due to the fact that 'bad' queries are taken care of by

these methods. Thus, our overall conclusion is that the probability of worst case behavior is very low, the average retrieval cost prevails almost everywhere over the query space and hence the constructed tries are either optimal or near optimal.

## INTRODUCTION—COMPUTER COMPARISON MEASUREMENT PROBLEMS

The comparison of interactive computer services is a frequent, important and essential activity for those involved in selecting from among alternative remote access services available through a computer network. The comparison and selection process can be very complicated, relying on both nonmeasurable and measurable comparison criteria. Nonmeasurable criteria, such as the availability of a particular compiler, are typically easy and inexpensive to evaluate. In contrast, for those criteria which are measurable, comparison calls for an expensive process of collecting and analyzing relevant performance measurements from the network computer services under consideration. (The term "network computer services" is used to refer to interactive computer services available via a computer network). Further, if measurement is not carefully planned to accommodate certain inherent theoretical, technical and economic problems, the measurements which result may be misleading or invalid. A legitimate question arises as to whether comparison measurements should be done at all. This paper addresses the feasibility of including measurement phases in the process of comparing and selecting interactive network computer services.

Two essential problems arise when measuring interactive services. The first is developing a test workload or "scenario" that is truly representative of a real workload. "Representativeness" is a critical property since measurement experiments are designed so that the performance of an interactive service while processing the test workload is assumed to be close to what its performance would be while processing the real workload. This representativeness problem is not addressed here, but will be discussed in the accompanying paper. The second problem in measuring interactive services arises while collecting and analyzing data about the performance of a test workload. Three aspects of the data collection and analysis problem must be considered

in order to determine the feasibility of comparison measurement:

1. *Theoretical*—Do statistical techniques which provide confidence statements about the probability of having made a correct selection exist for comparing interactive services?
2. *Technical*—Does the technology exist to apply sound theoretical techniques to the measurement phases of a selection process?
3. *Economic*—Is it economically feasible to perform measurement experiments?

These aspects of the data collection and analysis problem will be discussed in turn.

## A COMPUTER SELECTION MODEL

In order to discuss the feasibility of performing computer service comparison measurements, a model of the computer selection process is presented in Figure 1. The selection process is divided into three phases, leading progressively from the set of all computer services offered by those systems on a network to the isolation of the best one. Each phase involves evaluation of the services with respect to different classes of performance criteria. At each phase, those services which fail to satisfy the respective performance criteria are eliminated. The kinds of performance criteria that are evaluated are described briefly in this section. The measurement phases are discussed in detail in the following three sections.

### *Classification of performance criteria*

In choosing the best service from several alternative network computer services, performance criteria which describe what is meant by best must be determined. These

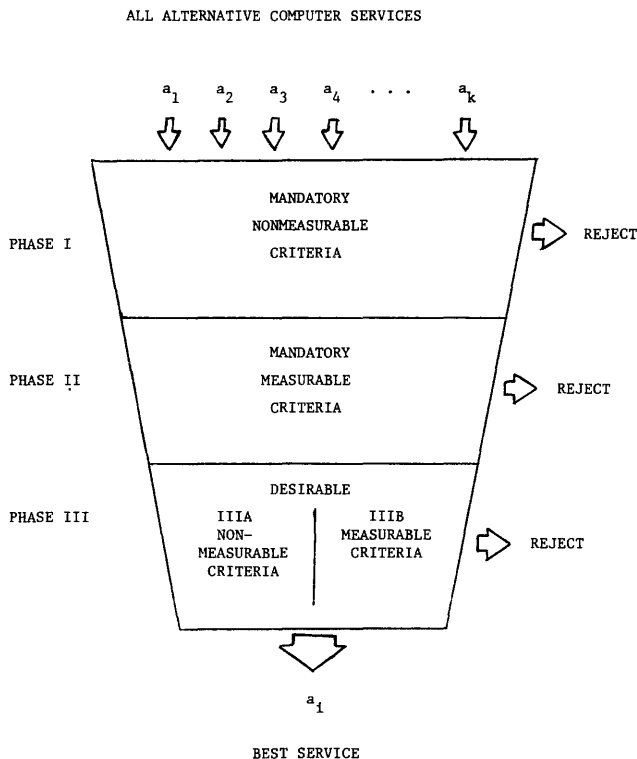

Figure 1—Computer selection model.<sup>3</sup>

criteria can be divided into those for which no empirical measurement is necessary and those whose values are derived from actual system measurements. For example, evaluating system documentation and amount of main memory does not require measurement collecting activity, whereas evaluating system turnaround time and response time for particular instructions clearly requires measurement.

Performance criteria can be divided further into those which are mandatory and those which are desirable.<sup>10</sup> Mandatory criteria are defined to be any performance requirements which must be satisfied by the computer services being considered for selection. Desirable criteria, on the other hand, are those which are not absolute requirements for system selection, but which would make the implementation of the user's work easier. Therefore, if a given network computer service does not include some desirable features, it would continue to be considered for selection, but the lack of each desirable feature would invoke some penalty on the respective computer service.

Based on the two characteristics described above, performance criteria can be classified as: Mandatory Nonmeasurable (MN), Mandatory Measurable (MM), Desirable Nonmeasurable (DN), and Desirable Measurable (DM). Examples of each class of criteria are provided in Table I.

#### Application of performance criteria

Figure 1 illustrates a sequence in which the classes of performance criteria should be applied in the process of

choosing the best network computer service. This sequence is composed of three phases. Phase I involves the application of MN criteria. This phase is managed easily since each computer service either does or does not have each required feature. All of those network computer services which do not satisfy the MN criteria are eliminated.

Phase II involves the application of MM criteria. In general, for each MM criterion, performance measurements are gathered from each network computer service and a decision is made as to whether or not the criterion is satisfied. Failure to satisfy a single MM criterion results in a service's elimination.

Finally, determination of the best alternative is made in Phase III. This phase is separated into two parts, Phase IIIA for the application of DN criteria, and Phase IIIB for the application of DM criteria. (Note: It is not implied that DN and DM criteria necessarily can be applied separately or in any particular order.) Phase IIIA requires an analyst to determine whether an alternative does or does not provide desired features. Provision of a particular desirable feature results in an alternative being credited with the "value" of that feature. This is done for all alternatives and all DN criteria.

The information required in Phase IIIB is similar to the information required in Phase II in that it can only be obtained by system management. Data are collected from each alternative network computer service being evaluated and compared, and on the basis of relative performance, one service is selected as the best. In both of these phases, comparison requires collecting and analyzing relevant performance measurements for the various network computer service alternatives under consideration—in Phase II, to select those satisfying certain mandatory performance requirements, and in Phase IIIB, to select the best remaining one. It is specifically these two measurement phases that are the topic of further discussion.

#### DATA COLLECTION AND ANALYSIS— THEORETICAL ASPECTS

A collection of measurements can often give an illusion of fairness and objectivity to a network computer service

TABLE I—Examples of Performance Criteria

TYPE	EXAMPLE
Mandatory Nonmeasurable	1. The system must be fully delivered and operational no later than September 1, 1979. 2. Timesharing service must include FORTRAN, Basic, Lisp, SNOBOL and editing facilities.
Mandatory Measurable	1. The mean-time-to-failure for a specific one month period must be greater than 4 hours. 2. 95% of all trivial command response times must be less than 1 second.
Desirable Nonmeasurable	1. It is desirable that the system include Pascal and COBOL facilities. 2. It is desired that the system provide a text editing capability.
Desirable Measurable	1. It is desired that the system provide a mean turnaround time for the benchmark run of 5 minutes or less. 2. It is desired that 95% of all trivial command response times be 0.5 seconds or less.

selection when in reality the measurements contain little information of value. This can be the case when a selection is based on methods and techniques which are not statistically sound. Suppose, for example, that an analyst executes 30 script runs on a particular network computer service, intending to use the measurements which result as a fair and objective evaluation of that service. As was demonstrated in a full-scale case study discussed in Reference 12, if the measurements are not collected properly, it is possible that as few as two or three of 30 such measurements are statistically independent. Hence, 30 measurements may be quoted as the basis for an evaluation, but in reality the actual information content is equivalent to that provided by a much smaller set of measurements. Thus, only an illusion of fairness and objectivity exists.

The above example illustrates that ignoring correlation among consecutive measurements can create a false sense of objectivity. Another problem arises if test conditions are such that the measurement error is relatively large compared to the difference between the services being compared. If appropriate statistical methods are not used to analyze the data, then the chance of selecting the best service by comparing measurement data may be no better than the chance of selecting the best service by random drawing.<sup>16</sup>

The comparison of computer services provided by a network, therefore, requires a methodology designed to lead to the selection of the best service, and to provide control of the probability of having made a correct choice. Methodologies dictated by classical statistical designs (which are inappropriate for network computer service selection) lead to regression analyses of the data, employing either analysis of variance or curve-fitting techniques. The questions that can be answered using such methodologies are of the type, "Is the performance of several alternative services the same?" (i.e. "Are the distributions of the performance measurements identical from a statistical point of view?") or "How does one particular service performance parameter depend upon the other service parameters?" In most network computer service comparison efforts, however, these questions are not appropriate. The question of real interest is, "Which service is the best?" or "How do the services rank from best to worst?" It is for problems of this type that statistical ranking and selection procedures were developed.<sup>8</sup> These procedures provide the theoretical foundation for valid measurement phases in a network computer service selection effort.

Statistical ranking and selection procedures are appropriate for three types of computer service comparison problems—ranking services by 1) comparing sample means, 2) comparing sample percentiles and 3) comparing sample proportions. In all three cases, the procedures specify the number of data points which must be collected from each service in a comparison study (or they specify a selection rule) in order to guarantee that the probability of a correct selection be at least a predetermined minimum value.

The use of a mean, percentile or proportion statistic for network computer service comparison is an analyst choice based on considerations about the comparison study's objectives, the statistical properties of the data, and the statis-

tical requirements of the selection methodology. Means often are used for comparisons when criteria such as script turnaround time or script cost are of interest because these performance measures tend to have approximately normal distributions. For comparison criteria such as response times for various types of interactive commands, which tend to have exponential-like distributions,<sup>7,15</sup> the mean is not as informative a statistic. Percentiles or proportions are more appropriate.<sup>4-6</sup>

A detailed description of how the three classes of statistical ranking and selection procedures can be applied to computer comparison studies has been presented in several recently published reports.<sup>2,3,11,12</sup> In general, the procedures provide information regarding the natural ordering of a set of  $k$  distributions, where each distribution is summarized by some (unknown) parameter like its mean or a specific percentile value. The procedures determine how the  $k$  parameters rank with respect to a prespecified standard (Phase II in Figure 1) or with respect to each other (Phase IIIB in Figure 1). The ranking is accomplished by collecting sample observations and computing an appropriate statistical estimate for each of the parameters. These estimates are then numerically ordered and, depending on the goal of a selection, inferences are drawn about the true population parameters (i.e., their true ranking). A variety of assumptions concerning the populations and data collection process can be made. These include assumptions regarding the underlying form of the distributions (e.g. normal, gamma) and the level of dependence between obtained observations.

A procedure for making a selection based on proportions is presented below as an example. Suppose a representative test workload (script) has been prepared to be run on several computer services available on a network, and it is desired to select those computer services which can run the script in 10 minutes or less at least 80% of the time. (Turnaround time is variable due to uncontrolled external influences such as other users of the service.) The procedure for making the selection is given in four steps. Assume the following definitions:

- $k$ —Number of alternative computer systems in a study
- $P^*$ —Desired level of confidence in the correctness of the selection results
- $n$ —Number of measurements collected from each computer system
- $C(thld)$ —Criterion threshold value; i.e., mandatory value for a particular performance measure (10 minutes for the above criterion)
- $X(i)$ —Number of measurements from the  $i$ th computer system which are less than  $C(thld)$
- $p(min)$ —Minimum proportion of measurements which must be less than  $C(thld)$  (80% for the above criterion)

This procedure for selection assumes that measurements are independent and that measurements from the same computer service have a common probability of being less than  $C(thld)$ . The procedure makes no assumption about the underlying form of the distribution of the data.

*Step 1*—Choose appropriate  $P^*$ ,  $C(thld)$  and  $p(min)$  values according to nonstatistical considerations.

*Step 2*—Collect  $n$  independent measurements from each of the  $k$  computer systems. The analyst chooses  $n$  based on nonstatistical considerations, bearing in mind that as  $n$  increases, more accurate estimates of each alternative's proportion will be attained.

*Step 3*—Let  $X(i)$ =number of measurements from system  $i$  which are  $<C(thld)$ . Note that since  $n$ , the total number of measurements made, is identical for each computer system, the  $X(i)$  values can be used to estimate a ranking of the true proportions.

*Step 4*—For each system, compare  $X(i)$  to a constant  $M$ , which is derived from ranking and selection theory. If  $X(i) \geq M$ , then include the computer system in the selected subset; otherwise eliminate it.  $M$  is determined by table lookup based on the parameters  $k$ ,  $n$ ,  $P^*$  and  $p(min)$ . Extensive values for  $M$  are tabulated in Reference 3 and also appear in Reference 12.

The conclusion to be drawn from the development of statistical ranking and selection techniques which are appropriate for computer comparison is that *theoretically*, statistically sound techniques are available for using mean, percentile or proportion statistics in either Phase II (evaluation of mandatory measurable criteria), or Phase IIIB (evaluation of desirable measurable criteria) of the selection process. (It should be noted that ranking and selection theory does not meet fully the needs of computer comparison experiments. Some extensions to the theory have been made<sup>9</sup> and several more are currently under investigation.) The next section discusses the technical feasibility of applying these techniques in actual network computer service comparison studies.

#### DATA COLLECTION AND ANALYSIS—TECHNICAL ASPECTS

A large-scale feasibility case study was conducted at the National Bureau of Standards to evaluate the time and cost required to apply statistical ranking and selection techniques in a computer service comparison study. Four large-scale heterogeneous remote-access time sharing systems were compared: a DEC System-10 running a TOPS-10 Monitor, a Honeywell 6180 running MULTICS, an IBM 360/65 running MVT/TSO and a UNIVAC 1108 running Exec 8. The major goal of the study was to determine if it was technically feasible, given modern measurement technology (such as automatic measurement machines and automatic interactive script drivers), to collect the amount of data generally required for analysis when using ranking and selection procedures. The specifications for the case study and the experimental results are presented here.

##### *Scenario and scripts*

A scenario for the case study, presented in Table II, was designed to be reasonably typical of the functional requirements of a real workload. It is not intended to be, nor is it, representative of any specific user's workload. The scenario

TABLE II—Scenario for the Case Study

1.	Logon to the system
2.	Execute a COBOL search of a bibliographic database
3.	Execute a FORTRAN version of a synthetic benchmark
4.	Copy an interactive FORTRAN program file to file INTR1
5.	Edit file INTR1 correcting a syntax error
6.	Edit file INTR1 correcting a logical error
7.	Compile file INTR1
8.	Execute file INTR1 which will interactively compute the prime numbers from 1-100
9.	Delete file INTR1
10.	Logoff the system

consists of commands representing two types of remote access interactive computing: transaction processing and interactive program development and execution.

The transaction processing was implemented in a COBOL program which executed a sequential search of a bibliographic database in order to retrieve a given set of entries. The database consists of 2400 records, each of which is 132 characters long. The transaction processing was accomplished by Item No. 2 in the scenario (see Table II). A synthetic module which was capable of being adjusted for varying amounts and types of CPU and I/O activity was executed next (Item No. 3 in the scenario). The last section of the scenario (Items No. 4-9) consists of commands to debug, compile and execute an interactive FORTRAN program which computes prime numbers.

The translation of the scenario into scripts executable on each computer service required interaction with personnel who possessed a thorough knowledge of each of the four respective operating systems. For each computer service two activities were required. First, it was necessary to establish permanent program and data files for use in each script execution. Then, instructions for the actual script execution were determined, sometimes including complicated control language constructs.

The specifications for running the scripts were typical of a real selection procedure. The user is concerned with the quality of a network computer service offered during a particular time period. If this quality is within acceptable limits, then service at all other times is assumed to be acceptable. In this case study, performance data was collected from each service only between 8:30 AM and 4:45 PM, Monday through Friday, in order to compare services under normal work day conditions.

##### *Experimental data collection and analysis*

Eight performance measures were chosen for computer service comparison in the case study. They are:

1. Cost.
2. Turnaround time for the entire script execution.
3. Response time for the bibliographic retrieval (No. 2 in the scenario).
4. Response time for the FORTRAN version of a synthetic benchmark (No. 3 in the scenario).

5. Response time for the copy command (No. 4 in the scenario).
6. Response time for the first edit command (No. 5 in the scenario).
7. Response time for the second edit command (No. 6 in the scenario).
8. Response time for the interactive calculation of all prime numbers less than 100 (No. 8 in the scenario).

The hardware/software configuration for the case study is illustrated in Figure 2. The scripts were executed on each system under the automatic control of a remote terminal emulator called the Network Access Machine.<sup>13</sup> Turnaround time, response time and cost data were automatically collected for each execution of each script by a minicomputer called the Network Measurement Machine.<sup>14</sup> (Many vendors distribute remote terminal emulators, and automatic measurement machines also are readily available on the market.) The data were analyzed using a statistical package called OMNITAB.<sup>9</sup> Means, percentiles and proportions were calculated. Since all of the ranking and selection procedures used require independent measurements, correlation coefficients were also calculated. The method of ensuring independence for the experimental data is described in Reference 12.

#### Comparison results

A sufficient amount of independent data was collected from the computer services in the case study to allow for a reasonably high statistical confidence in the comparison results. The details of selecting services based on the various measurement criteria can be found in Reference 12. Based

on the full-scale case study, it was concluded that it is *technically* feasible to execute statistically sound measurement phases in a computer service comparison study. The question remains, "At what expense can the technology be applied?"

#### DATA COLLECTION AND ANALYSIS— ECONOMIC FEASIBILITY

The amount of money available for a comparison study depends on the economic resources and policies of those sponsoring the study. So the question of economic feasibility only can be answered in the context of a completely specified comparison experiment. However, cost estimates from the case study described above provide guidelines for addressing this question.

The total cost to collect measurement data and compare the four services in the case study was estimated to be \$16,600. Personnel and equipment costs are itemized according to different tasks in Table III. Each task was performed by one professional and one technical person working in cooperation on a full time basis. Personnel costs are estimated at \$200/day for each person. This represents the average "burdened" (all overhead included) cost to the federal government per day for each person.

In a typical procurement study, the equipment cost from developing and running the scripts would be absorbed by the vendors. Therefore, although these costs are noted in Table III, no figures are entered. It is assumed that the equipment costs for the data collection and analysis are part of a selection effort. These activities require a specialized hardware and software configuration for about six weeks, with an estimated cost of \$1,500.

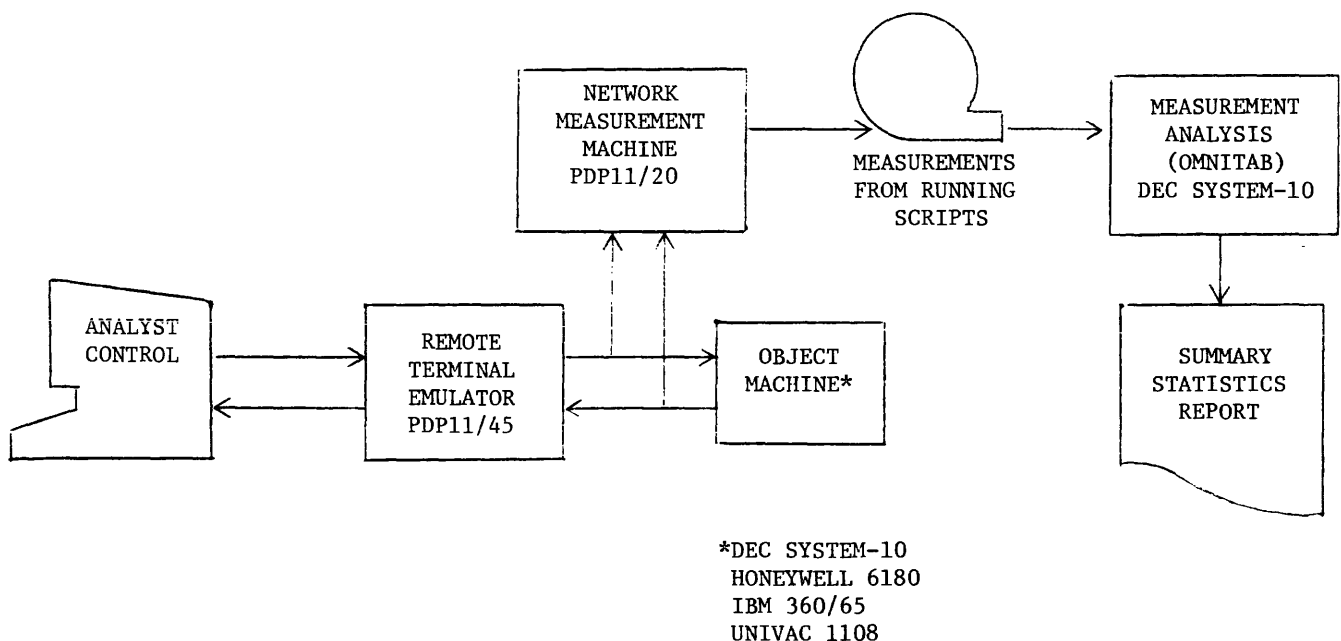

Figure 2—Hardware/software configuration for the case study.

TABLE III—Estimated Cost

A. PERSONNEL			
TASK	PERSON DAYS	COST (\$200/DAY)	
Scenario development	5	\$ 1,000	
Script generation (4 computer services)	12	2,400	
Control programs for remote terminal emulator	8	1,600	
Script runs (data collection)	30	6,000	
Data analysis	15	3,000	
Report generation	3	600	
Overhead (equipment failure, bad data, etc.)	2	400	
	75	\$15,000	
B. EQUIPMENT			
TASK	COST (\$)		
Script development (4 computer services)	*		
Script runs (150 runs/service)	*		
Data collection and analysis	\$1,600		
	\$1,600		

TOTAL COST = \$15,000 + \$1,600 = \$16,600

\* Supplied by the vendor

Since care was taken to design and execute the case study in the same way that a real computer service comparison would be done, the total cost figure of \$16,600 covers the measurement phases of a full-scale computer service comparison study. This figure, therefore, can be used as a basis for a reasonable cost estimate when making a decision about using the selection methodology in alternative comparison environments. The impact on cost due to an increase in the number of computer services or due to a change in the number of selection criteria is discussed next.

If more than four computer services are to be compared, then various personnel and equipment costs will change, but in different proportions. Time for scenario development will remain the same since only one scenario is needed regardless of the number of services being compared. The time required for script generation and for writing control programs for remote terminal emulation will increase in direct proportion to the increase in the number of services being compared. This is because time is necessary to translate the scenario into a system compatible script for each service. The total elapsed time for data collection (script runs) may remain the same or increase slightly, inasmuch as the requirement for independent measurements forces interleaving of script runs on the different services anyway. As more time is required to collect measurements, more money must be allocated for data collection equipment. The total increase for both data analysis and report generation would be about two more person-days for each additional computer service.

A change in the number of selection criteria to be applied will not have much impact on the cost of the study. Most automatic measurement devices collect data about every interactive transaction, even if it is not all required. So, increasing or decreasing the number of criteria used in a

selection has little effect on the time and cost of data collection. Also, most statistical analysis packages are as easy to run for one variable as for ten, so changing the number of criteria will have only minor effect on the time and cost of data analysis.

Based on the case study, it can be concluded that subject to certain practical constraints, it is *economically* feasible to compare services.

## CONCLUSION

The comparison of interactive computer services available through a network is a complicated process involving measurement and nonmeasurement phases. Measurement phases of a computer service comparison process can be validly executed if test workloads can be generated which are representative of real workloads, and if measurements can be made on the test workload using statistically sound techniques. This paper has discussed the theoretical, technical and economic feasibility of employing statistically sound data collection and analysis in a network computer service comparison. Based on the evidence presented and referenced here, it can be concluded that, given a representative test workload and sufficient funds to measure the performance of that workload as dictated by statistical ranking and selection procedures, accurate measurement phases can and should be included in a selection process.

# Characterizing a workload for the comparison of interactive services

by DOMENICO FERRARI

*University of California  
Berkeley, California*

## INTRODUCTION

Characterizing the workload is a necessary part of any system performance evaluation effort. This necessity is a consequence of the sensitivity of the performance indices of interest, be they productivity or responsiveness indices, to the nature, composition and intensity of the workload processed by the system being evaluated. No matter how we define it, performance cannot be expressed by quantities independent of the system's workload.<sup>1</sup>

Similarly, the performance of two or more systems cannot be meaningfully compared if these systems do not process the same workload. This statement applies not only to procurement problems, but also to problems of improvement and design, that is, whenever a performance comparison is to be made between two systems which differ from each other in some respect (see Figure 1). Since the purpose of the comparison is to expose the relative merits of the two systems, configurations, versions, architectures, or solutions through the differences between the values of some suitable performance indices, the workloads they process must be the same if their influences on these values are to be identical. Otherwise, the differences between the indices will reflect those between the workloads as well as those between the systems, and it will be difficult or impossible to distinguish the respective contributions.

The evaluation of a system's performance, or the comparison of the performances of several systems, should ideally be made under the workload that the system, or any of the competing systems, will have to process from the present to the end of its lifetime. This is, however, impossible, at least for most installations, since the workload is time-variant and its future evolution unknown. The only exception is that of those installations whose workload is constant in composition and intensity, and perfectly known (e.g., certain industrial control and manufacturing computers).

Moreover, even if the whole future workload were known (a very unrealistic assumption in the great majority of the cases), measuring or computing the performance of the system under its total workload would be impossible or impractical. A much more compact workload is therefore to be used in evaluations or comparisons. Since performance indices depend on the workload's nature and composition,

this more compact input to the system must be a model of the total workload it replaces;<sup>1,2</sup> in other words, it should accurately represent those properties of the workload which are of interest in the context where the model is to be used. And this is where the difficulties begin.

## THREE DEFINITIONS OF REPRESENTATIVENESS

In the technical literature, the term "representativeness" has been traditionally employed when referring to workloads (especially artificial ones, such as a set of benchmarks) used in performance evaluation studies. If we agree that, independent of their type, these workloads are in fact workload models, we should use the term "accuracy" instead. Perhaps, representativeness is usually preferred because of its vagueness, which very accurately reflects the lack of an exact definition of the underlying concept.

When is a workload model "representative" (or "an accurate representation") of a given workload? Probably, the most popular answer to this question is: When the model consumes the same physical resources at the same rates as the workload it tries to represent. This resource-oriented definition is unsatisfactory since

- a. It is heavily machine-dependent.
- b. The choice of the resources whose consumptions are to be considered and of the rate definitions influences the performance of the system (or systems) in a usually unknown way. For example, the set of the resources included in the characterization may be incomplete, or redundant; and, even if they are both complete and non-redundant, we generally do not know what consumption rates (overall means, moving averages, interval means, instantaneous means, or others) would be needed, or sufficient, to determine the performance indices of interest.

Drawback a is irrelevant in studies involving a system which is not supposed to be modified, for example when the capacity of an existing system is to be determined.<sup>3</sup> However, it becomes increasingly important as we move from these problems to improvement to procurement. Drawback b is unfortunately present in all contexts.

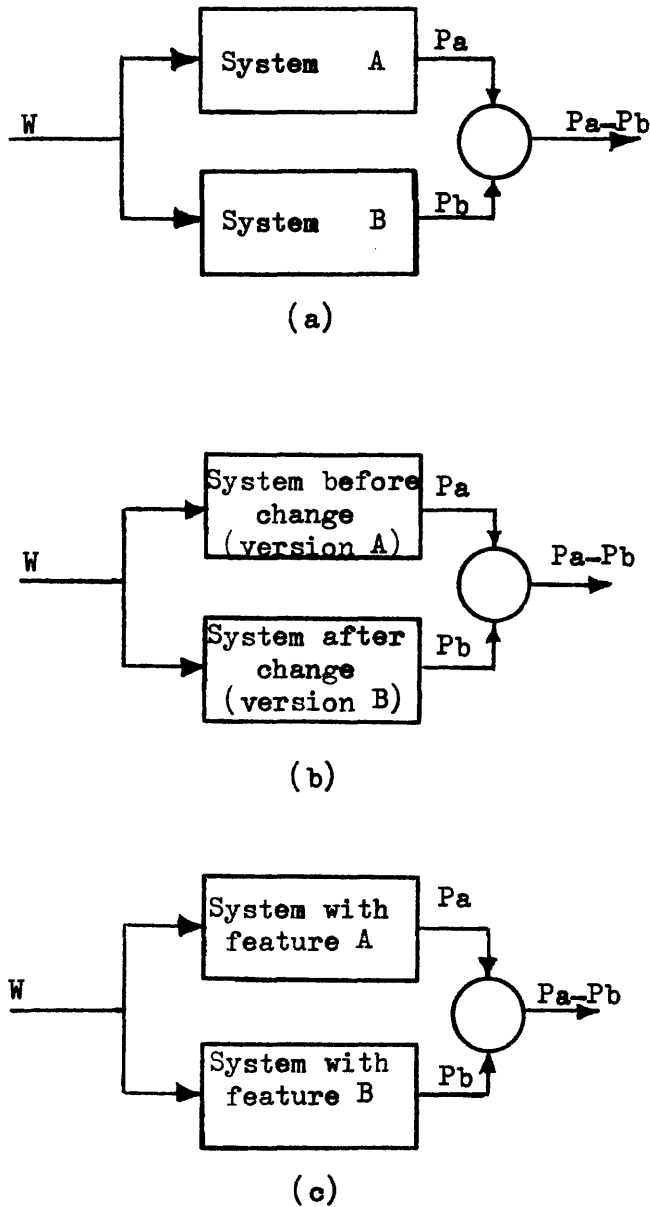

Figure 1—Conceptual schemes of performance comparison in (a) procurement, (b) improvement and (c) design environments. For the differences  $P_a - P_b$  between performance indices to reflect the relative merits of the systems being compared, these systems must process the same workload  $W$ , which is to be an accurate model of the actual workload.

An alternative definition is the one based on functional considerations: Workload  $W_b$  models workload  $W_a$  if it performs the same functions as  $W_a$ . When the workload to be modeled performs relatively few well-known tasks which are repetitively executed on large volumes of data (e.g., payroll computation, sorting, accounting, compilation, and so on), such a functional definition is in principle applicable to the case we are interested in, the one where workload  $W_b$  is to be much more compact—that is, to execute in much less time—than workload  $W_a$ . In this case,  $W_b$  may be obtained from  $W_a$  by suitably reducing the volume of

data to be processed by each of  $W_a$ 's functions; however, neither the relative proportions of the various tasks in  $W_b$  nor the criteria for choosing the input data for them can be determined by applying this workload model definition. Otherwise, the one above can only be used as a functional definition of the equivalence<sup>1</sup> between  $W_a$  and  $W_b$ , without implying or requiring that  $W_b$  be a sufficiently compact model of  $W_a$  or vice versa. An important application of functional equivalence will be illustrated.

A third answer to the question we asked at the beginning of this section may be dictated by the intended usage of the workload models to which the question refers. Since these models are to be applied in performance evaluation studies, what matters is the values of the relevant performance indices. Workload  $W_b$  is an accurate model of workload  $W_a$  for system  $S$  and performance index  $P$  if the values of  $P$  produced by  $W_b$  when running on  $S$  equal (with some error, which may be taken as a measure of the model's accuracy) those produced by  $W_a$  running on the same system<sup>2</sup> (see Figure 2). Note that  $P$  may be a set of global performance indices or of functions of such indices.

This, like the previous ones, can be seen as a definition of workload equivalence; however, unlike the functional definition, it can be applied without restrictions (except in

Figure 2—Performance-oriented definition of equivalence between two workloads  $W_a$  and  $W_b$ .  $W_b$  can be said to be a representative model of  $W_a$  with respect to  $S$  and  $P$  if  $P_a \cong P_b$  (a). If  $P'a \cong P'b$ , then  $W_b$  is a valid model of  $W_a$  even with respect to system  $S'$  (b).

the unlikely case of improperly chosen indices) to the equivalence between a workload and a compact model of it. A drawback the performance-oriented definition shares with the resource-oriented one is system dependence, but in this case the problem is one of model validity.<sup>1</sup> A model calibrated by comparing its output with that of the modeled system under certain conditions is then used under a variety of different conditions. Can it be expected to be acceptably accurate even under these conditions? In the case of a workload model, the conditions include the system *S* with respect to which the model is equivalent to the modeled workload. Let us assume that both the workload and the model can be transported, possibly by converting them, to system *S'*, which is a different version or configuration of *S*, or a totally different system. Are they still equivalent when *S* is replaced by *S'*? A general answer cannot, of course, be given. In fact, very little, if anything, is known in this area. We conjecture that some of the methods used to increase the validity of other models can be applied also to workload models. For instance, use of real instead of synthetic components and functional similarity may enhance this model's validity. Also, calibration based on performance indices more detailed than those we are interested in often widens a model's domain of validity.<sup>1</sup> If, for example, the performance indices in *P* are the mean and the variance of response times, the workload model could be calibrated taking the distribution of response times as the calibration criterion.

A definite advantage of the performance-oriented definition over the functional one is the guidance it usually provides in the design of a suitable workload model, as shall be seen below. What makes the performance-oriented definition appealing is its operational verifiability coupled with its philosophical soundness. Unfortunately, in a procurement context, the question of model validity discussed above may make the functional definition more attractive, or even, when the new system or service to be procured does not have a predecessor whose performance can be taken as a reference, the only applicable approach. In general we feel that, whenever feasible, a performance-oriented solution should be preferred, but the workload model should be made as functionally similar to the modeled workload as possible in order to widen the model's domain of validity.

### THREE LEVELS OF WORKLOAD MODELING

A workload and each one of its components (jobs, job steps, tasks, processes, interactions, transactions, and so on) may be modeled:<sup>1</sup>

1. At the physical level, i.e., by the consumptions and/or consumption rates of the resources (CPU instructions or time, main memory space, I/O channel time, disk transfers or time, disk space, and so on) of the physical machine or machines on which it is processed.
2. At the virtual level, i.e., in terms of the amounts and/or rates of the resources (higher-level language statements, virtual memory space, file accesses, data base

accesses and so on) of the virtual machine or machines on which it executes.

3. At the functional level, i.e., at the level of the applications tasks the workload has to perform.

When going from Level 1 to Level 3, the dependence of the characterization on the system decreases, while its proximity to the viewpoint of the end user increases. Thus, the end user's perception of what a workload is roughly corresponds to its characterization at the functional level, but the programmer's (or interactive user's) viewpoint is better represented by a virtual-level model. Actually, a programmer's task just consists of translating functional descriptions of workload components into programs which utilize the resources of a given virtual machine. A Level-1 equivalent of such a program is then obtained when its virtual resource demands are automatically translated into physical resource demands by language processors, the operating system, and the hardware of the physical machine. Thus, to be processed, an executable workload model must always become a physical-level model, independently of the level at which it was designed. If a model is based on a functional characterization, it has to be translated into its virtual-level equivalent, which will in turn be transformed by the system's software and hardware into a physical-level equivalent.

Our knowledge about how the variables to be used to characterize a workload can be defined and measured decreases from Level 1 to Level 3. Thus, characterization is easier at a lower level than at a higher level, and models should generally be designed at the lowest acceptable level. Different types of evaluation studies require different minimum levels of characterization. To evaluate a system's performance for such purposes as performance testing or determining the residual capacity, a Level-1 workload model is usually sufficient. In the context of an improvement study, a Level-1 model may be dependent on system aspects which could be modified as a final or partial result of the study. If this is the case, a Level-2 model will be necessary, since the comparison between the modified and the unmodified system is to be performed under the same workload, a condition hard to verify if the modifications affect the characterization on which the model is based. A Level-3 characterization will not be needed if, as is usually the case, the virtual machine will not be modified by the study. On the other hand, several different virtual machines are normally to be compared in a procurement study, which will therefore require a workload model based on a functional (Level 3) characterization.

Clearly, there are relationships between the levels at which a workload may be characterized and the definitions of workload model representativeness discussed in the previous section. The verification of functional representativeness requires a Level-3 characterization for the modeled workload and for its model. Similarly, with physical-level characterizations a resource-oriented definition of representativeness only can be used. Both the resource-oriented and the performance-oriented approaches are applicable at

any characterization level. Their common requirement is the existence of a machine on which both the workload to be modeled and its model can (at least conceptually) be run.

#### WORKLOAD MODELING FOR THE COMPARISON OF INTERACTIVE SERVICES

The general discussion in the previous sections will now be applied to the problem of procuring interactive services. We assume that a number of suppliers of computer services (single installations and/or networks) could be capable of processing a given interactive workload. The choice among them is usually made according to criteria influenced by a variety of factors. An important class of factors is that of performance indices, which in the present context are usually concerned with the responsiveness of the service to user stimuli.<sup>4</sup> One major difference between the equipment procurement problem and the service procurement problem is that system-oriented indices such as productivity and utilization, normally considered among the important ones in the former, are of no consequence in the latter.

Another difference, having the same origin, is that the workload the evaluators may analyze and, to some extent, control is only a fraction of the workload to be processed by the installations or by the networks being compared. Actually, in the procurement of computer services, we do not compare systems, but loaded systems. The fluctuations of the loads existing on the competing systems or networks make the statistical requirements of empirical comparisons, which are to be performed in an essentially uncontrolled environment, particularly demanding.<sup>5</sup>

As in all procurement contexts, the workload (which in this case is only part of the total load) must be characterized at the functional level. System independence (we should actually say "service-supplier independence"), which is necessary for the fairness of the competition, is normally achieved by preparing a scenario,<sup>6</sup> that is, a description of the functions to be performed by the model. These functions are described in a natural language and in user-oriented terms, since a formal workload description language, perhaps in the same vein as problem-statement or requirement-specification languages,<sup>7</sup> has not been developed yet. The system-independent scenario, which functionally characterizes the workload model, is then manually translated into a number of scripts, so that one or more scripts are obtained for each service to be compared. A script is a sequence of interactive commands to be input, containing information about the speeds at which they have to be typed in, and of think times between the output and the input of consecutive commands. Included in a script are also the programs whose execution is to be caused by its commands as well as the files and data bases to be accessed. Thus, the set of scripts (often consisting of only one) which are derived from the scenario for each service are, or ought to be, equivalent at the virtual level to the workload model represented by the scenario. This virtual model will then be translated into an equivalent physical model by the command interpreter, the operating system and the hardware when a remote terminal

emulator<sup>8</sup> (or some human users) inputs the scripts into the system (see the solid-line part of Figure 3).

Even though in practice much effort may be required to make sure that the scenario is translated into the scripts without unduly favoring or penalizing certain services with respect to others, and not always the results of this effort are successful, the procedure just described is philosophically unobjectionable. However, assuming that the workload is known, is the scenario a representative model of it? The answer depends on the definition of representativeness which is adopted. Most workload model designers implicitly or explicitly choose the functional definition and try to convince themselves as well as others that their scenario, while not doing exactly what the original workload does (how could it?), is indeed functionally representative. Sessions and sub-sessions are categorized according to their functions (text editing, program debugging, file manipulation, data base accessing, and so on), the frequencies of the various categories are measured, and a scenario representing a scaled-down picture of this functional characterization is somehow constructed.<sup>9,10</sup> No effort, however, can successfully conceal the large amount of subjectivity present in each decision. The lack of quantitative criteria and systematic methods makes it often necessary to resort to arbitrary choices. The situation is so hopeless that some evaluators find it easier to argue that representativeness is not important than to demonstrate that their scenarios are reasonably accurate models of a given workload. Can any improvements be made to this situation? If so, are they economically and technically feasible?

#### PRODUCING A MORE REPRESENTATIVE SCENARIO

Since the functional definition of representativeness is not easily applicable to compact workload models and does not suggest any systematic approach to model design, another definition not having these drawbacks should be considered. The performance-oriented definition is certainly an eligible candidate, but there is a major difficulty with it: What sort of performance should we use to determine whether a model is representative or not? If measurement of this performance is to be at least conceptually feasible (which is very desirable), we should choose to consider the responsiveness of a system on which the workload to be modeled can run. Assuming that such a system, to be called system Z, exists (for example, it might be the one on which the interactive applications constituting the workload were developed), there are at least two ways to proceed:

1. A scenario is designed as briefly described in the previous section: then, a set of scripts for system Z are derived from it (again as described above), executed on Z, and modified until they produce approximately the same performance as the entire workload to be modeled when running on Z: finally, either the scenario or the procedure to derive from it sets of scripts for

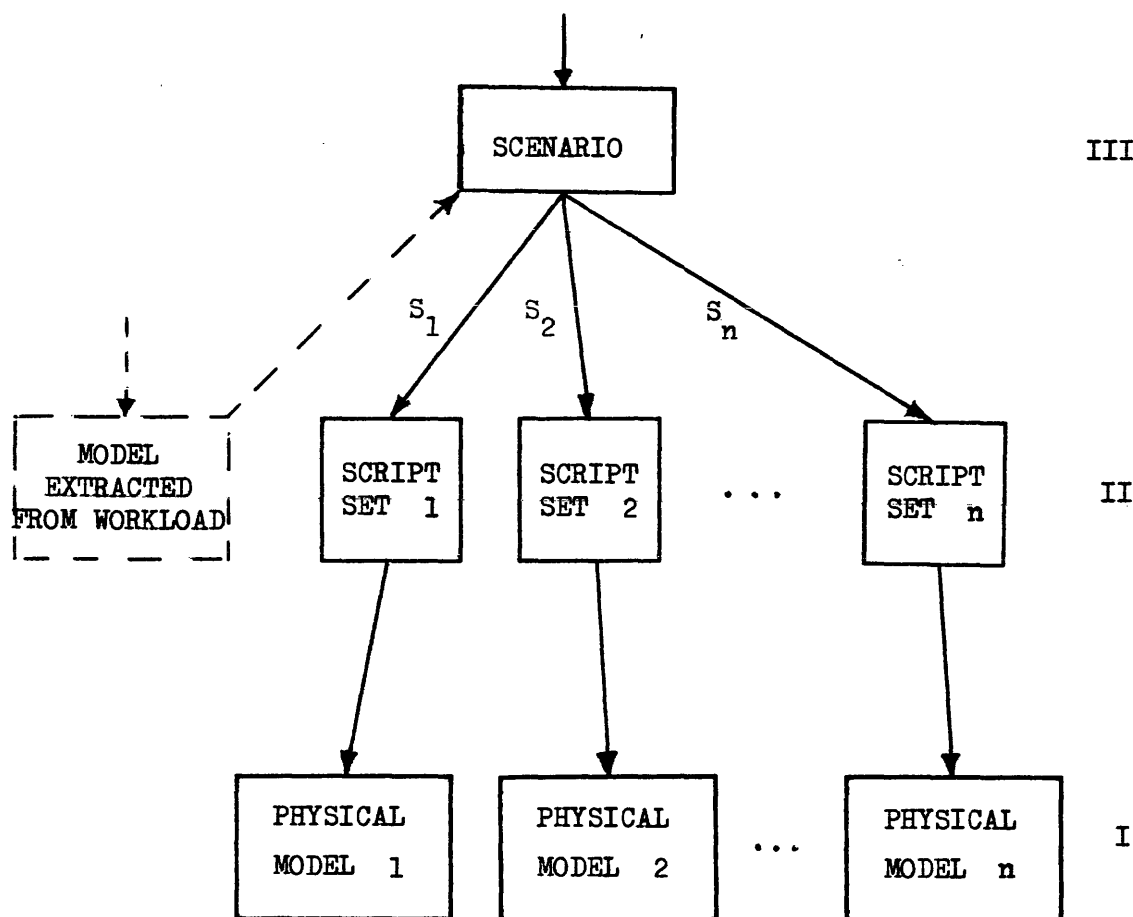

Figure 3—The tree of executable workload models for a procurement study of interactive systems or services  $S_1, S_2, \dots, S_n$ . Script sets often consist of only one script, which performs all the functions listed in the scenario.

other systems, or both, should be modified to reflect these changes.

2. A systematic method for extracting a representative scenario from a virtual-level characterization of the original workload is developed.

Approach 1 is likely to be quite cumbersome in practice, also because it probably involves a large number of measurement experiments. In principle, a method like 2, if one can be found, is certainly more attractive. The question is, therefore, whether a method for transforming an interactive workload into a much more compact one without appreciably affecting the responsiveness of a given system ( $Z$ ) can be found. Note that both workloads are assumed for convenience to be processed alone by system  $Z$ . If such a transformation is possible, the workload model should then be translated into an equivalent scenario (see the dashed part of Figure 3), an operation which is not conceptually complex but may be less than straightforward in practice when the peculiarities of system  $Z$ 's command language, operating system, and organization are to be dealt with. The scenario, which should be expected to be much more detailed than usual and less explicitly reflecting the main func-

tions of the original workload, is finally translated into sets of scripts for all the competing services. Another fundamental question is whether a model representative with respect to a dedicated system ( $Z$ ) continues to be such when running on another, non-dedicated system. This is the problem of model validity discussed in the second section. For one of the services being compared, that which is selected, it is possible to verify a posteriori whether the model's representativeness was affected by this drastic change of environment. For the others, not even this late verification is feasible. Thus, only the validity enhancement techniques mentioned in the second section can be applied, without any guarantee of success.

A number of obstacles must be overcome before an interactive-workload compaction method which leaves responsiveness unaffected can be obtained. Responsiveness indices are generally very sensitive to the command mix (types and rates) and to the order in which commands are input and processed. Thus, characterizing an interactive workload by the frequency distributions of command types and think times is not sufficient. Both the correlation among the commands issued by each user and the temporal relationships among the various command streams cannot gen-

erally be assumed to have a negligible influence on responsiveness. In order to preserve both to the largest possible extent, we may subdivide the workload to be modeled into a number of time intervals. Each time interval should be so long that the responsiveness index or indices chosen for defining representativeness can be meaningfully computed. If, for instance, the workload model's calibration criterion is based on the distribution of response times, enough interactions should be contained in each interval that

- The frequency distribution of their response times is statistically significant.
- The distortions due to the interactions in progress at the beginning or at the end of each interval have negligible effects on the corresponding distribution.
- The correlations between the indices (e.g., between the moments of the response time distributions) of consecutive intervals can be ignored.

Note that a similar subdivision is the basis of the "method of subsamples" used in simulation to compute the statistical accuracy of a given run's results or, alternatively, the minimum duration of a run which will produce results with a given accuracy.<sup>1,11</sup> Assuming that all of the above conditions are satisfied, a subdivision yields a large number of sub-workloads, each having an associated performance index or set of indices. For example, this set of indices may consist of the relative frequencies of response times within the  $k$  classes defined by the values  $t_0, t_1, \dots, t_k(t_{i-1} < t_i, i=1, \dots, k; t_0=0, t_k=+\infty)$ :

$$F_{ji} = n_{ji}/N_j \quad (i=1, \dots, k), \quad (1)$$

where  $n_{ji}$  is the number of interactions with response time  $t$  such that  $t_{i-1} < t < t_i$ , and  $N_j$  is the total number of interactions in the  $j$ th sub-workload. Note that the value of one of the  $k$  indices  $F_{ji}$  is functionally dependent on the values of the other  $k-1$  indices.

With all responsiveness indices of practical interest, the value of index  $P$  for the whole workload is given by

$$P = \frac{1}{N} \sum_{j=1}^M N_j P_j, \quad (2)$$

where  $P_j$  is the contribution of the  $j$ th sub-workload to  $P$ ,  $M$  is the total number of sub-workloads, and  $N$  is the total number of interactions in the workload. For most indices,  $P_j$  coincides with the value of  $P$  for the  $j$ th sub-workload, but sometimes this is not the case. For instance, when  $P$  is the variance of response times, contribution  $P_j$  is the sum of this variance for the  $j$ th sub-workload and the square of the difference between the mean response time of the  $j$ th sub-workload and the overall mean:

$$P_j = \text{Var } j + (E t_j - E t)^2 \quad (3)$$

Each sub-workload is thus characterized by its contributions to the values of the overall performance indices, e.g., by the values of the  $F_{jis}$ , or of  $E t_j$ , or of  $E t_j$  and  $\text{Var } j + (E t_j - E t)^2$ . This characterization may now be used to classify sub-workloads, that is, to cluster them into classes defined by values of the contributions relatively

close to each other. If more than one index is being considered, clustering methods<sup>3,12</sup> or joint-probability scaling techniques<sup>13</sup> will have to be applied. The objective of this operation is to reduce the original workload to a much more compact executable model by picking a relatively small number of representatives from each class. Note that, with joint-probability scaling, each class is composed of the sub-workloads contained within one of the regions into which the hyper-space of the characterizing variables has been divided.

Once the classes have been defined, how many representative sub-workloads should be selected from each class, and how should they be selected? Here again, the performance-oriented approach helps us find a satisfactory answer. Let  $C$  be the number of classes being considered, and let the  $h$ th class contain  $M_h$  sub-workloads ( $h=1, \dots, C$ ). The contribution  $P'h$  of each class to  $P$  can be defined in the same way as the contribution of each sub-workload, and Equation 2 will become

$$P = \frac{1}{N} \sum_{h=1}^C N'h \cdot P'h, \quad (4)$$

where  $N'h$  is the total number of interactions in the  $h$ th class. In turn,  $P'h$  can be expressed in terms of the contributions of the sub-workloads in the  $h$ th class as follows:

$$P'h = \frac{1}{N'h} \sum_{j=1}^{M_h} N_h j \cdot P_h j, \quad (5)$$

where  $N_h j$  is the number of interactions in the  $j$ th sub-workload of the  $h$ th class, and  $P_h j$  is its contribution to  $P'h$ . Note that, if  $P$  is the variance of response times,  $P_h j$  will be given by (3) where  $E t$  is to be replaced by  $E t'h$ , the mean response time of the class. Thus, (4) and (5) yield

$$P = \frac{1}{N} \sum_{h=1}^C \sum_{j=1}^{M_h} N_h j \cdot P_h j. \quad (6)$$

If the total number of sub-workloads in the model is to be  $m$  ( $m$  may be viewed as a design requirement), then the  $h$ th class will have to be represented by  $m_h$  sub-workloads such that

$$\sum_{h=1}^C m_h = m. \quad (7)$$

Assuming, with no loss of generality, that the first  $m_h$  sub-workloads are selected to represent each class, the model will produce a performance index

$$\begin{aligned} p &= \frac{1}{n} \sum_{h=1}^C \sum_{j=1}^{m_h} n_h j \cdot p_h j \\ &= \frac{1}{n} \sum_{h=1}^C n'h \cdot p'h, \end{aligned} \quad (8)$$

where  $n_h j$  is the number of interactions in the  $j$ th sub-workload included in the model from the  $h$ th class,  $p_h j$  is this sub-workload's contribution to the performance of the  $h$ th class in the model.

$$n = \sum_{h=1}^C \sum_{j=1}^{m_h} n_h j = \sum_{h=1}^C n'h \quad (9)$$

is the total number of interactions in the model, and  $p'h$  is the contribution of the  $h$ th class to the model's performance.

The performance-oriented definition of representativeness states that the model is representative if

$$p=P \quad (10)$$

Sufficient conditions for satisfying (10) are, from (6) and (8),

$$(1/n) \sum_{(j=1, mh)} nh_j ph_j = (1/N) \sum_{(j=1, Mh)} Nh_j Ph_j, \quad (11)$$

or, from (4) and (8),

$$n'h \cdot p'h/n = N'h \cdot P'h/N, \quad (12)$$

for all  $h$  ( $h=1, \dots, C$ ). Conditions (12) are satisfied if

$$p'h = P'h, \quad (h=1, \dots, C), \quad (13)$$

and

$$n'h/n = N'h/N, \quad (h=1, \dots, C). \quad (14)$$

Equations 13 are easy to satisfy, since the sub-workloads in each class have by construction very similar performances. Thus, it should not be hard to select  $mh$  out of  $Mh$  sub-workloads having approximately the same values of  $Ph_j$  so that the resulting  $p'h$  is about equal to  $P'h$ . Equations 14 say that the fraction of interactions from the  $h$ th class in the model should be equal to the same fraction in the original workload. In other words, classes should be proportionally represented in terms of their number of interactions, no matter how "heavy" or "light" these interactions are. If all sub-workloads contained the same number of interactions, Equations 14 could be written

$$mh/m = Mh/M, \quad (h=1, \dots, C), \quad (15)$$

and  $mh$  would be proportional to  $Mh$  with a coefficient equal to the inverse of the scaling or reduction factor  $r = M/m$ . Otherwise, determining the  $mhs$  will involve some iterations, since  $n$  in (14) is not given, but is to be computed as the sum of the  $n'h$ . The problem may be approached by computing the approximate  $mhs$  from (15), selecting  $mh$  sub-workloads from each class, determining the values of  $n'h$  and of  $n$ , and verifying whether equations (14), or rather (12), are satisfied. If not, the sub-workloads selected to represent each class should be replaced by others, and possibly their number should be changed, until Conditions (12) are satisfied within acceptable error bounds.

Once the sub-workloads to be included in the model have been selected, their ordering and their implementation as executable scripts are to be determined. If the assumption of negligible correlation between the performances of consecutive sub-workloads is satisfied, the relative order of samples from the original workload should be immaterial. Thus, this order can be dictated by various objectives, for instance by that of facilitating transitions from one sub-workload to the next in the executable model. Note that some of the statistical techniques which are applied in simulation can be used to verify the assumption mentioned

previously, as well as the significance of the sample taken from the original workload to construct the model.<sup>11</sup>

Transitions between consecutive sub-workloads will have to be smoothed so that a continuous script to be input from each terminal during the execution of the model can be obtained. Partial interactions, those which had already begun when the sub-workload started or were not completed at the end of it, will be completed, or eliminated, or modified, in order to minimize the distortions due to a transition. In most transitions, a major amount of turbulence is to be expected, since a number of terminals will have to switch from one subsystem (e.g., an editor) to another (e.g., a compiler). The impact of this turbulence on the accuracy of the model can probably be reduced by suitably modifying the sub-workload involved. The magnitude of such an impact cannot be predicted without experimentation. However, it seems desirable, though perhaps not very easily feasible, that the phase relationships among the various command streams be roughly preserved within each sub-workload during execution, for instance by making proper use of the transition periods and possibly by acting on think times, so that command arrival rates are not appreciably influenced by the responsiveness of the service. Note that this will probably require remote terminal emulators considerably more intelligent than usual.

We have implicitly assumed that the executable model will consist of a number of command streams to be input by a trace-driven remote terminal emulator. An alternative approach is the one based on synthetic sub-workloads. A synthetic sub-workload is a set of synthetic scripts whose performance can be changed by properly selecting the values of certain parameters. Both a synthetic sub-workload at the virtual level and its functional equivalent would generally be less realistic than their natural counterparts. However, their use could substantially facilitate workload model implementation. This subject, which has not been studied yet, is certainly among those which deserve a great deal of attention.

A third approach to workload model construction, probably the most attractive one, is directly suggested by the model design method described above. Since all the sub-workloads in a class are performance-wise roughly equivalent to each other, the model could be reduced to only one representative (possibly synthetic) sub-workload from each class, and performance could be computed as a weighted sum of the performances of these isolated sub-workloads, the weights being proportional to the numbers  $n'h$  of interactions in each class (see Equations 4, 8 and 14). A major difficulty with this method, which would on the other hand be very convenient since it would yield much more compact models and eliminate transition problems, is that of the bias introduced in the values of performance indices by the initial transients.<sup>1,11</sup> This bias is likely to affect all measured performances and not only that of the first sub-workload as in the two previous approaches. Application of the methods used in simulation runs<sup>11</sup> may reduce to acceptably low levels the inaccuracies due to the initial bias. This is another one of the many aspects of the workload model design procedure proposed here which must be experimented with.

## SUMMARY AND CONCLUSIONS

The road to more satisfactory and defensible workload characterizations is, especially in procurement contexts, a long and difficult one. A preliminary investigation into the feasibility of applying a performance-oriented approach in the procurement of interactive services has been described. After arguing that the accuracy (or, as it is usually called, the representativeness) of a workload model is essential in all evaluation contexts, three definitions of representativeness have been discussed. The three levels at which a workload may be characterized, and their relationships to the different types of evaluation studies as well as to the definitions of representativeness, have then been presented. Next, these general concepts have been applied to the comparison of interactive services for procurement purposes. A method for designing a representative workload model in such a context has been proposed. The method is based on the performance-oriented definition of representativeness and on the assumption that a model designed and calibrated at the virtual level of characterization for a given system is valid also when transported to the functional level and on other systems or networks offering interactive services. While this assumption, like many other aspects of the method, are still to be experimentally verified, the philosophies and procedures proposed here can probably be applied in a more straightforward, less expensive way to simpler environments and types of workload. The method described requires extensive measurements, the recording of long command streams, sophisticated remote terminal emulators, and is likely to produce substantially less compact models than desirable. However, it must be recognized that the problem is a very complex one, and that the current solutions to it, far from being satisfactory, are only made acceptable by the lack of any better approach. Furthermore, some ways of rendering the method and the model more feasible have been suggested. If the model can be reduced to one copy of a synthetic sub-workload per class, only the selected performance indices produced by the original work-

load have to be measured for each one of its sub-workloads, no tracing of command streams is necessary, neither transition problems nor complex phase-preservation issues arise, and maximum compactness is achieved. In spite of the number of important "ifs" still pending, the approach thus appears to hold some promise of practical applicability.

# Control of computing funds and resources in a networking environment\*

by BEVERLY O'NEAL and RONALD SEGAL

EDUCOM\*\*  
Princeton, New Jersey

## INTRODUCTION

Users or potential users of computing services at research and educational institutions are currently trying to meet their computing needs in cost-effective ways that will also provide them with high-quality services. As these individuals attempt to match their needs against the expanding menu of available alternatives (mini- and microcomputers; central campus facilities; and local, regional and national networks), they may face restrictions on their choices. Some institutions treat all users alike and, subject to budget constraints, they are allowed the same access to all services or face the same restrictions. At other institutions, some users and not others face restrictions on the amount of available computer funds and on the types of resources that can be purchased.

Often the treatment of users depends on how the institution bills for computing services. For example, access to local computing services is "free" at many institutions, and only very superficial efforts are made to allocate or account for computer usage. At others, users are given "funny money" accounts (accounts that represent funds pre-allocated to the computer center) so that local usage can be monitored and controlled. In both cases, there is little provision for the use of services other than the central facility. When "real" money (operational funds) is used to pay for computer services, users often have more flexibility in selecting services. Thus, institutional financial policies may be a major factor in determining how well the computing requirements of the user community are satisfied.

One often-proposed method of meeting some user needs for computing services is through a national resource sharing computer network. Such a network could provide access to specialized computing resources, minimize duplication of software development and promote a widespread exchange of resources among educators, researchers, administrators, and students.<sup>1</sup> Sixteen institutional participants worked

closely with EDUCOM in a recently-completed project<sup>2</sup> to investigate these issues in more detail. The participants included large universities and small colleges, public and private schools and teaching and research-oriented institutions. Interviews with key people at each institution concentrated on obtaining a deeper understanding of the institution's policies and practices with respect to computer usage and possible computer networking.

Although this paper is mainly concerned with the implications of the various types and levels of user control of funds on network participation, the discussion is relevant to most currently available computing options.

## INSTITUTIONAL PRICING STRATEGIES

The pricing structure established by an institution's computer center can be used to implement various objectives.<sup>3</sup> A common goal, for example, is to recover a fixed percent of the overall costs of the center (usually 100 percent). Since the net price to users often represents the sum of many component resource prices, the relative charges for these component services presents another degree of choice within the primary goal of cost recovery. Some institutions attempt to relate these prices to actual costs—i.e., the charges for memory, CPU, peripherals, etc. are directly proportional to their costs. Alternatively, the component charges may be directed towards encouraging efficient system utilization, allocating scarce resources, maximizing system usage and/or revenue or achieving a variety of other management goals.

Instead of setting prices by the separate components of a service, circumstances may indicate other strategies for selected services. These include charging a flat rate (usually hourly), pricing by service and unit input or output pricing (i.e., by item retrieved from a data base or by transaction processed). All of these approaches can be scaled to a given cost recovery rate if desired, and can be tuned to meet the objectives described earlier.

The usual approach in pricing is first to establish a base or standard price. Variations of this price can then be used by management to attain operational goals. For example, shift differentials are common procedures to encourage load

\* This work was supported by the National Science Foundation under Grant Number MCS75, "A Simulation and Gaming Project for Inter-Institutional Computer Networking."

\*\* EDUCOM is a consortium of more than 270 colleges, universities and non-profit organizations that serve higher education. It was founded to help its members make the most efficient use of computer communications technology.

leveling, and priority differentials are a traditional way to use the price mechanism to determine scheduling. Often there are variations in price to reflect institutional policy towards various user groups or categories. For example, surcharges are frequently placed on all outside users, with even higher surcharges if the user is not from an educational institution. It is common to bill users with outside funds at a rate equal to full cost recovery, while other internally-funded users may be charged a lower rate (i.e., they are partially subsidized by the institution). In this context, a billing percentage of zero for some users implies that they receive free computing. This approach is preferable to no billing since it permits monitoring and accountability. More important, it has been shown that when users know the actual cost of their computing, even if they don't have to pay it, they function in much the same manner as those paying the full charges.

### SOURCES OF USER FUNDS

In the past, many institutions offered computing free to their internal user communities. Although this practice still exists, at least partially, at many institutions, the current trend is towards charging in some fashion for computing services. Even if the charges do not amount to full cost recovery, they are useful for the purposes of allocating a scarce resource. At institutions that charge for computing services, a prospective user must look to either internal (institutional) or external sources of funding to pay for these services. At any institution, if a user does not feel that the internal services are appropriate, and wants to purchase services from an outside source, he must find a means of paying for these services.

#### *Internal sources of funds*

Internal funds may be allocated in different ways within the institution. Frequently, some or all computing is provided as a "free" resource. This was true for the main institutional facility for two of the small colleges in the project. At most institutions, this occurs primarily with special purpose micro- or minicomputer facilities. Usually, the "free" facility is a dedicated operation serving a small, homogeneous community within the institution such as a department or research project. Depending on their location in the organization and function, such facilities may be capitalized by state funds, government or foundation grants, tuition revenues, or departmental operating funds. In lieu of charges, there is usually an implicit allocation of resources depending on one's status or role in the organization, size or type of job, or the total system workload compared with the computing capacity (i.e., service may deteriorate as usage increases).

A second method used at many universities is to give money directly to the computer center for operating expenses. Users (generally for academic or internal administrative purposes) then receive accounts against which they

may draw. These funds, since they actually have been allocated to the computing center, may not be spent for any purpose other than computing at the local facility. At half of the institutions studied, computer charges for most local users were handled through a combination of free computing and "funny money." Although there may be an upper limit to the total amount of funds available to a user, it is usually a straightforward process to obtain additional funds.

There is a growing trend towards a third approach: Considering money for computing as part of the operating expenses of the department or college. Over a third of the institutions studied treat their computer budgets in this way. The decision on how much money is to be spent on computing is made (often at budget time) at the departmental level. Operating funds are usually considered as "real money" and the department, if not the user, has reasonable freedom to spend them as it sees fit—e.g., for an internal system, at a service bureau, for networking, etc.

These approaches have different implications for both the computer center and the user. In the "free resource" and "funny money" cases, the computer center has a fixed income with which it can budget its activities. Although this income may or may not meet what the computer center management perceives as its needs, it is a known amount that is negotiated periodically between the computer center management and the administration. The job of the computer center is then to provide the best possible service for the available money. In the third case ("real money"), however, the income is not so certain, since the computer center must compete with other resources that are vying for the users' dollars. This puts the center in a very different light. It must now stand or fall based on the quality and price of the service it provides relative to available alternatives, i.e., the computer center is running a "business."

For the user, the first two cases represent degrees in his perception of a free good. The former may appear to him more unlimited than the latter (that is, if he could just get his turn to use the facility!), but there is no sense in either environment of being able to exchange the use of this service for any other that he might need. That must be done by special appeal or process, and at an incremental cost. With operating funds, the tradeoffs are much more obvious and concrete. The user measures local services against alternative sources of computer services, if not also against the cost of new books or journals, graduate students, or secretarial help. He must then make a conscious evaluation of how much the local computer services are worth to him when compared to other options.

There are obviously various combinations of these methods. Many institutions, for example, use a combination of "real" and "funny" money so that users are billed at a specified percentage of the actual cost of their computer usage and university funds make up the difference.

#### *External sources of funds*

External sources of computing funds available to the user are usually research grants or contracts sponsored by gov-

ernment, industry, or other funding agencies. The process for obtaining these funds depends on the particular source involved. Typically, the user must take the initiative obtaining those funds, and often, in the process of obtaining them, they are earmarked for computing. In general, users' control of their externally-supplied money more nearly approximates the "real money" method of handling institutional funds. Again, the tradeoffs must be weighed by the user himself and a choice made.

For the computer center, users supported by external funds may represent a relatively unpredictable source of income. When a new grant is requested, the potential recipient decides what portion is to be spent for computing services. There is no guarantee that all of the funds indicated for computer services will be spent as planned, or that the grant will be awarded in the anticipated time frame. A majority of these funds come from granting agencies that can fluctuate in the level of their awards from year to year and there is no sure continuity. This uncertainty is one price that the individual researcher must pay for the added control that comes with outside funding. In aggregate, however, the income from such outside sources is normally fairly predictable, and the computer center management becomes very adept at estimating what this will be.

#### USER OPTIONS FOR OBTAINING COMPUTING RESOURCES

Depending upon the policies established by the institution for the expenditure of computing funds, a potential user with computing needs and funds is often faced with a choice of options. The money may be spent at the local computing facility (which may be a service purchased externally by the institution); to purchase services from an external source such as another university, a research institution, or a service bureau; or to purchase his own hardware, such as a minicomputer.

At institutions participating in the project, users with external sources of funds had the most freedom to exercise options that they selected. Those who use institutional operating funds to purchase computing services face more restrictions but usually have some degree of choice. Users with internal funds for computing, however, find it very difficult to purchase from any source except the local computing center.

##### *Local services*

Most institutions historically have had a single general purpose computer center that satisfies most of the needs of local users. As the cost of hardware drops, institutions are frequently offering several alternate centralized facilities. A common example is that of running student jobs and CAI (Computer Assisted Instruction) on a particular machine that is often a minicomputer. It is still the case, however, that most users are restricted to internal services and that,

although there may be multiple campus facilities, the choice for any given user or application is usually quite limited.

##### *External services*

There are several factors that must be faced in deciding whether or not to purchase a service externally. If the desired service is not available locally, the first question is usually, "Can it reasonably be added to the local service offerings?" Larger institutions offer most standard services. Services that they do not, and possibly cannot, offer locally include such things as large data bases, specialized application packages, and bibliographic retrieval systems. If there were a large demand for any of these, the institution might consider acquiring the service. However, for a growing number of specialized services, it is not cost-effective to do so when both installation and maintenance costs are considered. Such services are likely candidates for outside purchase.<sup>4</sup>

Another consideration is the quality of service. This is not as important in measuring local service as it should be but usually enters into the decision in evaluating external suppliers. As more external options become feasible, the issue of their comparison with local services will arise more frequently. For example, are external services a user option if they are "better" or less expensive than the local service? How does the quality of service, support, documentation, etc. of the external supplier compare with that of the local facility? How reliable is the external supplier as compared to the internal facility? Not only must the user considering an external source be aware of such factors, he must be able to evaluate their importance to him.

##### *Dedicated computing*

The number of applications in which the purchase of a mini- or microcomputer system makes sense is increasing. Hardware costs are decreasing rapidly, while performance is improving. Minicomputers can now meet many user needs at a low cost, while offering a degree of control and flexibility that the user cannot exert over the local computer center. In addition, minicomputers often can provide an interface to the central and network computers in addition to providing dedicated, low-cost, stand-alone service.

In addition to their role in satisfying specialized campus-wide needs (CAI, administrative systems, etc.), the price performance ratio of small systems justifies serious consideration at the project or departmental level. Typical applications include word-processing, introductory programming courses, monitoring and control of research experiments, specialized scientific software packages, and small simulations used by multiple students.

It is beyond the scope of this paper to comment on the problems (often hidden) associated with small computers, such as estimating their full cost, maintenance difficulties, support problems, software shortcomings, etc. At the user level, constraints on the availability of such resources are

similar to those for acquiring external services. Those users with internal operating funds or specific outside sources of funding are usually the only ones that can consider such acquisitions. Often the review process is more stringent and specific than for outside services since there is a capital investment involved.

At many institutions such acquisitions are not dealt with in an organized fashion and this has led to a diversity of incompatible equipment and duplication of capabilities. Given the total cost and net impact on the organization of these mini- and microcomputers, the need for institutional-level policies and coordination is becoming critical.

#### AVAILABILITY OF COMPUTING RESOURCES TO USERS

##### *Machine resources*

If more than one computer is available at an institution, certain classes of users may be restricted to particular facilities. The most common examples of these are the use of specific computers for class instruction or administrative data processing. Even if there is only a single computer, the institution may impose restrictions on the resources available to certain user groups. Samples include limits on CPU time, maximum memory allocations, limits on disk storage space, or job priorities. Systems with restrictions such as these usually have ways in which the limits can be raised by special request.

At institutions that use "funny money," or no prices at all, controls are important and may be quite involved. Several institutions imposed restrictions, for example, on the types of jobs that could be run by the various user categories. Others imposed resource limitations also based on type of user. One institution had developed an involved cutback algorithm whereby overusage by one class of users impacted only that class and no others. Another operated by dividing the day into periods for administrative usage and periods for academic usage. Within the academic time slots at this institution, usage was on a first-come-first-served basis.

When computing is financed partially or totally by "real," or operating, money there is less need for these types of controls. At such places, the pricing mechanism usually serves as a simple, effective allocation mechanism. To the extent that a free market environment is considered desirable, the motivation for using real money for computing increases.

##### *Support services*

There are two major areas in which human resources are required—consulting and programming. A few institutions provide extensive support free of charge in both these areas, while most only offer casual consulting free and charge for programming or extensive consulting. Some institutions offer minimal consulting and no programming whatsoever.

Different users at a single institution may receive different levels of support. For example, students can usually get information about running jobs but cannot obtain programming help from the consultants. On the other hand, a user with outside funds can often pay for both programming and additional consulting services from the computer center staff.

At most institutions in the project, limited consulting was available free of charge. Most of them allowed all users to buy programming services with computing funds although one institution did not allow student funds to be used to purchase such services and two institutions provided no programming at all.

#### INSTITUTIONAL REVIEW PROCESS

Most institutions consider it necessary to have a review group to provide an institutional view on the use of facilities other than the local centralized facility, whether they be external services or the acquisition of individual minicomputer systems. A variety of titles are in use, such as "Computer Review Board," "Computer Advisory Committee," or "Computer Center Oversight Committee." In addition to its role in reviewing outside purchases, it often also functions as a committee overseeing or advising the local computer center on purchases and budgets. Typically, members represent a variety of functional areas including faculty, department heads, heads of large research projects, computer center management and administrators. Usually the group is an institution-wide committee, although it may function on a college basis. At state institutions, there may be parallel legislative and institution-specific groups. At smaller institutions the review process may be performed by one person, such as the computer center director.

The areas of concern to this committee also vary. In some cases it reviews only proposed purchases of hardware, or only cases in which institutional funds are to be spent on external services. It may, however, have responsibility for all aspects of computing at the institution.

At some institutions, as long as the money involved is from outside sources, approval is almost automatic. Thus, a user with a research grant may have no difficulty in getting authorization to purchase a mini-computer or to buy time from a service bureau, whereas a faculty member wanting to use departmental computing funds to buy access to a specialized package offered elsewhere may find this extremely difficult.

About a third of the institutions had established a formal review committee as described above for the purchase of outside service. Another third had a review process that was performed either by the computer center director or through an administrative office such as the vice president for research or administration or the university's finance committee. The rest of the institutions had no such review process, either because all users had operating funds and were unrestricted, or there was such a low level of outside usage that any cases were handled on an *ad hoc* basis.

Computing at an institution is perceived differently by the

various constituencies that come in contact with it. The administration often has one perception, while the computer center director may have a second, and the users a third. The review process should be the place where these sometimes conflicting viewpoints can be resolved and translated into institutional priorities and policies.

There is a clear requirement for a review process at most institutions, and many are moving in this direction. However, emphasis to date has been on the approval or disapproval of specific requests, rather than on the establishment of mechanisms for providing more general policy guidance. As the number of options increases, institutions are recognizing the benefit of establishing overall policies for guiding and coordinating their computing decisions. For example, recommendations for standardization of time-sharing terminals have come from several committees, policies for network access permission have come from others, and a few have taken the initiative and promoted policies for acquisition and operation of campus minicomputers.

## USER CATEGORIES

Users at any given institution can be grouped in a variety of ways to reflect source of funds, computing activity or homogeneity of grouping. Institutions in the project were asked to define categories that represented the major levels at which funding and usage are controlled. In general, the categories selected represented line items on the institutional budget. Although many of the variations were unique to individual institutions, the many common elements in the groupings reflect the similarities in how computer usage is perceived at educational and research institutions. These groupings exist because most institutions do not treat all users alike. Instead, the rules that apply to a user, and the control that he has over how and where his computing money is spent, depends largely on the category into which he falls.

The groupings used were surprisingly similar across the institutions. Almost all of the educational institutions, for example, had a category entitled "instruction." This included classroom use of the computer both in teaching a programming language and as a tool in discipline-related subjects. Another grouping used by the majority of the institutions was that of institution-funded research. This represented student and faculty work for which there was no outside source of funds. One institution separated such research work into that done for masters' theses and that done for Ph.D. dissertations. Typically, these two categories, instruction and internally-funded research, had great difficulty receiving permission to do computing on anything except the centrally provided facilities. Even in "real money" environments, central review committees were less than sympathetic to most requests for external expenditures or local capital investments by these users.

Three-quarters of the participants identified externally-funded research separately, and one even separated government-funded research from other externally-funded research. Those that did not use this category to distinguish

users either had almost no externally-funded research (the very small teaching-oriented colleges) or felt that this was not a useful distinction since all users had "real money," i.e., this category was merged with institution-sponsored research. In general, funded researchers had the most control over their own computing destiny. By definition they have hard dollars to spend, their expenditures do not place a drain on institution revenues, and hardware acquisition or outside computing is often an explicit part of their grant or contract. Even so, there are often pressures to use the local facility if at all possible.

Administration was also a separate category at three-quarters of the institutions. At most locations administrative work was performed on the same facility used for academic applications. By virtue of their place in the decision-making hierarchy, this group of users should be expected to have great flexibility of choice in making computing decisions. Up until now the choice seems to have been made between separate administrative facilities and the campus computer center. Security and privacy concerns, the cost of running large processing jobs, and the perceived need for control and flexibility have all contributed to this limitation on options.

Two-thirds of the institutions identified computer center staff usage as an explicit item. The rest generally assumed that since these users were not billed, there was no need to explicitly identify or budget for their usage. The philosophy was that staff usage was a fixed and necessary part of the facility workload. Except for explorations of remote resources by user services personnel on behalf of their customers, there is rarely any justification for computer center staff to seek alternatives to the facility that they operate.

The final category identified by most sites was that of external users of the local facility. About a fifth of the organizations further separated outside educational use from other external use. Where this was done, non-educational users were billed at a higher rate than educational users. In general, even outside educational users paid a somewhat higher rate than internal users. Obviously, this group of users usually has no difficulty in "going elsewhere" for services whenever it chooses.

Although these were the most common categories of usage, there were a few variations and one notable exception in categorization. Instead of following these breakdowns, one institution reported usage by schools and administrative units. This reflected the philosophy of decentralized control, i.e., each school had to account for computing expenditures as part of its operating funds.

## CONCLUSIONS—NETWORKING IMPLICATIONS FOR USERS AND THEIR CONTROL OF RESOURCES

### *Groups likely to benefit from networking*

**Outside users.** It is evident that some classes of users are more likely to use a network, or other alternatives to the central computer center, than others. The most obvious

example is that of the outside (non-institutional) users of a computer center. These users are not directly affiliated with the institution and have no restrictions to prohibit their purchasing services elsewhere. Often they are purchasing raw computing power rather than the entire package of service and user support. In these cases, they are likely to go elsewhere for service anytime that they perceive it is in their best interest to do so. At most educational institutions these users represent a very small fraction of the total usage and are generally considered only as purchasers of excess capacity.

**Externally-supported researchers.** Users whose research is supported by external research funds are likely to both use and benefit from a network. The nature of their work often requires special packages or services that may not be offered at their institution. In most cases they are faculty members or graduate students who are familiar with those services that are useful in their work and that exist outside their own institution. This category of user, therefore, is likely to know about applicable remote resources (via professional or discipline contacts), and is also in a position to take advantage of them since the institution is likely to have less control over how their funds are spent than it does over other users.

**Users of specialized resources.** Any user who needs a specialized or unique resource is a likely candidate to benefit from a network. Examples of specialized resources include unique hardware, CAI systems, statistical packages, econometric models, planning models, and specialized data bases. These are the resources that may not be available at the local institution, and would be very expensive, if not impossible, to establish locally. Users of specialized resources may fall into any user category. Unfortunately, it is their category rather than their need that is likely to be the primary determinant of whether or not they may obtain these services via a network. There are indications, however, that this situation is slowly changing. For example, review committees are much more sympathetic to requests for outside service when the resource is not available locally (many state this as a formal policy). Institutions, even those that provide local service as a free good or on a "funny money" basis, are recognizing the need to support outside usage in these circumstances.

#### *Groups unlikely to benefit from networking*

**Student users.** Except for special packages like CAI materials, student instructional needs are less likely to be met through networking. Programming courses and the use of simple models and packages are the kinds of applications that can be accommodated very effectively at most local centers. In many cases a dedicated minicomputer may best serve such a group. Particularly in programming courses, access to outside services will not enhance the basic quality of instruction. An exception to this may occur at smaller schools that can not support the full range of programming languages. In such cases, the use of other facilities over a network may provide the only access to that service.

**Computer center staff.** The staff of the computer center is likely to be the most knowledgeable about networking possibilities and availability. They may be able to get free (or very cheap) trial accounts at other institutions and may try out new packages over the network for their user community. Their own need for these services, however, is limited since they are employees of the central facility and their job is to facilitate its use. Their budget in "real money" is likely to be extremely limited, and although they may be a major source of information, they are unlikely to become a major purchaser of network services.

**Traditional administrative users.** Administrative data processing, for a number of reasons, is less likely to be performed over a network. Primary reasons are the perceived need for control over the computing resources used, the concern for security, and the volume of input and output. Administrative applications are often very time-dependent and usually receive highest priority in the case of a crisis. On a network, such work has no assurance of special treatment and must be adapted to the schedule of the host computer. The second concern, security, is often mentioned but is actually less valid. Unauthorized access to such data may, in fact, be more difficult at an institution that is accustomed to protecting the data of a variety of outside customers. At present, networks are most effective for applications that require only a nominal amount of data input and output. Consequently, communications capacity limitations and the cost of data transmission currently impose severe barriers to administrative applications.

It does not appear that the overall situation is likely to change in the near future for traditional administrative applications. However, with the advent of decision-making tools such as planning and forecasting models, and specialized hardware dedicated to "office automation," there are indications that new, non-traditional applications will be carried out in the most appropriate manner. Again, the place of this user community in the decision-making hierarchy of most institutions makes it likely that it will be able to acquire both funds and authorization as the need arises.

*Groups that could benefit from a network but are unlikely to use one*

**Student users.** Some student instructional work might benefit greatly from expanded network services, and yet be unlikely to have access to a network. In particular, the use of discipline-oriented computer programs as teaching devices falls into this category. Marketing models, political science data bases, chemical reactor simulations and econometric statistical packages represent computer resources of this nature that are not offered at every institution, and yet could represent a useful supplement to course work.

**Internally-funded researchers.** Internally-funded researchers, although they could also benefit from a network, are less likely than funded researchers to fully utilize one. The attractiveness of a network here lies in the specialized services that can thus be obtained; i.e., the need is similar to

that of externally-funded researchers, but the funds and flexibility are not available.

The primary problem that the above groups face when considering networking is that services purchased over a network must be paid for with real money, and this represents an apparent cash drain on the institution. To the extent that the user can demonstrate that the value justifies the total cost, and adequate funds are available, this is not a serious problem. In many cases, although there is a net cost saving to the institution by not doing the work internally, this is difficult to demonstrate, particularly in an environment where the user pays less than the full cost for local computing. The solution lies in reorienting institutional accounting and billing procedures so that these trade-offs can be made explicit. In other words, if it is cheaper overall to go outside than to do the work internally, one should be able to show this in a straightforward manner.

#### *Needed organizational changes in a networking environment*

**Computer center focus on providing services.** Computer centers must gradually change their images from that of providers of general computing capacity to that of providers of computing services. In this context, they must focus on how they might best help the user to satisfy his computing needs, rather than trying to adapt his needs to fit their offerings. This concept is much easier to state than to implement. Hardware budgets, number of employees and sophistication of equipment are traditional measures of responsibility that are easy to quantify and evaluate. Service or cost-effectiveness of service are generally accepted concepts, but very difficult to measure. Administrative officers must find a way to motivate their computer center to focus on the latter concepts in looking at its performance.

**Expanded responsibility for user services.** Particularly in a networking environment, the role of user services must be greatly expanded. It must be able to direct the user to available service options and alternatives, to assist in the selection process, and to assist the user in utilizing remote resources. All this is in addition to their more traditional services relative to the local facility. Although this new role is a difficult one, it is necessary before the computer center can effectively function as a provider of service as previously described.

**More direct control for users.** The current situation with respect to outside services at most educational institutions can be summarized as a financial consideration: Those with "real" or outside money usually may spend it where they like; those with "funny" or internal money are usually constrained to the local facility. This institutional posture may

not show any relation either to need or to cost/benefit considerations. In order to effectively function in a service environment, control over choice, and the responsibility for those choices, must shift from the institution to the user (or at least to the department). The user must be given both the motivation to examine alternate modes of obtaining service, and the authority to act on his decision. His decisions need not be based on cost alone, but could also include considerations of reliability, user support, suitability of service to his needs and ease of use.

**Make economic implications of choices more explicit.** One of the major barriers to implementing the concepts just described is that the true economic implications of alternatives are rarely very explicit. Users are often faced with a choice, for example, between "free" internal computing and relatively expensive outside alternatives. In reality the incremental cost of providing the internal service may very well be higher than that of going outside. The evolution from free computing to real money will help this situation, as will an environment that motivates the computer center to focus on cost-effective service instead of merely the internal provision of service.

**Implications for networking.** Although networking offers a very attractive alternative for meeting certain computing needs, it will probably never be a very large percent of the computing usage at the average institution. However, for the user who cannot find what he needs locally, it represents a significant alternative for meeting his requirements through the purchase of external services. Such usage will grow slowly as institutions experiment with this mode of usage and accept it gradually where it proves successful. Financial concerns will continue to be a major factor, and users with their own source of funds will have more ready access to the network. This will gradually change as institutions begin to view computing as a service rather than a facility, and users acquire more control over their selection of such services.

## INTRODUCTION

Educational and research institutions are increasingly becoming concerned with determining the best means by which their computing requirements can be satisfied, since these needs are becoming increasingly varied and are continuing to expand. Simply installing more processor power is no longer a solution. More types of software support, ranging from languages to specialized applications packages, are needed. Various types of data bases must be made available. Each of these entails the development of the necessary facilities as well as continuing maintenance. While technological developments are continuing to reduce the cost of raw computing power, the cost of software is continuing to rise relentlessly. Accordingly, it is becoming economically impossible for many institutions to support the breadth and variety of software that their users desire.

One oft-talked-about solution to these growing problems is the computer network. For example, by linking institutions together it would be possible to share the development and maintenance costs of software and specialized data bases over a much broader user base. Clearly, it is unlikely that there would always be a nice fit between the services economically supplied locally and the services available over a network. On the other hand, it is clear that a national educational and research computing network would contribute toward the solution of the escalating support costs being encountered. It would also address the problem of nonlocal availability of unique or specialized resources.

There are obviously drawbacks to such a national network. Yet, the potential is so great that considerable interest exists. For example, EDUCOM (a consortium consisting of more than 250 colleges, universities, and nonprofit organizations and dedicated to helping its members make the most effective use of computer and communications technology), with the financial support of the National Science Foundation, organized a series of General Working Seminars on the subject of computer networking in higher education and research. Invited participants were drawn from the ranks of university administrators, computer center directors, users from key disciplines, and computer scientists.

The results of the General Working Seminars have been

set forth in a very readable book<sup>1</sup> and shall not be repeated here. However, a general observation concerning the participants' conclusions is pertinent. Regardless of their professional role, all participants agreed that it is now technically feasible to create a national network linking computer facilities at colleges, universities, and research institutions. While technological problems do remain to be overcome, these were viewed as minor in relation to the non-technical difficulties confronting such a network, difficulties involving economic, political, and organizational considerations. Accordingly, it was believed critical to obtain a clear understanding of these factors before embarking upon any large-scale network development.

A variety of projects have been conducted to examine various aspects of networking. For example, a study by Weingarten, Nielsen, Whiteley and Weeg<sup>2</sup> examined the effects which the National Science Foundation's Regional Networking programs have had upon institutional computing activities. Berg<sup>3</sup> has examined the exchange of computing services in relation to comparative advantage and international trade concepts from economics. Heller<sup>4</sup> studied the relative price differentials between institutions for processing different types of standardized jobs. This represents an empirical study of the comparative cost advantages of different computing facilities, independent of the advantages of greater service offering availability.

No one project, however, has taken a comprehensive look at the overall impact of a national network linking institutions of higher education and research. The concerns voiced at the General Working Seminars, coupled with the networking interests of many institutions, led to the formation of a comprehensive three-year investigatory project funded by the NSF and conducted by EDUCOM.

Experimentation on a national basis with a prototype network was rejected for a number of reasons. Such an effort would be very costly, would severely restrict the alternatives that could be investigated, would disrupt the normal operations of the affiliated institutions, and would require a significant commitment of energy and personal time from many key individuals.

Accordingly, a simulation approach was taken to investigate the non-technical issues confronting a national edu-

cation and research computing network. This paper reports upon just one aspect of the overall study, namely the economic impact which affiliation with such a network might have upon member institutions.

## THE NETWORK SIMULATION PROJECT

The network simulation project conducted by EDUCOM was divided into three phases. The first phase consisted of basic data collection. Eighteen education and research institutions participated in the project, each contributing a voluminous amount of data with respect to the computing resources which they maintained and operated (hardware and software facilities), as well as data with respect to current operations (pricing schedules, priorities, demand levels by service type, and turnaround times as a function of demand levels). In addition, data was collected on user profiles. A network simulation model to operate upon this data was constructed. The results of this project phase have been reported previously.<sup>5-11</sup>

Phase two expanded and updated the accumulated data base. Visiting teams interviewed administrators, users, and computer center personnel at each institution. Computing policies, practices, and decision rules, as well as institutional computing goals, were deduced from the interview data, confirmed with each institution, and added to the data base.

Phase three enhanced the basic simulation model, so that it could be operated in three modes:

- As a basic simulation model, with all decisions at each institution being reflected by programmed decision rules.
- As a "straw network" game, with the player making decisions for his institution but with pre-programmed decision rules making all other decisions.
- As a full network game, with all decisions being made in parallel by institutional representatives.

The basic simulation model was used to investigate a number of issues such as network stability to induced shocks; traffic flows as a function of price, service levels, and policy decisions; and migration and usage patterns. The straw network game was used by each of the participating institutions to learn about the possible effects of network membership and to experiment with alternative policy decisions. The full game was employed during a three-day session held at EDUCOM with representatives attending from each of the participating institutions. In addition, these attendees participated in a number of workshops. Project findings are summarized in Reference 12.

Although institutions have a variety of reasons for seeking to join and participate in a national computer network, all share a common concern—namely, the likely economic impact of participation. Economics is the glue that binds all portions of the institution together, and the economic impact of national network membership is something that would be felt indirectly if not directly by all members of the institution.

Accordingly, it is important to consider in some detail the possible economic consequences of network membership.

## CASH FLOWS

When "cash flow" is mentioned in connection with a network, the associated thought is often "unplanned cash flow imbalances." It is very likely that there will be a net cash flow (either inflow or outflow) between any one institution and the other institutions on the network, for it is very unlikely that an institution's exports of computing services would exactly match its imports. Further, because of the variations in demand and supply, the net cash flows are very likely to differ from the desired or budgeted level.

### *Cash flow imbalances*

Whether a net cash flow will or will not pose a problem for a specific institution is a function of three characteristics—the size of the net cash flow (relative to the total computing budget and to the budgeted level of net cash flow for that institution), the size of the cash inflow and outflow individually relative to the total computing budget, and the rate at which the magnitude of the net cash flow is changing.

### **Relative size of net cash flow**

A net cash inflow or outflow will have little impact if it totals only a small percentage of an institution's total computing expenditures or of an institution's budgeted level of net cash flow. An institution may plan to run a small surplus to relieve budget problems or to run a large deficit because it chooses to purchase services externally rather than maintaining a larger on-campus computing capacity. In either case, so long as the difference between planned and actual is relatively small, the net cash inflow or outflow is not likely to impact the institution significantly.

A large net cash flow, relative to budget, may have a significant impact. If steps were not taken to increase (decrease) capacity or to restrict the purchase (sale) of services, there would necessarily be an effect upon an institution. An unexpected net cash outflow would require funds to be diverted from other activities or would require deficit financing on the part of the institution. An unexpected net cash inflow may be used to support other activities (or it may be law flow to another organization, e.g., the state treasurer). It may also impact the service received by internal computer users and may cause other side effects (e.g., tax implications, violation of restrictions on unrelated income or source of income).

### **Size of the cash flow components**

Independent of whether cash inflows match cash outflows, there should be a concern for the size of the cash inflows and outflows relative to the institution's overall com-

puting expenditures. For example, a high level of external service purchases should raise questions concerning continued availability of these services to the institution's members and the possibility of negotiating volume discounts from volume suppliers. On the other hand, a high level of sales to external users should raise questions concerning the likelihood of continued demand for these services. In either case there should be a concern about possible contractual arrangements, quantity discounts, volume guarantees, and the like. The sudden termination of a major supply source could seriously impact the continuation of the users' educational and research computing while the termination of a major demand source could remove revenue needed to support relatively high fixed costs of the computing facility. In either case, there is a potentially significant economic impact upon the institution, and the risk must be recognized and dealt with accordingly.

However, unless an institution happens to offer a very popular specialized service, it is expected that the cash flows will be relatively small. Even in those cases where the cash flow is intended to be relatively large, there are mechanisms to protect against the increased risk. Thus, risks previously described should not discourage economically sound arrangements. It is just that the importance of proper contractual arrangements to protect the interests of both buyer and seller becomes much greater in these circumstances.

#### **Rate of change of net cash flow**

The fixed costs associated with the operation of a computing facility are relatively large. Thus, in the short run, a rapid change toward greater cash inflow would result in deteriorating service or response time, while a change toward lesser cash inflow would result in operational losses (or reduced surpluses) with such budgetary shortfalls having to be met with other institutional funds. Because of the relative inflexibility of short term cost/capacity adjustments in a computing facility, a rapid change in net cash flow can have potentially serious consequences.

On the other hand, more slowly evolving changes offer the potential for lesser impact, since there is more time for the institution to make appropriate adjustments in purchase/supply levels.

#### *Areas improved by differential cash flows*

There are a number of impacts which may stem from the above-described factors. These impacts are controllable in the sense that cash flows can be controlled with management attention. The key is to make sure that proper and timely control is exercised.

#### **Minimum acceptable central facility**

Most institutions feel for reasons of control, local service, prestige, and so forth that there is a minimum size and capability level below which they would not want to reduce their central computing facility. (Often, this minimum size

is not very far below current capacity.) Such a capacity floor introduces a number of complications into network membership.

For example, the existence of a minimum capacity target implies that the central facility should operate at greater than or equal to the specified minimum capacity. Otherwise, the institution would be paying more than it should for computing, representing a direct drain on the institution's budget. The only alternative to an outright subsidy (paying for the operating deficit) is to attempt to increase net income through price adjustments. However, higher prices may encourage additional business to flow to the network (thereby decreasing revenues and requiring that prices be raised again in a continuing cycle) and lower prices may not generate sufficient additional demand to overcome the reduced revenue from existing business.

A minimum capacity level may also result in a number of institutional goals being overridden. For example, an institution may desire to provide its entire user community with ready access to a national network so as to enhance the effectiveness of teaching and research. However, if this results in insufficient business being directed to the institution's own computing facility, then pressures will develop to restrict network access. Network access may be rationed, outside usage may be taxed (to make internal use look economically more attractive to the user), or network use may be prohibited for certain types of computing (or for certain types of users such as students).

#### **Hard versus soft funding for computer services**

Many institutions fund internal computing with so-called soft money. That is, the institution directly supports the computing facility's budget and then allocates or rations usage by distributing time or "funny money" credits to users. The "funds" so distributed to users have no value for anything other than local computing, hence the term "soft." In contrast, all network computing will involve "hard" or real dollar expenditures. Thus, institutions must find additional hard money to fund those network services that are utilized, as additional cash outflows will be triggered.

The funds to support network usage may come from four sources. They may come from hard dollars earned from the sale of computing services to the network (analogous to earning foreign exchange in international trade), or they may come from a reduction in support for the institution's own computing facility. Additional hard funding may be obtained from reductions in other programs or activities at the institution, or it may be obtained from new funding sources. However, in pursuing new sources of funding, network usage would potentially have to compete with all other institutional programs seeking additional funding support.

#### **Network sales viewed as an asset exchange**

An institution that is selling computer services to network users is in essence performing an asset exchange, exchange-

ing a portion of its computing facility for dollars. Whether or not this is advantageous depends upon the institution. For example, many state universities currently receive a fixed allocation from the state legislature to support computer operations; in turn, all revenues from services go to the state. Computing service sales to the network under these conditions would be disadvantageous, for the institution would essentially be losing part of its computing capability without receiving any benefit in exchange.

### Revenue source

Membership in a network is often looked upon as a revenue source. There is a widespread belief that institutions can "make a profit" by selling computer services. (Clearly, not all institutions can be net sellers of services, although obviously some will be.) However, even for net sellers of service, the opportunity to generate net income is not without cost.

First, if capacity is expanded to support outside service sales, then increased capital and operating costs must be considered along with the investment risk (users may switch to another facility at a later date, leaving the institution with excess capacity). Second, if capacity is not expanded proportionately, the institution's own users will be "paying" for the outside usage in terms of longer turnaround times and increased congestion. In fact, if the institution offers a priority surcharge scheme, internal users may literally subsidize outside usage through the priority charges required to maintain the same turnaround time.

### BUDGETING PROCESS

The budgeting process will also undergo change in a networking environment. At the present time most institutions make an estimate of sponsored research computing (based upon research contracts in-house and upon proposals outstanding) and an estimate of the appropriate level of educational, administrative, and unsponsored computing. These figures are compared with the budget requirements of the computing facility in order to serve the aggregate workload, and a final budget is established for each type of computing. Funds for these activities are then allocated to the prospective users, using either soft or hard dollars, depending upon the policy of the institution.

With a national networking environment, two new factors appear—use of the local computing facility by external users and use of external computing services by local users. The former is a source of hard dollars, while the latter consumes hard dollars. The budgeting process still goes through the estimation phase as before. However, estimates must also be made of external use of the local facility. This estimate is more difficult to make, since an institution will generally have little knowledge of the computing plans of external users for the forthcoming budget period. (This is another reason why service guarantee/minimum volume agreements can be advantageous.) Since less is known about the volume

and timing of external demands, there is likely to be a greater error surrounding their estimate. Hence, the institution should be prepared to accept a greater shortfall of revenue or a greater excess of demand at its computing facility than customary.

The budget preparation process must also address the needs of internal users for outside services. The use of network services by internally-funded users can be tightly controlled, since the institution is in a position to dictate limits on the amounts that can be spent. The real risk arises if the institution ties the level of external use by these users to the level of service supplied to external users over too short a time span, so that fluctuations in external sales would disrupt the educational and research process.

### PRICING PRESSURES

Most institutions presently operate their computing facilities as a quasi-monopoly. A variety of constraints (both funding and administrative) are established to restrict users to the local facility. However, participation in a national network implies much greater freedom for users to move to external computing sources to satisfy their computing needs, and institutions will be subject to a number of new pressures—pressures that will constrain some of the ways in which they might seek to price their computing services.

### *Specialization*

As one would expect, different types of computers have different relative advantages in processing a specified workload. As the study of Heller<sup>4</sup> showed, no one installation was least expensive for all types of work. Each had a relative advantage for some types and a relative disadvantage for others. Thus, no matter how well an institution is operating its local computer facility, there will be external services that will likely be more cost-effective for certain types of work.

As a result there is likely to be a trend toward specialization of the services offered by different facilities. As various segments of one facility's business are drained off by other facilities having a comparative advantage, the institution is forced to compete in those areas in which it has a comparative advantage. Thus, there will be pressures to specialize. This may or may not be in keeping with the institution's objectives.

### *Price structure*

Differences between facilities are not limited to computer power alone. Many installations operate in a bundled fashion, with service and support factored into the computer rate. Accordingly, by shopping around, a user can select one service offering good support for program development and another service offering "cheap cycles" for those occasions when turnaround and support are not important.

Thus, pressures will develop to move each member institution toward a common, unbundled pricing structure (though not toward the same prices). To the extent that an institution fails to price some component of a service, there is a significant loss potential. Business that does not take advantage of the favored resource (but pays for it) will be lost, and business that does use the favored resource (but doesn't pay for it) will be gained. Revenue is likely to be lost, unless the institution adjusts toward an unbundled price structure. Such a change may or may not be in keeping with an installation's operating philosophy.

#### *Cost-recovery disparities*

No two institutions are exactly alike, and their accounting systems are likely to be even more dissimilar. Thus, the costs that are included in the rate-setting process will vary. Even if two institutions have identical computing equipment, staff salaries, and rate structures, the values calculated for those rates are likely to differ due to differences in the cost bases or cost-calculation procedures used. Even among the eighteen participating institutions in this project, we found wide variations in reported costs in environments that would appear similar or comparable. Thus, many institutions are likely to feel there is "unfair competition" from institutions whose accounting systems might yield a lower cost base for budget and rate purposes.

#### *Local service advantages*

To place the previous factors in perspective, it must be remembered that every institution has many significant competitive advantages with respect to its local user population. For example, there is the general desire of users to "do it here" where things are more familiar and where they may have greater control or can obtain better responsiveness from the "establishment." There is also the inertia factor. Computing is not a uniform commodity, and there are significant conversion barriers to switching sites and services. Consulting and other user assistance can be provided better locally. There is also a cost associated with using a network (e.g., transmission costs), so each institution can offer a built-in cost advantage to its local user community. Thus, there will always be room for an institution "to do its own thing" without fearing the immediate departure of most of its local users.

### CONSTRAINTS ON A FREE-MARKET NETWORK

In theory, the national network should be a competitive market place that permits competition between facilities to squeeze out operational inefficiencies and to encourage new entries when service offerings are inadequate. Users in such an environment would shop for the facility offering the greatest comparative advantage for their computing needs. As a result, more computing would be performed for the same

cost, and everyone would be a winner. In practice, however, this may not happen. The stage is set, but there are a number of constraints which may preclude such competition.

#### *Non-comparable services*

Many of the computing services to be made available over the network are expected to be unique or specialized services. By their very nature these services will not be offered by many institutions. Hence, a competitive market for those services is unlikely to develop.

#### *Legal*

A variety of legal constraints, ranging from prohibitions on serving commercial organizations to prohibitions on serving out-of-state organizations, may restrict the ability of a computer facility to sell its services externally over a national network. The constraints will vary, depending upon educational discount contracts, state laws, and institutional charters.

#### *Tax*

Most educational institutions are exempted from property and income taxes with respect to their educational facilities and activities. To the degree that various taxing jurisdictions declare network service activities and revenue to be a non-educational use of facilities, an institution's ability to participate in the network may be sharply curtailed. Whether any commercial work will be tolerated and whether the provision of services to other educational institutions will be viewed as an educational or a business enterprise will depend upon the local taxing authorities' interpretations of their laws and regulations. However, the economic impact upon an institution could be significant, as could the constraints upon network affiliation.

#### *Federal*

An internal computing facility serving federally-funded computing users is required to share its costs fairly among the various users. There is an elaborate body of procedures associated with the definition of "fair costs." Normally, so long as the federal government pays these "fair" rates and other users, internal or external, pay no lower rate, the institution may charge whatever rate it desires.

However, will federally-funded network users from other institutions still be considered outsiders on whom surcharges may be levied, or must these users be considered part of the internal federal sharing community which must be charged the lowest rate? Also, the importing and exporting of computer services by an institution may be viewed simply as an exchange of services, in which case an institution would have to make representations to its auditors about the fair-

ness of another institution's charges. (Under the exchange interpretation, the computing charges of the external computing facility would have to be included in the local computing facility's cost base.)

One of the features often mentioned in connection with a national network is a provision for software royalties. This would enable the developer of a program or routine to establish a usage fee, providing an incentive to individuals to develop and share high quality software. It is anticipated that an individual could specify any royalty level he wished, depending upon his perception of the quality of his work and its value to others. However, arbitrarily established surcharges for internal users are not likely to be acceptable to government auditors, and the consequences could be severe if a broad set of external users (e.g., those with federal funding) were to be considered "internal users" for rate purposes. Thus, federal regulations may have a significant impact upon one of the planned mechanisms to stimulate the development and sharing of quality software.

#### *Loss of freedom*

The decision to supply service to external users may result in a loss of freedom for the supplying institution. If the supplier were to see itself as offering a full-fledged service rather than temporarily selling excess capacity, it would lose the freedom to modify network service availability unilaterally in order to accommodate local needs.

By the same token, unless the user of an external service has some form of service availability agreement, he may be giving up control over his computing supply. Thus, some other organization, with which he is not affiliated, would have the power to change the availability or conditions of his access.

#### *Growth*

Even if an institution were able to compete freely in a national computing marketplace, there are a number of constraints upon growth (both upwards and downwards) of its computing facilities that may limit network participation.

- Institutional charter—The institution may not be able to operate an auxiliary, revenue generating enterprise, so that external business would have to be minimal.
- Desired facility size—The institution's goals for a local facility may prevent the facility from being reduced to its economically optimal size.
- Entrepreneurial risk—The institution may not be willing to accept the entrepreneurial risk associated with installation of additional computing capacity and the sale of computing services to an external market.
- Capital investment—An institution may not be able to expand facilities to serve external users because of an inability to obtain capital funds.

## EVOLUTION OF NETWORK COMPUTING FACILITIES

All of the factors discussed above appear to dictate against a significant change in the size of an institution's computing facility. However, there are ways around these problems. The following subsections suggest ways in which network computing facilities might evolve.

#### *Evolution of major network suppliers*

The establishment of a separate, wholly-owned corporation to serve network demands (when business exceeds the institution's growth limitations) is a likely mechanism for providing popular computer services to a national marketplace. Many institutions have indicated a desire to make their services available to other educational and research users. However, should these services prove very popular and should demand exceed what can conveniently be served, we have observed a willingness of institutions to consider setting up a separate organization to serve a national network community.

This mode of network facility development has already been observed in practice. For example, library cataloging services started out as small offerings on the host institution's computer facility. However, in the case of BALLOTS and OCLC, as the volumes of these services grew, they were spun off by their host institutions into separate service-providing organizations. Thus, the national network could evolve to a number of institutions providing minimum service volumes and a number of commercial organizations providing larger volumes of specialized services.

#### *Evolution of major network buyers*

The facility that is a successful network service buyer is likely to have evolved along one of two paths. On the one hand, it may have become a smoothly-operating, specialized facility that provides a limited range of services and imports the bulk of its requirements. The computing facility (hardware, software, and staff) would have become oriented toward providing a selective number of high quality, specialized services. Other services would be supplied to users via network purchases. The facility itself might be large or small, depending upon the volume of those specialized services it might sell to others.

On the other hand, the network buyer may have become a very small, limited computing facility. The institution may have reached this point either via a conscious decision to install limited local hardware capability, or by a decision to reduce the hardware configuration and scale of operation of an earlier facility. In either case network services would be used to enhance the breadth and cost-effectiveness of the computing services offered to the local user community.

## COST CONSIDERATIONS

The availability of a wide array of computer services will have a number of cost-related impacts upon an institution and its internal user community. In particular, the benefits (costs) will accrue to (will be borne by) different portions of the institution. The following represent a sample of the considerations which an institution should evaluate in reaching a decision on network participation.

### *User cost savings*

The previously-mentioned study by Heller<sup>4</sup> indicated that the total cost to run a standard benchmark job at each of a number of institutions spanned a wide range. Variations of more than 10:1 were observed in job cost from one institution to another. This variation provides a significant opportunity for a user to "shop around" and obtain meaningful cost savings for his particular type of work.

On the other hand, if an institution has the capability and the capacity to do the work locally but the user takes his work elsewhere for processing, the total amount spent externally will be a direct loss of income for the institution. Note that the loss to the institution will exceed the user's savings. In order to maintain the same "net income" position, the institution must reduce the size of its own computing facility (e.g., hardware, software, staffing level reduction) and/or obtain a compensating volume of business from other external network sources. Thus, when evaluating the user benefits that might accrue, an institution must also consider the actions that it will have to take to compensate.

### *User cost increases*

Computing is not a uniform commodity, so one cannot substitute "Brand A" for "Brand B" effortlessly. Therefore, in order to obtain the savings indicated by the job processing-cost differentials described above, it will be necessary for the user to investigate the relative costs and advantages/disadvantages of different facilities. In addition, when he makes a decision to use "Facility X," the user must learn the command language and control statements for that facility and learn to work with a remote user consulting organization.

All of these activities require an expenditure of the user's resources. The institution or the network may provide some assistance. For example, data on processing costs for common benchmark programs at all facilities might be provided, so that the user would have information on which to limit his field of investigation. However, learning to operate with a new facility is a cost the user must always bear. Even if this did not involve an accounting charge, there would still be the cost of lost time, personal effort, and energy. Thus, the potential cost savings must be reduced by these added costs.

### *Facility cost savings*

The availability of network revenues may permit an institution's computer facility to expand to a more economic size and take advantage of economies of scale. This would permit unit cost savings to be passed on to all users, internal and external alike. Usage growth may also permit the facility to upgrade its support levels for certain services, or to support new services which were not economic at lower usage levels.

Similarly, the availability via the network of external service suppliers may also permit an institution's computer facility to obtain cost savings by not expanding (or by actually contracting) its scale of operation or its offerings. For example, a facility may be able to avoid a costly upgrade to new hardware by off-loading some of its growing local demand to outside service suppliers. Or a facility may be able to reduce its support costs by dropping services whose support is very costly or difficult to provide or whose use is infrequent. Such services can be eliminated locally, since they could still be obtained remotely via the network. Thus, a network connection offers a variety of cost saving alternatives.

### *Institutional benefits*

The availability of specialized computer services via a network connection may enable an institution's research community to be more competitive in obtaining external research funding. That is, researchers might be able to undertake activities that had been foreclosed to them previously due to lack of proper computational facilities. Greater research breadth and facilities' availability may also enhance the institution's educational program, aid student and faculty recruitment, and enhance the institution's reputation. Further, to the degree that researchers are successful in attracting additional external research support, the indirect or overhead charges against these research contracts will make a positive contribution to the support of the institution's facilities and general operations.

## PERSPECTIVES

The various types of economic impacts that have been discussed must be characterized as potential impacts; they might or might not occur. Their significance will depend upon the particular institution, the type of network, and the operating environment. However, each impact can potentially occur, so it needs to be considered explicitly.

On the other hand, reading the list of potential impacts gives an overall negative impression, for there are many things that can go wrong. Yet, many of these negative events are not likely to occur. Consider, for example, the long list of things that could go wrong with a jet airplane. Fortunately, most of the possibilities on that list never occur, and we continue to use commercial air transport safely. Therefore, let us consider what types of networking situations are

likely to occur, based upon the data provided by the participating institutions.

Initial network usage is likely to involve specialized services that are not available locally. (Such specialized services would include application packages, data bases, as well as "cheap raw cycles.") There is little expectation that major portions of an institution's internal users' workloads would be processed externally. Likewise, there is little expectation that any supplier would capture a major portion of another institution's processing load. There will, of course, be exceptions. For example, Harvard not too long ago gave up a major portion of its local computing capability, choosing to rely instead upon service purchased remotely from MIT. However, it is expected that network flows for exports and imports of computer services will be in the range of five percent to 15 percent of an institution's overall processing budget.

At this level of interaction, many of the potential funds flow problems discussed above become manageable. At worst, an institution might face a 15 percent reduction in business due to internal users going out on the network for service and no external users choosing to make use of the facility. While no one looks forward to a 15 percent budget cut, it is not likely to cause severe dislocations. The impact may be further softened, since many institution's workloads are growing and since network utilization is expected to phase in gradually.

Similarly, the other worst case (no internal users make use of network services but network users add 15 percent to the processing load on the facility) does not pose a significant danger. Most facilities either have some excess capacity available or have planned various small enhancements that will increase capacity at moderate cost. Thus, the increased demand should be accommodated without undue service deterioration, expense, or risk.

Pressures stemming from service-level comparisons (e.g., turnaround time, software quality) are likely to be present but muted due to the high conversion costs between facilities and the existence of user inertia. As long as these pressures remain moderate, they will exert a healthy influence on operations. However, unlike the other areas, this one has a much greater potential to become serious. If an institution is not operating close enough to the "customary" service levels, or if it is operating old, inefficient equipment, it might well be placed under rather severe competitive pressures.

The various constraints on a free-market network represent very real issues. Many institutions believe that these issues will not become serious so long as network business represents a "small enough" proportion of their business. On the other hand, network business amounting to 15 percent of revenues may not be "in the noise level," especially for facilities with multi-million dollar annual budgets. It is impossible to speculate as to the likely outcome. Impacts of some of these issues will depend upon the rulings and interpretations of local governmental jurisdictions; thus an inconsistent pattern of effects may be seen across the country. In other cases, similar situations have not arisen previously, so there are no precedents from which to extrapolate.

The constraints upon facility growth, while formidable

sounding, are not expected to be a severe limitation on network development. Most facilities are not expected to face significant growth problems. The few that might face very high external demand levels are likely to be those with a pre-existing entrepreneurial disposition, sites that would be willing to create a new business enterprise to provide the demanded services to the network user community. This has been an observed growth pattern in university computing operations, and administrators generally expect analogous behavior in a networking situation.

The cost savings and other benefits that have been described appear for the most part to be real. That is, it appears that users will be able to gain the benefits described within the bounds of a reasonable expenditure of effort. Thus, the promise of a national network in many respects appears realizable.

# Approaches to concurrency control in distributed data base systems\*

by PHILIP A. BERNSTEIN and NATHAN GOODMAN

Harvard University  
Cambridge, Massachusetts

## INTRODUCTION

Whenever multiple users or programs access a data base concurrently, the problem of concurrency control arises. The problem is to synchronize concurrent interactions so that each reads consistent data from the data base, writes consistent data, and is ultimately processed to completion. In a distributed data base this problem is exacerbated because a concurrency control mechanism at one site cannot instantaneously know about interactions at other sites. No fewer than 30 papers on this topic have appeared to date. Our purpose is to survey this literature, concentrating on three approaches—locking, majority consensus, and SDD-1 protocols—which together subsume the bulk of the literature.\*\*

Distributed concurrency control is complex and our treatment is, of necessity, sketchy. We urge the interested reader to consult the source materials listed in the bibliography.

## BACKGROUND

### *Preliminary definitions*

A **distributed data base management system** (abbr. DDBMS) is a collection of sites interconnected by a network. Each *site* is a computer running a local (i.e. non-distributed) DBMS, and the *network* is any computer-to-computer communication system. We assume that sites are widely dispersed geographically, so the network must employ long-distance communication media. Consequently, inter-site communication is qualitatively slower and more costly than intra-site computation.

We define a *data base* to be a collection of data items. In practice, a *data item* may be a field, a record, a file, etc. This "level of granularity" is important, but does not impact concurrency control and so we leave it unspecified.

Each data item may be stored at any site in the system,

and moreover each may be stored *redundantly* at several sites. Redundant data improves the robustness and performance of a DDBMS and must be supported by general purpose systems. Unfortunately, it is also a major source of complexity. A stored copy of a data item is called a *stored data item*. Though it is impossible for all stored copies of a data item to be identical at every instant of time, it is essential that all "converge" to the same final value. We use the term *logical data item* when the distinction between "data item" and "stored data item" requires emphasis.

Users interact with the DDBMS by entering *transactions*, by which we mean a program or on-line query that accesses the data base. Transactions have two important properties in our model—(1) We assume they represent complete and correct computations: i.e. each transaction, if executed alone on an initially consistent data base, would terminate, output correct results, and leave the data base consistent. (2) We assume transactions obtain data from the data base by issuing Read commands to the DDBMS, and modify data by issuing Write commands. The arguments to these commands are *logical data items* and it is the responsibility of the DDBMS (a) to choose *one* stored copy of each data item for Reads, and (b) to update *all* stored copies of each data item for Writes. We model a transaction as a sequence of Read and Write operations paying no attention to its internal computations.

The *read-set* of a transaction is the set of logical data items it reads, and its *write-set* is the set of logical data items it writes. Two transactions *conflict* if the write-set of one intersects the read-set or write-set of the other. Similarly, two operations conflict if one is a Write and they operate on the same data. It is a fundamental theorem of concurrency control that two transactions require synchronization only if they conflict. (The converse need not be true, as we shall see in the fifth section).

### *Serializability*

A *log* is a sequence of Reads and Writes. A log is *serial* if the Reads and Writes for each transaction are contiguous (see Figure 1). Such a log represents an execution in which no transactions execute concurrently. Since we assume each

\* This work was supported by the National Science Foundation under Grant MCS-77-05314 and by the Advanced Research Projects Agency of the Department of Defense, contract number N00039-78-G-0020.

\*\* References on these approaches are listed in the bibliography by topic. We will limit our use of in-text references in the interest of readability.

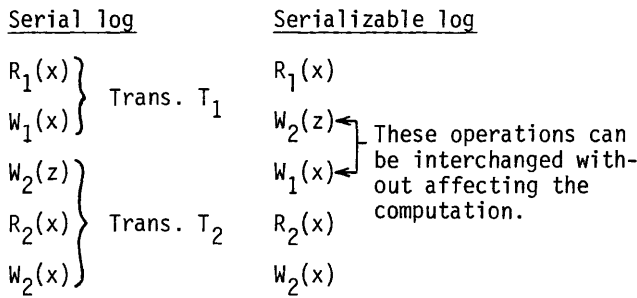

Figure 1—Serial and serializable logs.

transaction preserves consistency if executed alone, a serial sequence of transactions also preserves consistency. A log is *serializable* (abbr. *SR*) if it is "equivalent" to a serial log, meaning that for all initial data base states it produces the same output and the same final data base state as some serial log. Since serial logs preserve consistency, and SR logs are equivalent to serial logs, SR logs preserve consistency as well.

In a DDBMS, each site processes a different log. We define a *distributed log* (abbr. *dlog*) to be a set of logs, one per site. A *serial dlog* is a dlog in which each component log is serial and reflects the same total ordering of transactions (i.e., all transactions are in the same relative order in all logs in which they appear). A dlog is *serializable* if it is equivalent to a serial dlog.

Serializability has been adopted almost universally as the correctness criterion for DBMS concurrency control; all the approaches we describe follow this convention. Alternate correctness criteria are discussed in References 20 and 22.

*Other aspects of concurrency control*

In addition to ensuring serializability, a concurrency controller must guarantee *termination*; it must operate *robustly*; and it must operate *efficiently*.

A transaction may fail to terminate for one of three reasons—(1) *Deadlock* may occur, i.e. two or more operations might be forced to wait for each other. (2) Some operation may be *indefinitely postponed* by an unexpected conspiracy of events. Or (3) *Cyclic restart* might be experienced, meaning that the transaction repeatedly reaches a blocked state and is aborted and restarted. Every concurrency control approach is susceptible to some combination of these problems.

With respect to robustness, all approaches face essentially identical problems. We discuss this issue in the sixth section.

The efficiency of a distributed concurrency controller is determined principally by how much inter-site communication it requires. Typically, message delays in long distance networks are tenths of seconds, and network capacity is the scarcest system resource. In analyzing the performance of a controller, then, it is reasonable to study its communication behavior, and ignore other aspects. We compare the performance of various approaches in the Conclusion section.

DISTRIBUTED LOCKING ALGORITHMS

Locking is the most widely used concurrency control technique. We describe locking first in the centralized DBMS context and then present several extensions for distributed systems.

*Centralized locking*

Locking synchronizes transactions by explicitly detecting and preventing conflicts. When a transaction issues a Read or Write command, the DBMS attempts to "set a lock" on the desired data item; the lock is "granted" only if no other transaction holds a conflicting lock. If the lock is not granted, the requesting transaction waits until the lock is available and can be granted.

Since the DBMS processes all Read and Write commands from every transaction, it can automatically generate lock requests for each command. This is important because it allows programmers to ignore concurrency control issues when writing their transactions.

Eswaran et al.<sup>16</sup> prove that locking is sufficient to ensure serializability provided no transaction requests new locks after releasing a lock. This usually amounts to having transactions hold all locks until they finish execution.

Since transactions are made to wait for unavailable locks, the possibility of deadlock exists (see Figure 2). Deadlocks can be detected by maintaining a *deadlock graph* in the DBMS. The nodes of the graph represent transactions and the arcs represent the "waiting-for" relationship; an arc is drawn from transaction  $T_i$  to transaction  $T_j$  if  $T_i$  is waiting

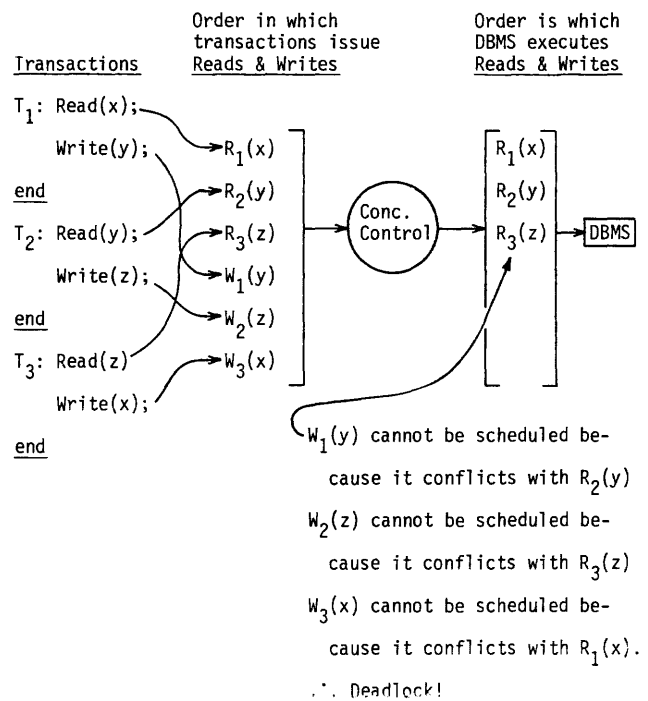

Figure 2—Deadlock

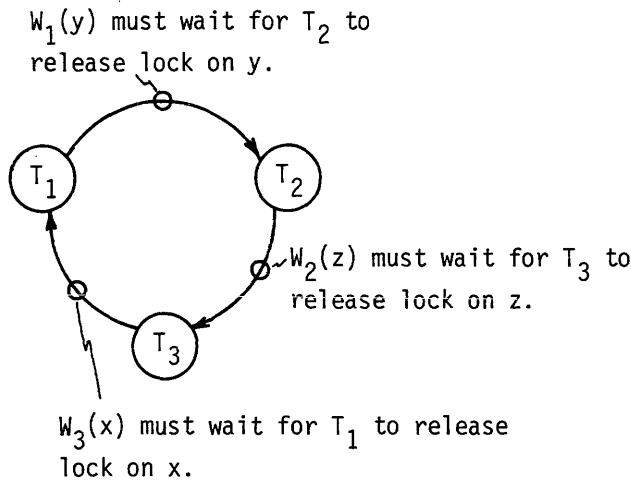

Figure 3—Deadlock graph for Figure 2.

for a lock held by  $T_j$  (see Figure 3). There is a deadlock in the system if and only if the deadlock graph has a cycle.<sup>5</sup> If a deadlock exists, some transaction in the cycle is backed out and restarted. This deadlock elimination technique can potentially lead to cyclic restart. A simple way of avoiding this problem is to always abort the “youngest” transaction involved in the deadlock. Other solutions to cyclic restart are described in the section on Conflict-Driven Restarts.

Indefinite postponement can be prevented in a locking system by processing lock requests on a first-come-first-served basis. Other solutions are discussed in References 14 and 19.

*Primary site locking*

Primary site locking is a simple extension of centralized locking. One site of a DDBMS is designated to be the “primary site” and it manages all synchronization. When a transaction wishes to access data at *any* site, a lock is requested from the *primary* site. The primary site processes lock requests exactly as described in the previous section, the only difference being that lock requests come in over the network. Similarly, issues of termination are handled by the primary site exactly as in centralized locking.

Although locks are centralized at the primary site, the data base is, of course, distributed. Once a transaction is granted a lock, it may access data at whatever site has a copy. It is important that if a transaction updates a data item that has many stored copies *all* copies are actually updated before the lock is released; otherwise another transaction can read a copy of the data item before the first update propagated there. It is also important that read-only transactions follow the locking discipline, or else they could read inconsistent data (see Figure 4). This point is often overlooked in discussions of distributed locking, yet is important because most applications predominantly consist of read-only transactions.

The principal drawback of primary site locking is that the

primary site tends to be a bottleneck—the capacity of the primary site to process locks bounds the capacity of the entire distributed system.

*Primary copy locking*

Primary copy locking is an extension of primary site locking that eliminates the primary site bottleneck. For each logical data item, one copy is designated the “primary copy”; when a transaction wishes to access a data item, it locks the primary copy. Since the primary copies of different data items may be stored at different sites, no single site is primary in any sense. This eliminates the bottleneck, but introduces a new problem—deadlock detection.

To test for deadlock, all sites with some primary copy must participate. For example, Figure 5 illustrates a deadlock involving two sites which cannot be recognized locally by either site. The solution is to designate one site of the DDBMS as the “deadlock detector”; periodically each other site sends it a list of newly granted or released locks, and newly pending requests. The deadlock detector then operates as in the centralized case.

As with primary site locking, if a transaction writes into a data item, all copies must be updated before the lock is

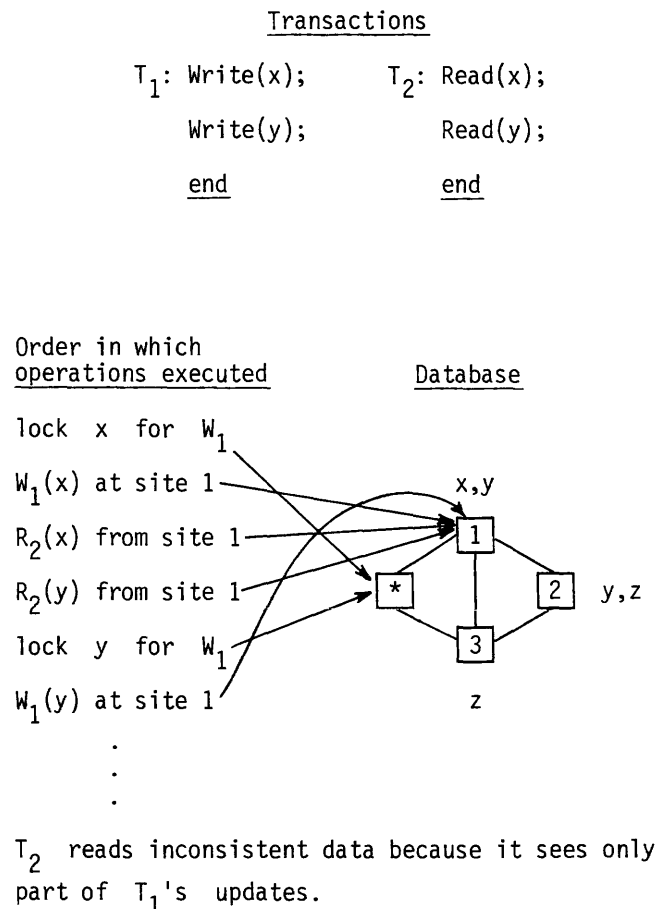

Figure 4—Read-only transactions must lock, too.

<u>Transactions</u>		
$T_1$ : Read(x);	$T_2$ : Read(y);	$T_3$ : Read(z);
Write(y);	Write(z);	Write(x);
<u>end</u>	<u>end</u>	<u>end</u>

Order in which locks are requested at each site

site 1

lock x for  $R_1$

• lock x for  $W_3$

site 2

lock y for  $R_2$

• lock y for  $W_1$

site 3

lock z for  $R_3$

• lock z for  $W_2$

Database

None of the •'ed locks can be granted, hence the system is in deadlock. But deadlock graphs at each site are acyclic:

site 1

site 2

site 3

Figure 5—Multi-site deadlock.

released; and read-only transactions must follow the locking rules, too.

*Conflict-driven restarts*

An interesting variant of primary copy locking has been described by Rosenkrantz, Lewis and Stearns.<sup>33</sup> The mechanism, which we call *conflict-driven restart*, uses a model of transaction execution in which each transaction is active at only one site at a time and moves from site to site during its execution. When a transaction wishes to access a data item at a site, it tests whether it conflicts with a previous access made by an in-progress transaction. If it does conflict, one of three actions is possible—it waits, it is restarted, or the other transaction is restarted. Since testing for conflict

is equivalent to asking whether a data item is *locked*, this approach is essentially a locking mechanism.<sup>12</sup>

The analysis of conflict-driven restart yields interesting observations about termination problems. If the system responds to conflict by making the requesting transaction wait, deadlock is possible. To avoid deadlock Rosenkrantz et al. propose two mechanisms that substitute *restarts* for waiting. Both mechanisms require that transactions be assigned unique "timestamps" when they are submitted. Intuitively, timestamps correspond to the time a transaction was submitted, and have two important properties—timestamps assigned at any particular site must strictly increase with time, and timestamps assigned at different sites must be different. Timestamps are used to resolve conflicts as follows. In one mechanism, called the *Wait-Die System*, the requesting transaction waits if it has a smaller timestamp (i.e. is older); else it is restarted. In the second mechanism, called the *Wound-Wait System*, the requesting transaction waits if it has a larger timestamp (i.e., is younger); else the transaction it conflicts with is restarted.

Rosenkrantz et al. prove that both mechanisms avoid cyclic restart, but the details of their behavior is quite different. In a Wound-Wait system, an old transaction may be restarted many times, whereas in a Wait-Die system old transactions are never restarted. It is suggested that Wound-Wait produces fewer overall restarts, but the justification is more intuitive than analytic.

MAJORITY CONSENSUS ALGORITHM

The majority consensus algorithm of R. Thomas<sup>37</sup> was one of the first distributed concurrency control mechanisms proposed. Many of Thomas's ideas have found their way into more recent designs.

The majority consensus algorithm as presented by Thomas assumes a fully redundant data base, meaning that every site has a stored copy of every logical data item in the data base. A transaction executes at one site. Its Read commands access stored data at its site, and do so *without* locking or any other synchronization. Whenever the transaction issues a Write command, the name of the data item being updated and its new value are recorded in an *update list*; the data base itself is *not* modified at this time. When the transaction completes, the update list is sent to all sites and each site votes on it. If a majority of the sites vote "Yes," the transaction is *accepted*, and the updates are installed at all sites. Otherwise the transaction is restarted. The heart of the algorithm is the rules that determine how each site votes.

A site votes "Yes" on transaction  $T$  if

1. The data items read by  $T$  have not been modified since  $T$  read them (the algorithm requires that a data item must be read before it can be written).
2.  $T$  does not conflict with any transaction  $T'$  that is *pending* at the site ( $T'$  is *pending* if the site has voted "Yes" but  $T'$  has not yet been accepted or rejected system-wide).

One way to meet Condition 1 is to use locking; but the majority consensus algorithm uses a timestamping technique instead.

Transactions are assigned timestamps as in "conflict driven restart," and each stored data item is tagged with the timestamp of the most recent transaction that has updated it. Also, update lists are augmented to include the name of each data item read by the transaction and its timestamp. Now, when a site receives an update list it can compare timestamps to determine whether Condition 1 holds. Since augmented updated lists specify transactions' read-sets and write-sets, Condition 2 is easily checked as well.

If Condition 1 is not satisfied, the site "vetoes" the transaction and it is restarted. If (1) is satisfied but (2) is not, the site cannot vote on this transaction until the pending one is resolved. Since different sites receive update lists in different orders, they vote in different orders and deadlock could result. To avoid deadlock, the site votes "No" if (1) holds, (2) does not hold, and the transaction has a larger timestamp (i.e. is younger) than the pending one. If a majority of sites vote "No," the transaction is restarted.

The voting rules ensure that two conflicting transactions are both accepted only if one has read the other's output. Since both transactions received a majority of "Yes" votes, some site, say *S*, must have voted "Yes" on both transactions. Since they conflict, *S* must have installed one before voting on the other; this guarantees that the second read the first one's output, for otherwise *S* would not have voted "Yes." This is sufficient to guarantee serializability.

**THE SDD-1 APPROACH**

The SDD-1 DDBMS<sup>39-42</sup> employs a qualitatively different approach to concurrency control. Each of the preceding methods synchronizes *all* conflicting Reads and Writes. However, not all conflicts can violate serializability (see Figure 6). SDD-1 exploits this fact by means of two mechanisms—*conflict graph analysis*, and *timestamp-based protocols*.

*Conflict graph analysis*

Conflict graph analysis is a technique for determining which conflicts require synchronization. The method begins with the definition of *transaction classes*. A transaction class is defined by a read-set and write-set. A transaction is a member of a class if the transaction's read-set and write-set are contained in the class's read-set and write-set (respectively). Associated with each class is a *transaction module* (abbr. TM), a software DBMS component that serially processes transactions from that class. Since transactions in a single class run serially, only transactions in different classes can "interfere." Hence, only inter-class conflicts need be considered.

Due to the way classes are defined, transactions in different classes can conflict only if their corresponding classes conflict. Class conflicts are modelled by an undirected *con-*

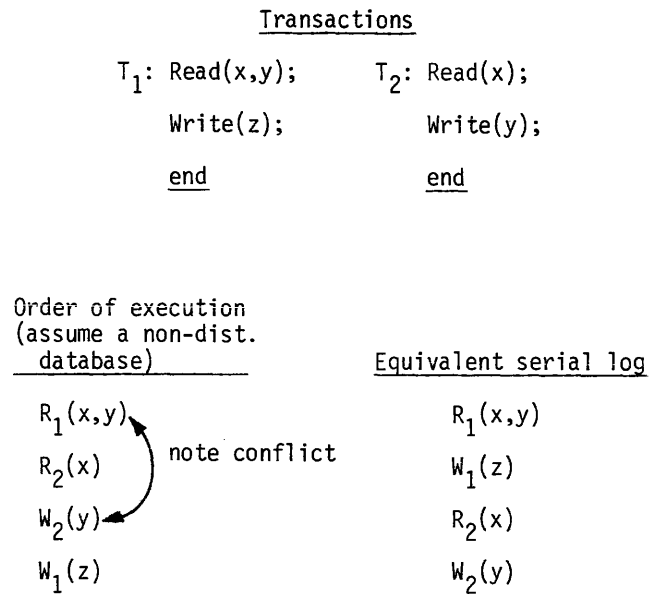

Figure 6—A conflict that does not violate serializability.

*conflict graph* whose nodes represent class read-sets and write-sets, and whose edges represent conflicts. (There is also an edge between the read-set and write-set of each individual class. See Figure 7.) The important property of a conflict graph is that transactions that do not lie on a cycle are always serializable and do not need synchronization. Only transactions that lie on cycles require synchronization.

In a conflict graph system, the conflict graph is constructed and analyzed statically when the data base and classes are defined. Classes that do not lie on cycles are noted; the TMs corresponding to these classes are 'told' not

Class definitions:

- $C_1$ : read-set = { $x,y$ }, write-set = { $z$ }
- $C_2$ : read-set = { $x$ }, write-set = { $y$ }

Conflict graph

Note: Transactions  $T_1$  and  $T_2$  in figure 6 are in classes  $C_1$  and  $C_2$  resp. Since the conflict graph is acyclic, their conflict cannot violate serializability (see text).

Figure 7—Conflict graph.

to use synchronization when executing transactions. The remaining TMs must synchronize their transactions.

Locking is one correct way to synchronize transactions that lie on cycles. If all transactions on cycles use locking, all executions are serializable.<sup>12</sup> However, other synchronization mechanisms are possible.

#### *Timestamp-based protocols*

SDD-1 uses timestamp-based synchronization protocols in place of locking. While the details of these protocols are too involved for this paper, their basic structure can be sketched.

Each edge from one class's read-set to another's write-set represents a conflict that must be synchronized if the edge lies in a cycle. This synchronization occurs during the processing of Read commands. Suppose the read-set of class  $i$  conflicts with the write-set of class  $j$ , and suppose  $T_i$  is a transaction in class  $i$ . To process a Read for  $T_i$  at site  $S$ , the concurrency controller waits until  $S$  has processed all Writes for transactions in class  $j$  that are "older" than  $T_i$ ,\*\*\* but no Writes for transactions in class  $j$  that are "younger" than  $T_i$ . This has the same effect as locking the data shared by  $i$ 's read-set and  $j$ 's write-set.

The advantage of timestamp-based protocols lies in the wide range of protocols that can be used. There is a special protocol for read-only transactions which is more efficient than locking. There is a special protocol for infrequently run transactions that places a heavier synchronization burden on these transactions while reducing the synchronization required for common transactions. In addition, all protocols use timestamps to resolve conflicts, so deadlock is prevented without the overhead of a detection algorithm.

The correctness of conflict graph analysis and the SDD-1 protocols is proved in Reference 41.

## ROBUSTNESS

Component failures are inevitable in a DDBMS, and any practical concurrency controller must operate correctly despite them. Problems of three types arise—(1) A failed site may hold information needed to synchronize in-progress transactions. (2) A failed site may hold stored copies of data items being updated by a transaction. (3) A transaction that is updating data at several sites may fail after performing some updates but not all of them. No mechanism yet developed attains 100 percent robustness and it is believed that no such mechanism is possible.<sup>4</sup> Given this apparent limitation, one cannot prove that a concurrency controller is, or is not, robust; all one can do is express the *level* of robustness it attains.

\*\*\* SSD-1 assigns unique timestamps to transactions in the same manner as majority consensus.

#### *Loss of synchronization information*

When a site holding synchronization information fails, there are two options. One is to *abort* all in-progress transactions that depend on the information. If transactions are short and failures occur infrequently, this simple approach is satisfactory. The alternative is to maintain redundant copies of synchronization information. Techniques for managing these redundant copies have been proposed by Alsberg and Day<sup>26</sup> and Menasce et al.<sup>31</sup> The techniques are presented in the context of primary site or primary copy locking, but could be adapted for other approaches.

The Alsberg and Day technique employs a *back-up* for each primary copy. When transaction  $T$  wishes to access data item  $x$ , it requests a lock against the primary copy as described in the section on Primary Copy Locking. If the concurrency controller decides to grant the lock, it forwards this information to the back-up, which records the lock in memory. Only when the lock is safely recorded at the back-up is transaction  $T$  permitted to access  $x$ . If the site containing the primary copy fails, the back-up can immediately take over and a new back-up selected. This scheme offers 100-percent protection against single-site failures, but of course is susceptible to multi-site failures. Protection against multiple failures can be improved by using multiple back-ups, although Alsberg et al.<sup>27</sup> argue that one back-up is sufficient for most applications.

Menasce et al.<sup>31</sup> propose a similar mechanism designed for multiple back-ups. The heart of their approach is a communication procedure for ensuring that all locks are received by all back-ups, and a procedure for reconstructing consistent lock tables following site failures.

#### *Non-availability of stored data items*

Suppose a transaction issues a Write command against a logical data item  $x$ , and some stored copy of  $x$  is unavailable. Since the DDBMS must update *all* stored copies of  $x$ , we have a problem. The DDBMS could delay the Write until all stored copies were simultaneously available, but this might never happen. Or it could abort the transaction, but then the availability of a data item would *decrease* as more copies of it were maintained. The solution is to buffer Write operations against non-available sites and to perform them when the failed site recovers. By buffering the Writes at multiple sites, increased protection against multiple failures can be achieved. This technique is sometimes called *spooling*.<sup>47</sup>

#### *Transaction failures*

If a transaction fails before completion, a serious concurrency control problem is created—every Write performed by the transaction must be backed out to avoid leaving partial results in the database. The usual technique for doing this is called *two phase commit*.<sup>4</sup>

While a transaction executes, all Writes it performs are placed in temporary files and not the permanent data base. When the transaction completes, it issues Commit messages to each site holding temporary files, whereupon the temporary file is merged into the permanent data base. If the transaction fails before sending the first Commit, no updates are installed. If it fails after sending some but not all Commits, the sites holding temporary files can recognize the situation and can consult the other sites. If any site did receive a Commit, all sites will perform the update.

This technique achieves 100-percent protection against failures of the transaction alone, but is not fully robust with respect to multi-site failures. Hammer and Shipman<sup>47</sup> describe mechanisms for improving the multi-site robustness of two phase commit.

## CONCLUSION

We have presented several approaches to distributed concurrency control, and the obvious question is, "Which one is best?" We have no clear answer to this question, but a comparison of the methods may be helpful.

First, all methods presented here are *correct*—they all guarantee serializable executions. Second, the methods offer slightly different degrees of concurrency—conflict-driven restart and majority consensus offer slightly less concurrency than conventional locking; conflict graph analysis combined with locking offers slightly more concurrency than conventional locking; and conflict graph analysis coupled with SDD-1 timestamp protocols offers an "incomparable" degree of concurrency, meaning it allows some executions the other techniques prohibit, while prohibiting some executions the others allow. Termination issues are best understood in the context of locking, and locking is the only technique for which termination can be proved. Majority consensus is susceptible to cyclic restart, and conflict graph analysis coupled with SDD-1 protocols can lead to indefinite postponement; in practice, however, the probability of non-termination can be made acceptably small. With respect to robustness, all approaches share the same problems, and the same techniques. So the approaches compare almost identically on these four issues, at least.

The remaining area of comparison is *performance*. As explained in the section on Other Aspects of Concurrency Control, the key determinant of performance is communications behavior. Unfortunately, few quantitative performance results are available and we shall limit ourselves to basic observations.

Primary site locking requires inter-site communication whenever a lock is requested or released. In principle, primary copy locking could require the same amount of communication, but in a well configured system we would expect to do better. The reason is *locality of reference*—in many distributed applications, the majority of transactions access data *local* to the site at which they run. If that data is the primary copy, all lock requests can be processed locally. Of

course, this advantage cannot be realized for data items that are heavily accessed from multiple sites.

The performance of the SDD-1 technique similarly depends on application-specific factors. If many transactions run in classes that do not require synchronization, the system will require few synchronization messages. Since the class definitions are tunable, classes can (in principle) be designed so that frequently-executed classes do not lie on cycles. However, if most transactions run in classes that do require synchronization, the communication overhead involved will be comparable to locking.

The performance of majority consensus is comparable to primary site locking with these differences—all locks are in effect requested in a single message; in return for this savings, though, multiple restarts may have to be endured.

The material we have presented on each approach is a bare outline. We have left out many important details and variations, and we urge the interested reader to consult source materials directly.

## ACKNOWLEDGMENTS

# Access control mechanisms for a network operating system\*

by HELEN M. WOOD and STEPHEN R. KIMBLETON

National Bureau of Standards  
Washington, D.C.

## INTRODUCTION

The growing recognition of the need for computer system security has resulted in the design, development and installation of "patches," packages and even new operating systems intended to provide higher degrees of data and systems protection. With the increased utilization of computer networks and current developments in the area of network operating systems (NOSs)<sup>40,19,30</sup> the requirements for security in networking environments are also coming under investigation.<sup>26,42</sup> While research and development are still ongoing in the NOS area, it is vital to ensure that requirements for the security and integrity of data are well specified and that mechanisms for achieving the needed levels of systems protection are included in the design of the NOS. This will ensure that subsequent production versions of NOSs incorporate such mechanisms—thus, charting a course away from the otherwise inevitable "retrofit security" situation.

Military applications have been the source of much of the computer and communications security knowledge. However, what is cost-effective in enhancing systems security for a military application may impose an untenable burden on a commercial or public system. To assist the manager/analyst in identifying appropriate security mechanisms, this paper identifies a set of access control capabilities which should be considered for inclusion within a general purpose NOS. Before identifying the actual mechanisms involved in enhancing NOS security, an NOS environment is briefly described. An overview of computer network security requirements is then provided and suggested approaches are referenced.

The second section identifies the specific access control functions required by the type of network operating system described in the first section. The implementation of these access control mechanisms in the NBS Experimental Net-

work Operating System (XNOS) is presented in the third section, followed in the fourth section by a discussion of current status and future plans.

### *The NBS experimental network operating system*

Network operating systems are commonly viewed as the mechanism for masking system differences from users. The functional objective of a NOS is to support and simplify access to existing services and to expedite the construction and subsequent accessing of new services by simplifying interaction among systems and between systems and users. A major design goal for implementing a NOS on an existing computer network is that the NOS is transparent to the participating host systems. This goal is achievable through a consolidation of NOS support functions into a Network Interface Machine (NIM), as suggested by Kimbleton.<sup>29</sup>

The National Bureau of Standards has developed an Experimental Network Operating System, XNOS, to demonstrate the feasibility of such general purpose NOSs and to facilitate the investigation of the capabilities and limitations inherent in such systems.<sup>30</sup> Figure 1 illustrates the user view of the network, while Figure 2 identifies the current XNOS configuration.

The major computing requirements of XNOS are fulfilled by an XNOS Network Interface Machine (XNIM). The XNIM is, in fact, the focal point for user-system and system-system interactions. It serves, among other things, as a translator for commands (e.g., MOVE <file>, DELETE <file>) and a transformer for data flowing between network processes. The first role provides the XNOS user with a standardized view of network resources by supporting a common command language for all participating hosts.<sup>18</sup> The latter capability, termed Remote Record Access (RRA), provides (1) the means for transmitting data between systems, and (2) the mechanisms for accessing and preserving the meaning of structured data as it is transmitted across heterogeneous systems.<sup>46,47</sup>

While the remainder of this paper will discuss access controls within the context of the NBS XNOS implementation, it should be noted that the functionality of the solution approach applies to the general class of NOSs represented by the NBS system.

\* This work is a contribution of the National Bureau of Standards and is not subject to copyright. Partial funding for this work was provided by the U.S. Air Force Rome Air Development Center (RADC) under Contract No. F 30602-77-F-0068. Certain commercial products are identified in this paper in order to adequately specify the procedures being described. In no case does such identification imply recommendation or endorsement by the National Bureau of Standards, nor does it imply that the material identified is necessarily the best available for the purpose.

Figure 1—User view of network.

### Network security requirements

The growth of time-sharing and other forms of computer networking have increased the vulnerability of data in computer systems. Not only are more systems being accessed by remote users, but large amounts of data are shipped between systems.

Systems without adequate protection mechanisms are vulnerable to threats including theft, fraud and vandalism. Potential losses range from unauthorized use of computing time to the unauthorized access, modification, or destruction of valuable data. Perpetrators of such abuse may be otherwise honest individuals wishing to play a few computer games, or sophisticated corporate spies, hoping to learn trade secrets or perhaps acquire the list of a competitor's top ten accounts. (Computer crime is extensively treated in the literature.)<sup>33-36</sup>

In order to appreciate networking-specific security needs, it is useful to identify the relevant components of a network and their vulnerabilities. For these purposes, a network may be defined as consisting of three parts—host system(s), data communications equipment (e.g., communications nodes and links—often termed "communications subnet") and terminal systems.

At the terminal equipment level, certain security techniques such as controlled access to terminal rooms or the incorporation of an identification signal within each terminal may be useful in "securing" a network, but certainly are not adequate in themselves. It is crucial, however, to know who the person using any particular terminal is in order to determine that person's rights and privileges on the network. The process of verifying the claimed identity of a user is termed user authentication.

Access control is the cornerstone of computer network security. It includes not only authentication, but also authorization—the granting of the right to access an object to a user. An object may be a person, program, or process. A user is either a person or a program (process) working for the benefit of that user.

When data communications facilities are involved, as in

Figure 2—XNOS initial configuration.

the case of a network, the vulnerability of data and systems is greatly increased. Categories of threats in a communications environment include passive and active wiretapping, between-lines entry and piggy-back infiltration. Petersen and Turn describe a number of such threats.<sup>37</sup> Encryption is one of the techniques used to provide protection in a communications environment. It may be applied in a link-oriented or end-to-end fashion.

The federal government has adopted a Data Encryption Standard (DES) for use in the protection of transmitted data.<sup>16</sup> Numerous works discuss such modern encryption techniques.<sup>6,20,12-14,3</sup> Karger identifies some of the limitations of end-to-end encryption and Kent presents protocols for the protection of interactive communications.<sup>26-28</sup> Included are techniques for key distribution and resynchronization following channel disruption.

There are many aspects to computer and network security. We have highlighted several security methods and techniques in an effort to establish a framework for a discussion of NOS access control mechanisms. This is certainly not, however, a comprehensive treatment of computer security. Numerous excellent guides into this area are available (e.g., References 8, 42, 41, 24, 7, 31 and 2).

### Network security center approach

Before beginning the discussion of NOS access control functions, we shall briefly describe one example of a suggested approach to computer network security. This approach, the Network Security Center (NSC), is of special interest here because of the possibilities suggested by the common functions that an NSC and a NOS with access control capabilities share, as well as the powerful system that would result from a combination of NSC and NIM functions.

The NSC utilizes one or more dedicated minicomputers, termed Network Security Centers (NSCs), for validating user identity (authentication) and to some extent checking user access rights (authorization) to network resources. This approach, which has been extensively treated elsewhere, is briefly summarized in the remainder of this section.<sup>4,5,22,9</sup>

The NSC is responsible for the following functions: (1) authentication, (2) authorization, (3) establishment of a secure communications path for user access to network resources and (4) the collection and/or distribution of appropriate information relative to this connection (e.g., audit data collected, user profile information supplied to host). Fundamental to the concept of a NSC is the assumption that a highly secure encryption algorithm, such as the DES, will be used to protect all information transmitted between participating systems. Such algorithms employ both enciphering and deciphering operations which are based on a binary number called a key. The key consists of a string of binary digits used directly by the algorithm. A unique key chosen for use in a particular application makes the results of encrypting data using the algorithm unique.

Intelligent Cryptographic Devices (ICDs) must exist at a level below the NSC. An ICD is used to establish a protected

connection between two network entities after authentication and authorization checking have taken place. This ICD must be capable of being remotely keyed—by the NSC only. Furthermore, whenever a dialog is completed the corresponding connection must be broken to ensure that other users do not have an opportunity to “piggy-back” an authorized user and thus gain access to restricted resources. Figure 3 presents a simplified view of a network incorporating a Network Security Center.

In order for a user to gain access to a computer on a network which incorporates an NSC, the following steps must occur:

1. The user initially connects to the NSC.
2. The NSC performs authentication and authorization checking.
3. After validation of the user's claimed identity and successful authorization check, NSC then “keys” the ICD for the user's device (e.g., terminal) and the target host with a “one-time” session key.
4. The user and target host then communicate directly over encrypted lines.

The protocol for establishing secure communications links in an architecture incorporating both XNIM and NSC would be somewhat different in that two or more host-to-host connections would be required for the same work session.

## NOS SECURITY REQUIREMENTS

In order to provide data protection in a NOS environment, one must first support overall network security, as discussed in the preceding section. The requirement that a NOS be nearly transparent to the host precludes any extensive development of host specific, access control software for the purpose of improving NOS security. The focal point for NOS security, then, becomes the NOS support computer—the NIM.

Achieving/enhancing security in a NOS environment through use of a NIM gives rise to two issues—(1) determination of the appropriate extent or degree of NIM security services and (2) identification of the security capabilities/services that a NIM can provide.

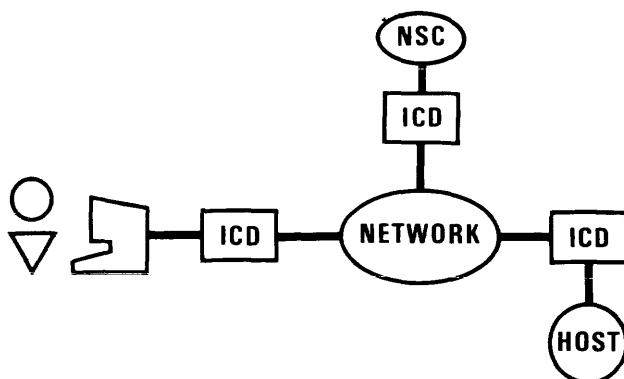

Figure 3—Network security center configuration.

## Level of security

Increasing the effectiveness of one component in protecting the system usually results in diverting an attacker's penetration efforts to another, more vulnerable, system component. Since the NIM is the component which changes an “ordinary” computer network into a NOS, it is vital that the NIM does not become the “weak link” in the security structure of the net. This implies that the level of security provided by an NIM should not be less than that of any other network component.

As no capability comes without cost, it would not be cost-effective to provide security “overkill” and far exceed the highest degree of protection offered elsewhere in the network. Thus, an appropriate level of NIM security support would appear to be a level equal to or *slightly* greater than that of the most secure of the remaining network components.

## Support computer security functions

A NOS provides an opportunity to enhance the security of a computer communications network. This is primarily because, as noted by Linden, “a large class of security problems can be solved by putting a level of indirection between a subject and the object it is seeking to access.”<sup>25</sup> Within the category of NOSs being considered, the NIM acts as an intermediary between users and systems and systems and systems. Thus, the NIM can take advantage of its relationship with network hosts by properly utilizing the authentication mechanisms provided at each host. It can also control access to network resources via authentication and authorization checking techniques at the NIM level.

## Use of host security mechanisms

Several opportunities exist for the XNIM to capitalize on host-supported mechanisms to enhance overall NOS security. Some of the obvious techniques are discussed in this section.

### Authentication

When remote users are granted access to computer resources, authentication of the user's identity is critical. Due to their relatively low cost and ease of implementation, passwords are the most commonly used mechanism to achieve personal identity authentication.<sup>43,44</sup> In fact, passwords are used by nearly all multi-user systems within the federal government and all commercial time-sharing systems.<sup>1</sup> Other automated techniques (e.g., dynamic signature verification, hand geometry) are also beginning to make an appearance.<sup>17,23,10</sup>

The problem with passwords is that they are not used to full advantage by humans. Easy-to-guess passwords such as children's names, initials, birthdates and mothers' birth

names are among those commonly selected. Even the practice of using randomly selected passwords from the English language reduces the password space significantly. As a result, such passwords are easier to determine by exhaustive searching than random strings of characters. In addition, changing passwords frequently is a nuisance to most users.

Since the NIM's relationship with the NOS-participating host is similar to that of a terminal user, it is a trivial matter to enhance the protection of NOS objects (i.e., data and programs) maintained on the host by incorporating good password utilization procedures into the NIM. For example, "remembering" frequently changing passwords is certainly no problem for the NIM. Moreover, protection of these passwords within the NIM system can be accomplished through encryption, memory protection and other such techniques.

Making the password difficult to guess is best accomplished by careful selection of the size of the password and of the alphabet from which the password is constructed. Anderson provides the following guideline for the determination of an adequate password size,  $S$  (in characters).

$$(R/E)(4.39 \times 10^4) \times (M/P) <= A^S \quad (1)$$

where  $R$  is the transmission rate of the line in characters per minute,  $E$  is the number of characters exchanged in a logon attempt,  $P$  is the probability that a password will be found during  $M$ , the period over which the systematic testing is to take place (in months of 24 hours per day operation) and  $A$  is the alphabet size.<sup>2</sup>

Of course the NIM could be directed to use the largest password space available for each supported system. With the resulting fixed password size per system, one then specifies an acceptable probability  $P$  for the NOS-supported network host, and determines the maximum lifetime ( $M$ ) allowed to ensure that level of confidence. Solving for  $M$  in Formula 1 then yields

$$M <= (E/R) \times A^S \times P / (4.39 \times 10^4) \quad (2)$$

As an example, assume that the probability of finding a six character password on a NOS-participating host must be no greater than .001, the logon attempt involves the exchange of 100 characters and the line speed is 1800 characters/minute. Then, for a 26-character alphabet (e.g., English), the password lifetime  $M$  must be no longer than a third of a month (i.e., about 10 days).

Requiring would-be users to re-dial the computer system after several (e.g., three) unsuccessful logon attempts would increase the effective password lifetime in the above example. These and other factors should be taken into consideration when attempting to determine the "right" mix of variables needed to provide the required degree of protection. Still, from this discussion it is clear that the NIM can easily surpass the average user in the practice of effective password techniques. Other techniques for better utilization of password schemes are thoroughly discussed by Wood.<sup>43-45</sup>

### File naming

Assume that a network attacker has succeeded in masquerading as the XNIM or another, valid user and is now logged directly onto a network host (i.e., the XNIM is not in the path from user to host system). At that point, a number of factors interrelate in determining the degree of damage that an individual can do. Should his or her goal be the indiscriminate destruction of data files, then only the access controls of the host system, coupled with the access rights of the authorized user being imitated, can limit the success of the attacker. The XNIM certainly has no control, direct or indirect, in this situation.

However, if a successful system penetrator is instead seeking to locate specific information, his job can at least be made more difficult by the use of non-informative file naming conventions. For example, if there is one NOS-owned account on each participating host system, then the files of all NOS users would be maintained in the same account space with such nondescript names as "NOS001," etc. No indication need be made at the host level of the actual "owners" of these files, since from the host's viewpoint, the NOS is the owner. If possible the NOS should also be the only party granted any access privileges to these files.

### Compartments

To further complicate the efforts of masqueraders to locate information, an NOS could maintain two or more accounts (i.e., compartments of information) on each participating host. Thus, for  $N$  account spaces, the probability of selecting the correct account on the first try would be reduced to  $1/N$ . With the probability of successfully penetrating any account through masquerading kept at a minimum by effective use of passwords, the net result is an increase in the protection of the NOS files.

File compartments also exist at a finer degree of granularity. Consider the case of a penetrator successfully masquerading as an authorized XNOS user, when accessing network resources through the XNIM. Since XNOS functions only operate on an XNOS-user-account basis, access to or destruction of all XNOS-maintained files requires possession of the appropriate set of access rights. Thus, total destruction of XNOS-maintained files would require emulating the set of users whose pooled access rights cover all XNOS files.

### NIM intermediary functions

Access to NOS resources that are utilized via the NIM can be controlled at the time of system access and data access. Data access, in turn, may be effected at the file, record and data item level. Within this paper, file access will be the smallest degree of data granularity addressed in detail. Record and data item access control within a NOS

environment are currently under investigation and therefore will only be briefly mentioned.

#### System access

System access usually involves user authentication techniques. Within the NOS, system access takes place at what is commonly called "login" or "logon" time, at both the NIM and the participating host systems. At the time a user logs into the NIM, password or other user authentication mechanisms should be used. If, in the course of a NOS session, multiple NIMs need to communicate, then likewise each NIM must authenticate itself to the other in a like manner. The fact that each NIM-host communication is in support of a single, specific user, serves to restrict the damage that can be done by an imposter.

The issue that now arises is, "What identity does/should the NIM process claim?" The alternatives are (1) a special (NOS) account (or set of accounts) could be maintained on each participating host for NOS sessions or (2) a NOS user could be required to maintain individual accounts on each system to be used on his behalf. In the latter case, the user would have to provide the NOS with all personal user-ids and associated passwords. Furthermore, in the event that two or more users request networking sessions involving the same target host, an equivalent number of connections would have to be effected between the XNIM and the host.

The former case, however, has the consequence of maintaining all NOS-user files for a given system within the same target system NOS account(s), as previously discussed. Providing effective access controls in this situation necessarily requires trust in the NOS-NSC process handling the account. This is not an unreasonable requirement for so critical a component of the NOS.

#### Data access

Access control may be enforced through discretionary or non-discretionary systems. The former implies a system wherein the "owner" of an object (e.g., file, program) can grant access rights to individual users.

Non-discretionary systems, on the other hand, deny users such rights. Instead, access to objects is granted on the basis of labels which specify the access class of the given object and the clearance of the subject requesting access. These labels may be changed only by the System Security Officer or equivalent.

Pure non-discretionary systems are inappropriate for most civilian NOSs as they preclude flexibility and selectivity in object sharing. Conversely, discretionary systems require object owners to explicitly identify individuals or groups to whom access rights are granted. Therefore, it seems desirable to aim for a combination or hybrid access control system for an NOS. Labels (i.e., clearances and classifications) would provide a security filter or first line of control to network resources, while object owners retain the right to

selectively grant or deny access privileges to individuals and groups within that general framework.

At the highest level in such a hybrid scheme, the rights of a user or process to access an object (e.g., file, record, data item) can be determined by a set of rules which specify the clearance (i.e., label) required to access an object of a given access class. A lattice security model has been proposed to enforce such controlled access to data among distributed computer systems.<sup>26,27</sup> This model is briefly described in the next section.

Given that the flow of data through a network is governed by an appropriate non-discretionary model, then the particular rights of individuals and processes to access and operate on that data must be determined. Such rights are often called usage restrictions and define the "mode of access" permitted to the data. Example modes of access include READ, WRITE, APPEND and EXECUTE. The mode of access allowed by a given user (subject) to a set of data (objects) may be defined by an access control list (ACL), as implemented in the Multics operating system.<sup>39,32</sup>

Other data access issues include local vs. remote authorization checking and the complications that result from the capability of one party to grant access rights to another. The mechanisms for determining authorization can become quite complex when, for example, person A grants person B a set of access rights to a given object X and among that set of rights is the right to grant access to object X. In this context, the implications of granting a user READ privileges to an object should be fully considered. Once a user has been given READ rights to a file, for example, it is conceivable that a user process will copy the file. In such a case, it would be inappropriate for the NIM to expend much effort facilitating multi-level GRANT capabilities. This differs from the case for NOS-supported data base access.

#### Data flow control

The applicability of the "lattice security model"<sup>11</sup> for controlling access to networked systems has been examined.<sup>26</sup> This model was originally derived from the military classification system and is intended to be a non-discretionary access control system. Therefore, objects are assigned access classes and subjects are assigned clearances. For a subject to gain access to an object, it must be "cleared" for the object. A subject does not have the discretion to grant access to objects to other subjects who are not cleared for the objects. The basis of the lattice model is a set of partially ordered access classes from which subject clearances and object classifications are chosen. There must be a lowest access class that is strictly less than any other access class and a highest access class such that it is strictly greater than all other access classes.

An example of a simple lattice would be the set of access classes {SECRET, PUBLIC}. In this case the ordering is a total ordering—PUBLIC<SECRET. The military security lattice, on the other hand, has two components—a sensitivity level and a category set. Sensitivity levels are {UN-

CLASSIFIED, CONFIDENTIAL, SECRET and TOP SECRET}. Categories involve the further segmentation of sensitivity levels into collections of information requiring special access permission ("need to know").

To ensure the integrity of the data, an individual or process with a given clearance is not allowed to WRITE to a process or data file with a lower access class. READs from a set of data at a lower access class are allowed. Although these restrictions do not inhibit the flow of data from, say, an unclassified file to a process with secret clearance within an individual host, complications arise when data is being accessed across host boundaries. In order for a process on one host (HOST A) to "read" data from another host (HOST B) HOST A must send a request for data to HOST B. This request is analogous to a WRITE to HOST B, and thus we have a violation of the confinement property.<sup>26</sup>

Acceptable solutions to this problem depend on the nature of the application and the security characteristics of the participating hosts. However, it is worth noting at this point that in most civilian NOSs the potential existence of trap doors (the primary threat against which much of this model is directed) is not a pressing concern.<sup>38</sup> Therefore, a less rigid approach to controlling access would quite possibly be sufficient to achieve the required level of NOS security.

## XNOS SECURITY MECHANISMS

Security-enhancing mechanisms have been incorporated in the NBS XNOS to control access to (1) the XNOS monitor, (2) network files and (3) data elements within network files and data bases. The first two are discussed in this paper. The third is still under investigation.

A secure operating system was not available for the XNIM implementation. However, it is assumed that such a system is a prerequisite for an operational NOS which intends to provide access control to network resources. There are current efforts ongoing in the development and verification of a secure operating system for a minicomputer of the same architecture as the NBS XNIM (i.e., DEC PDP 11/45).<sup>38</sup>

### System access

Consistent with conventional operating systems, access to XNOS is granted via passwords at XNOS "login" time. Since the XNOS-monitor is resident on the XNOS NIM (XNIM), which in turn is implemented on a real operating system (Bell Laboratories' UNIX time-sharing system), the user must first be recognized as a valid XNIM (unix) user. At this stage, authentication is accomplished by the possession of the appropriate pair (unix-user-id,unix-user-password). The user must then be identified as a qualified XNOS user by presenting the XNOS subsystem with an additional (preferably different!) password. In accordance with recommended password techniques,<sup>43-45</sup> the XNOS password table is maintained in an encrypted form.

To facilitate the prototype development and feasibility demonstration, XNOS currently maintains only one account

on each supported host system. All user files, therefore, are kept in one account space and it is only necessary for XNOS to supply its own password to the target system when logging on. XNOS then keeps internal directories associating XNOS users with particular files in each target host account.

### File level access

File level access control is accomplished in two stages—(1) access control specification (for files, users, and commands) and (2) XNOS command processing.

#### Access control specification

The decision to incorporate both discretionary and non-discretionary access control mechanisms within the XNIM-based XNOS monitor implies the need for the following information: (1) Object security classifications, (2) User clearances and (3) The specific rights to access specific objects possessed by specific users.

XNOS maintains a profile of each authorized user. This profile includes that user's security clearance category (e.g., "3-B,C"). Only the XNOS "super-user" (i.e., System Security Officer) has the ability to change a user's clearance.

Within XNOS, access control lists similar to those in Multics are used to contain the first and third of the above information items.<sup>39</sup> At present, four classification levels are supported for all XNOS files—numbered zero through three. The assignment of classification names is arbitrary. For purposes of discussion, we can assume the following classification scheme:

- 3—Top Secret
- 2—Secret
- 1—Confidential
- 0—Public

This particular scheme represents a strict partial ordering, since each security classification level is greater than the next lower level. In order to support the general lattice security model for data flow control, it must be possible to specify disjoint, "need-to-know" subclassifications (i.e., compartments) at any given (other than the greatest or lowest) level. Thus, Level 1 (Confidential) could be further divided into parts 1.A, 1.B, and so forth. Classification 1.A could correspond to *Confidential: Government Contracts* or *Confidential: Payroll*, for example.

At this, the non-discretionary level of control, a person attempting to access (or grant access to) a file must have a security clearance at least as great as the classification of the object. Furthermore, if the person's clearance is equal to that of the object, then the "need-to-know" category of the prospective user must match the subclassification of the object. Thus, the user who has a Confidential level clearance to see confidential objects relating to Payroll (classification 1.B) would not be granted access to files classified 1.A.

To support discretionary access control, owners of files

ACCESS RIGHTS FOR:	testfile
SECURITY LEVEL:	1.A
OWNER:	wood
NAME	MODE
wood	r ea
kimbleton	r

Figure 4—XNOS file profile and access control list.

(as indicated in each file's access control structure) may grant up to four modes of access privileges to specified users. The available modes are read (R), write (W), execute (E), and append (A). With this capability, we now can fully specify the requirements and capabilities needed to access each file. Such a specification is shown in Figure 4. Note that a user must explicitly authorize access privileges for one's self to one's own file. This helps the user protect his files from himself.

#### XNOS command processing

In order to ensure flexibility—a mandatory design requirement for an experimental system such as XNOS—the security-related input/output characteristics for XNOS commands are maintained in a table. This table specifies, for each XNOS command, the minimal set of access privileges a user must possess to invoke the command with the given parameters (e.g., file names). A portion of the command access requirements table is shown in Figure 5.

The decision to grant or deny access is made at run-time. Thus, for example, although user Smith may have been explicitly granted the right to read file F1, classified at level 3.C, the clearance level of Smith at the time of the access request may result in the denial of access. Smith may have had clearance 3.C at the time F1's owner granted read privileges to him; however, it is possible that Smith's clearance changed in the interim. Such run-time decision-making allows the XNOS system to be reasonably dynamic, in that the latest security-related information is used in determining access rights.

On the other hand, the decision to grant or deny access needs to be made as soon as possible in order to minimize the computational and communications-related burden on the XNIM and the rest of the supported network. Therefore, the user's access rights are matched against the classification of both input and output files *before* any data access operations are begun. For example, to COPY <file1> TO <file2>, the user would have to be cleared at least to read file1 *and* to write to file2 *before* the transfer would be initiated.

#### Data item-level access

One of the two basic functional objectives of a network operating system is preservation of meaning in transmitting structured data, e.g., records, between heterogeneous systems.<sup>30</sup> Accomplishing this objective requires four major types of supporting information in addition to the binary string representing the record. These are (1.) the structure of the record and the storage order of its data elements, (2.) data element types, (3.) data element representations (which may be dependent on both computer and compiler) and (4.) data element names (to support differing source and destination names or differences in source and destination storage order representations).

Given knowledge of data element names, one potentially has the opportunity to control access to these data elements. Such control can prove highly desirable since it supports enhanced sharing of data subject to unrestricted access while providing required access restrictions and without necessitating separate files, as would otherwise be mandatory.

As is the case for file level access control, data element-level access should also be supported by both discretionary and non-discretionary controls. This implies the need for managing a significant amount of access control-related information. As a result, although the access control decision is implemented by XNOS—e.g., if access is denied XNOS will not support the retrieval and transmission of the data element—in practice such decisions are likely to be closely related to the utilization of database management systems (DBMSs).

NBS is currently developing an Experimental Network Data Manager (XNDM) to investigate the problems of interfacing network users to dissimilar DBMSs. An XNDM

COMMAND	INPUT MODE	OUTPUT MODE
append	ra	ra
compare	r	----
copy	r	rw
delete	rw	----
erase	rw	----
rename	rw	rw
type	r	----

Figure 5—XNOS command requirements.

provides an excellent opportunity for examining issues related to data element-level access control. Consequently, a key component of the NBS XNDM is an Access Control Mechanism supporting discretionary and non-discretionary controls. Revocation of grants of access privileges uses a mechanism similar to that described in References 21 and 15 based on time-stamping.

In addition to supporting both discretionary and non-discretionary controls, the XNDM Access Control Mechanism also differs from counterparts for individual DBMSs through permitting distribution of access information across systems. Thus, in processing a query emitted by a source program *S*, one of the key steps is collecting the access rights of *S*. These rights are then transmitted, together with the query to a destination system where they are compared against the access requirements of the specific data elements. If access is not rejected, the appropriate data is retrieved. Otherwise, a rejection notice is returned to the calling program.

A major problem in implementing network wide data element-level access controls is resolving the issue of how much trust one will place in an operating system using unverified code. To circumvent this problem, all XNDM access control information is also resident in the XNIM. Thus, the arguments which one would make in establishing the appropriate level of trust are analogous to those used in discussing file-level access control issues earlier in this paper.

## CONCLUDING REMARKS

The goals behind the XNOS access control mechanism implementation were much the same as those motivating the entire XNOS project—to demonstrate the feasibility of the concept and, while doing so, identify the design alternatives inherent in the development of such a capability. While we feel that these goals have been achieved, there is no intent to claim that the implementation approach is in itself the definitive one. In fact, as a part of the ongoing NBS investigation of NOSs and related higher-level communications protocol issues, the XNOS implementation previously described by Kimbleton is currently undergoing a major restructuring and re-implementation.<sup>30</sup>

Given the type of NOS architecture exemplified by the NBS XNOS, network operating systems can be used to enhance network security. The skillful utilization of existing host security mechanisms, such as password techniques, can result in an immediate increase in protection, as the NOS support computer can be relied upon to use the pre-programmed, recommended procedures for selecting, changing and protecting its passwords. Furthermore, by adding a level of indirection between network resources and those wishing to access them, the NOS not only achieves a higher degree of resource protection, but does so without requiring changes to the participating host systems. It remains for system and network managers to determine the required level of security for a particular system or network.

## ACKNOWLEDGMENTS

The authors wish to acknowledge the efforts of Larry Gelberg, who assisted in the design of the file-level access control mechanisms and programmed and installed these security features in the NBS Experimental Network Operating System.

# Public key vs. conventional key encryption\*

by CHARLES S. KLINE and GERALD J. POPEK

University of California  
Los Angeles, California

## INTRODUCTION

As distributed computer systems grow and their convenience attracts uses for which maintenance of privacy and security is important, the means by which encryption is integrated into these systems also becomes important. Encryption is the only practical way by which secure, private communication can be conducted while employing untrusted media to carry the transmission. The interest has spurred developments in the use of conventional encryption algorithms and there is even a federal standard algorithm for commercial use.<sup>4</sup> In addition, an innovative approach to encryption, called public key algorithms, has recently been proposed as a way to address many of the key distribution and other problems which are present in conventional algorithm-based approaches.

Here we examine the general classes of functions desired of encryption algorithms as they are integrated into computer systems, and discuss the characteristics and properties desired in each case. We then look at the two general approaches—conventional algorithm-based, and public key-based. In every case we examine, we conclude that the two approaches are essentially equivalent. Neither approach has any particular advantage over the other. This conclusion is surprising, since one's intuition may suggest that public key algorithms are intrinsically superior because of their potential additional flexibility. Certainly, many public key proponents claim so. Yet, upon closer examination, the advantages of public key systems evaporate when one actually integrates them into a larger system.

In fact, we will see that the major unsolved problems are not concerned with key distribution, or the development of trusted software, but instead with the need for strong algorithms, whatever their form, and for reliable authentication methods: ways by which the human being can be effectively identified by the computer system.

## PUBLIC KEY AND CONVENTIONAL ENCRYPTION ALGORITHMS—GENERAL CHARACTERISTICS

Encryption provides a method of storing data in a form which is unintelligible without the "key variable" used in

the encryption. Basically, encryption can be thought of as a mathematical function

$$E = F(D, K)$$

where  $D$  is the data to be encoded,  $K$  is the key variable, and  $E$  is the resulting enciphered text. For  $E$  to be a useful function, there must exist an  $F'$ , the inverse of  $F$ ,

$$D = F'(E, K)$$

which has the property that the original data can be recovered from the encrypted data if the value of the key variable originally used is known.

However, the use of  $F$  and  $F'$  is valuable only if it is difficult to recover  $D$  from  $E$  without knowledge of the corresponding key  $K$ . A great deal of research has been done to develop algorithms which make it virtually impossible to do so, even given the availability of powerful computer tools.

The "strength" of an algorithm is traditionally evaluated using the following assumptions. First, the algorithm is known to all involved. Second, the analyst has available to him a significant quantity of matched encrypted data and corresponding cleartext. He may even have been able to cause messages of his choice to have been encrypted. His task is to deduce, given an additional, unmatched piece of encrypted text, the corresponding cleartext. All of the matched text can be assumed to be encrypted through the use of the same key variable which was used to encrypt the unmatched segment. In particular, therefore, the difficulty of deducing the key used in the encoding is directly related to the strength of the algorithm.

Recently, Diffie and Hellman<sup>1</sup> proposed a variation of the conventional encryption methods that may in some cases have certain advantages over standard algorithms. In their class of algorithms, there exists

$$E = F(D, K),$$

as before, to encode the data and

$$D = F'(E, K')$$

to recover the data. The major difference is that the key  $K'$  used to decrypt the data is not equal to, and cannot be easily derived from, the key  $K$  used to encode the data. Presumably there exists a pair generator which based on some input

\* This research was supported by the Advanced Research Projects Agency of the Department of Defense under Contract MDA 903-77-0211.

information produces the matched keys  $K$  and  $K'$  with high strength (i.e. resistance to the derivation of  $K'$  given  $K$ ,  $D$ , and matched  $E=F(D,K)$ ).

The value of such a public key encryption algorithm lies in some potential simplifications in initial key distribution, as well as for "digital signatures." The key  $K$  used to encrypt the data is expected to be publicly known, and is referred to as the public key. The key  $K'$  used to decrypt the data would be kept secret and is referred to as the private key.

## SYSTEM FUNCTIONALITY

There are a number of privacy and security-related functions which are desired from a distributed computer system. Each of the classes of functions which have been suggested will be discussed, together with the properties desired of the function.

The assumptions made regarding the threats against which protection is desired include tapping of lines, introduction of spurious traffic and retransmission of previously-transmitted genuine traffic. It is assumed that malicious attacks are expected, and that there do not already exist secure, high bandwidth paths between those who wish to communicate in a private manner. This typically is the case when common carrier transmission media, including packet-switched services, are employed.

### *Private communication*

This is the conventional use of encryption. In the distributed systems being envisioned, such as a large-scale computer network, it is viewed as desirable to separately protect each different conversation from every other. That is, the goal is to guarantee that each user/user connection is protected via encryption separately from all other connections. Therefore, each conversation needs its own key pair in conventional methods, and each user must have his own public/private key pair in the public key schemes. As a result, there can be a formidable key distribution problem. Any solution to this problem should not, in the view of many, depend on a single, central key distribution center, since the security of the entire network could depend on it, and the center contains high potential for abuse.

### *Internal authentication*

In constructing a distributed system, it is not uncommon for the sites in the system to be connected using common carrier circuits, so that a potentially large amount of switching mechanism may be involved in the links. Hence, the sites may wish to exchange several messages each time that they recommence operation, to assure that they are each connected to the right sites. The usual method seen in computer systems today, where one member of the pair reveals some secret information to the other, is unacceptable in

general if one is concerned about spoofing. The conventional form of this problem concerns authentication of the user to the system, via some form of a login protocol.

In networks, however, the problem is mutual—each "end" of the channel may wish to assure itself of the identity of the other end. Quick inspection of the class of methods used in centralized systems show that straightforward extensions are unacceptable. Suppose one required that each participant send a secret password to the other. Then the first member that sends the password is exposed. The other member may be an imposter, who has now received the necessary information to pose to others in the network as the first member. Whoever goes first potentially reveals his secret to a spoofer, who can then masquerade and collect other secrets. Obviously, extension to a series of exchanges of secret information will not solve the problem. It only makes necessary a several-step-posing procedure by the imposter. A different approach is in order.

### *Datagrams*

In the private communication function, it is generally understood that the parties wishing to communicate are willing to pay some reasonable amount of overhead to get the private conversation established, so that a key distribution algorithm involving several messages would be quite suitable, for example. However, in the case of short messages, or datagrams, it is generally viewed as unreasonable for the actual transmission of the short message to require significant overhead, such as several preceding messages to set up the channel. On the other hand, some queuing delays at the sending or receiving site may well be acceptable if the number of overhead messages can be significantly reduced. Also, the datagram function is similar to mail, in that the receiver need not be active, or logged in, at the time the message is received.

### *Digital signatures*

The goal here is to provide a way by which the author of a digitally-represented message can "sign" it in such a fashion that the "signature" has similar properties to the analog signature written in ink for the paper world. Without a suitable digital signature method, many have argued that the growth of distributed systems will be seriously inhibited, since large classes of applications would be precluded.

The properties required of a digital signature method include the following:

1. **Unforgeability**—It should only be possible for the author to create the signature for any given message.
2. **Authenticity**—There must be a straightforward way to conclusively demonstrate the validity of a signature in case of dispute, even long after authorship.
3. **No repudiation**—It must not be possible for the author of signed correspondence to subsequently disclaim authorship.

4. Low cost and high convenience—The simpler and lower-cost the method, the more likely it will be used.

*Minimum trusted mechanism: Minimum central mechanism*

In all of these functions, it is desirable that there be minimum trusted mechanism involved. This desire occurs because the more mechanism, the greater the opportunity for error, either by accident or by intention (perhaps by the developers, maintainers, etc.). One wishes to minimize the involvement of a central mechanism for analogous reasons. This fear of large, complex and central mechanisms is well justified, given the experience of the failure of large central operating systems and data management systems to provide a reasonable level of protection against penetration. All the Kernel-based approaches to software architectures have as their goal the minimization in size and complexity of central, trusted mechanism. Others are distrustful that a centralized, governmental (presumably) communication facility, or even a large common carrier can be trusted to assure privacy and other related characteristics. These general criteria are quite important to the safety and credibility of whatever system is eventually adopted. They also constrain the set of approaches that may be employed.

PRIVATE COMMUNICATION—KEY DISTRIBUTION

There are several requirements which any encryption protocol must satisfy. First, the encryption algorithm must be strong. Second, the keys to be used must be chosen and stored securely. Third, the keys must be communicated securely. Finally, authentication must be provided to separate this conversation from others which may use, or have used, the same key. Of these issues, the main problem is key distribution.

Conventional and public key systems solve these problems in different ways. In conventional systems, a new key is typically requested for each new communication. A key controller (which may or may not be centralized) chooses all keys, and performs any protection policy checks. The key controller only communicates the keys, establishing the communication channel if the protection checks succeed. The key controller communicates the keys chosen utilizing the same communications system as will be used for data transfer, but using previously arranged secret keys between the controller and the parties in the planned communication. However, it is straightforward to design the system so that the secret keys are stored in read only storage of the encryption units and never revealed. No authentication mechanism is needed to separate the new secure channel from prior ones, since the new keys chosen effectively form an authentication—no prior messages are useful.

Public key advocates claim that one of the advantages of public key algorithms over conventional algorithms lies in potentially simplified key distribution. Simply put, public key advocates argue that an automated "telephone book"

of public keys can generally be made available, and therefore whenever user  $x$  wishes to communicate with user  $y$ ,  $x$  merely must look up  $y$ 's public key in the book, encrypt the message with that key, and send it to  $y$ .<sup>1</sup> Therefore, there is no key distribution problem at all. Further, no central authority is required initially to set up the channel between  $x$  and  $y$ .

It is clear, however, that this viewpoint is incorrect—some form of a central authority is needed and the protocol involved is no simpler nor any more efficient than one based on conventional algorithms.<sup>5</sup> First, the safety of the public key scheme depends critically on the correct public key being selected by the sender. If the key listed with a name in the "telephone book" is the wrong one, then there is no security. Furthermore, maintenance of the (by necessity machine-supported) book is non-trivial because keys will change; either because of the natural desire to replace a key which has been used for high amounts of data transmission, or because a key has been compromised through a variety of ways. There must be some source of carefully maintained "books" with the responsibility of carefully authenticating any changes and correctly sending out public keys (or entire copies of the book) upon request.

Needham and Schroeder<sup>5</sup> exhibit protocols to provide the desired properties for public key systems, and show that there are equivalent protocols for conventional algorithms. The protocols are equivalent both in terms of numbers of messages required as well as in the mechanisms which must be trusted. In particular, the public key must be requested from the central authority (be it implemented in a centralized or distributed manner) and transmitted in a way which guarantees that the right key is received. Since the public key is reused, some authentication mechanism, such as a sequence number, is required to isolate this communication from others which may have used the same key. The communications required to retrieve the key and to establish the authentication mechanism make the public key distribution algorithm entirely equivalent to conventional algorithms.

Some public key advocates have suggested ways to avoid requesting the public key from the central authority for each communication. First, a cache of keys can be kept (a small local "telephone book") and frequently used keys will be found there.

Second, a concept known as certificates has been suggested.<sup>3</sup> A user can request that his public key be sent to him as a certificate. A certificate is a user/public key pair, together with some certifying information. For example, the user/public key pair may be stored as a signed message from the central authority. When the user wishes to communicate with other users, he sends the certificate to them. They each can check the validity of the certificate using the certifying information, and then retrieve the public key. Thus, the central authority is only needed once, when the initial certificate is requested.

Both the previous approaches have several problems. First, the mechanism used to store the cache of keys must be correct, since it will be relied upon. Second, the user of the certificate must decode it and check it (verify the sig-

nature) each time before using it, or must also have a secure and correct way of storing the key. Perhaps most important, as keys change the cache and old certificates become obsolete. This is essentially the capability revocation problem revisited.<sup>10</sup> Either the keys must be verified (or re-requested) periodically, or a global search must be made whenever invalidating a key. Notice that even with the cache or certificates, an internal authentication mechanism is still required.

Public key systems also have the problem that it is more difficult to provide protection policy checks. In particular, conventional encryption mechanisms trivially allow protection policy issues to be merged with key distribution. If two users are not to communicate, then the key controller can refuse to distribute keys.\*\* However, public key systems imply the knowledge of the public keys. Methods to add protection checks to public key systems add an additional layer of mechanism.

### INTERNAL AUTHENTICATION

There are a number of straightforward encryption-based authentication protocols which provide reliable mutual authentication without exposing either participant. The methods are robust in the face of all the network security threats mentioned earlier. The general principle involves the encryption of a rapidly changing unique value using a prearranged key. In the following we outline a simple authentication sequence between nodes *A* and *B*. At the end of the sequence, *A* has reliably identified itself to *B*. The analogous sequence is needed for *B* to identify itself to *A*. Typically, one expects to interleave the messages of both authentication sequences.

Assume that *A* uses a secret key, associated with itself, in the authentication sequence. The reliability of the authentication depends only on the security of that key. Assume that *B* holds *A*'s matching key (as well as the matching keys for all other hosts to which *B* might talk).

1. *B* sends *A* in cleartext the current time of day as known to *B*.
2. *A* encrypts that time of day using its authentication key and sends the resulting ciphertext to *B*.
3. *B* decrypts *A*'s authentication message, using *A*'s matched key, and compares it with the time of day which *B* had sent. If they match, then *B* is satisfied that *A* was the originator of the message. If the received time of day is not much older than the current time of day, *B* is satisfied that the message has not been delayed and retransmitted.

This simple protocol does not expose either *A* or *B* if the encryption algorithm is strong, since it should not be possible for a cryptanalyst to be able to deduce the key from

\*\* This approach blocks communication if the host operating systems are constructed in such a way as to prohibit cleartext communication over the network.

the encrypted time of day, even if he knew what the corresponding cleartext time of day was. Synchronized clocks in the network are not required. Further, since the authentication messages change rapidly, it is not possible to record an old message, retransmit it, and have it treated as valid by the recipient.

Authentication protocols such as these require the prior distribution of secret keys. If data security is the goal, no formal authentication protocol is actually required when all data transmissions are encrypted, since possession of the key serves as prima facie evidence that the participants are the appropriate ones, as well as providing the mechanism empowering the communication. Nevertheless, authentication protocols can give immediate assurance, and protect against the playback of previously recorded traffic.

### DATAGRAMS

Datagrams are short messages from one user to another. These messages should be delivered with relatively low overhead if services such as electronic mail are to be practical. In addition, it is desired that buffering be performed at the recipient site. That is, the mail should be delivered as soon as possible to the recipient site, and stored there, even if the desired user is not logged in.

Assume that a user at one site wishes to send mail to a user at another site. Using conventional encryption algorithms, the first user would request a connection to the second user, and a new key would be chosen and distributed by the key controller to each end of the communication channel. That key is sent using the secret keys of the two users.

However, since the second user may not be signed on at the time, a daemon process is used to receive the mail and deliver it to the user's "mailbox" file for his later inspection. It is desirable that the daemon process not need to access the cleartext form of the mail, for that would require the mail receiver mechanism to be trusted. This task can be accomplished by sending the mail to the daemon process in encrypted form and having the daemon put that encrypted data directly into the mailbox file. The user can decrypt it when he signs on to read his mail. In that way, the daemon only needs the ability to append to a user's mailbox file.

In order for the user to know the new key used for this mail, however, the key distribution algorithm described earlier must be modified. Rather than send the key for this connection to both the sender and the receiver, the key controller sends the key twice to the sender, one copy encrypted with the sender's secret key and one copy encrypted with the receiver's. The sender can prepend the copy of the key encrypted in the receiver's secret key to the mail before transmission. When the recipient signs on, his own mail program will examine the mailbox file, find the key message encrypted with his secret key, decrypt it to obtain the key for that message, and then use that key to decrypt the remaining text.

In the case of public key encryption algorithms, the mail problem is somewhat simplified since the recipient knows

what key to use in decryption (his private key). However, authentication is not possible since the recipient is not present when the message is received. Thus, it may be a replay of a previously sent message. This problem can be prevented in the conventional encryption algorithm case via various protocols with the key managers, for example, by time-stamping the mail and having the recipient keep track of recently used mail keys.

Both mechanisms just outlined do guarantee that only the desired recipient of a message will be able to read it. However, as pointed out, they don't guarantee to the recipient the identity of the sender. This problem is essentially that of digital signatures, and is discussed in the next section.

## DIGITAL SIGNATURES

The need for digital signatures has by now become apparent to many. At first, it appeared that public key methods would be superior to conventional ones for use in digital message signatures. The method, assuming a suitable public key algorithm, is for the sender to encode the mail by "decrypting" it with his private key and then send it. The receiver decodes the message by "encrypting" with the sender's public key. The usual view is that this procedure does not require a central authority, except to adjudicate an authorship challenge. However, two points should be noted. First, a central authority *is* needed by the recipient for aid in deciphering the first message received from any given author (to get the corresponding public key, as mentioned). Second, the central authority must keep all old values of public keys in a reliable way to properly adjudicate conflicts over old signatures (consider the relevant lifetime of a signature on a real estate deed for example).

Further, and more serious, the unadorned public key signature protocol just described has an important flaw. The author of signed messages can effectively disavow and repudiate his signatures at any time, merely by causing his secret key to be made public, or "compromised." This fact has also been pointed out by Saltzer.<sup>13</sup> When such an event occurs, either by accident or intention, all messages previously "signed" using the given private key are invalidated, since the only proof of validity has been destroyed. Because the private key is now known, anyone could have created any message claimed to have been sent by the given author. None of the signatures can be relied upon.

Hence the validity of a signature on a message is only as safe as the *entire* future history of protection of the private key. Further, the ability to remove the protection resides in precisely the individual (the author) who should not hold that right. That is, one important purpose of a signature is to indicate responsibility for the content of the accompanying message in a way that cannot be later disavowed.

The situation with respect to signatures using conventional algorithms initially appears slightly better. Rabin<sup>9</sup> proposes a method of digital signatures based on any strong conventional algorithm. Like public key methods it too requires either a central authority or an explicit agreement

between the two parties involved to get matters going.<sup>\*\*\*</sup> Similarly, an adjudicator is required for challenges. Rabin's method, however, uses a large number of keys, with keys not being re-used from message to message. As a result, if a few keys are compromised, other signatures based on other keys are still safe. However, that is not a real advantage over public key methods, since one could readily add a layer of protocol over the public key method to change keys for each message as Rabin does for conventional methods. One could even use a variant of Rabin's scheme itself with public keys, although it is easy to develop a simpler one.

However, *all* of the digital signature methods described or suggested above suffer from the problem of repudiation of signature via key compromise. Rabin's protocol or analogues to it merely limit the damage (or, equivalently, provide selectivity!). It appears that the problem is intrinsic to any approach in which the validity of an author's signature depends on secret information, which can potentially be revealed, either by the author or other interested parties. Surely improvement would be desirable.

### *A reliable digital signature method*

A simple, obvious solution is to interpose some trusted interpretive layer between the author and his signature keys, whatever their form. For example, suppose the list of keys in Rabin's algorithm were not known to the author, but instead were contained in a secure Unit (hardware or software). Whenever the author wished to send a signed message, he merely submitted the message to the Unit, which selected the appropriate keys and then used the signature algorithm. Each author would have access to such a Unit.

The loading of each Unit requires some examination. In particular, the means which are used to select keys and insert them into each Unit must be correct if mail challenges are to be handled satisfactorily. That is, there must be some trusted Source of keys (and matching "standard message" in the Rabin protocol), and the key list for each author/recipient pair must be deliverable in a correct, secret way to the appropriate Units. We will call the collection of Units and the Source(s), together with their internal communication protocols, a Network Registry (NR). Such an NR appears required to solve the problems raised earlier. Note that some secure communication protocol among the components of the Network Registry is required. However, it can be very simple; low-level link style encryption would suffice.

For safety and efficiency, the NR functions presumably should be decomposed and distributed throughout the network. In particular, the failure or compromise of a local NR would then only have local consequences. One can even

<sup>\*\*\*</sup> In his paper, Rabin describes an initialization method which involves an explicit contract between each pair of parties that wish to communicate with digitally-signed messages. One can easily instead add a central authority to play this role, using suitable authentication protocols, thus obviating any need for two parties to make specific arrangements prior to exchanging signed correspondence.

construct local NR components of the Network Registry in a decentralized way so that compromise of more than one component would be required before a message signature was affected.

The Registry concept is quite common in the paper world. A local government's real estate recorder's office is probably the most commonly known example.

*Simplification of the proposed signature architecture—  
Specialized digital signature protocols unnecessary*

Once the necessity of a Network Registry is recognized, including a guaranteed authentication mechanism, it appears that simplifications in the mechanisms required for digital signatures can be made that seem to remove the need for specialized digital signature protocols. Instead, any of a collection of simple methods will suffice.

In particular, in order for the Network Registry to operate satisfactorily (including performing user authentication), it clearly must be distributed, and clearly must be able to communicate securely internally among the distributed components. Given that such facilities exist, then the following is an example of a simple implementation of digital signatures which does not require a specialized protocol or encryption algorithm:

1. The author authenticates with a local Network Registry component, creates a message, and hands the message to the NR together with the recipient identifier and an indication that a registered signature is desired.
2. A Network Registry (not necessarily the local component) computes a simple characteristic function of the message, author, recipient and current time, encrypts the result with a key known only to the Network Registry, and forwards the resulting "signature block" to the recipient. The NR only retains the encryption key employed.
3. The recipient, when the message is received, can ask the NR if the message was indeed signed by the claimed author by presenting the signature block and message. Subsequent challenges are handled in the same way.

This simple protocol involves little additional mechanism beyond that which was needed by the Network Registry anyway. It does require that the Network Registry be involved in every message signature and validation. However, recall that all of the unadorned signature methods reviewed earlier require involvement of some form of a Network Registry for at least the first message between any two parties. Public key protocols must check the "telephone book," and Rabin's method requires either a contract or a Network Registry. Furthermore, when one adds a more complete Network Registry on top of those other signature methods to correct their repudiation problem, all methods involve the NR for each message. Note that this protocol also does not require the NR to maintain any significant storage for signature blocks.

*Performance and safety*

Certain elementary precautions should be taken in the design of the Network Registry to avoid unnecessary internal message exchanges and to assure safety of the keys used to encrypt the signature blocks. Performance enhancements presumably would involve distributing the signature block calculation. Safety enhancements could include the use of different keys at each distributed site, replicating sites, and employing a signature block computation which requires the cooperation of multiple sites. Each of these facilities is straightforward to build and so they are not discussed further here.

It has been speculated that the task of constructing a Network Registry would be simpler using public key systems, since only the secret key of the Registry needs to be stored securely. However, using conventional encryption the Registry could encrypt all the private keys using a master key which belongs to the Registry. Thus, it is again the case that only the master key of the Registry needs long-term secure storage.

From the preceding discussions, we conclude that the digital signature algorithms proposed heretofore are unsatisfactory, and the improvements required to correct their inadequacies make the use of a specialized digital signature algorithm unnecessary.

We note here that the safety of signatures in this proposal also depends on the future history of protection of keys as before—in this case those held by the Network Registry. However, there are several crucial differences between this case and previous proposals. First, the authors of messages do not retain the ability to repudiate signatures at will. Second, the Network Registry can be structured so that failure or compromise of several of the components is necessary before signature validity is lost. In the previous methods, a single failure could lead to compromise.

## USER AUTHENTICATION

While digital signatures are important, it is necessary to realize that there still *must* exist a guaranteed authentication mechanism by which an individual is authenticated to the NR (presumably directly the local Unit). Any reasonable communication system of course ultimately requires such a facility, for if one user can masquerade as another, all signature systems will fail. What is required is some reliable way to identify a user sitting at a terminal—some method stronger than the password schemes used today. Perhaps an unforgeable mechanism based on fingerprints or other personal characteristics will emerge.

Once the user has been correctly identified to the system, public key systems also must deal with the problem of retrieving the recipient's private key. That key *must* be securely stored, either in part in the user's head (not a very secure place), or somewhere else. Various forms of storage are possible: for example a simple card the user carries around with him, or in the system itself. However, the

storage must be in a form which is not useful to anyone else. For example, if the user loses the box containing his key, no one else should be able to use it, nor decipher its contents. This requirement means that the box itself can not be used as the sole user authentication mechanism. In addition, the key must be stored in the box in an unreadable form, presumably encrypted using some system key. The user must first authenticate himself to the system, have the system read the box, decode the key, and store it securely for use.

Once it is recognized that the system must be able to store keys securely, it becomes clear that the box just suggested can be dispensed with, except possibly as part of a user authentication mechanism. The system then would store users' private keys. Once a user has authenticated himself, the system can retrieve the key. This approach avoids the problem of requiring the user carry around a card, and makes revocation/change of keys simpler.

Thus, there appears to be no advantage in the use of public key systems over conventional ones for user authentication or private key storage, since keys must be securely stored in either case. In fact, in conventional encryption, only the keys used for initial connection establishment with the key controllers require long-term storage. Others only remain as long as the connection is in use.

## CONCLUSIONS

Based on the preceding discussions, we draw several conclusions. First, the debate over the relative advantages of public versus conventional key encryption algorithms is just not very important, at least for the class of applications discussed in this paper. In either approach, there must exist a similar amount of secure mechanism that must be trusted. Public key algorithms do not aid that problem to any significant degree. In any event, a strong algorithm is needed. Whether it is public key-based or a conventional one doesn't matter much at all, compared to the overriding necessity that it be strong. If strong conventional algorithms are easier to develop, as has been speculated,<sup>12</sup> research would be better devoted to that area rather than public key systems. Once suitable algorithms are available, the remaining weak link in the principles of secure, distributed systems lies with the requirement to accurately authenticate the user to the system.

Also, it seems that the digital signature methods which have been proposed, both public key- and conventional algorithm-based, do not adequately protect recipients of signed documents from repudiation of signatures by the author revealing the secret key(s) employed. The difficulty appears intrinsic to the approaches being taken. An alternative is available which overcomes this problem; however, that involves a small amount of trusted software.

The necessary underlying mechanism required to support improved digital signature methods, as well as other user-visible secure network communication protocols, is relatively well understood, and takes account of the important requirement that the amount of trusted mechanism involved be minimized for the sake of safety.<sup>8</sup>

In more global terms, this discussion of network security has been intended to illustrate the current state of the art. Assuming a common carrier philosophy, then general principles by which secure, common carrier-based, point-to-point communication can be provided are reasonably well in hand. Of course, in any sophisticated implementation, there will surely be considerable careful engineering to be done.

However, this conclusion rests on one important assumption that is not universally valid. Either there exist secure operating systems to support the individual processes and the required encryption protocol facilities, or each machine operates as a single protection domain. A secure implementation of a Key Distribution Center or Registry is necessary in any case. Fortunately, reasonably secure operating systems are well on their way, so that this intrinsic dependency of network security on an appropriate operating system base should not seriously delay common carrier security.

## MME OVERVIEW

The increasing sophistication of military systems and decreasing time frame for making decisions make it essential to provide the military commander better quality information faster. With today's technology, messages can traverse several thousand miles in fractions of a second, but hours are lost at either end, both in entering the message into the communications system and in delivering it to the person who can act on it. Even after the message is delivered, an officer acting on it requires background information to formulate a proper response. More often than not, that information is available only after time-consuming searching through ponderous files. The response is usually an outgoing message which must be coordinated with other people, many of whom are not in the immediate vicinity of the message drafter. Hand-carrying the draft to these people slows the response still further. In times of crisis this system can easily become overloaded, throwing the entire operation into disarray.

This message management problem seems an excellent candidate for automation. Users of the ARPAnet have had a form of on-line message service for more than seven years. There is no question that the technology exists, but whether it will be cost-effective in the military environment is not so clear.

In December 1975 the Defense Advanced Research Projects Agency (DARPA), Commander Naval Telecommunications Command (NAVTELCOM), Commander Naval Electronic Systems Command (NAVELEX), and Commander-in-Chief, Pacific (CINCPAC) signed a Memorandum of Agreement<sup>6</sup> stating their intention to conduct an experiment at CINCPAC Headquarters whose express goal was to "evaluate the utility of interactive message service capabilities in a military environment." The experiment is called the Military Message Experiment (MME).

To have the military conduct an experiment of this sort is highly unusual. More traditionally the user community

would state their requirements in a Request for Operational Capability (ROC), which is interpreted and converted by some agency of the service into a system specification in the form of a Request For Proposal (RFP). The RFP is subject to further interpretation by the various contractors, first in their proposals in response to the RFP and later in the implementation by the winning contractor(s).

Although this procedure has apparently served well for procurement of more traditional systems, experience indicates it has been less successful in the field of computer automation, especially in data management systems like a message service, where the requirement is seldom well understood and the many levels of interpretation between the ROC and the final system lead to products poorly suited to the real requirement. The implications of a particular system design are subtle; if some aspect is inappropriate, it is often virtually impossible to change. ARPAnet experience has shown that the effectiveness of a message service is strongly dependent on ease of access to the system, how often people look at their messages, how "official" such messages are considered to be, *ad infinitum*. Further, the message service is often just the tip of the iceberg as users begin to understand the capabilities the system offers outside pure message processing. If the message service is used extensively, it intimately affects individuals' work style in ways that are difficult to predict. Thus it is very risky to try to specify "requirements" when replacing a paper, pencil and typewriter world with modern "office automation" tools. Attempts at management information systems have shown it is particularly difficult to provide a user interface that is acceptable to high-level managers, so it is not even clear precisely who will sit at the terminals or how these people will interact with senior officers.

The MME is a computer-world equivalent of a "fly-before-buy" test of a message service in an operational military environment. The test is relatively small and inexpensive compared to the cost of multiple installations of a "production" system. The hope is the experiment will provide

enough experience and understanding of interactive message handling that subsequent production systems will be successes rather than expensive lessons in how not to automate the process. In June 1977 the U.S. House Appropriations Committee put a moratorium on virtually all new development of "message systems" by the Department of Defense until results from the MME can be evaluated.

The MME is being conducted at the CINCPAC Headquarters, Camp Smith, Oahu. The test community is approximately 100 officers and staff personnel in CINCPAC's command center and "operations" directorate (called J3). Twenty-four video display terminals are provided for user interaction with the service. Seven printers are located throughout the headquarters for local hard copy. The host processor is a PDP-10 (KL processor) manufactured by Digital Equipment Corporation running the TENEX operating system developed by Bolt, Beranek and Newman.<sup>4</sup> The PDP-10 connects to CINCPAC's AUTODIN (AUTOMated Digital Information Network) terminal computer, called the LDMX (Local Digital Message eXchange). The LDMX supports the current message handling service at CINCPAC; it prints copies of all CINCPAC's incoming AUTODIN messages and accepts outgoing messages through an optical character reader, sending them to their specified addressees via AUTODIN.

#### TECHNICAL RESPONSE TO THE MME

The message service being used for the MME is called SIGMA, developed at the University of Southern California's Information Sciences Institute especially for this experiment. As such it is an "experimental" system to be used in an "operational" military environment to test the effectiveness of a "secure" "interactive message processing" service. Consider some of the issues implied by these terms.

##### *"Experimental"*

The primary purpose of the MME is to determine the effectiveness of interactive message processing in a military environment and to provide a technology-transfer path to apply the knowledge and techniques gathered to future generations of military systems. Many design philosophies are implied in such a context. The system developed must be flexible enough to adapt to a changing understanding of the problem and additional requirements imposed by the user community. It must concentrate on issues of functionality and suitable user interfaces. This does not imply that other issues such as sizing and performance are not important—the system must still be responsive and large enough to support a meaningful experiment—but the system need not be cost-justified itself, merely sufficient to gain understanding of the functional and cost issues. And, perhaps most important, the system must be highly instrumented to allow collection of various data reflecting the manner in which users operate the message service. Analyses of these data allow evaluation of user performance and usefulness of ser-

vice facilities, and provide a further understanding of the potential role of interactive message services in the military environment. All of these factors were considered and respected in the development of SIGMA.

##### *"Operational"*

To gain the most accurate picture of the MME's potential impact on the military community, an early decision was made to perform the experiment in an actual military environment, the CINCPAC headquarters. Since CINCPAC already has an effective manual message system whose use is well understood by its personnel, SIGMA presents a message processing model which is intuitively similar to the existing manual one in order to gain early user acceptance. This decision implied choosing terminology which matched standard military usage,<sup>5</sup> and providing functions which, where possible, were similar to the manual ones. Since the military users operate the on-line system as only a part of their normal jobs, SIGMA has been designed to be highly self-instructive.

##### *"Secure"*

An important requirement for the SIGMA service is that it meet military security specifications. Although this test system will be operated only by personnel classified at Top Secret, it is a test objective that the message service address the multi-level security issues identified by previous research.<sup>3,1</sup> To satisfy this objective, SIGMA implements a security model which behaves as though SIGMA were running in such a "provably secure, kernel-based" operating environment; this model is described in Reference 2. Although the provably secure environment does not yet exist on TENEX, SIGMA's emulation of it allows the users to interact in a manner virtually identical to that they would encounter if SIGMA actually ran in the secure environment.

##### *"Interactive message processing"*

SIGMA has been designed to be a "complete" interactive message service for CINCPAC. Its user interface responds to the needs of computer-naive users in several ways. Since this community will not receive much special training in SIGMA's use, an online Tutor and Help facility has been designed to take on the bulk of this responsibility.<sup>7</sup> The Tutor, like the rest of SIGMA, takes advantage of the specially designed MME terminal,<sup>8</sup> which features multi-window displays and two-dimensional editing.

The command formats are defined by SIGMA's Command Language Processor (CLP). The user instructs SIGMA through a set of function keys or by typing commands in a predesignated "command window" on the screen of the MME terminal. The CLP parses and interprets these instructions; it is table-driven so instructions may be added or modified easily. The CLP expands commands and parame-

ters that are only partially entered and corrects misspelled words to the degree that it can, based on the user's personal directory of named objects as well as the command table. A Prompt facility is provided which allows the user to ask about required parameters for a given command without losing any of his operational context. This powerful command language interface is an essential ingredient in providing the user the highly supportive environment needed for users with little or no experience with computers.

#### SIGMA—APPLYING INTERACTIVE TECHNOLOGY TO MILITARY MESSAGE PROCESSING

In common with other styles of mutual communication, message processing has distinctly cyclic characteristics—a message is initiated; its contents are refined from draft to final form; it is approved and sent to its intended recipients; a recipient reads it, perhaps forwards it to colleagues; the information contained within invites (or requires) a reply; the reply is initiated, and the process repeats. Message processing as practiced at CINCPAC differs from other styles primarily in its highly formal nature, with guidelines governing nearly every aspect.

The entire message processing task can be roughly separated into three areas of closely related activities: Message management, incoming message processing and outgoing message processing. As implied by the cyclic nature of the communication process, none of the activities in one area is disjoint from those in other areas. For the purposes of presentation, however, the facilities of the SIGMA message service are described according to these three areas.

##### *Message management*

A message service must facilitate all phases of message management. The following sections summarize SIGMA's support in this area.

##### **Messages**

Messages are SIGMA's fundamental concern. They are composed of a diverse set of fields; a field's contents depends on its type. For example, a "TO" field contains a list of addressees, a "TEXT" field contains a succession of uninterpreted paragraphs, while a "SUBJECT" field can only have a single line of text (of arbitrary length). Although AUTODIN traffic is its primary focus, SIGMA also supports formal in-house communications (*Memos*) and informal messages (*Notes*). They differ slightly in the fields they contain and the ways in which SIGMA processes them.

##### **Folders, entries, and selectors**

*Folders* are the users' basic mechanism for organizing and storing collections of messages in SIGMA. They contain *en-*

*tries* which are pointers to messages. A folder entry, an abstract of its message, contains information such as the message's precedence, security, sender, type and subject, which are considered by SIGMA as attributes of the entry. An entry for an incoming AUTODIN message might look like

```
22 R UU Auto 04222Z DEC 78 From:
    JCS WASHINGTON DC INCOMING Act: J3
    Subject: AIRCRAFT INFORMATION
```

The above entry is number 22, with routine (R) precedence, unclassified (UU) security, AUTODIN type, whose date/time is 04222Z DEC 78, etc. When a folder is DISPLAYed (the capitalized part of verbs are SIGMA commands), a numbered list of entries is put on the terminal's screen.

For use in commands, entries from folders can be identified in three ways: 1) By their number, 2) by default to the current entry, 3) by HEREding the entry number, i.e., putting the terminal cursor into an entry and depressing the "HERE" key. With this scheme most folder entry commands—DISPLAY, DELETE, FORWARD, etc.—have three forms. Using DISPLAY as an example, they are

```
DISPLAY ENTRY entry-number
DISPLAY ENTRY
DISPLAY NEXT ENTRY
```

The first is a typed command. The second is a function key which can take a HEREd entry; without one it will display the current entry. The last is also a function key. Some commands like DELETE and FILE (which copies entries from one folder to another) take entry lists, in addition to simple entry numbers, as parameters.

As objects themselves folders can be CREATED, DISPLAYed, DELETED, RESTORED (the inverse of DELETED), and FILEd into. In addition, user directories of folders can be VIEWed and assuming access is permitted, folders can be shared among users.

Often a user wants to extract from a file a class of entries which have some uniform characteristics. For example, he might wish to work on his messages according to their precedence. SIGMA provides *selectors* for this task. Selectors are boolean expressions composed of attributes of entries. When applied to folders they act as filters, returning lists of entries whose members satisfy their criteria. When the user has a folder displayed he can use the two selector commands, RESTRICT and AUGMENT, to change his display to exactly those entries he has selected. Thus after DISPLAYing a folder, a user can see all secret entries from CINCPAC by typing the command

```
RESTRICT SELECTION SECRET AND FROM
CINCPAC
```

The user can AUGMENT his display in a similar manner. If he now wants to add to this display those entries whose

precedence is routine, he types

#### AUGMENT SELECTION ROUTINE

AUGMENT and RESTRICT commands are "stacked" so that the user can always back up to his previous display using the BACKUP function key.

At any point during a sequence of RESTRICTs and AUGMENTs the user can CREATE a named selector which reflects the logical "ANDing" (for RESTRICT) and "ORing" (for AUGMENT) which led to the current state. In addition, he can CREATE a named selector directly by typing in the boolean as an additional parameter. DELETE, RESTORE, and VIEW commands apply to named selectors. A user's directory of named selectors can be VIEWed, and if access is permitted selectors may be copied from other users.

The richness of entry attributes makes selectors easy to use for creating relevant folder displays. SIGMA commands that operate on entries apply only to those entries currently in view, i.e., selected. So if entries 5, 15, 22, 27 were selected, four uses of the DISPLAY NEXT function key would step through only those messages.

#### Comments

Message fields and folder entries may be annotated with arbitrary text strings by means of the COMMENT command. Comments are identified by the user making them and have additional access properties; they can be public, private (to the commentor), or restricted to a named user. Comments are created by pulling a HERE in the desired message field or folder entry. The COMMENT command is then entered with the access specification and in response SIGMA will create a new field ready for editing.

#### Editing and text objects

Fields can be edited in two ways—by modifying the display with local editing functions provided by the terminal, and by various SIGMA commands. Suffice it to say the terminal provides a full complement of editing capabilities.<sup>8</sup> In addition to those capabilities, SIGMA has its own editing commands. The PICKUP function key command deletes the characters between two HEREs, putting them into an unnamed buffer. The PUT function key inserts the contents of the same text buffer at the current cursor position. The MOVE function key, a composition of PICKUP and PUT, moves the text between the two HEREs to the current cursor position. COPY is the same as MOVE except the characters are not erased. These commands give the user the capabilities to erase, move and copy large amounts of text conveniently.

Text that is to be reused in messages or commands can be created and stored as a named *text object*. A text object is nothing more than a series of uninterpreted paragraphs, and can be CREATED and edited using all the capabilities

described above. A user directory of text objects can be VIEWed; they can be DISPLAYed, DELETED, RESTORED and, if the access is correct, copied from other users. Named text objects can also be used in conjunction with the PICKUP and PUT commands.

The content of a text object is unrestricted. No semantics are applied until it is put into an interpretable field. Once it is there, SIGMA acts on it depending on the type of field into which it was put. For example, text in an address list is checked for legal user names; when put into a field in which multi-paragraphs are allowed, the text is formatted.

SIGMA has not explored all the potential of text editing. So while it has a FINDSTRING command, it doesn't have one for text substitution. The experimental use of SIGMA at CINCPAC will provide feedback related to the adequacy of our editing model.

#### The SIGMA display

SIGMA divides the MME terminal screen into four windows. The FLASH window at the top of the screen contains three lines. The first is updated every minute and gives general operating information, time of day, and so forth. The FEEDBACK line tells the state of SIGMA processing and conveys error information. The STATUS line will be described below. SIGMA commands are typed into the two line COMMAND window below the FLASH window.

The remainder of the screen is the user's working space, which may be occupied by one or two windows. When a user DISPLAYs a folder, text object, or message, the object is "opened" and put into the EDIT window. If another object of the same type is already opened, then it is FINISHED, i.e., stored away with all new edits saved. If the open object is of a different type, then it is moved off the screen, though still opened, to make room for the newly DISPLAYed one. The STATUS line names all the open objects with the first name on the list identifying the one currently on the screen. Three function keys, SHOW FOLDER, SHOW MESSAGE and SHOW TEXT, can be used to put the appropriate object back into the EDIT window.

The VIEW window shows objects which the user names with the VIEW command. It is cleared by the CLEAR VIEW function key. This window is not editable and is used only for reference (text can, however, be copied from it). It is shown at lower intensity to distinguish it from the EDIT window. The EDIT window occupies the full screen when nothing is viewed; otherwise, both share the screen.

This section has given a functional view of SIGMA by describing its objects and some of its legal operations. The next two sections will give a more structured view of the tasks which compose message processing.

#### Incoming message processing

In the military, formal AUTODIN messages are sent from the commander of an organization to the commander of

other organizations, never between individuals within the organizations. This practice requires the receiving command to determine the appropriate recipients within the command for every incoming message. Naturally the correct assignment of recipients is a critical part of the incoming processing task.

CINCPAC employs a content-based scheme to determine the correct recipients. The first stage of this process is implemented by the LDMX message processor. By scanning the header and selected fields of the message contents, LDMX makes a preliminary assignment to the top management level (directorates). Although LDMX is capable of more detailed assignment, CINCPAC chooses to allow its directorates to perform their own routing internally. Within the MME target population (J3, the Operations directorate), this next level of routing is performed manually by an administrative office (J301). Using both catalogued tables of routing assignment and his specialized training, J301 scans each incoming message and determines its disposition. Such disposition can be any or all of the following:

Action	Typically each message is assigned to an <i>action officer</i> . He is responsible for any actions or response to be made by the J3 directorate, and is said to <i>have the action</i> for the message.
Info	In addition to a responsible officer, the contents of the message may be of interest to other officers as well. Such officers are said to receive an <i>information</i> copy of the message.
Readboard	Certain messages may be of interest to large groups within the directorate, and occasionally to all of J3. Such messages are placed in binders called <i>readboards</i> , which are then circulated through the directorate.

While the J301 assignment is generally accurate, it is neither complete nor infallible. An officer receiving a copy of a message may determine that other officers not designated by J301 should also receive copies. Occasionally the action assignment for a message is not appropriate; after seeing a message, an action officer may decide that another officer is better qualified to handle it and "sells the action" to him. Thus, the propagation of copies and/or action of a message may continue for several stages beyond the J301 assignment. Based on data compiled at CINCPAC, an average of 40 copies of a message is required to reach all its recipients.

SIGMA supports incoming message processing with a variety of facilities. They can be roughly divided into the three areas of delivery, reception, and redistribution.

#### Delivery

SIGMA was designed to merge naturally into the existing message processing milieu at CINCPAC. Through the special LDMX interface, SIGMA's Reception Daemon receives the text of incoming AUTODIN messages, parses them, builds the SIGMA internal representation, and stores the re-

sulting SIGMA-formatted messages in its message data base. To allow methodical retrieval of messages by arrival times, SIGMA also places an entry in a special folder called a *Date File*, a new instance of which is created each day to contain entries for all AUTODIN messages received during that day. A user can then see an index of all messages received on a particular day by simply DISPLAYing the corresponding Date File.

The high fan-out of incoming messages makes it impractical to provide a separate copy of each message to each eventual recipient. The scheme adopted in SIGMA was designed to minimize on-line storage requirements while still providing convenient access to messages. Messages are stored only once, in the central message data base. Each recipient receives not a copy of the message, but an abstract containing a useful subset of the message's contents. An instance of this abstract, called a *citation*, is created for each message transaction between users. Each citation sent to a folder causes a new folder entry to be appended (indeed, the terms *citation* and *folder entry* are often used interchangeably), a task performed by a special SIGMA background process, the Citation Daemon. A citation is small (approximately five percent the size of a message) and thus is much more economical to replicate than the full message.

All users access and modify the single copy of a message. Obviously such activity cannot occur unrestricted, or the integrity of the message contents and the users' intended changes could not be preserved. To allow such operations, a special scheme correctly assimilates parallel modifications, preserving both the consistency of the message and the users' intentions.<sup>9</sup>

Since messages flow into the J3 directorate constantly (approximately 1000 per day), the available secondary storage would soon fill unless appropriate steps were taken to reduce the number online. To make room for incoming messages, an archival scheme has been implemented. Using frequency of access as a rough guide, SIGMA moves inactive messages onto bulk storage (magnetic tape), from which users needing access to messages can request retrieval. Mechanisms are also provided to allow shorter retention periods for selected messages.

#### Reception

Once citations have been sent to a user, he must be allowed to see them, access their referenced messages, and dispose of them as he sees fit. These capabilities revolve around a repository for incoming citations, a special SIGMA folder known to each user as his *Pending File*. Analogous to a mail in-basket, a user's Pending File receives all citations destined for him.

Physically, a Pending File is implemented as a SIGMA folder, and can thus be manipulated by the wide variety of folder operations—DISPLAY of referenced messages, COMMENTing, cross-sectioning via RESTRICT and AUGMENT, etc.

Since all citations for a user are appended to his Pending File, he must eventually delete nearly all of them, lest he

exceed the folder size restriction (which is in excess of 6000 entries). This does not imply that a user must lose references to important messages, however, since a user may create an arbitrary number of other folders where he may FILE them.

Frequently, messages of great urgency to a user may arrive. In such cases the user would like to be notified immediately, rather than wait until he happens to notice it appear in his Pending File (which might be some time if he were DISPLAYing some other folder). To allow a user to specify criteria for incoming messages for which he wants immediate notification, SIGMA provides the Alert facility. The user activates the Alert facility by creating a SIGMA selector named ALERT\_SELECTOR. If such a selector exists, each incoming citation is matched against it to determine if it meets the Alert criteria. If so, the citation is added to a special *Alert List*, the format of which is very similar to that of a folder, and the bell at the user's terminal is rung. The user can then display the Alert list without disturbing his open folder, and access any of the referenced messages in a manner similar to that for folder entries. In addition, a count recording the number of active alerted citations is maintained in the SIGMA flash line.

### Redistribution

As explained in the description of the Delivery task, the routing provided by LDMX is not sufficient to reach all appropriate recipients. Additional routing is provided by the administrative J301 function, which supplies the bulk of the specific routing assignment, and by individual officers, who either supplement or correct the J301 assignments. SIGMA provides this flexibility by means of its redistribution facilities.

To effect the bulk routing assignment at the directorate level, SIGMA provides the ROUTE command. With this single command, J301 can specify action assignment, info distribution, and readboard creation for an entire group of messages. Using the RESTRICT and AUGMENT operations to select a class of similar messages, J301 can then perform a complete routing assignment for the whole class in a single step.

Individual officers needing to perform further redistribution have two more limited redistribution commands. The FORWARD command allows one user to send an information citation ('FOR\_INFO') to another. The ACTION command is similar, but implies that the originating officer transfers the action assignment to the designee (by means of the 'FOR\_ACTION' citation). Additionally, the ACTION command causes an entry to be placed in the issuing user's *Action Log*, a special folder which contains a record of all action assignments he has made. Since CINCPAC wishes to keep a central accounting of action assignments, users normally share a single Action Log (via SIGMA's shared folder capability).

All redistribution commands account for the further distribution of messages by appending records to certain message fields. In each message a *Distribution* field records each user who has received an info citation, while an *Action*

field records the full history of action assignments. Thus it is possible to ascertain all users involved in a message's redistribution by examining its appropriate fields.

### Outgoing message processing

In the existing manual system, CINCPAC officers deal exclusively with so-called "record traffic." Even when the contents of a message are routine, the onus of representing an entire command's viewpoint adds a measure of importance. Consequently highly formalized procedures have developed at CINCPAC to ensure that messages transmitted from the CINCPAC organization have been thoroughly reviewed and approved by a responsible authority.

In addition to supporting an on-line implementation of the review/approval process, SIGMA has augmented the media of communication. In addition to the existing formal traffic (AUTODIN messages), SIGMA has added two new message formats, formal internal and informal.

- Formal internal messages (memos) are similar to content and form to AUTODIN messages, but the addressees are other SIGMA users. This provides CINCPAC personnel with a formal (recorded) medium to send official communications within the CINCPAC organization.
- Informal messages (notes) provide an off-the-record message medium for informal communication. Such messages, which are not reviewed or recorded, provide an alternative to face-to-face or telephone communication.

The outgoing message processing in SIGMA is roughly divided into four phases: drafting, coordination, release and transmission.

### Drafting

During the drafting phase the original message is composed. The sources of the original contents of the body and various fields vary, depending on the type of message being prepared. SIGMA supports the following commands for message drafting:

- |        |  |
|--------|--|
| CREATE | An empty message form is created, with blanks for the editable message fields. The contents of any desired fields must be filled in by the drafter.  |
| COPY   | This command, which requires an existing message as a parameter, copies all of the non-header fields into the new draft message. It is useful for pro forma messages which are sent frequently and whose contents are basically similar. |
| REPLY  | This command also takes a message parameter, and creates a new draft in reply to the subject message. In this case, the addressees   |

are derived from the subject message, the subject is copied, and the referenced message cites are copied with a cite to the subject message appended as an additional reference.

Once he has created his draft message, the author has the following alternatives:

- He can save the draft for later use (via the FINISH function key). This can be done to hold an incomplete draft for later completion, or to save a pro forma message to make it available for later COPYING. To make later retrieval of such saved drafts convenient, SIGMA puts a citation referencing the draft in the user's Pending File, so its existence is remembered and it remains easy to access.
- He can send the message for review if it is a formal message. This process, called Coordination, will be described in more detail.
- If authorized, he can cause the message to be transmitted to its addressees. This will be described in the section on Release.

### Coordination

Within CINCPAC there exists a formal procedure for review and revision of a message prior to its release. The drafter can request several other officers to review the message, make comments, suggest changes and give a general disposition regarding the message. This procedure, called *chopping*, permits CINCPAC to acquire a consolidated opinion from a cross-section of responsible officers before a message is sent.

SIGMA supports a style of coordination more general, although perhaps less flexible, than the manual CINCPAC procedure. The message drafter may designate any number of users in a field called the *Chop List*. With the special COORDINATE command, the drafter can specify that any or all of the users on the Chop List be requested to act as reviewers for the message (they are referred to as *coordinators*), causing a special "FOR\_CHOP" citation to be sent to each of the designated users.

A coordinator is notified of the drafter's request to review a message by receipt of the FOR\_CHOP citation in his Pending File. He can display the message, and will see the drafter's most recent version. The coordinator can make comments or suggest revisions to the message; if so, the changes are not applied to the drafter's copy, but rather to a copy belonging solely to the coordinator. In deciding upon his changes he has access not only to his own version and the drafter's, but to other coordinators' as well.

When a coordinator decides that he in turn would like comments from other users (perhaps subordinates or other colleagues), he may further designate other coordinators. This "sub-coordination" is exactly analogous to that initiated by the drafter. In this case his sub-coordinators see his version of the message when they first display it.

When a coordinator has finished his review of a message

he may indicate his global disposition of the message by means of the CHOP YES and CHOP NO function keys. These commands cause a "CHOPPED" citation indicating the appropriate disposition to be sent to the drafter (or higher level coordinator), who is thereby notified that this coordinator has finished his review.

During the coordination process, the drafter (or a higher-level coordinator) can monitor the coordination process by means of a status field, which indicates the progress of each coordinator. When coordinators have finished their reviews he can view their versions and note suggested changes and comments. He can incorporate changes by duplicating them in his own version or by copying the changed sections from the coordinators' versions. If he is not satisfied with the resulting message or wishes to elicit further review, he can initiate another coordination cycle, which will result in additional FOR\_CHOP citations being sent. If the drafter is satisfied with the content of the message, he can initiate the Release process.

### Release

Because of the formal nature of record communication, certain officers, designated *release authorities (releasers)*, are solely empowered to approve outgoing record traffic. SIGMA provides the same enforcement by checking each attempt to transmit a message against a list of authorized releasers (since the three different message formats have different levels of formality, a separate list is maintained for each).

When a drafter has determined that a draft message is ready for transmission, he must gain the approval of an appropriate releaser (unless he himself is one, in which case he can release it himself). He does this by using the COORDINATE command after designating the releaser's name in a special *Release* field, causing a "FOR\_RELEASE" citation to be sent to the releaser. After receiving this citation a releaser has options similar to those of a coordinator. He can display the drafter's and coordinators' versions, seeing comments and suggested changes. In particular, he may examine the "chop" disposition of the various coordinators to determine whether he is satisfied that there is sufficient agreement among them. If he is not satisfied he can make his own comments and changes and specify CHOP NO, in which case a citation is sent back to the drafter. But if the message is in order and the releaser is satisfied, he can initiate transmission via the RELEASE command, whereupon the message leaves the preparation phase and is sent for transmission processing.

### Transmission

When approved by a releaser, a draft message is prepared for transmission by the SIGMA process called the Message Daemon. First the draft is marked as transmitted; this prevents it from being further modified or transmitted again. A new message is then created to contain the transmitted ver-

sion of the draft message. Fields which are appropriate for transmission are copied from the draft; others which do not belong in transmitted messages (such as comments, chop lists) are omitted.

When the contents of the transmitted message are prepared, the appropriate transmission medium is determined. If the message is destined for AUTODIN, the message is sent through the LDMX interface to be transmitted to the AUTODIN network. If it is an internal message, the transmitted message (in internal SIGMA format) is entered into the SIGMA message data base, and "INCOMING" citations are sent to each of its addressees.

## CONCLUSIONS AND USER REACTIONS

Our initial opinion after studying the CINCPAC environment was that an interactive message service could be extremely effective. The CINCPAC staff was enthusiastic about the possibilities and endorsed the experiment to the point that they were willing to serve as the test-bed for it. Now the experiment is underway and we are beginning to learn whether our optimism has been well founded.

Although at the writing of this paper formal results are not yet available, CINCPAC users have been using the service for six months. They have already asked for changes and extensions to the service; some, like ROUTE, have been implemented. As expected, the use of such a service is altering the style in which many officers operate.

Probably the most dramatic effect is on J301 who previously required seven hours to process the new messages that arrive overnight. Using SIGMA this process is reduced to less than an hour-and-a-half. Furthermore the feeling is the assignments made are generally better, primarily because the same assignment is made to entire classes of messages at once, thereby assuring uniformity.

Another group of users that has been heavily influenced by SIGMA normally get their messages from J301 about 9:00 AM, two hours after they come in in the morning. They have found that with SIGMA they can go directly to the Date Files for the day and, using Selectors, get the messages of interest without waiting for J301 to distribute them. They are also able to find messages requiring their action that have been assigned incorrectly to others, messages that they simply never saw before SIGMA was available to them.

There are still many improvements requested by CINCPAC users which SIGMA has not yet addressed. Indeed, the list is already large even at this early date:

- The ROUTE command was put into SIGMA in response to a direct request from J301. Other composite commands can be visualized. It would be nice to have a powerful facility for building such "macros" from existing commands. However, such a feature touches heavily on many difficult user interface issues.

- The ALERT mechanism is fundamental but acts only on incoming messages. Some users have expressed interest in a general facility based on a variety of different events.
- Users have expressed a desire for the ability to search the full message database with a mechanism like selectors. SIGMA has no model to support this expensive operation at this time.

Although the experiment is just beginning to collect useful information, it is clear that SIGMA is having an impact on the message processing at CINCPAC. SIGMA appears to be rich and flexible enough to support the goals of the experiment to gain insight for future military message systems. As the users become more involved with interactive message handling their awareness of its capabilities and potential is being sharpened and their requests for functional enhancements are more accurately based on realistic needs.

The injection of a research project, like SIGMA, directly into an operational military environment is an unusual event. This approach offers the military a more active role in developing relevant software for sophisticated applications. The MME effort is showing that the transition from the laboratory to an operational setting can be accomplished for such an experiment, which should dramatically shorten the normal technology-transfer path.

## INTRODUCTION

Anyone who has been a part of a large software effort knows of its peculiar afflictions and special problems. The literature teems with guidelines, rules and conventions for designing and managing such systems; in fact, there are probably more books written about large systems than there are large systems. This paper will make no attempt to add to this literature; instead it will simply report our experience over the last five years in the design and implementation of SIGMA.<sup>3</sup> This introspective study is meant to be not a pedagogical paper but a reflective, often humbling, diary.

SIGMA is the interactive message processing system built at the University of Southern California Information Sciences Institute (ISI) for the Military Message Experiment (MME).<sup>2</sup> It is currently in active use at Camp Smith in Hawaii, supporting about 100 users, of which 24 may be concurrently online. SIGMA comprises about 270 modules totaling some 2500 routines. This makes approximately 200,000 lines of source code or some two edge-feet of listings. The point, of course, is that SIGMA is big by any metric. The software was designed and written by a revolving group of five to seven expert programmers, making SIGMA about a 30 man-year program. This is by no means a gigantic effort by industrial standards, but large when judged by research community criteria.

Our experience should not be taken lightly. Deadline pressures notwithstanding, the ISI environment is conducive to high-quality output. Each project member has a private office, an HP2640A CRT terminal, access to an inhouse library and all the facilities one expects at a computer research center. Our successes or failures are generally a result of our own ingenuity and intelligence or lack thereof, respectively.

## SIGMA ARCHITECTURE OVERVIEW

The SIGMA message service runs on a Digital Equipment PDP-10 under the TENEX timesharing system<sup>1</sup> and is written in the BLISS system implementation language.<sup>6</sup> The SIGMA system is divided into two functional areas: the user jobs, which interact with the message service users; and the daemons, a collection of background processors that perform non-interactive functions.

### *The SIGMA user job*

An instance of the SIGMA user job is created for each user who logs into the system. As seen in Figure 1, the user job is composed of five major components. The Terminal Driver interfaces the specially modified HP2649A terminal<sup>4</sup> to the rest of the user job. The Command Language Processor (CLP) reads command input, parses it, builds a command specification called an Execution Request Block (ERB), and passes it to the Functional Module (FM), through a protocol called EC99. The FM is responsible for the actual execution of commands, and thus it has two main tasks: to manage the display of information on the terminal, and to manipulate SIGMA's objects.\* The former task is performed by a module called the Virtual Terminal (VT), which builds and maintains display lists for the terminal. The latter function is done by the FM directly for text objects and selectors, and by two

\* SIGMA supports four kinds of objects. *Text Objects* are lists of uninterpreted paragraphs. *Messages*, of which there are several kinds, are lists of various message fields. *Folders* are lists of message citations; a citation is an abstract of its associated message. *Selectors* are boolean expressions applied to folders in order to access only those citations whose attributes match those named by the selector.

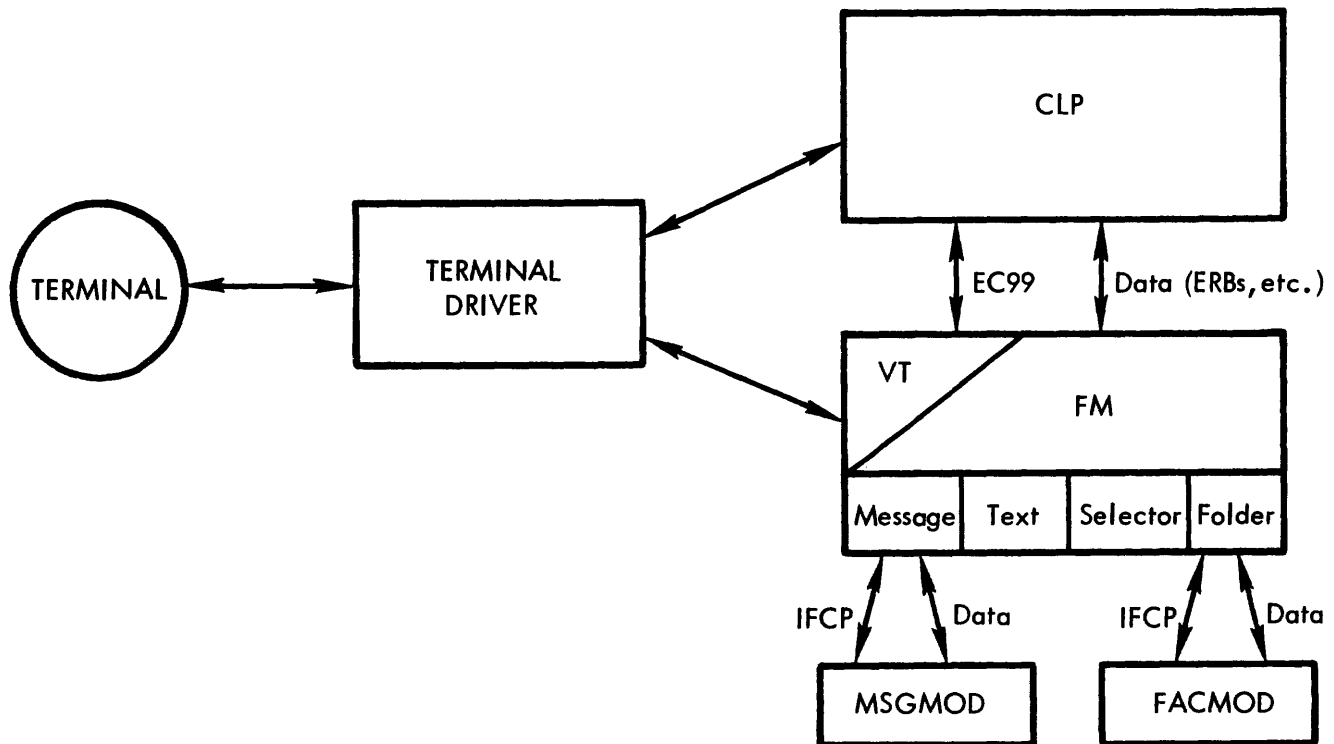

Figure 1—SIGMA user job.

special-purpose modules called the Folder Module (FACMOD) and Message Module (MSGMOD) for folders and messages, respectively. Because of address space limitations, FACMOD and MSGMOD are located in separate TENEX forks (processes) and require a special Inter-Fork Communication Protocol (IFCP) to communicate with the FM.

#### The SIGMA daemons

The SIGMA daemons are responsible for tasks that require no direct user interaction and can thus be performed in background. These include management of the shared data bases (messages and folders), message reception and transmission, archive retrieval, and printer spooling. The daemons process requests received through input queues; the source of such requests may be the user jobs or other daemons. To provide operations personnel with the ability to control the daemons, a Configuration Control Program (CCP) communicates operator requests to daemons.

#### A SIGMA TIMELINE

Figure 2 represents our first effort at producing a milestone diagram for SIGMA's development. This event-oriented chart provides a general impression of how SIGMA developed.

The project, which started in September 1973, was first

called Information Automation (IA). Approximately one year later a series of six IA papers were produced defining the components of what was to be SIGMA and by January 1975 a full system design was published. This 200-page document represented about ten man-years of effort culminating the period we now call "designing in a vacuum."

The first SIGMA, which we will call SIGMA 0 (although it was both unnumbered and unnamed), made its debut a year later in December 1975. It didn't do much, but it did have a front-end that talked to users, a minimal FM that executed a few message manipulation commands, a terminal simulator that was to be functionally equivalent to the terminal being designed for our project, a primitive debugging mechanism, and a simple text editor.

The next year was spent getting SIGMA 1.0 ready for a system evaluation which was to take place in Boston in February 1977. This pubescent period saw SIGMA take on functional substance. The first daemons were written; the concepts of folders, text objects, and selectors were implemented; and the FM was rewritten to encompass all the new objects. SIGMA 1.0 was slow and bulky, but showed enough promise to be the service selected for the Military Message Experiment. We knew even then that the daemon design and implementation were hopeless, but other things had to be done first. SIGMA's performance had to be improved.

Performance was the project watchword for SIGMA 1.75. Since the functionality had become stable, we were able to carefully analyze the system's flow of control, data paths, communication demands and so forth, a study which led to

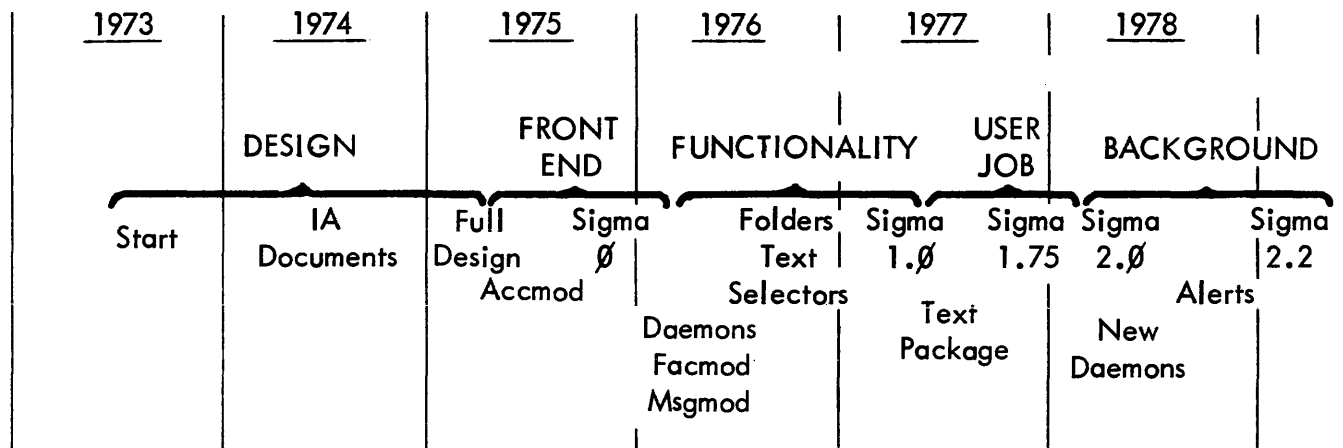

Figure 2—A SIGMA timeline.

optimizations spanning all parts of the user job. This performance transition was particularly trying. Still, by December 1977 it was running at an acceptable speed. The changes we made were so dramatic that SIGMA 1.0 seemed like ancient history.

The time had finally come to deal with the daemons. Their original design was based on principles that led to an overly-complicated implementation whose data flow can euphemistically be described as baroque. The irony is that by SIGMA 1.75 we realized that all the requirements that led to this design were either too expensive or superfluous. This time the daemons were redesigned and rewritten based on our experience of what background support was actually needed.

The new daemons had a great effect on our project. The 1.75 daemons were hopeless to maintain, difficult to debug, and resistant to change; the 2.0 daemons of July 1978 were elegant by every programming standard. SIGMA could finally be called a mature system. Now and only now could we think about functional enhancements that involved the daemons.

The remaining part of 1978 was spent preparing for SIGMA 2.2. Among the new features was Alert processing, an addition which made the online user immediately aware of activity in his personal pending file. The Alert concept had been knowingly lacking since SIGMA 1.0 but was not practical to implement until we redesigned the daemons and had a stable user job.

While in this timeline we seemed to be responding to individual and isolated problems as they appeared, a more abstract view of the development reveals a coherent top-down design. The first year we designed a message service in great detail. The first SIGMA was produced in year two with the emphasis on the front-end components, the CLP and the terminal. The functionality, defined and implemented during year three for SIGMA 1.0, was demonstrated in Boston. Following that came the architectural wirebrushing of the user job, culminating in SIGMA 1.75 in year four. The new functional daemons came during the fifth year together with a round of improvements for SIGMA 2.2.

Even though we actually followed a sensible path in SIGMA's development, our failure to realize what was happening proved to be both costly and frustrating. No doubt all retrospective analysis is concise and relevant; still, early recognition of certain principles would have prevented the chaotic nature of our progress. The next section will present those principles as a pseudo-mathematical theory of software development.

## LARGE SYSTEM DESIGN THEORY

Now that SIGMA has matured we compared its current design and implementation with the one planned in the initial system design. This comparison shows that about the only thing that survived all those years is the system diagram found in Figure 1. There is something futile about the first axiom:

*Axiom 1—Early system design should identify only large namable components.*

Perhaps this is the best that you can do when designing in a vacuum. SIGMA 0 wasn't very good but it did show that our top-level design was sound. Lacking some sharp insight we believe that:

*Axiom 2—A complete running system is necessary to verify even a top-level design.*

The implications of this axiom are severe. When the system is being put together, a placeholder is needed for every component regardless of expense. We knew, for example, that even though the SIGMA terminal was scheduled for late 1976, we needed a simulator for it in order to design the CLP and FM. The man-years spent on this known throw-away piece of software were eminently worthwhile, substantiating the following:

**Theorem 1—Every major component of a design must be implemented in some form.**

Our FM in SIGMA 0 produced the necessary results. It showed that the CLP/FM interface was sound and the terminal model was maintainable by the VT. Even though the

FM barely worked, nothing would have been learned if it didn't run. Trite as it may sound:

**Corollary 1.1—All implemented components must work.**

SIGMA 0 showed us that some of our high-level concepts were designed correctly. However, the implementation experience also taught us other things.

The original FM had too many features, among them a concept called Placemarks. These were named locations within message bodies that the user could assign and address for various purposes. They were hard to implement, and in fact did not survive the transition to SIGMA 1.0. Placemarks may or may not have proved useful, but this was not the time to find out; suffice it to say that much valuable time was wasted here.

ACCMOD was the first complete message manager for SIGMA. It had a data base model for the way it serviced the FM. In other words, it owned the message being displayed and was involved in every facet of its editing. Besides just having performance problems, ACCMOD was a huge, unwieldy piece of code. In the simpler file model, MSGMOD gets the message to the FM who "owns" it during the editing session, and then MSGMOD stores it when the user is done. The important knowledge we obtained from ACCMOD was that its model was wrong. However, a simpler implementation would have shown this as well.

One thing we designed right was the communication of common data between the forks of the user jobs. Data (such as who was logged on, the ID of the open message, etc.) was kept in memory shared between them. The effect was like a FORTRAN COMMON block. This simplest of interfaces served so well that we still use it as originally designed. Of course, we understand its limitations, but we haven't reached them yet.

This Placemark/ACCMOD/Common experience shows clearly that a project should:

**Theorem 2—Start small in early design and implementation phases.**

It is hard to overestimate the pragmatic value of **Theorem 2**. Its realization leads to a natural evolution in which the designers can cheaply reflect on their basic ideas and perhaps modify them before they run out of funds or energy. We should note that there were no daemons at this time. We were still designing them as if they would suddenly appear like Pallas Athena, springing full-grown from the forehead of Zeus. An understanding of **Theorem 2** would have led us to a more conservative first-pass design.

The work which led to SIGMA 1.0 represented a new direction for the project, one that was not fully appreciated at the time. SIGMA 0 verified our front-end model; SIGMA 1.0 would define the system's functionality as needed by the FM. Had we realized that this was the real effort, we could have avoided the complexity found in the daemons. In other words:

**Axiom 3—You can't aim high on every component at the same time.**

Many things happen during a design cycle: Ideas are tested, system modules are inspected, some things work well, and some things are thrown out. Typically, some things stabilize. The CLP did by the time SIGMA 1.0 was released.

The FM was beginning to at the same time. Unfortunately, what had stabilized throughout the user job was our text-handling routines called ZT. ZT was a loose collection of low-level functions. Given these primitive routines each implementer developed his own set of macros and functions, all based on the ZT structure. By the time we realized its performance and design implications, ZT was hard to remove from the user job. The TEXT package that replaced ZT simplified SIGMA by imposing a coherent text-processing model on the project. What we should have realized is:

**Axiom 4—Recognize which component is stabilizing during a design cycle and aim high for it.**

These two axioms are the heart of our evolutionary design theory. Even with unlimited resources, we believe a project will do better to focus its attention on one major component at a time. Some scientific reasons, ranging from interface issues to manpower expenditure, are easy to generate. But one which is often missed is that very little is learned when an overdesigned module is rewritten or modified—it is better to build up from minimum capabilities than tear down from unneeded ones. This "hourglass design," in which one starts high and must then strip away features before a redesign is possible, is a painful way to develop a system.

Consider the daemons. Their original design was based on four requirements:

1. SIGMA would run in a distributed network environment.
2. High-priority requests would need to be processed quickly.
3. Individual long requests could not be allowed to hold up the daemons.
4. Error results must be returned to the user in a synchronous mode.

The ramifications of these early requirements were severe. The first implied a logon procedure so that the daemons knew the location of its users. This meant that when the daemons went down so did all the users, bad in operational use in Hawaii and hopeless for development at ISI. The second requirement led us to an implementation of duplicate processors with different priorities in case a high-priority request came in. The "multiprocessor" environment was also prepared for the third requirement in which a request could monopolize a processor. Finally, returning requests to the user, as necessitated by (4), implied a single output process for distributing results.

By SIGMA 1.75 all those requirements were shown to be spurious and the code supporting them was removed. What was left were daemons with the barest capabilities. From them together with our experience with 1.75 we were able to redesign and rewrite the daemons to be elegant and functionally relevant in just four months. This lesson is our first major result:

**Theorem 3—Avoid the hourglass design syndrome.**

Figure 3 depicts this theorem graphically. The syndrome is seductive and debilitating. The natural ego of a designer/programmer drives him to build to the hilt. We've all seen this happen in design meetings. A few capabilities are clearly required; some others are suggested and incorporated. Once

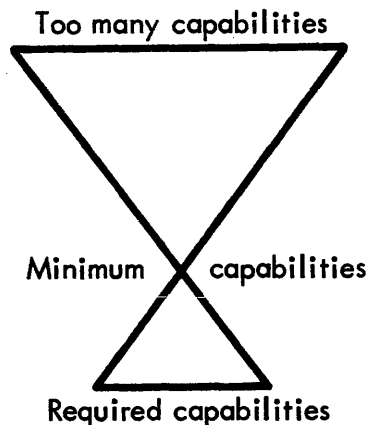

Figure 3—The hourglass design.

rolling, this juggernaut is hard to stop, and a concise design suddenly belongs to a committee. PL/I is an old example; SIGMA's former daemons are our contribution.

FACMOD is an example of how smoothly evolution can take place. Folders contain message entries and are the place from which messages are displayed. Besides just being displayable, entries can be keyworded, deleted, filed into other folders, commented, selected by various criteria, etc. Instead of building in all these capabilities, the first FACMOD had only the barest set. FACMOD came up quickly and grew with our needs. Naturally, many of the requirements we foresaw were added later, but many were not. The message is clear:

**Theorem 4—Underdesigned components are needed during a system's evolution.**

We have talked about system design in terms of focus on mainline modules, aiming high in selected pieces, underdesigning others. *Axiom 4* also alluded to stabilizing factors within all parts of the system. Those are important to watch for. As important are sections that are critical for one reason or another. Two examples in SIGMA are the IFCP package and the Terminal/Terminal Driver communication protocol.

The IFCP is the data channel between the FM and both MSGMOD and FACMOD. It was independent of application and unlikely to change regardless of the direction of any of those components. The IFCP had to be robust and solid; it was serving many masters. It was recognized as a critical component of SIGMA and designed accordingly.

The terminal protocol raised different issues. Even though the transmission lines at ISI between the terminal and the Driver were virtually perfect, we knew that lines at other installations might not be. Without knowing how bad lines could be, we anticipated the worst and built a robust protocol that included acknowledgments, timeouts, retransmissions, and checksums. Our experience in the Boston review and in Hawaii made us glad that we did. So, underdesign is good, but:

**Theorem 5—Aim high for critical sections.**

Part of aiming high is to understand in detail what is expected of the component under examination. Before the daemons were redesigned in aim-high mode, a firm require-

ments specification was written for them. This document gave our design and implementation a well-defined target. The VT never has received this treatment and remains loosely organized. It seems that part of aiming high means that:

Corollary 5.1—Firm requirements are needed for mainline components.

Requirements are one thing, and documentation is another; the former precedes implementation while the latter follows it. Once a major component of the system has been written, complete documentation should be generated for it. Much lip service is paid to this liturgy; we are no exception. All the good reasons for documentation are easy to list but one that is understated is that undocumented components take on an orphan flavor if the writer leaves. This happened to the VT. It passed from hand to hand, each programmer leaving his mark, but no one documenting anything. So:

Corollary 5.2—Fully document mainline components as they are written.

As important as **Theorem 5** and its corollaries are, their duals are just as important:

**Theorem 6—Aim low for noncritical system components.**

Corollary 6.1—Noncritical components need only tentative requirements.

Corollary 6.2—Small documentation effort should be spent on noncritical components.

Noncritical system components should get aim low treatment—the daemons and ACCMOD should have but didn't, FACMOD and COMMON should have and did, the VT and ZT shouldn't have but did. The technical issues here are not controversial. However, the psychological one of producing work that is less than your best arises. Perhaps a good manager should assign his best programmer to produce such code, since ego is less likely to be a problem. Even though the code is known to be throw-away, it still has to work (Corollary 1.1).

The theme of aim-low also brings out questions of performance. The development leading to SIGMA 1.0 paid virtually no attention to performance. We used flexible data structures, clean interfaces between modules, and straightforward coding techniques. SIGMA 1.0's performance was poor but not unexpectedly so. When performance became an issue, we analyzed SIGMA using Program Counter (PC) samples, a technique that takes snapshots of running code to tell what code is being executed. We found, for example, that our storage management package needed tight optimization, since it was active all the time. That was expected, but we also found that some heavily used operating system facilities took several orders of magnitude more time than we expected. This stunning information taught us that:

*Axiom 5—A priori, it is impossible to know in which sections of code performance will be critical.*

With the PC samples as a guide optimizing SIGMA's code in the user job was straightforward: the character output to the terminal was rewritten at a 10-to-1 saving, the FM's folder handling was changed from linked lists to an array structure, FACMOD and MSGMOD calls were tuned to specific needs, and a TEXT package was incorporated to replace ZT. These changes were extensive and revolution-

ary; still, they didn't affect the overall design. Assuming that the early design gets you within one or two orders of magnitude of your target, we believe that:

*Axiom 6—Performance is "easy" to add later.*

Once all these changes were made, we had a much faster, sleeker, less flexible User Job. At this point another PC sample test showed that the Text package had an inefficient look-up routine that needed recoding. *Axiom 5* tells us about anticipating performance, but here we have a case where the code didn't even exist at design time. The evidence is clear:

**Theorem 7—Performance should not be an early design goal.**

This theorem promotes an ideal which served SIGMA poorly. In following it we found ourselves with a SIGMA 1.0 that was very slow when compared to one of our competitors during the Boston review. The "fast" system did not have the capabilities of SIGMA, although that fact together with the above performance principles was lost on some (fortunately not all) of the reviewers. The performance of SIGMA 1.75 vindicated our development strategy.

Until now the discussion has addressed design theory with an undercurrent of implementation examples. With the evolutionary principles we are proposing, design and implementation are inextricably tied together. Now the focus will shift to the implementation side.

The literature rightly pays much attention to storage handling, searching and sorting, queue modeling, etc., because of their widespread use. To have poorly implemented packages of this sort is ludicrous, whether you are aiming high or low. Besides avoiding code duplication, these modules have a unifying effect on a system. Our careful implementation of free storage, lexicons, and queues were based on the principle that:

*Axiom 7—Good support packages are essential and well understood.*

Support tools are important, but a good supporting environment for testing is essential. From the beginning we realized that since BLISS had no debugging facilities we would have to provide our own. A system-error package was built to take over control when an error was detected. The programmers had an ASSUME (boolean,message,data) statement available that invoked the system-error mechanism if the boolean was false. The package was small when we started (no hourglass design here) and grew as SIGMA evolved. Note however, that small and aim-low are not the same:

**Theorem 8—Aim high on debugging tools.**

It is time to formalize an assumption that conveys our theory. We have been cavalier about the implementation effort required by our evolutionary model. Yet each design cycle, whether it was the CLP, the FM or the daemons, was followed by a painless implementation phase. Once understood:

**Theorem 9—System components are easy to build with good support tools.**

This optimistic theorem runs contrary to prevailing, perhaps self-serving, opinion. Our contention that well defined modules can be cranked out comes from innumerable cases,

from both SIGMA and other sources. It's just not hard to build "one." Yet what we have tried to show throughout this paper is that a large system needs to evolve, since many decisions can be wrong. We have shown how things can be designed or modeled poorly.

Even knowing where to put functionality can be a problem. As an example, the original SIGMA design included a component called the Personal Daemon (PD). An instance of this background process was created for each user job, and its intended purpose was to provide a background processing capability which was active even when the user was not. Alerts were originally designed to be a PD function. Since we neither knew all the potential functions of such a process nor had the time to develop them, we (correctly) gave it aim-low treatment. As the design of SIGMA was reworked from 1.0 to 2.2, each of the existing hypothesized PD functions was reassigned to another area. With nothing left to do, the PD was removed. Unfortunately:

*Axiom 8—Often you guess wrong.*

Every component of SIGMA has been rewritten. Large pieces of code were abandoned: ACCMOD (twice), the FM, the daemons, the PD. It is the nature of the evolutionary design theory that:

**Theorem 10—Almost everything gets thrown away.**

Even aim-high modules can be re-examined and thrown away. SIGMA had a directory scheme for storing and retrieving messages based on a lexicon package (height-balanced AVL trees). It worked from the beginning and never was looked at until our performance cycle. When it got dumped for a simpler scheme we knew nothing was sacred:

Corollary 10.1—Don't be afraid to throw stuff away.

Once this fear is conquered, a lot of pressure is removed from a design/programmer staff—certain kludges are accepted, simplicity encouraged. The aim-low paradigm coupled with **Theorem 10** means that each component will get a second chance during an aim-high cycle. The CLP got it by SIGMA 0. Functionality made the FM the focus of SIGMA 1.0. The entire user job got aim-high treatment for 1.75. Finally, the daemons were the target for 2.0. Each cycle left a little more of SIGMA hardened, i.e.,

Corollary 10.2—Every development cycle will focus on a permanent component.

Even though we didn't realize it at the time, SIGMA followed an orderly development cycle. It would be nice to attribute this outcome to our careful long-range planning, but that is not the case. The things we did were circumstantially good or bad. Performance, redesign, and new requirements all imply that a large system is a moving target. Simply stated, the first fundamental result is:

**Theorem 11—No one can implement a large system in one pass.**

It is seductive to think that you can. Even more seductive is the notion that a long, studious design is the answer; we tried and failed. Every aspect of SIGMA proved the statement made by our last theorem:

**Theorem 12—A large mature system must evolve; it cannot be designed.**

This second fundamental result is borne out by all large

systems. There is no good reason to suspect that anyone can design a big system down to the bit level using any known methodology.

## CONCLUSIONS

The theme of this paper is applicable only to large, multi-year projects. Though many of the principles are relevant to any effort, the theory applies to a "design a little, implement a little, design some more, implement some more . . ." paradigm, rather than the "design it, implement it" one. The most important early decision is to recognize which model is appropriate. Remember the two fundamental theorems.

A relevant issue, not previously mentioned, is the choice of a programming language for a project of SIGMA's magnitude. When we faced this decision, INTERLISP<sup>5</sup> was brought up. Though it comes with a marvelous programming environment, its lack of speed and address space problems made it impractical to use. Once BLISS was chosen for SIGMA, all code was written in it. Perhaps a better scheme would have been to write an aim-high interface, in the IFCP manner, to exist between forks written in BLISS and others written in INTERLISP. Then aim-low modules, perhaps written in INTERLISP, could have been put together very quickly. Using this strategy implies a strong commitment to this design philosophy.

We all guess wrong (*Axiom 8*) but perhaps the main reason that this theory is not in general use is that people don't like to reprogram modules they have coded before. But a large

software project has many people on it, so the solution is obvious. Let the aim-low implementation drive the design; when aiming higher, let someone else implement it. The daemon and FM rewrites were perfect illustrations of this point.

As with top-down programming, egoless programming, or chief programmer teams, no magic is offered. This theory is not a panacea for all software problems. Lousy designs and poor programmers will still defeat any methodology. What we do offer is a guess as to how to make a long-term project less painful and more rewarding.

# The terminal for the Military Message Experiment

by ROBERT STOTZ, PAUL RAVELING and JEFF ROTHENBERG

*USC Information Sciences Institute*  
Marina del Rey, California

## INTRODUCTION

One of the technical challenges faced in the Military Message Experiment (MME) is providing a system that is easy to learn and operate by the typical action officers who are the users of the message service. These people have no computer background and have neither the time nor the inclination to master a complex system in order to accomplish a simple task such as reading their message traffic, which they already do effectively. The system must offer some new capabilities to make it attractive, but above all it must be comfortable and natural to use. A most critical ingredient of the user's interface to the system is the terminal.

To provide the desired naturalness and ease of use, we want to make available the same sorts of facilities that the user has at his desk, where he is able to scan quickly through large amounts of data, see whole pages of text at once, and easily change his attention back and forth between pages of different documents. He is able to view several documents at the same time and edit or annotate a message at any spot by simply writing there. With paper and pencil these abilities are effortless and natural. We would like to be able to give him the same capabilities in our on-line system with the same simplicity of use.

Unfortunately we are constrained by such practical considerations as the cost of the terminal hardware, its maintainability, the amount of desk space that it occupies, etc. Like most such devices, the MME terminal is a compromise between conflicting goals.

In the early days of the MME program it was envisioned that users would be distributed all over the island of Oahu and that the host computer would be on the mainland. The long delays involved (a satellite hop and an unknown number of network nodes) argue for providing buffering and processing power in the terminal itself in order to guarantee responsiveness to the user (an essential attribute of a natural interface). Economics restricts the speed and memory size of the terminal processors. The terminal that has resulted is different in concept than any currently on the market.

## OPERATING WITH THE MME TERMINAL

The style of interaction we have attempted to achieve is to have the user feel he is talking directly to the application

program, with the terminal transparent to him. Simple but powerful two-dimensional editing functions are available in the terminal with a one-to-one relation between a keystroke and the execution of a function. The editing operations automatically format the screen dynamically so at all times the user sees a well ordered presentation of his data. Because of instant response to these operations, the user feels he is editing the document directly (rather than executing abstract commands to a computer which makes the changes for him, which is really what is happening).

To further this impression, the terminal masks the user from its memory limitations. The user can scroll through a full document without having to break it into pieces that will fit on screen or in memory. To achieve this the terminal has considerably more display buffer memory than screen space. The terminal gives the user the impression that it holds the entire document locally, even though it is really bringing new data in from the host as needed.

The naturalness of the interface rests on the principle that "what you see is what you get." The user merely edits a text image on screen to cause the system to make the semantic changes to the database that those editing changes imply. This editing often has the side effect of controlling some operation; for example, the addressees for a message are thought of as simply names in the "To" field of the message, which is filled in by editing the screen along with all the other message fields. The user is not forced to think of these names as active arguments to the message sending process, which the application program must parse, check for validity, and perhaps correct, before accepting them.

To allow flexibility in the data presentation made to the user, the terminal has a variety of highlighting facilities, such as inverse video, underlining, and half-intensity. Basic editing and dynamic formatting are done in the terminal, but the application program has control over how text is highlighted, what format constraints apply and where editing is allowed to occur, with granularity down to a single character. Thus the data sent to the terminal contains editing, highlighting and formatting attributes, as well as the text itself.

To give a user the ability to view several objects simultaneously or quickly switch to views of different objects, the terminal provides a facility called "windows." Each window can hold a different data object and can be independently scrolled, giving the user the impression that he is

working directly on the entire document. Windows may be established by the application program to occupy only part of the screen, so several can be displayed at the same time. They may be moved on or off screen almost instantaneously, making it easy for the user to shift his attention between objects.

The terminal also supports a variety of command language styles. The terminal has function keys whose actions are assigned by the application program, but it also allows typed command input, menu selection (using the cursor to point), and an ability to refer to arbitrary characters on screen as arguments to commands.

#### IMPLICATIONS FOR THE APPLICATION PROGRAM

The terminal's style of interaction has profound effects on the application program. First it implies a rich data structure. A sequential file does not lend itself to arbitrary editing conveniently. Whatever representation the application program has of the documents it deals with, it must be able to extract and send to the terminal the controls for editing, highlighting and formatting along with the text. It also must be able to change its database to match the changes reported from the terminal, and make correct semantic interpretation of these changes. We call this application resident model of the data in the terminal the "Virtual Terminal" (VT). There must be a VT for each active window in the terminal.

In most alphanumeric applications, changes to the database are made only as a result of the execution of some command through a command interpreter. The semantic content of the command is extracted, the change is made to the database, and then the appropriate display information is generated from the new data and sent out to the terminal. SIGMA, the application program for the MME<sup>2</sup>, operates in this manner on many of its commands.

SIGMA, however, also allows changes to the database through screen editing. In this case the changes to the text that are sent by the terminal go to the virtual terminal, where their semantic impact is interpreted, and the database updated. In this way the meaning of the database can be changed as a side effect of editing, rather than by direct command execution. For example, while filling in a message form the user enters the contents of a message address field. So far as the user or the terminal is concerned this is just text, like any other text in the message. But since it is an address field, SIGMA parses the text, extracts user names and builds an address structure in the database, one element per addressee. If the text or format of the address field is changed as a result of SIGMA's semantic interpretation (e.g., addressees' names might be corrected), the necessary modifications are sent out to the terminal.

Since the terminal does its own formatting, the application program considers text of a paragraph as a continuous stream. Only where the structure of the text dictates (e.g., paragraph beginnings) does the application force format controls. The usual ASCII control characters CR (carriage return) and LF (line feed) do not appear in SIGMA's representation of text.

#### THE USER'S VIEW

The MME terminal is a Hewlett-Packard 2649A CRT Terminal (an OEM version of the HP2645A terminal<sup>1</sup>), with microcode supplied by ISI. The CRT holds 24 lines of text. SIGMA permanently assigns the top three lines as Status lines, where system and user status is continuously reported and error messages appear. The most frequently used SIGMA commands are assigned to 30 function keys. Other commands must be typed in the Instruction window, which occupies the next two screen lines below the status lines. The remaining 19 screen lines make up the working space; they may contain a View window for reference only, a Display window for editing, or a split between Display and View to allow referring to one object while working on another.

Two keypads next to the standard keyboard keys control the local terminal operations, including cursor movement (by character, word, line or window), character insertion (any of the normal typewriter printing keys), deletion (by character, word or line), scrolling of independent windows, and a special function called HERE. The terminal maintains the screen format, automatically breaking a long line at a word boundary and wrapping the remainder onto the next line. The carriage return key forces subsequent text to start on a new line.

#### FUNCTIONAL DESCRIPTION OF THE MME TERMINAL

Since the 2649 is microprogrammable, the functional operation is entirely defined by the microcode. Communication between the application program in the host computer and the terminal is done in blocks of data, representing a complete command from the application to the terminal (dispatch) or a complete report of some new condition in the terminal to the application (notice).

The terminal is basically a half-duplex device, in that it is either in input state (keyboard active) or output state (host computer active). During input state the user has at his disposal the full screen-editing capability. The terminal switches to output state whenever a function key is pushed (e.g., the EXECUTE key, which causes SIGMA to interpret and execute the contents of the Instruction window, is a function key). During output state the keyboard is disabled. The terminal is returned to input state when the host sends a special "Continue" dispatch. Strictly speaking, the system is not half-duplex because in output state the terminal does send certain control notices required to maintain consistency between the terminal's database and the host's model.

Communications between the terminal and the host is really one computer talking to another. Each transmission must be error-free; otherwise the computer's model and the terminal's model may not match. To insure the needed reliability of data across potentially noisy lines, a fully synchronized block retransmission protocol is used.

## Windows

The MME terminal is designed to hold up to seven separate items of text in areas called "windows." Windows are allocated and deallocated by the host (never by the terminal). They are of arbitrary size so long as the total contents of all the allocated windows does not exceed the memory capacity of the terminal. Although the host fills the windows by sending data to them, the terminal does its own memory management and decides what data to keep when it nears its memory limits.

Windows may be thought of as numbered text buffer areas. A window may be assigned to occupy any contiguous portion (full horizontal lines) of the screen, such as lines 15 through 23, with an operation called "map." Normally a window contains more lines of text than will fit on the mapped area (it may also contain less). "Map" places that portion of the data from the window that will fit onto the screen, while any excess data beyond the screen area is stored in "margins," areas logically considered to be above and below the window's mapped screen area. Data scrolls on-screen from these margins.

Several windows may be mapped on different areas of the screen at the same time, which allows a user to view several text objects simultaneously. A window may also be unmapped, which means it remains in the terminal memory, but is not visible to the user. Figure 1 illustrates the terminal with four windows, three of which are mapped. The host may switch the contents of the screen from one text item to another very quickly by "unmapping" the displayed object and mapping the new object.

Mapped windows scroll independently. The ROLL UP or ROLL DOWN keys cause scrolling in whatever window the cursor is in. This operation is done entirely within the terminal, without telling the host. Therefore, although the host always knows what text is in each window and what windows are mapped onto which screen lines, it usually does not know exactly what text is visible on screen at any time.

## Domains

In the MME terminal all text is stored in "domains," the atomic unit for the communication of text between the host and the terminal. Each window is made up of a contiguous string of domains. Domains may be any length up to 100 characters. Any character stored in the terminal can be uniquely identified by its window, domain identifier within the window, and character position within the domain. Domains have format, highlight, and control attributes assigned when the domain is created. The user is not aware of the domain structure of text, except as domain attributes are apparent to him. Figure 2 illustrates the domain structure for part of a SIGMA display.

Normally each domain starts at the character to the right of the last character of the previous domain and may wrap around onto the next line. However, the application program may set a domain to be "formatted," which makes the domain start on the next line at the left margin of the screen,

regardless of where the previous domain ends. In this case the blank space to the right of the previous domain is essentially undefined to the application program, since it cannot be identified by domain ID and character position. The terminal will not allow the cursor to move to an undefined location. If a user attempts to move his cursor into such an area, it will jump to the next enterable domain.

The 2649 allows any combination of blinking, underlining, inverse video and half brightness on a character-by-character basis. The MME terminal limits this highlighting to a domain basis; that is, all characters in a domain are highlighted the same. Character set selection is also done as a domain attribute.

Domains also have editing control attributes set by the host when domains are created. They control whether the cursor may enter the domain, whether the domain is editable (from the keyboard), whether characters within the domain may be marked with a HERE, and whether the domain will accept carriage returns. Space is left for assigning other attributes.

When a user edits text he is changing the contents of some domain. If, for instance, he inserts or deletes characters, the domain expands or contracts appropriately and the domain is recorded as "Changed." Nothing is sent to the host until the user begins to edit another domain, at which time the terminal will send the host the new contents of the previously edited domain (via a "Changed Domain" notice) and record this new domain as the Changed domain. Thus the host computer may be, at most, one domain change behind what is in the terminal. Eventually the user will push a function key, carriage return, or the HERE key. The first action the terminal takes on these keys is to lock the keyboard and send out the pending Changed Domain notice if there is one. It then processes the key pushed, which ensures that the host always has the up-to-date state of the terminal before performing any operation on the data (all SIGMA commands are initiated by a function key).

Most often the data displayed come from the application program, in which case the host computer creates the domains and sends them to the terminal. However, the terminal will generate domains in three special instances.

1. When user editing causes a domain to exceed 100 characters, the terminal will generate a new domain and tell the host its location, ID, and contents in the form of a special "Extraction" notice.
2. A carriage return creates a new "formatted" domain and a special "EOL" notice is sent to the host, reporting the location and the ID of the new domain.
3. The HERE key marks the character at the cursor position as a parameter for a subsequent command by splitting it off into a new, one-character domain with inverted video and non-editable attributes. This mark will stay associated with that character regardless of any editing the user might do thereafter before the command is executed. Merely reporting the character position in the domain and the domain ID is not sufficient. The "HERE" notice contains all the information needed to identify the position of the marked character,

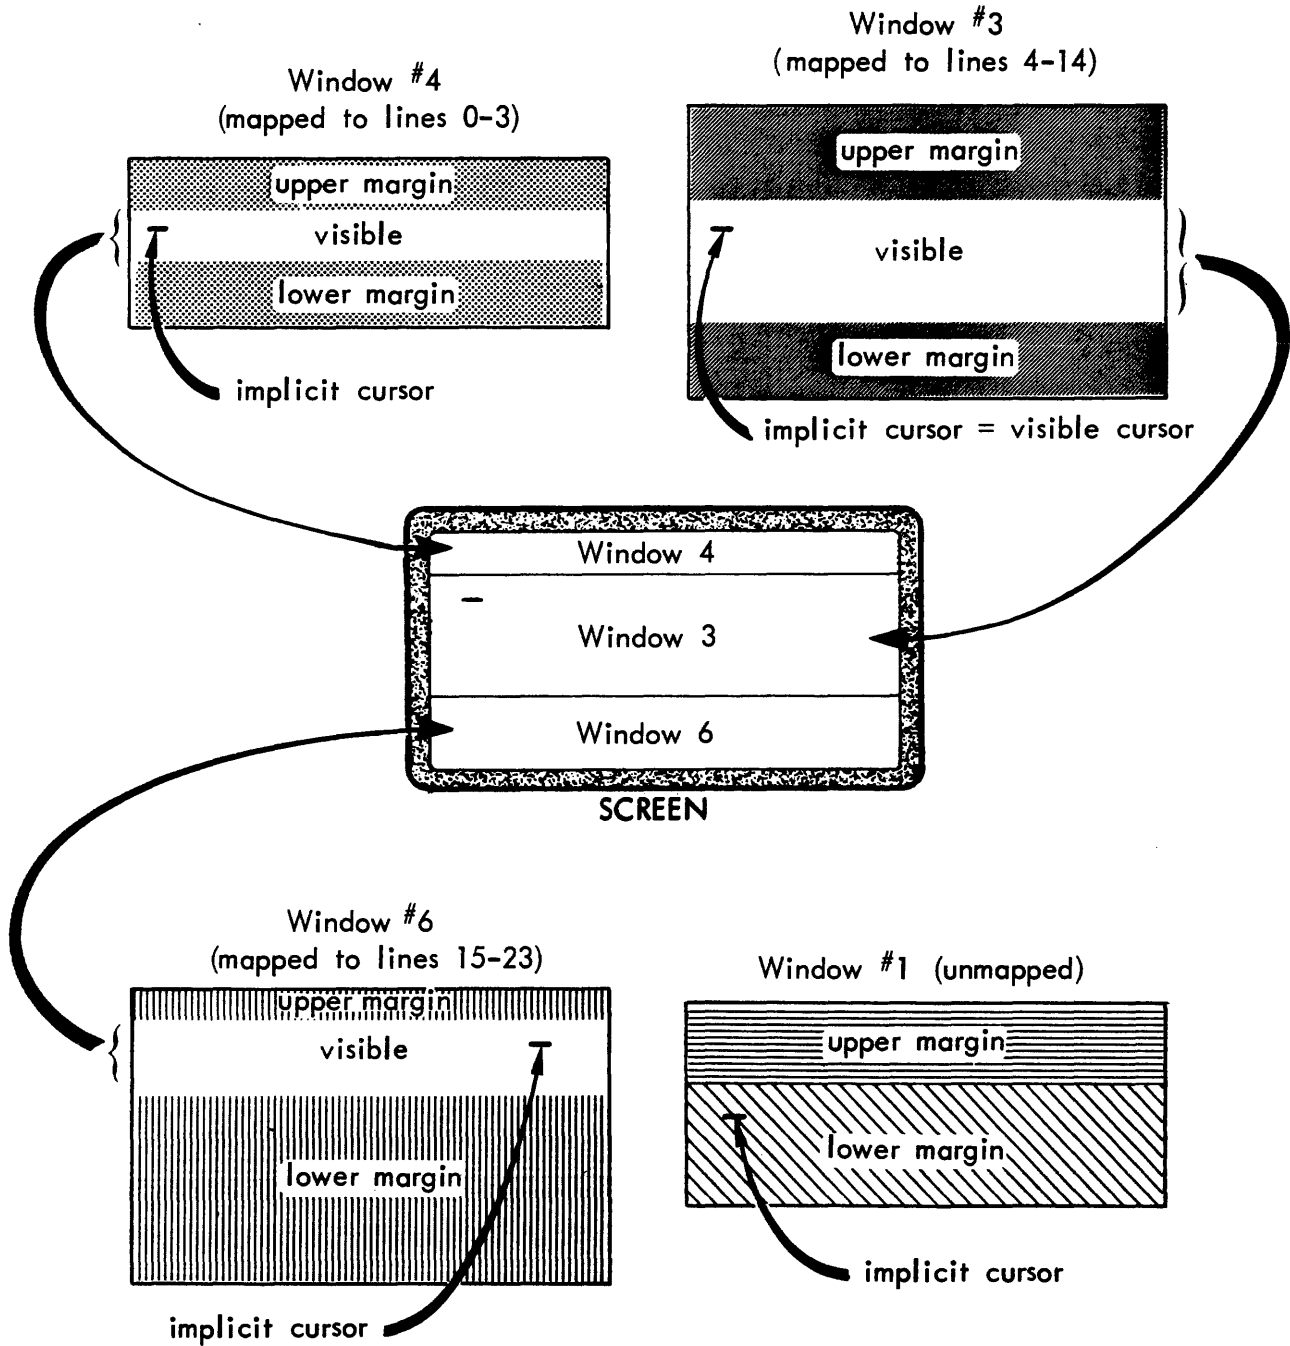

Figure 1—Multiple windows.

how the old domain was split, and the ID of the new domains created.

*Flash lines*

The terminal has an eighth window called the Flash window. If it exists at all, it is assigned to the top of the visible screen, and can be set by the application to occupy from zero to 24 lines. It has no domain structure and has fixed

attributes. It is always non-enterable, and has no highlight or formatting properties. SIGMA uses the Flash window for status and other output-only information, since it does not have to keep around a corresponding data structure for this window.

*Cursor control*

Although there is only one visible cursor, each window may have an implicit cursor position. When more than one

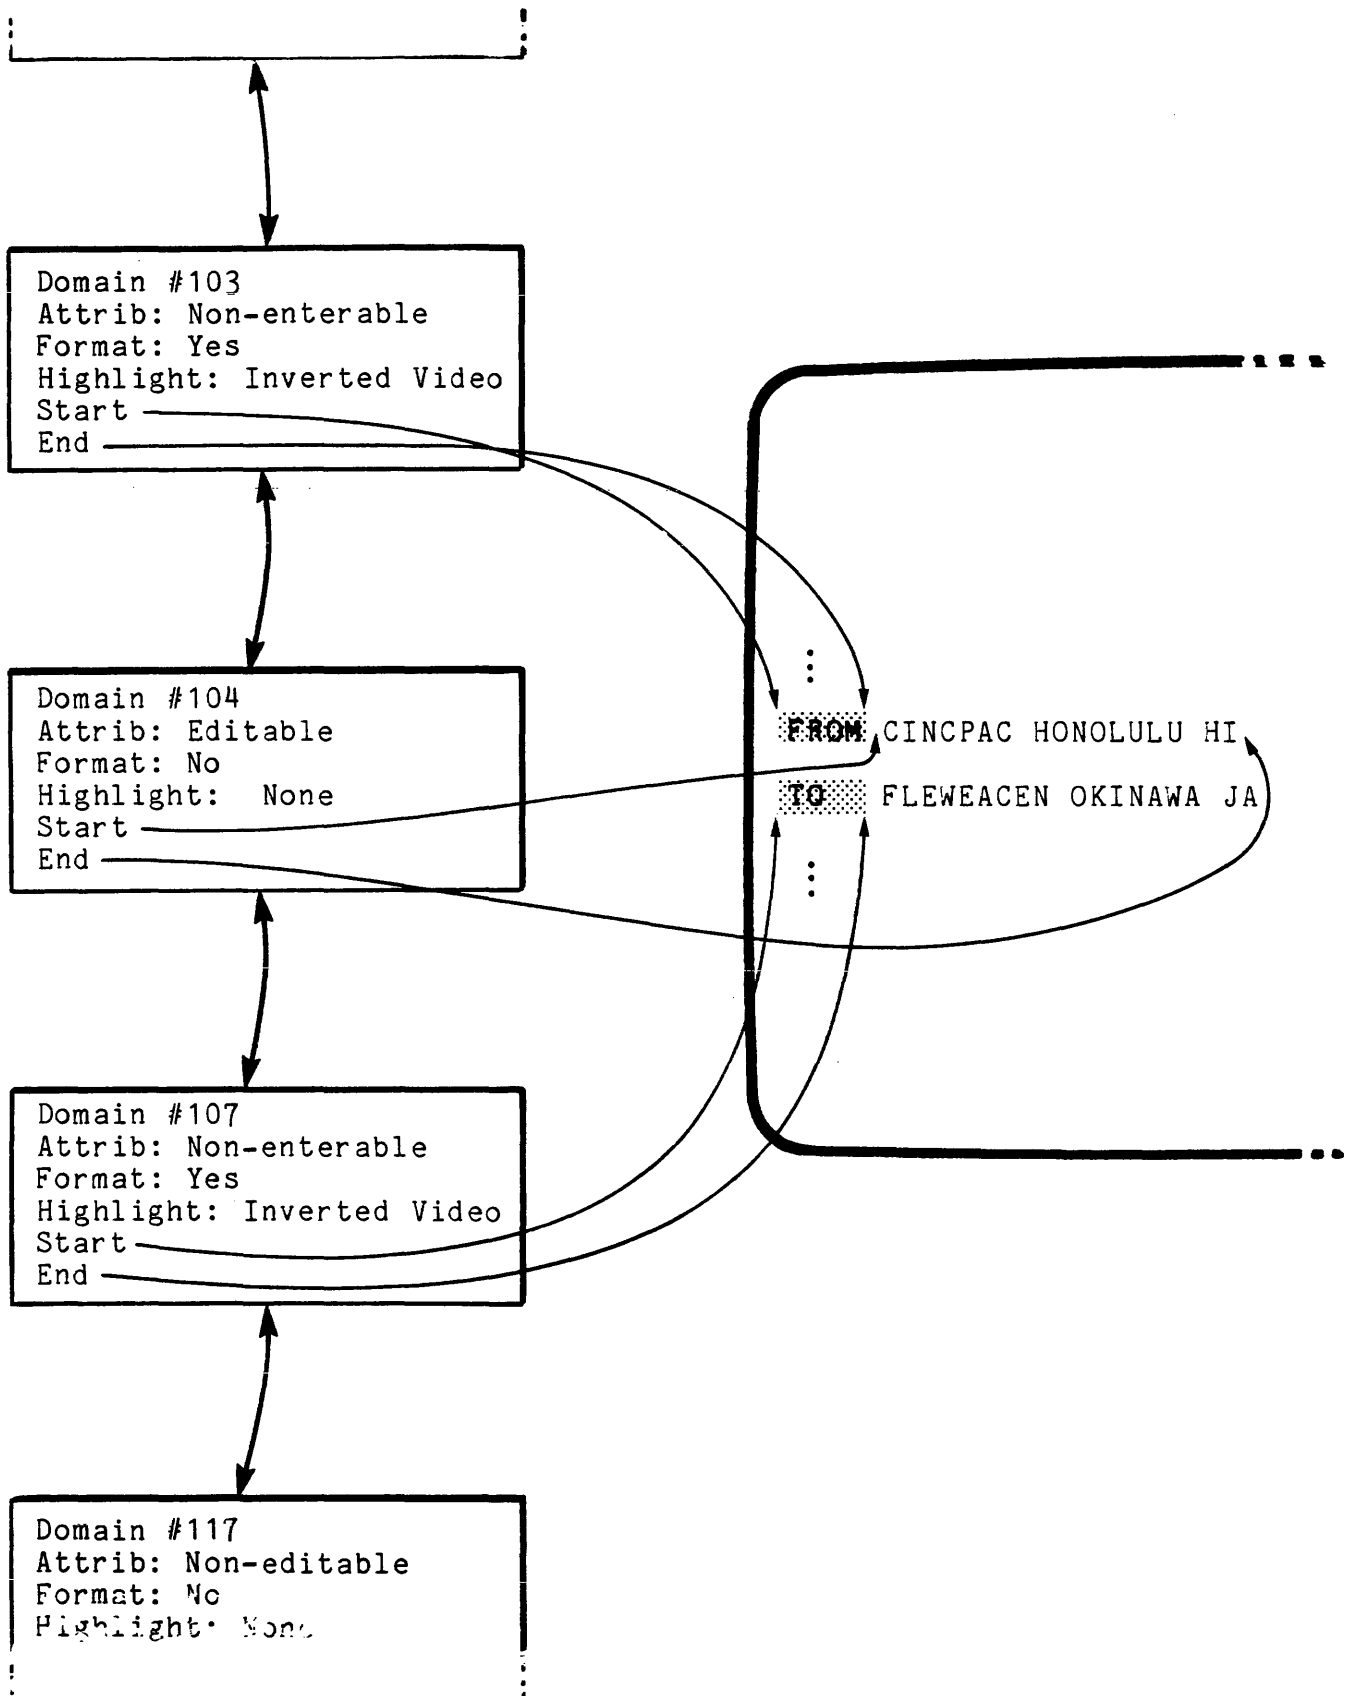

Figure 2—Domain structure.

window is mapped on screen, the UP WINDOW or DOWN WINDOW key causes the cursor to move to the implicit cursor position of the adjacent window.

The host has two controls over the implicit cursor for a window: 1) On what character in the window it should be and 2) on what line on the screen (for mapped windows) it should be. For unmapped windows, the latter translates to "on what line on the screen it would be if the window were mapped." A separate dispatch is provided for each. This limited form of cursor control is the only way that the host can establish what data is shown on screen. Since the user can scroll the screen contents, this is transient control at best. The host also has a dispatch to put the actual visible cursor into the desired mapped window (at the implicit cursor position).

### *Scrolling*

The terminal's basic heuristic for mapped windows is to keep extra lines of text in margins above and below the lines that are on-screen. This lets the user scroll in either direction without having to go to the host for more data. Whenever the terminal assesses that a margin is getting too small, it will send a "Vacancy" notice to the host asking for more data for that margin. The terminal calculates the number of lines of data to ask for based on the size of the on-screen area, the number of lines in the margin, and the amount of memory left in the terminal.

### *Memory management*

The 12K bytes of display memory in the terminal are allocated as necessary for each dispatch. When the remaining memory is reduced to a prescribed limit, the terminal tries to reclaim memory from unmapped windows, and if that does not yield enough, from large margins of mapped windows. Memory is reclaimed by deleting domains and their contents from the edge of the margin and then telling the host through a "Scroll" notice. A Scroll notice identifies the last domain deleted and from which margin it came. It is important that the terminal be able to generate Scroll notices even when the keyboard is locked and the host is in control, for it is during this state that the host will send the data that reaches the memory limit. The terminal must be free to reclaim memory right away in order to have room for the next dispatch, which may already be in the terminal's input buffer.

It is possible for the terminal to try to reclaim memory from the same margin into which the host is writing. To prevent this, the host can set special "No Reclaim" controls for each margin of each window, and the terminal will not reclaim memory from a window margin so marked. The host must be careful not to leave these No Reclaim controls on, or the terminal will quickly run out of margins from which it can reclaim memory and the terminal memory will become full.

## CONCLUSIONS

The MME Terminal is now operating with SIGMA at CINCPAC Headquarters. It appears to be successful in providing an interface that is quick to learn and natural to use. Editing is easy to master, since the operations provided are simple and their results immediate. The user deals with large messages or files as single continuous entities, which appear to be completely contained within the terminal. The user never has to consciously "send" an editing change to the host; he simply makes the change, just as he would on paper.

The terminal's most obvious limitation is the small size of the screen (24 lines of 80 characters), compared to the full page printed on paper that users are used to seeing. This is particularly noticeable when operating in split screen mode looking at two objects. This limitation, however, points out what we consider to be a significant technical contribution of the MME terminal.

By dealing in terms of windows and domains, and letting the terminal format the text and control the flow of data (via Vacancy and Scroll notices) we have achieved a division of labor which makes the application program almost completely independent of the terminal characteristics. The high-level protocol that achieves this also supports the natural user interface style we sought. The application program has no knowledge of, or concern for, the amount of memory in the terminal. Since the terminal manages its own memory and tells the host when and how much data to send, the application program never needs to consider whether the text "will fit."

Furthermore, the application program assumes very little about the size or characteristics of the display screen. A small section of code in SIGMA, which controls the mapping of windows to screen lines, knows that the terminal has 24 lines. It has no idea how many characters fit on a line, or whether the terminal has proportional spacing, or what kind of display technology is employed.

The application program is also completely unconcerned about details of the terminal's editing facilities. For instance, SIGMA does not know the terminal does not have a "type-over" mode, or that it does have a "word delete" key. The terminal could scroll a line at a time or a page at a time. Adding a positioning device like a "mouse" or a joystick would not affect SIGMA at all. In theory, one could add a "replace string" function internal to the terminal if he wanted without affecting the application program (we chose not to because we feel such operators should be global to the entire document and therefore belong in the host).

The protocol isolates the physical and functional features of the terminal from the application program, which allows us to take advantage of new, more capable terminals with more memory, larger screens and more powerful editing features without having to rewrite the application software. At the same time we maintain the desired interactive coupling between the terminal and the host.

We believe a protocol which provides this independence is needed to foster the use of "intelligent" terminals for network applications. We are advocating the development

of a protocol to support communication with such powerful terminals, which we are calling the Network Virtual Processing Terminal protocol (NVPT). We do not propose that the MME terminal protocol in its current form is sufficient for NVPT, since it does not yet provide adequate format or editing controls. It needs to accommodate a variable number of display windows and visible screen lines, and issues such as backward compatibility with teletypes and down-load capabilities must be considered. We do feel, however, that the protocol in MME provides a good starting point for

discussion of an NVPT and we invite constructive criticism directed toward achieving such a goal.

# On-line tutorials and documentation for the SIGMA message service

by JEFF ROTHENBERG

*USC/Information Sciences Institute  
Marina del Rey, California*

## INTRODUCTION

The highest goal of the SIGMA service has been to successfully make the transfer from the computer science research environment to the working military message processing environment for which it was intended. One of the problems leading to the failure of such technology transfer in the past has been a lack of appreciation for the importance of the way a system is introduced into a working environment, how users are trained in its use, and how it is documented from the users' point of view. This paper describes SIGMA's approach to these issues.

The target users of SIGMA are military personnel at CINCPAC engaged in message processing. The functional aspects of this military message processing environment are described elsewhere.<sup>4</sup> The target users understand and competently perform complex and important tasks. The training and documentation material for SIGMA assumes that the users are already expert at their jobs and that they will quickly become proficient at using SIGMA if it is presented to them in familiar terms.

The fact that target users cannot afford the time for extensive scheduled classes or other means of collective instruction suggested that on-line tutorial and help facilities be developed to allow a user to learn at his own pace and to a self-determined depth, and to minimize the need for classroom or one-to-one personal instruction. A short introductory lecture gives an overview of SIGMA and shows users what it can do for them. From there on, the user refers to on-line aids for most of his training, using human consultants only when necessary. While reference aids also exist in hardcopy form, it was strongly felt that on-line references should be available whenever the user is working with SIGMA. On-line references have the advantage that they are guaranteed to be available, they can be kept dynamically up to date more readily than hardcopy, and they can exploit knowledge of the user's state to pinpoint what he is most likely to need help with. The initial design proposal for these training and documentation facilities was published in May of 1975,<sup>3</sup> and a requirements document for the actual documentation was published in June of 1976.<sup>2</sup>

The strategy for training and documentation in SIGMA involves three avenues of attack. The Command Language

Processor (CLP), which parses the user's input commands, implements a Prompt facility that allows the user to see which commands are legal in his current state. The Help facility provides on-line access to detailed reference material. The Tutor provides a complete curriculum of on-line Lessons and Exercises.

## THE SIGMA TERMINAL

The SIGMA (MME) terminal is described elsewhere,<sup>5</sup> but a brief description is in order here. The terminal consists of a keyboard with a number of special function keys and a CRT screen divided into several horizontal (full-width) windows.

SIGMA uses the top two lines of the screen for alert and status information called the Flash and Status Windows, respectively. The third line is a Feedback Window which SIGMA uses to give feedback to commands the user executes (e.g., error messages). Following the Feedback Window is the Command Window, in which the user enters typed commands.

The remainder of the screen is used as a working area consisting of a Display Window (where data objects can be displayed and edited), and/or a View Window (where data objects can be shown for reference but not edited).

The terminal supports multiple windows that may or may not be "mapped" onto the screen. For example, the user can have a data object displayed in the Display Window and can press a key to split the screen and map another object into the View Window. The documentation facilities described below make use of this mapping feature to take over the screen for documentation purposes (at the user's request), and later restore it to its original state.

## PROMPT

When the user presses the key labelled PROMPT on the SIGMA terminal keyboard, the CLP remaps the working area of the screen as a Prompt Window and shows all commands that are legal in the current state. (When the user hits PROMPT again, the original state of the screen will be mapped back again.) If the user cannot recall the arguments

or form of a command he is typing, he can hit PROMPT and be shown the various forms of the command he has begun. If he types an ambiguous command in the Command Window and tries to execute it, the CLP will respond with an error message (in the Feedback Window) telling the user that the command is ambiguous and suggesting he press PROMPT. If the user then presses the PROMPT key, the CLP shows Prompting of all those commands which it cannot yet disambiguate based on what has been typed in the Command Window. Commands that are close to what the user typed (e.g., which match the number and types of the given parameters) are shown highlighted.

For example, suppose the user has a file named Pending and a text object named Papa. If he types "D P" in the Command Window and hits PROMPT, the Prompt facility will show four possible commands:

```
Display Text <Existing Text Name>
Delete Text <Existing Text Name>
Display File <Existing File Name> <Security>
Delete File <Existing File Name>
```

With each command is shown a brief description of its function and a stylized form of the command with its parameters.

Once a command (or list of commands) is shown by Prompt, the user can select one of the commands with the cursor and press PROMPT again; this expands the description of that particular command, showing the syntax and meaning of each of its parameters.

## ON-LINE HELP

If the user needs a more detailed description of a command or cannot remember which command to use, he can request the next level of documentation: Help.

### *Compatibility of on-line and hardcopy reference material*

Considerable effort was devoted to making the on-line Help database semantically identical to the hardcopy printed Reference Manual so that the user would not find these alternate forms of documentation incompatible or confusing. At the same time, however, syntactic differences between the printed form of a Reference Manual and an on-line reference database had to be allowed for. For example, the printed form requires page numbers, section headings and chapters, whereas the on-line form is accessed interactively, making this organization irrelevant and cumbersome.

```
HELP      SERVICE FACILITIES
BACK     FORWARD
```

The Current Term field shows the Term for which HELP is currently displayed. The New Term field allows the user to type in a new Term for which he wants Help. Spelling correction is provided by means of the same algorithm employed by the CLP.

The documentation facility was designed to automate semantic compatibility while allowing syntactic variation so that documentation writers (documentors) would find it easy to maintain both on-line and hardcopy reference material in an up-to-date and interlocked form.

### *Using on-line help*

SIGMA documentation is organized under a large set of "Terms," which are words or phrases that name various aspects of the system. Terms include all command and parameter names, classes of data objects and operations, and procedural matters relevant to the user's work situation. They are essentially a set of keywords and key-phrases that semantically cover SIGMA and the environment in which it is embedded. Several synonymous Terms may refer to the same information. The actual documentation for a given Term consists of text called a "cell" (a word SIGMA users never see). The display of a cell can be scrolled; it is not broken into frames in the sense of screenfuls or pages.

### *Requesting help*

If there is a command or part of a command in the Command Window when the user presses the HELP key, Help is provided for the Term corresponding to the command word. If the Command Window is empty, pressing HELP results in a "top-level" Help display which is just a description of how to use the Help facility itself. (This is implemented simply by having the Help facility provide Help for the Term "HELP.")

### *Use of the screen in help*

When Help is activated, the Feedback Window displays a message telling the user that Help is being shown below and how to "get out" (that is, how to return to what he was doing before he hit HELP). The Flash and Status Windows are unaffected. The Command Window and work area (Display Window and/or View Window) are mapped away, and the remainder of the screen is divided into two windows analogous to the Command Window and Display Window. (When the user returns from Help to his previous state, the screen is returned to the state it had before he hit HELP.) The lower of the two Help windows shows the actual documentation cell for some Term.

The topmost of the Help windows consists of two lines which appear as

```
Current Term: Some Key Phrase
New Term:
```

### *Selectable terms*

The other four fields are shown in inverse video highlighting. The convention followed in the Help facility (and explained in the top-level Help display) is that anything that

appears on the screen in inverse video is itself a Term for which the user can get Help simply by selecting the highlighted field with the cursor and pressing HELP again. Thus the Terms HELP and SERVICE FACILITIES are always available whenever the user is getting Help; he has only to move the cursor into either of these fields and press HELP. SERVICE FACILITIES shows an Index-like list of the major topics and commands in SIGMA; when it is selected, the lower Help Window shows what is effectively a menu of topics on which Help is available. Any Term that appears highlighted (in inverse video) in this list can be selected similarly with the cursor. The user can thus use Help as a menu-driven access facility, or he can type in specific Terms to be accessed (at New Term). Whenever the Help display is changed, the Current Term field is changed to show the Term whose documentation cell is being displayed.

The fields BACK and FORWARD are also shown highlighted. These are not really Terms, but are "virtual function keys" which allow the user to retrace his steps through previous Terms for which Help has been displayed.

#### *Documentation writing and maintenance*

As explained above, the design of the documentation facility included a concern for how documentation is written and maintained for two syntactically disparate but semantically identical forms: hardcopy and on-line Help. The printed Reference Manual for SIGMA is generated using a traditional formatting system driven by commands embedded in the text to be formatted.

The on-line version must display selectable Terms as highlighted words or phrases which the user can select as described above. It must also allow the definition of Terms. The documentation text itself is generally the same as that in the hardcopy Manual. In order to make it possible for the user to select occurrences of Terms within the text, the documentor can flag words or phrases as potential Terms. An occurrence of a Term is shown as selectable only if the documentor flags it as a potential Term AND the Term is actually defined in the current database.

In order to make writing and maintaining documentation easy, a single combined source is used for both forms. Special bracket pairs control documentation preprocessing by signalling that characters are intended for either the hardcopy Manual or the on-line database or both.

## THE TUTOR

The final level of detail in documenting SIGMA consists of a full curriculum of on-line Lessons and Exercises covering most of the features of the system. The primary goal in designing the Tutor was that the user be able to take Lessons on-line and try out various commands in a Protected Mode. That is, the Tutor guarantees that the user can do no harm to any real data (his own or anyone else's) when taking a Lesson. However, it was felt that any attempt to interpret or simulate the action of commands would sooner or later

result in divergence between the Tutor's simulation and the real behavior of SIGMA. The only way to keep the user's faith that a Lesson describes the system as it really works is to effectively let the system simulate itself.

The Tutor supports two related features: Lessons and Exercises. A Lesson is a detailed description of some aspect of SIGMA. As of this writing some dozen Lessons have been written. The user can take any Lesson at any time by using the command "LESSON j." No order is enforced, though the Lessons are arranged in a logical sequence for most users' needs. A user can retake a Lesson any number of times, can quit in the middle, and can start up in the middle the next time.

#### *On-line lessons*

The user asks for a lesson with the command "LESSON" which takes a lesson number. The available lessons are listed in the hardcopy Reference Manual and in on-line Help. When the user executes the LESSON command, the Lesson text is displayed in the working area of the screen. The Feedback Window shows a message telling the user he is in a Lesson and how to get back to what he was doing before he entered the Lesson. The Lesson text shown in the working area can be scrolled through, just like any display on the SIGMA terminal. Lessons provide complete discussions of the most important topics having to do with using SIGMA. Most of the Lessons have Exercises associated with them, which they suggest the user take.

#### *On-line exercises*

An Exercise is generally a very short and specific task that the user can try in the Tutor's Protected Mode (a phrase the user never sees). Lesson 2, for example, discusses a user's special data object called the Pending File and then suggests that the user try Exercise 1 to display a Pending File. Later in the Lesson, the user is shown how to display messages from a file, and Exercise 2 is suggested, which allows the user to display a message. In keeping with the nonassertive philosophy of the Tutor, the user is not coerced in any way into trying the Exercises. He can skip some or all of them, can take them in any order and can retake them any number of times.

The user takes an Exercise by typing the command "EXERCISE k" in the Command Window. The Exercise number automatically refers to that Exercise for the Lesson in progress. When the user enters the Exercise, the working area of the screen (which had displayed the Lesson) is remapped to display the Exercise. The Feedback Window displays a message telling the user he is in an Exercise and how to get out of it.

An Exercise describes how to specify some particular command or set of commands and suggests that the user try them. In order to try them, the user simply moves the cursor into the Command Window and types the command, just as he would if he were not in the Tutor at all. At this point, the

Command Window is simply parsed by the CLP as always. However, the resultant parsed command is not immediately executed but is first passed to the Tutor for scrutiny. The Tutor compares the command with the list of allowed commands for this Exercise. If there is a match, the Tutor allows SIGMA to execute the command; otherwise, it displays a message in the Feedback Window telling the user the command he typed did not match any of those in the Exercise.

#### *The protected mode*

The screening of commands by the Tutor is performed after the CLP has parsed them. Thus the match is not between what the user typed and what the Exercise said he should type but rather between the parse of what he typed and a parsed form encoded with the Exercise. The result of this approach is that the semantics of what the user typed are compared with the desired semantics in the Exercise. Any alternate form that the CLP can recognize as the same target command will pass the Tutor's inspection as the desired command. This behaves correctly in a pedagogic sense, in that the user is considered to have completed the Exercise successfully if he achieves the desired result, regardless of how he achieved it. (The next level of this approach<sup>1</sup> is to actually allow the command to execute and compare the result of its execution with the desired state. This comparison is harder to define and perform, and allowing execution makes it harder to guarantee the Protected Mode. It was felt that for efficiency and safety command-level matching was the best solution for SIGMA.)

In order to provide the Protected Mode, the Tutor must not only screen which commands can be executed, but must in some cases switch the data objects on which a command operates so that "real" data is never used. If real data were used, it would also be hard for the Exercise to refer to what the user was seeing when he displayed data. By using special Tutor data, the Tutor both protects the real data and has a handle on what the user sees when performing the Exercise. The Tutor's only interference with the execution process is to switch data objects in the parsed command after the CLP has parsed it and before it is given to SIGMA to execute.

#### *Use of the screen in exercises*

When the user executes a command within an Exercise, SIGMA is unaware that the Tutor is involved, and the screen is used just as it would be if there were no Exercise displayed. The Tutor is responsible for mapping away its own display and allowing SIGMA to display what it will. However, once the user has executed a command he must be able to return to the Exercise to see what to do next. A toggle is provided which allows the user to switch the screen between the "normal" state (as it appears after executing a command) and the "Exercise state" (which maps the Exercise

text into the work area). To prevent confusion the Tutor uses the Feedback Window to keep the user aware of what he is looking at and how to toggle to look at the opposite state of the screen. In practice this requirement for toggling in an Exercise is no worse than flipping back and forth between a figure and a description of that figure on two different pages in a printed lesson.

#### *Tutor summary*

The Tutor has proved a powerful training device whose use has greatly facilitated the introduction of SIGMA to users in a working environment. It frees users to learn at their own pace and their own convenience. It provides the security of always knowing that there is a detailed and dynamically up-to-date description of the operation of SIGMA available at the user's fingertips whenever he is running SIGMA.

## RESULTS AND CONCLUSION

Formal statistics have not yet been gathered on the Military Message Experiment as a whole or the training process in particular. To date about 100 users have been exposed to the introductory lecture on SIGMA, and about two-thirds of those users have taken at least some of the on-line Lessons. As expected, the earlier Lessons have sufficed to get users started using SIGMA; most users have not found it necessary to take the later Lessons which deal with the full range of features in SIGMA. It is too early to give quantitative results as to the efficacy of on-line training for SIGMA, but indications are that users are able to gain competence and facility with the system by means of the supplied on-line training aids combined with human interaction and consulting.

The success of introducing any system into a real-world environment depends on many factors. An attitude of respect for the end user is crucial in all phases of producing a user-oriented system, and it permeates the design of SIGMA. The awareness of the need for on-line Help and Tutorial facilities is only half the battle for good user documentation: equally important is the style in which the documentation and training material are written. All condescension must be avoided, and if the documentor is a member of the Computer Science community he must keep in mind that he is writing for users whose expertise is different from—though probably no less than—his own.

SIGMA's three-pronged attack on documentation includes a Prompting facility, a fully integrated on-line Help and hardcopy Reference Manual, and a complete curriculum of on-line Lessons and Exercises under the Protected Mode of a Tutor. This approach has proved an efficient way for users to learn how to use SIGMA and to access reference materials while using it.

# Maintaining order and consistency in multi-access data

by RONALD TUGENDER

USC/Information Sciences Institute  
Marina del Rey, California

## MULTI-ACCESS DATA—A LONG-STANDING PROBLEM

The problem of controlling simultaneous access to shared data runs throughout the history of computer science. In order to preserve the consistency and integrity of such data, computer scientists and programmers have developed locks,<sup>6</sup> semaphores,<sup>3</sup> the notion of critical sections,<sup>4,3</sup> monitors,<sup>5</sup> and innumerable other techniques, both concrete and abstract. The great interest in such mechanisms throughout the computer community, both in the literature and in practice, is indicative of the importance of the problem.

### *Classical examples*

Control over simultaneous access is necessary in countless practical applications, one of the most common of which is the need to guarantee strictly sequential access to critical resources by competing—conceptually or literally—parallel executing processes. To provide the necessary interlocking, implementors have used techniques such as the simple lock and its more sophisticated cousin, the mutual exclusion semaphore. In each of these, before being allowed to access the critical resource, a competing process must pass a decisive test, engineered to ensure that

- Only one process can pass the test, no matter how many processes are competing or how frequently they attempt access.
- Once a process has passed the test and is granted access to the resource, no other process can pass until the first has “released” the resource.

A different type of control over simultaneous access is necessary to satisfy another problem, referred to in the literature as the “Readers and Writers Problem.”<sup>2,1</sup> In this case several readers accessing shared data wish to ensure that the data they are reading remains constant during the reading period. It can be summarized by the following rules:

- Any number of Readers may access the data simultaneously, but if any Reader has access, no Writer may also have access until all Readers are finished.

- Once any Writer has gained access, no Reader or other Writer may have access until the Writer has finished.

### *Multi-access objects in SIGMA*

Neither of the above techniques is appropriate if any of the competing processes need extended access to the resource. Any process doing so would block other processes from completing their tasks, potentially lengthening the time required to complete them significantly and, in an interactive environment, slowing the response time. In a situation in which a process needs read access to a data object for a long time, possibly concluding with a need to modify the object, neither of the above techniques can offer the guarantee of integrity of the data as well as provide timely interactive response when many processes are competing.

In the SIGMA message service<sup>8,7</sup> the two most important and frequently used data objects, *messages* and *folders*, are both typically shared among several users. At any time, any or all of the users allowed to share one of these objects may “open” it (request read and potentially write access), read through it for an arbitrarily long time and modify it in any of several ways. A scheme had to be developed which allowed simultaneous access by several users for arbitrary lengths of time, preserved a consistent image of the object for each user even while it was being modified by others, and both permitted and correctly assimilated modifications made in parallel by several users. At this point a description of the users’ perception of the two SIGMA shared objects is in order, to illustrate the issues involved in parallel modification.

### **SIGMA messages**

A SIGMA message is conceptually similar to a formal business letter with a sender, addressees, a body and various other information. In draft form (i.e., before it is sent), it may be read and revised by several reviewers before it is actually approved for sending. Several people may be involved during the draft/revision process, and for time efficiency it is often desirable for them to work in parallel. SIGMA provides this parallelism by giving each reviewer an

up-to-date copy of the current draft message, allowing him to edit, revise and comment as he sees fit. Each user's rendition of the message, called a *messagette*, contains all the original, unmodified parts of the original draft, his own modified sections replacing their original counterparts, plus any new text and comments.

After the message has been sent (referred to as a transmitted message), its character changes. It is no longer a draft entity, subject to revision. Just like a letter which has been dropped into a mailbox, it has become an official document, the contents of which are now on record. Users may read it and make comments, but are not allowed to change its contents in any way.

### SIGMA folders

A SIGMA folder can be likened to a file into which messages are placed. In SIGMA, however, the folder contains not the messages themselves but rather abstracts, called *entries*, containing a pointer to the actual message (for retrieval purposes) and a subset of the information contained in the referenced message. When messages are sent to a user, the entries referencing them are automatically placed in a particular folder named "Pending" (analogous to a mail in-basket). A user can create other folders and copy entries between them, where the number of folders needed or the significance of the entries placed into them is left entirely to the user's discretion. To help him locate specific entries within folders, a user is provided a rich set of searching tools, including the ability to associate entries with user-chosen keywords. A user can also place comments on entries and delete entries that are no longer needed in the folder.

A user may permit any or all of his folders to be accessed by other users, in which case the other users are allowed the same searching facilities available to the owning user, as well as to read the abstracts, make and read comments, and retrieve referenced messages. To allow users to peruse folders conveniently, SIGMA also maintains a place-marker in a folder for each user, marking the last entry he has referenced; when he next accesses that folder, he will be returned to the same entry.

### Further complications

The requirement that many users be allowed to modify an object in parallel posed several logical as well as implementation problems. It became apparent that the solution involved more than simply providing the correct form of interlock apparatus; it also had to preserve as much as possible the intent of the modifiers. This caused two complications well beyond the scope of the classical techniques described earlier:

1. "Whoops, where'd it go?"—From the application system standpoint, even assuming that writers are prevented from simultaneous modification, logical incon-

sistencies can still occur if they can write arbitrarily when it is their turn to write. Consider an object represented as a linked list, where the types of modification allowed are *add*, *replace* and *delete* elements of the list. What does it mean to *replace* an element just *deleted* by another writer, or to *add* an element adjacent to one just *deleted*?

2. "That's not how I remember it!"—Just as important as the ability to produce a logically consistent object is the need to have the updated object conform to each user's expectations of how it should appear after modification. Consider the typical situation which occurs when several authors or reviewers are allowed to edit a draft document in parallel, and they specify disparate sets of changes to a common secretary. When the updated draft appears, one or more authors may be surprised that the new draft does not reflect the changes they specify.

Clearly the above situations could be avoided if some restraints were placed on the types of modifications allowed. In the latter case, for example, the problem lies not in the authors nor in the secretary, but rather in the revision process which allowed parallel modification of a common data object. To avoid the confusion the secretary could have requested that each author confine himself to a different section of the document during a given review cycle, which would ensure that the various sets of modifications would not seriously conflict. While not a perfect solution, some restraint on the types of modification permitted was necessary to allow SIGMA to preserve the basic intent of the modifying users.

### AUGMENTING THE CLASSICAL SOLUTIONS

In light of the previous observations, the approach taken to provide parallel modification comprised two main components. The first was to carefully constrain the types of modifications permitted to the several users so they would cause neither irreconcilable conflicts nor unexpected results. The second involved finding a representation by which the modifications could be expressed.

#### *Limiting modification*

Determining in which ways to limit modification was a delicate issue. If the limitations were not strict enough or not along the correct dimension, the several sets of changes would conflict too much; if too restrictive, the users would be prohibited from expressing the changes they wished (and should be allowed) to make. The data objects involved, messages and folders, and the operations supported on them were thus designed with the goal of making the necessary limitations seem natural rather than confining.

#### **Limitations applied to draft messages**

In draft messages, SIGMA imposes its limitations on parallel modification by slightly constraining the draft/revision

model. Rather than portray a message as a shared entity, with all reviewers attempting to edit the one version into the form they want it, SIGMA effectively gives each user his "own" rendition of the message, to modify as he wishes. The process of successively refining a draft involves the selective reading and inclusion of desired segments of various users' messegettes, reading and possibly taking action on comments and suggestions, eventually resulting in a new draft. While the assimilation of the various changes and suggestions would normally be expected to be performed by the original author, any reviewer would have access to the same information and tools to create his own rendition.

The approach of giving each user his own rendition of a draft message avoids the complications described earlier.

1. Messegettes are logically and physically separate. Since each user may write only into his own messegette, modifications specified by several users contain no conflicts to produce logical inconsistencies.\*
2. Each user works with his own rendition of the message. While he has access to other users' messegettes, from which he can incorporate desired sections, his message always accurately reflects only changes *he* has made.

Users are thus allowed a free hand in composing or revising draft messages, while still retaining the ability to read, reference and comment upon other users' versions.

#### Limitations applied to transmitted messages

As previously described in the analogy to conventional mail, the content of transmitted messages is not subject to arbitrary modification. Users are restricted to a small set of operations.

- *Comment*—A user may place comments on any desired part of a transmitted message.
- *Forward*—A user may specify that the message be forwarded to one or more other users. A notation of the users receiving such forwarded copies is appended to certain message fields.

The limited scope of these operations avoids the undesirable complications.

1. All the types of modifications that users can specify are non-conflicting.
  - Inserting a new comment is strictly additive, requiring no change to the message's basic contents. Multiple comments specified in the same place in the message are simply added one after the other.
  - Editing an existing comment causes no conflict, as each user may modify only his own comments.
  - Forwarding is also an additive operation, simply appending the names of the forwarded addressees to the end of the appropriate field.

2. With the possible exception of the order in which comments or forwarding entries appear in the message (since users may comment or forward in parallel), the updated transmitted message conforms to each user's expectations.

#### Limitations applied to folders

The structure and use of folders prohibit providing a copy for each user, as in draft messages. The replication of storage to keep the multiple copies would be too expensive (folders tend to become quite large), as would the processing necessary to add each new entry to all of the copies. Consequently, all users access and modify the same folder object. Clearly, not all users may be allowed to modify a folder arbitrarily. As shown earlier, such a situation would lead to chaos unless some limitations on modification are imposed.

Fortunately, a compromise was found which provided the appropriate limitations without unduly constraining the capabilities of the users. Since it was logical to permit the owner of a folder more latitude in modifying it than other users, the limitations imposed differed, as follows:

- *Owner*—The owner is allowed all possible modification capabilities, including the abilities to
  - Delete the folder entirely
  - Delete and modify entries
  - Add keywords to entries
  - Append entries to the end of the folder
  - Add or modify comments (his own)
  - Keep a place-marker in the folder
- *Non-owner*—Non-owning users are permitted only the latter three capabilities. Note that these are all basically append-like operations, causing no structural changes to the folder.

This two-level capability scheme avoids the undesired complications described earlier.

1. The owning user alone can specify "dangerous" (structure-modifying) changes, so conflicts cannot occur. As in messages, appending data to the end or modifying data pertaining only to a specific user (comments, place-markers) do not produce conflicts.
2. The only departures from users' expectations occur when entries are deleted by the owner: comments specified by other users for deleted entries simply disappear; a place-marker specifying a deleted entry is adjusted to the nearest entry remaining. In all such cases the behavior is reasonable and does not constitute a significant departure from users' expectations.

#### Representing and applying parallel modifications

Once the appropriate limitations had been established to eliminate textual inconsistencies between the modifying users, there remained the issue of providing a mechanism

\* Subject to additional considerations discussed later.

which allowed changes to be assimilated into a common data object regardless of the number of users reading or updating the same object in parallel. It was also considered desirable to preserve a consistent image for readers during their access of an object (the goal in the Readers and Writers Problem); changes performed by other users should not cause objects to "change underneath them."

To provide the consistent image of an object during a user's session, a temporary copy of the object is made upon access. The reading and modification are then performed upon the copy, ensuring that no unexpected changes occur during the session. However, when a user's modifications have been completed, the net effect of the specified changes must then be performed on the central copy (called the *base* copy), which constitutes the "real" object to the rest of the users. Note that the modified copy cannot in general simply be substituted for the base copy; if any other users were making changes in parallel, such a strategy would cause all sets of changes but the last to be lost. Rather, the mechanism developed for SIGMA centered upon a construct called a  $\Delta$ -file.

### The $\Delta$ -file concept

When referring to a change in a variable (say  $x$ ), mathematicians often express it as  $\Delta x$ , meaning "the change in  $x$ ." To obtain the new, updated value of  $x$  (call it  $x_{\text{new}}$ ), one must take the old value ( $x_{\text{old}}$ ) and apply the change ( $\Delta x$ ), which in mathematics is done by addition, i.e.,

$$x_{\text{new}} = x_{\text{old}} + \Delta x$$

The notion of  $\Delta$ -files in SIGMA is conceptually similar to the mathematical  $\Delta$ . Each user, when accessing an object, is given a local copy. As he modifies it, his changes are remembered. When his changes are complete, SIGMA places into the  $\Delta$ -file a record of the effective changes applied by the user to the object. A  $\Delta$ -file thus represents the distillation of changes made by a user to his local copy of an object in an editing session, which, if "added" to the base copy, would produce the changes specified by the user.

The analogy to the mathematical  $\Delta$  is complicated by the possibility of having several  $\Delta$ -files produced in parallel by different users, each referring to the same base copy. Since the users work independently, the order in which the  $\Delta$ -files are applied cannot be guaranteed. If one user makes changes which conflict with those of another user, the consistency of the base file and maintenance of users' intentions cannot be guaranteed. But, as previously described, the types of modification allowed cause no significant conflicts.

### What's in a $\Delta$ -file?

When a user modifies an object, the  $\Delta$ -file produced contains not the new contents of the object but rather a specification of the modifications that need to be performed on the base (original) copy to make it conform to the user's changes. The following types of change specifications used

in SIGMA  $\Delta$ -files, called  $\Delta$ -operations, are sufficient to describe all possible changes to SIGMA objects.

- *Add*—Add a new item of data to the object adjacent to some other data item.
- *Delete*—Delete a data item from the object.
- *Replace*—Replace the contents of a data item with a new value.

For efficiency in applying the changes to the base copy, the identification of the data items to be affected by the  $\Delta$ -operations is done by an absolute, rather than symbolic, addressing scheme. This avoids costly searching to locate affected items, but requires that the addresses in the base copy at the time the  $\Delta$ -operations are performed match those which existed at the time they were generated. The constancy of these absolute address references is guaranteed by the non-conflicting nature of  $\Delta$ -files and the internal structures of messages and folders, which do not require address manipulation in response to modifications.

### Mechanics of assimilating $\Delta$ -files

Once the various  $\Delta$ -files have been generated, the task remains of applying them to the base copy. Rather than assign this task to the SIGMA user processes, it was decided to create separate processes (one for messages, one for folders) to execute this assimilation function, implemented in the SIGMA system as shared background processes known as *daemons*. When a SIGMA process creates a  $\Delta$ -file as the result of user changes, it enqueues a request to the appropriate daemon, supplying the name of the object to be modified and the name of the  $\Delta$ -file in the form of a physical location identifier (PLID), an operating-system-dependent path name describing the location of the  $\Delta$ -file information. The daemons execute these requests in order, finding the referenced PLIDs and applying the contained  $\Delta$ -operations to the named objects. A diagram depicting the process of  $\Delta$ -file incorporation is shown in Figure 1 (although the SIGMA message service processes many shared objects, the figure concentrates on just one such object, in the process of being modified in parallel by several users). Note that the order in which  $\Delta$ -files are processed is arbitrary, but the consistency of the resulting updated object is preserved by the non-conflicting nature of the changes they contain.

The division of labor in the updating task between the SIGMA processes and the daemon provides several benefits. It allows the  $\Delta$ -file incorporation task to be performed by a separate background processor, insulating the SIGMA processes from a significant processing burden (hence user-perceived response time delay) which they would otherwise encounter whenever an update operation was performed. And since the SIGMA processes have no need to modify the base copy of an object (all writing is done in the  $\Delta$ -files instead), the daemon can be given exclusive write access to the base copy. Combined with the "copy-on-access" discipline imposed to maintain a consistent view of objects for

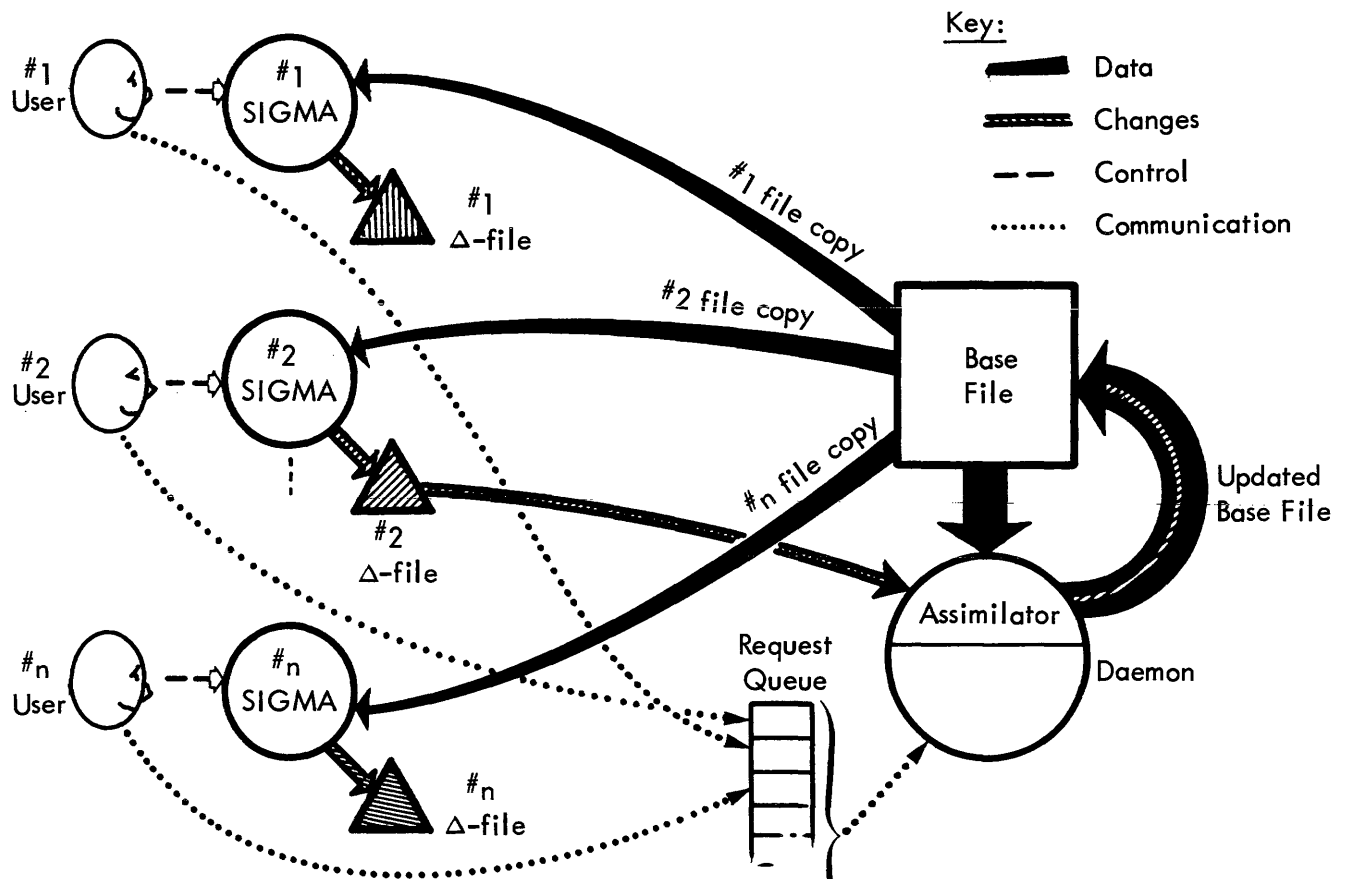

Figure 1—The  $\Delta$ -file mechanism.

users, no costly interlock is necessary to prevent access conflicts between the daemon and the SIGMA processes.

**Flaw in the non-conflict assumption**

Despite the careful considerations described earlier regarding limitations on modification, a significant flaw developed, although it was not specifically connected to parallel access. Rather, it developed as a side-effect of the division of labor between the generation of changes (by users through their SIGMA processes) and their application to the base copies (performed by the daemon). Since the daemon is an asynchronously operating request-driven process, there is typically a measurable time interval between the generation of a  $\Delta$ -file and its assimilation into the base copy. During this interval, whose duration depends upon system load and daemon backlog, a user's pending changes are not reflected in the base copy. If the user accessed the object during this period, he would find that the object did not contain his changes, violating the requirement to preserve user expectations. Moreover, if the user were allowed to access the old copy anyway, and made changes which conflicted with those of the pending  $\Delta$ -file, the assumption of non-interference of  $\Delta$ -files would also be violated.

The inescapable conclusion was that a user could not be allowed to access the old (unmodified) copy of the object; he could only access the object with his previous changes incorporated. The following approaches were considered:

1. The user's SIGMA process could keep track of the pending  $\Delta$ -file and note whether its assimilation had occurred. If not, the SIGMA process could perform the assimilation itself to recreate the modified object. This approach required significant bookkeeping and additional computing in the SIGMA process to duplicate that soon to occur in the daemon. Also, it would not be able to account for changes made by other users.
2. The SIGMA process could prevent the user from proceeding further in his terminal session until the assimilation of the  $\Delta$ -file were complete. This would introduce an unnecessarily severe degradation in user-perceived response time at the conclusion of editing of each object.
3. The SIGMA process could prevent a modifying user from accessing the object again until the previous changes had been assimilated. While this approach could temporarily prevent a user from accessing a particular object, it would not inhibit him from executing

SIGMA operations not pertaining to that object, unlike (2) does.

Since in practice it is rare that a user attempts to re-access an object before the daemon has had the opportunity to perform the  $\Delta$ -file assimilation, Approach 3 was chosen. While not an elegant solution, the infrequent temporary denial of access to a specific object poses a negligible inconvenience and is thus a minimal impediment to users.

## CONCLUSIONS

The multi-access scheme described in this paper has been in operation within the SIGMA message service for over three years. This experience has shown the approach to have successfully satisfied the requirements needed to provide multi-access to SIGMA's shared data objects. Following are several of the most successful aspects of the SIGMA multi-access methodology:

- Parallel access to shared objects by an arbitrary number of users (processes) occurs with no conflict.
- Each user is satisfied that his changes to a shared object are faithfully recorded.
- Users accessing shared objects are not confused by other users' changes during their own editing sessions.
- The limitations imposed on modifications are natural rather than cumbersome, and do not overly constrain users.
- The concept of a  $\Delta$ -file and the resulting non-conflicting, incremental update of shared objects is a powerful technique to apply to the multi-access problem.
- The division of labor between the foreground (SIGMA)

and background (daemon) processes provides two significant benefits—the ability to avoid expensive reader/writer interlocks on shared objects, and the shifting of the processing burden away from the user process to achieve better user-perceived response.

While this methodology was developed specifically for the SIGMA message service application, the concepts involved are much more general. Similar techniques could be successfully applied to many other shared data applications, such as command-and-control, data base management systems, information retrieval systems, or any other application in which many users can have access to common data and in which preserving the intent (and hence the trust) of those users is an important concern.

# Exact solution for the initialization time of packet radio networks with two station buffers

by DANIEL MINOLI

*Bell Telephone Laboratories  
Holmdel, New Jersey*

## INTRODUCTION

The Packet Radio Network (PRNET), a store-and-forward packet-switching system sharing a single radio channel via multi-access techniques and spread spectrum, is an effective communication medium for data and voice transmission in situations requiring fast deployment, non-fixed hardware locations, encryption and anti-jamming in hostile military environments.<sup>1-5,14,15</sup>

Many investigators have developed analytical solutions for the performance of channel access schemes typically employed (pure ALOHA, CSMA, etc.).<sup>7-13</sup> These studies have shown, among other things, that PRNET's can be easily saturated and become unstable unless efficient routing and flow control algorithms are used. To enable point-to-point packet transportation the network station assigns a code (label) to each repeater; the process of assigning such labels is referred to as "network initialization." The initialization procedure assumes that the network topology is not known a priori and is changing with time. Thus, the initialization procedure involves mapping of network topology, determining network structure (labels for repeaters) and transmitting labels to the repeaters.

Notwithstanding its importance,<sup>19</sup> the problem of initialization has not been studied extensively except in References 5, 16, 17 and 18.

In this paper we present a Markov chain model which enables one to obtain in closed form the optimal rates at which repeaters and station must transmit initialization packets and labels to minimize the network initialization time in a one-hop network, two buffer station. This is an extension of the work reported in References 17 and 18.

In Reference 17 a Markov Chain model for initialization of 1-hop packet radio networks was discussed; with this model the total initialization time must be obtained numerically by solving a set of linear simultaneous equations. For an  $m$  repeater network the number of such equations turns out to be  $0(m^3)$ . Hence, this model is not applicable for analyzing large networks.

The complexity of such models can be reduced by modifying the label queue management from a random selection discipline to a first-in, first-out (FIFO) discipline; the number of linear simultaneous equations that need to be solved

can be reduced from  $0(m^3)$  to  $0(m^2)$ . In this case we can actually go a step further, and obtain closed-form solutions. In Reference 18 the exact solution for the initialization time with one station buffer for the label queue was derived.

In this paper we formulate a new Markov Chain initialization model based on FIFO queue management and we derive exact solutions for this new model when the station has two buffers for the complete interference case. Our most important result is that the network initialization time is relatively insensitive to the station transmission rate, but the repeater transmission rate must be carefully chosen to achieve rapid initialization.

## INITIALIZATION AND INITIALIZATION PROTOCOL

Network initialization must be performed whenever the network resumes operation from cold, or whenever the network topology changes. Such topology changes may occur quite frequently; this may be due to decreases in repeater transmission ranges due to battery power drainage or equipment failure; or due to the severe variations in received signal strength caused by the topology of the terrain, man-made structures, foliage, multipath distortion and fading. In addition to this problem of monitoring RF connectivity, the potential mobility of the network must be taken into consideration; the initialization algorithm and its efficiency are particularly significant in such cases.<sup>4</sup>

The initialization procedure considered in this paper—and which is typical for this operation—consists of the following steps: a non-initialized repeater transmits Repeater-On-Packets (ROPs) informing the station of its existence and unique identification; a station program determines a label for the specific repeater and the station places a Label Packet (LLP) in its Label queue for transmission to the repeater. We refer to this queue as the station buffer. After the repeater has received the LLP and acknowledged its receipt, the repeater is considered labeled. The time required to initialize all repeaters is the network initialization time.

We consider a PRNET with a single station and  $m$  repeaters in which all devices can communicate directly; a slotted ALOHA access scheme is assumed. In such an environment, the available channel is time slotted into segments of

Figure 1—States of a repeater during initialization and possible transitions from status 1 (non-initialized) to status 5 (initialized).

and where:

$p$  = Repeater transmission rate

$q$  = Station transmission rate

$I(i)$  = Average number of interfering repeaters, given  $i$  repeaters are initialized.

The expression is exact for complete interference, i.e.,  $I(i) = m - 1 - i$ .

**NUMERICAL RESULTS FOR THE TWO-STATION BUFFER CASE**

Figures 2, 3, and 4 depict the optimal parameter values and initialization time for complete interference, for  $I(i) = 2$ , and no interference, respectively, for an  $m$ -repeater network. The optimal values were obtained by point-by-point search and are accurate to two significant digits.

Figure 5 shows the initialization time as a function of  $m$ , parameterized on  $I(i)$ . The initialization time for a one-buffer system is shown for comparison.

The following can be observed:

1. The optimal station transmission is nearly constant at  $q^* \approx 0.40$ , showing a slight tendency to decrease as  $m$  increases.

Figure 2—Complete interference, two buffers.

Figure 3—Partial interference,  $I(i)=2$ , two buffers.

2. There is only a very small difference in the optimal station rate at low or high interference.
3. For complete interference  $p^* < 1/m$ , and for large  $m$ ,  $p^* \approx 0.7/m$  (empirically determined).
4. As the interference decreases,  $p^*$  increases (as expected);  $p < 1/m$  and  $p^* \approx 0.8/m$  for large  $m$ .
5. As the interference decreases, the initialization time decreases. There is a reduction of about 15 percent in initialization time as we go from complete interference to zero interference.

COMPARISON OF ONE-BUFFER AND TWO-BUFFER CASES

Single station buffer

It was shown in Reference 18 that the initialization time for a single hop  $m$ -repeater packet radio network is given

by:

$$I = \sum_{i=0}^{m-1} \left\{ \frac{1}{(m-i)p(1-p)^{m-i-1}} + \frac{1}{q(1-p)^{i(i+1)}} + \frac{1}{(1-q)(1-p)^{m-i-1}} \left( 1 + \frac{[1-(1-q)(1-p)^{m-i-1}]}{q(1-p)^{i(i)}} \right) \right\} \quad (4)$$

A comparison between the previous cases shows:

1. The station's optimal transmission rate decreased 10 percent as we went from one buffer to two buffers. This is explained by the fact that in a two-buffer situation there is no pressing urgency to clear the one occupied buffer since another is available for accepting ROPs.
2. The repeater's transmission rates are unchanged on the average, indicating that the repeaters can be ignorant of the station's buffer number.

Figure 4—Zero interference, two buffers.

3. The initialization time decreased as we went from one buffer to two buffers. Approximately 15 percent less time is required with two buffers than with one buffer.

## CONCLUSIONS

Closed-form solutions for the initialization time of a single-hop packet radio network were obtained. The solutions are for the case in which the station has one or two buffers for storing and sending labels and when it uses a first-in-first-out queue management strategy. The slotted ALOHA access scheme was assumed. The optimum values of repeater and station transmission rates as a function of the interference pattern of repeaters were experimentally obtained. These optimum rates result in minimum initialization times.

The following conclusions emerge from the studies:

1. The initialization time with two buffers at the station

is approximately 15 percent smaller than with one buffer, for the same interference pattern and network size.

2. The optimal station transmission rate,  $q^*$ , is nearly independent of  $m$  (number of repeaters), for both values of the buffer size; however,  $q^*$  decreased 10 percent as we went from one buffer to two buffers. Thus,  $q$  is a function of the station's architecture only.
3. The optimal repeater transmission rates were independent of the buffer size on the average, indicating that the repeaters need not be aware of the station's buffer structure.
4. The optimal repeater transmission rate increases about 20 percent as interference goes from complete to zero; the initialization time decreases about 15 percent as we go from complete interference to zero interference.
5. In both cases for large  $m$  optimal repeater transmission rates were proportional to  $1/m$  where  $m$  is number of repeaters in the network.

Figure 5—Initialization time as a function of  $m$ ,  $I(i)$  and  $b$ .

## APPENDIX A—INITIALIZATION MODEL

### Transition probabilities

Because of the assumptions of complete interference and FIFO it is easy to compute the state transition matrix. For the complete interference case, a packet is successfully received by the station, if all other repeaters and the station are silent. Similarly, for a packet to be received successfully by a repeater it is required that all repeaters be silent.

We associate a status with each repeater during the initialization process, as in the second section. The state of the system is defined by the number of repeaters in each status. Given the present state of the chain  $(m_1, m_2, m_3, m_4, m_5)$ , where  $m_i$  is the number of repeater in the status  $i$ , the following list enumerates all possible transitions. We consider  $m_3=0$  and  $m_3=1$  separately.

1. No repeater received a label in the previous slot ( $m_3=0$ )
  - a. Successful ROP when station queue is not empty. This requires  $m_1>0$ ,  $0<m_2+m_4<b$ . Transition to state  $(m_1-1, m_2+1, 0, m_4, m_5)$  occurs with probability  $(1-q)m_1p(1-p)^{m_1+m_2-1}=Z_1'$ .
  - b. Successful ROP when station queue is empty. This requires  $m_1>0$ ,  $m_2+m_4=0$ . Transition to state  $(m_1-1, m_2+1, 0, m_4, m_5)$  with probability  $m_1p(1-p)^{m_1+m_2-1}=Z_1''$ . Since  $Z_1'$  and  $Z_1''$  represent probabilities of mutually exclusive events, we will use one notation  $Z_1$  which will denote  $Z_1'$  or  $Z_1''$ , depending on the event.

- c. Successful label to a repeater with status 2. This cannot occur in the present model unless  $m_4=0$ . Transition to state  $(m_1, m_2-1, 1, m_4, m_5)$  with probability  $Z_2=(1-p)^{m_1+m_2}q$ .
  - d. Successful label to the repeater in status 4. This requires  $m_4>0$ . Transition to state  $(m_1, m_2, 1, m_4-1, m_5)$  with probability  $(1-p)^{m_1+m_2}q=Z_3$ .
  - e. Else remain in same state with probability  $1-Z_1-Z_2-Z_3$ .
2. Some repeater received a label in the previous slot ( $m_3=1, m_4=0$ )
    - a. Successful ETE Ack. Transition to state  $(m_1, m_2, 0, m_4, m_5+1)$  occurs with probability  $(1-p)^{m_1+m_2}(1-q)$ .
    - b. Unsuccessful ETE Ack; transition to state  $m_1, m_2, 0, m_4+1, m_5)$  with probability  $1-(1-p)^{m_1+m_2}(1-q)$ .
  3. If the present state is  $(0, 0, 0, 0, m)$  go to state  $(m, 0, 0, 0, 0)$  with probability 1.

It is elementary to verify that a unique stationary vector,  $(\Pi_1, \Pi_2, \dots, \Pi_n)^T$ , exists for this chain. Also, if the  $n$ th state is completely labeled state,  $(0, 0, 0, 0, m)$ , then the expected inter-arrival time between visits to state  $n$  is  $1/\Pi_n-1$ . Hence, the expected initialization time is  $1/\Pi_n-1$ .

#### APPENDIX B—DERIVATION OF SOLUTION FOR A TWO-BUFFER MODEL WITH FIFO SERVICE DISCIPLINE

By a cycle of a Markov chain we mean a section of the state transition diagram. We consider cycles  $C_i$  such that

1. The  $C_i$ s are disjoint.
2. Any state of the chain belongs to one cycle.
3.  $C_i$  and  $C_{i+1}$ , when considered as graphs, are isomorphic for all but possibly the first and last case.

The solution strategy involves computing the expected time to traverse one cycle, and then summing these over cycles  $0, 1, \dots, m-1$ .

##### General strategy

It can be observed that closed-form computations are relatively easy when the number of states by which one can enter a cycle is one. To achieve this, we define the following cycles:

- Cycle  $-1$  Start with  $(m, 0, 0, 0, 0)$   
End with  $(m-1, 1, 0, 0, 0)$
- Cycle  $i$  Start with  $(m-i-1, 1, 0, 0, i)$   
End with  $(m-i-2, 1, 0, 0, i+1), i=0, 1, 2, \dots, m-2$
- Cycle  $m-1$  Start with  $(0, 1, 0, 0, m-1)$   
End with  $(0, 0, 0, 0, m)$

Note that Cycle  $-1$  involves only the successful sending of a ROP to the station while the Cycle  $m-1$  involves only the labeling of the last repeater after all others have been labeled, after this repeater has successfully sent a ROP.

Thus at the beginning of Cycle  $i, i=0, 1, \dots, m-2$ , there are  $m-i-1$  repeaters with status 1, one repeater with status 2, and  $i$  repeaters with status 5.

Figure 6 illustrates the states for a typical cycle  $0 \leq i \leq m-2$ . SR, SL, SE, UE represent successful ROP, successful label, successful ETE ACK, and unsuccessful ETE ACK, respectively; notice that now there are three separate classes of routes which the chain can take to traverse the cycle. Each cycle starts with 1 ROP in the buffer. Either one of the following classes of routes can be taken:

1. Another ROP is received by the station before a label is received by a repeater (follow the lower route passing through states  $4_i, 5_i$ , and possibly  $6_i$ ).
2. The label is received and acknowledged by the repeater before another ROP is received (upper route without cross over passing through states  $2_i, 0_i$ , and possibly  $3_i$ ).
3. The label is dispatched several times but before it is successfully acknowledged another ROP is received (upper route with cross over passing through states  $2_i, 3_i, 6_i$ , and  $5_i$ ).

Our calculations involve examining the expected time to traverse each of these classes of routes, and deciding with what probability each is chosen.

Let  $E[T_i]$  be the expected time to go through cycle  $i$ ; then the total expected initialization time is the sum of the expected times required to traverse each cycle:

$$I = \sum_{i=-1}^{m-1} E[T_i] \tag{B.1}$$

Since Cycle  $-1$ , and  $m-1$  are different, we address these first. Throughout the analysis we use the fact that the geometrical distribution is memoryless; that is, if  $\tau$  is a geometrically-distributed random variable; then

$$Prob(\tau > i + j | \tau > i) = Prob(\tau > j)$$

for  $i, j$  integers.

In our case  $\tau$  is the time spent in a specific state of the Markov chain; the time to leave any state is geometrically distributed.

Consider the following particular scenario. The chain is in state  $A$ . If event  $E$  occurs transition to state  $B$  occurs; else if  $\bar{E}$  (its complement) occurs go to state  $C$ . Remain in state  $C$  until some other event  $F$  occurs then return to state  $A$ . See Figure 7. Let  $E[T_{AB}]$  and  $E[T_{CA}]$  be the expected time to go from  $A$  to  $B$  and  $C$  to  $A$ , respectively. Because of the abovementioned memoryless property we obtain

$$E[T_{AB}] = \frac{1 + (1 - p(E))E[T_{CA}]}{p(E)}$$

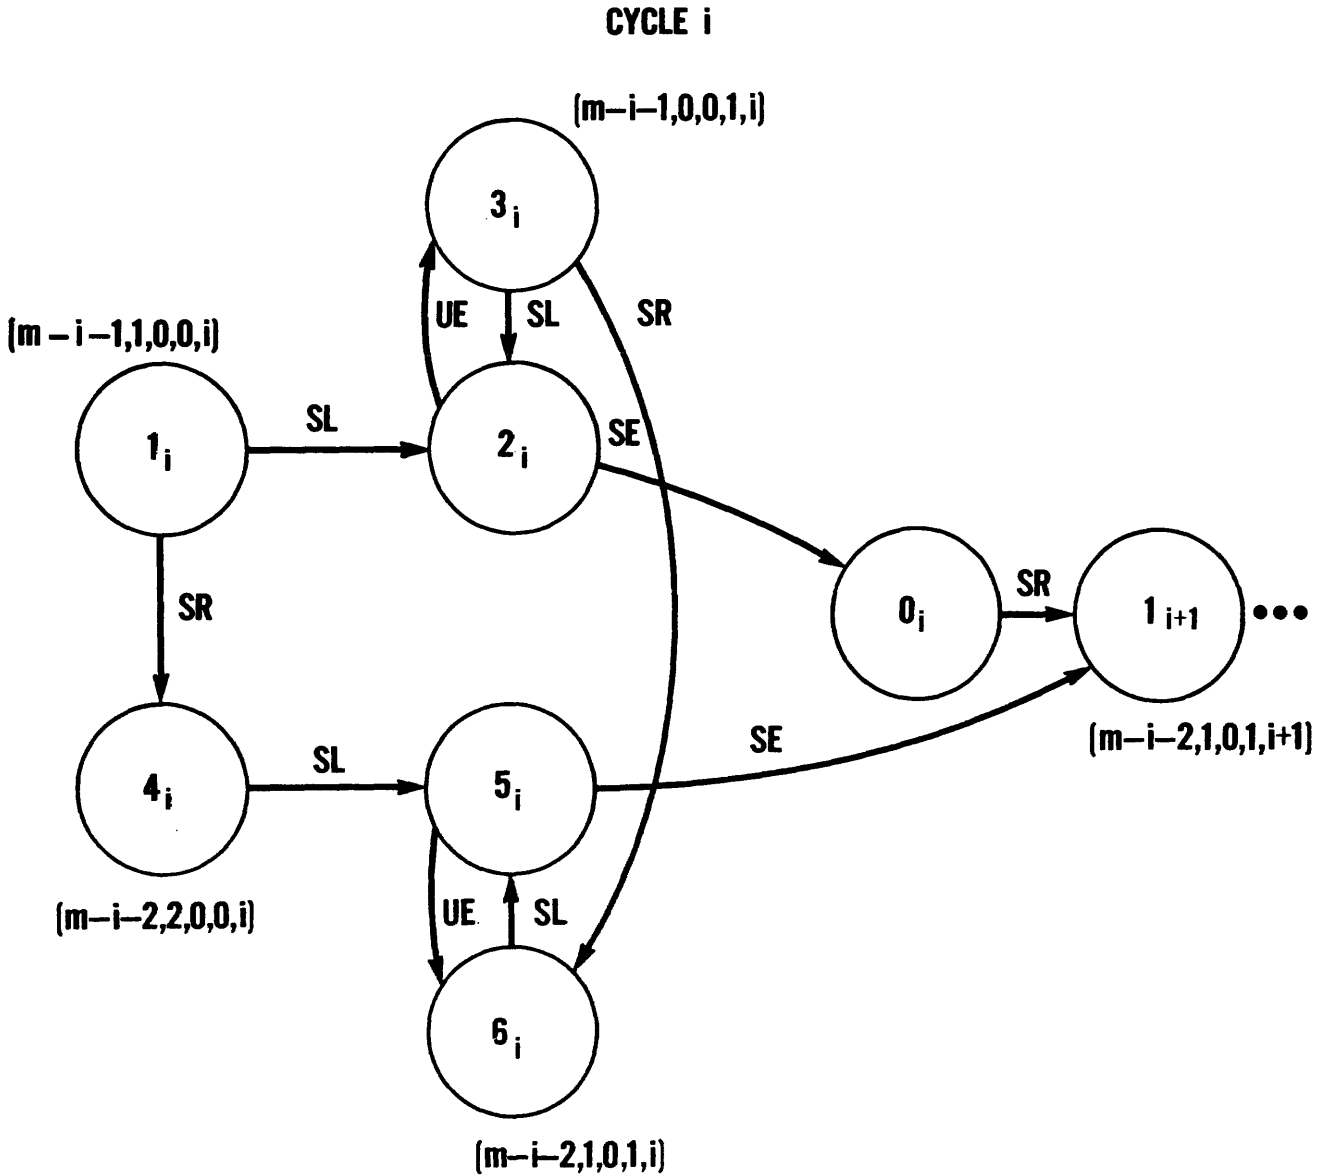

Figure 6—Cycle  $i$ ,  $i=0, 1, \dots, m-2$ .

*Cycles  $-1$  and  $m-1$*

Figure 8 depicts that section of the state transition diagram for cycle  $-1$  and  $m-1$ .

**Evaluation of  $E[T_{-1}]$**

This involves a SR, given that all  $m$  repeaters are uninitialized; this requires one repeater to transmit and all others to remain silent. Thus the expected time of Cycle  $-1$  is:

$$E[T_{-1}] = \frac{1}{P_{0,-1,0}} = \frac{1}{mp(1-p)^{m-1}} \quad (B.2)$$

**Evaluation of  $E[T_{m-1}]$**

Observe that, except for the number of unlabeled repeaters, this section of the state diagram is the same as a cycle

for a one-buffer problem. As in Reference 18 we obtain

$$\begin{aligned} E[T_{m-1}] &= E[T_{1_{m-1}2_{m-1}}] + E[T_{2_{m-1}0_{m-1}}] \\ &= \frac{1}{q(1-p)} \\ &\quad + \frac{1}{P_{2_{m-1}0_{m-1}}} \\ &\quad \{1 + E[T_{3_{m-1}2_{m-1}}](1 - P_{2_{m-1}0_{m-1}})\} \end{aligned} \quad (B.3)$$

where  $P_{2_{m-1}0_{m-1}} = Prob$  (ETE Ack is successful.)

Since every repeater is silent at this stage, we only require that the station be silent; thus,  $P_{2_{m-1}0_{m-1}} = (1-q)$ , giving the expected time for Cycle  $m-1$ :

$$E[T_{m-1}] = \frac{1}{q(1-p)} + \frac{2}{1-q} \quad (B.4)$$

Figure 7—Transition time under memoryless distributions.

Evaluation of  $E[T_i]$ ,  $i=0, 1, \dots, m-2$

For a typical Cycle  $i$ , we are interested in quantifying the time needed to traverse it. Such time is made up of various components, indicated as follows:

**Computation of  $E[T_{1,i+1}]$**

To compute this expression, assume that at the current slot the state of the chain is  $1_i$ , then condition on the outcome of the next slot. It is easy to derive

$$P_{1,2i} = \text{Prob}(\text{go from } 1_i \text{ to } 2_i) = q(1-p)^{1+I(i)} \quad (B.5)$$

$$P_{1,4i} = \text{Prob}(\text{go from } 1_i \text{ to } 4_i) = (1-q)(1-p)^{m-i-1}p(m-i-1) \quad (B.6)$$

Then, referring to Figure 6, we see that

$$E \left[ T_{1,i+1} \mid \begin{array}{l} \text{outcome of} \\ \text{next slot} \end{array} \right] = \begin{cases} 1 + E[T_{2,i+1}] & \text{if a label is delivered} \\ 1 + E[T_{4,i+1}] & \text{if a ROP is received} \\ 1 + E[T_{1,i+1}] & \text{if neither of the above} \end{cases} \quad (B.7)$$

where we have made use of the memoryless property previously described. Unconditioning, we obtain:

$$E[T_{1,i+1}] = (1 + E[T_{2,i+1}])P_{1,2i} + (1 + E[T_{4,i+1}])P_{1,4i} + (1 + E[T_{1,i+1}])((1 - P_{1,2i} - P_{1,4i})) \quad (B.8)$$

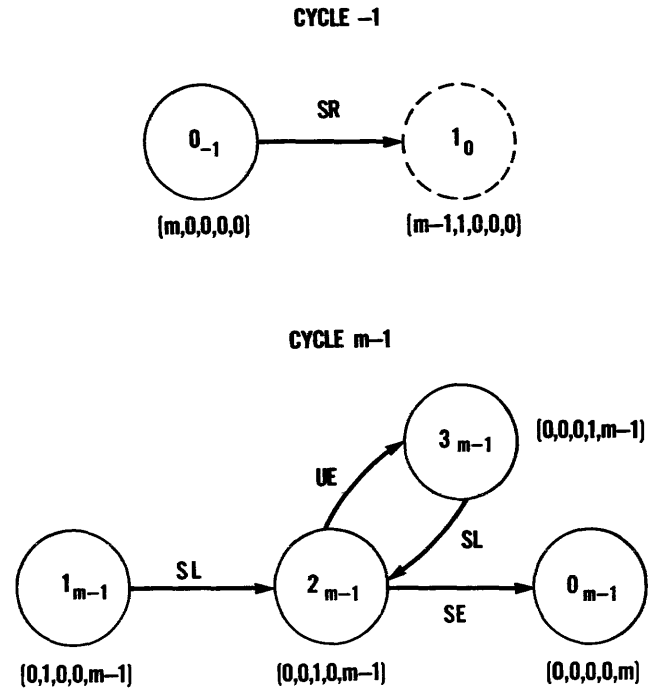

Figure 8—Cycles  $-1$  and  $m-1$ .

Solving for  $E[T_{1,i+1}]$ , we obtain:

$$E[T_{1,i+1}] = \frac{1 + P_{1,2i}E[T_{2,i+1}] + P_{1,4i}E[T_{4,i+1}]}{P_{1,2i} + P_{1,4i}} \quad (B.9)$$

We notice that to proceed we need  $E[T_{2,i+1}]$  and  $E[T_{4,i+1}]$ ; we address  $E[T_{4,i+1}]$  next.

**Computation of  $E[T_{4,i+1}]$**

Referring to Figure 6, we see that

$$E[T_{4,i+1}] = E[T_{4,5i}] + E[T_{5,i+1}] \quad (B.10)$$

We now evaluate the expressions on the right-hand side of Equation B.10. It is quite simple to show that:

$$E[T_{4,5i}] = \frac{1}{P_{4,5i}} = \frac{1}{q(1-p)^{1+I(i)}} \quad (B.11)$$

since we require a successful label delivery from the state  $(m-i-2, 2, 0, 0, i)$ .

To obtain  $E[T_{5,i+1}]$  we must condition on the outcome of the next slot, namely whether the ETE Ack is successful or not. Using the analysis applied to the one buffer case we find:

$$E[T_{5,i+1}] = \frac{1}{P_{5,i+1}} \{1 + E[T_{6,5i}](1 - P_{5,i+1})\} \quad (B.12)$$

Note that:

$$P_{5,i+1} = (1-p)^{m-i-1}(1-q) \quad (B.13)$$

since we are in state  $(m-i-2, 1, 1, 0, i)$ , and the station

and all other unlabeled repeaters must be silent for the ETE to be successful. Also

$$E[T_{6;5_i}] = \frac{1}{P_{6;5_i}} = \frac{1}{q(1-p)^{i(i)}} \quad (\text{B.14})$$

since one less repeater is now active after state  $6_i$  is reached. Finally:

$$E[T_{4;1_{i+1}}] = \frac{1}{q(1-p)^{1+i(i)}} + \frac{1}{(1-p)^{m-i-1}(1-q)} \left\{ 1 + [1 - (1-p)^{m-i-1}(1-q)] \frac{1}{q(1-p)^{i(i)}} \right\} \quad (\text{B.15})$$

#### Evaluation of $E[T_{2;1_{i+1}}]$

Assuming the current state of the chain to be  $2_i$  and conditioning on the event of the next slot, namely whether the ETE Ack is successful, we immediately see

$$E \left[ T_{2;1_{i+1}} \mid \begin{array}{l} \text{event of} \\ \text{next slot} \end{array} \right] = \begin{cases} 1 + E[T_{0;1_{i+1}}] & \text{if ETE Ack} \\ & \text{successful} \\ 1 + E[T_{3;1_{i+1}}] & \text{if ETE Ack} \\ & \text{unsuccessful} \end{cases} \quad (\text{B.16})$$

Note that (see Figure 6):

$$P_{2;0_i} = \text{Prob (ETE Ack is successful from state } 2_i) \\ = (1-q)(1-p)^{m-i-1} \quad (\text{B.17})$$

Unconditioning, we get:

$$E[T_{2;1_{i+1}}] = P_{2;0_i}(1 + E[T_{0;1_{i+1}}]) \\ + (1 - P_{2;0_i})E[T_{3;1_{i+1}}] \quad (\text{B.18})$$

Since

$$E[T_{0;1_{i+1}}] = \frac{1}{(m-i-1)p(1-p)^{m-i-2}} \quad (\text{B.19})$$

(due to the fact that the station is automatically silent when the label queue is empty) we obtain:

$$E[T_{2;1_{i+1}}] = 1 + P_{2;0_i} \frac{1}{(m-i-1)p(1-p)^{m-i-2}} \\ + (1 - P_{2;0_i})E[T_{3;1_{i+1}}] \quad (\text{B.20})$$

Thus, we need to find  $E[T_{3;1_{i+1}}]$ .

#### Evaluation of $E[T_{3;1_{i+1}}]$

Note this calculation is more complicated than the single-buffer case because it is possible to transfer from  $3_i$  to  $6_i$ ,

i.e.; another ROP is received before label delivery. Again, we condition on the next slot.

$$E \left[ T_{3;1_{i+1}} \mid \begin{array}{l} \text{event of} \\ \text{next slot} \end{array} \right] = \begin{cases} 1 + E[T_{2;1_{i+1}}], & \text{if label successful} \\ 1 + E[T_{6;1_{i+1}}], & \text{if ROP successful} \\ 1 + E[T_{3;1_{i+1}}], & \text{if neither} \end{cases} \quad (\text{B.21})$$

Unconditioning:

$$E[T_{3;1_{i+1}}] = (1 + E[T_{2;1_{i+1}}])P_{3;2_i} + (1 + E[T_{6;1_{i+1}}])P_{3;6_i} \\ + (1 + E[T_{3;1_{i+1}}])(1 - P_{3;1_{i+1}} - P_{3;6_i}) \quad (\text{B.22})$$

where

$$P_{3;6_i} = \text{Prob (ROP is successful from state } 3_i) \\ = (m-i-1)p(1-p)^{m-i-2}(1-q) \quad (\text{B.23})$$

$$P_{3;2_i} = \text{Prob (label is successful from state } 3_i) \\ = q(1-p)^{i(i)} \quad (\text{B.24})$$

Solving, we obtain:

$$E[T_{3;1_{i+1}}] = \frac{1 + P_{3;2_i}E[T_{2;1_{i+1}}] + P_{3;6_i}E[T_{6;1_{i+1}}]}{P_{3;2_i} + P_{3;6_i}} \quad (\text{B.25})$$

$E[T_{6;1_{i+1}}]$  can be written as:

$$E[T_{6;1_{i+1}}] = E[T_{6;5_i}] + E[T_{5;1_{i+1}}] \quad (\text{B.26})$$

where:

$$E[T_{6;5_i}] = \frac{1}{q(1-p)^{i(i)}} \quad (\text{B.27})$$

and  $E[T_{5;1_{i+1}}]$  was derived two sections ago. Hence, we obtained an equation for  $E[T_{3;1_{i+1}}]$  in terms of  $E[T_{2;1_{i+1}}]$ . Together with the equation of the third subsection, we have a system which must be solved simultaneously.

#### Evaluation of $E[T_i]$ —The final result

We now pull things together; from the beginning of the third subsection we have:

$$E[T_{1;1_{i+1}}] = \frac{1}{P_{1;2_i} + P_{1;4_i}} + \frac{P_{1;2_i}}{P_{1;2_i} + P_{1;4_i}} E[T_{2;1_{i+1}}] \\ + \frac{P_{1;4_i}}{P_{1;2_i} + P_{1;4_i}} E[T_{4;1_{i+1}}] \quad (\text{B.28})$$

From the next subsection we have:

$$E[T_{4i+1}] = E[T_{4i}] + \frac{1}{P_{5i+1}} \{1 + E[T_{6i}](1 - P_{5i+1})\} \quad (B.29)$$

We only need  $E[T_{2i+1}]$ . From the next two subsections we have:

$$E[T_{2i+1}] = 1 + P_{2i}E[T_{0i+1}] + (1 - P_{2i})E[T_{3i+1}] \quad (B.30)$$

and

$$E[T_{3i+1}] = \frac{1}{P_{3i} + P_{3i+1}} + \frac{P_{3i+1}}{P_{3i} + P_{3i+1}} E[T_{2i+1}] + \frac{P_{3i}}{P_{3i} + P_{3i+1}} E[T_{6i}] + E[T_{5i+1}] \quad (B.31)$$

The following procedure is employed:

1. Substitute  $E[T_{5i+1}]$  (which has just been computed) into Equation B.31.
2. Solve the system of Equations B.30 and B.31 for  $E[T_{2i+1}]$ .
3. The answer to 2 is in terms of  $E[T_{6i}]$ , which was just derived; substitute this expression.

We thus have  $E[T_{2i+1}]$ , namely:

$$E[T_{2i+1}]$$

$$= \left\{ 1 + (1-q)(1-p)^{m-i-1} \frac{1}{(m-i-1)p(1-p)^{m-i-2}} + [1 - (1-q)(1-p)^{m-i-1}] \left[ \frac{1}{(m-i-1)p(1-p)^{m-i-2}(1-q) + q(1-p)^{i(i)}} \right] + \frac{1}{(1-p)^{m-i-1}(1-q)} \cdot \frac{(m-i-1)p(1-p)^{m-i-2}(1-q)}{(m-i-1)p(1-p)^{m-i-2}(1-q) + q(1-p)^{i(i)}} \times \left[ 1 + \frac{1}{q(1-p)^{i(i)}} \right] \right\} \cdot \left\{ 1 - \frac{[1 - (1-q)(1-p)^{m-i-1}]q(1-p)^{i(i)}}{(m-i-1)p(1-p)^{m-i-2}(1-q) + q(1-p)^{i(i)}} \right\}^{-1} \quad (B.32)$$

Substitute Equations B.29 and B.32 into Equation B.28; we obtain Equation 3, that is,

$$E[T_{1i+1}] = E(T_i) = \text{Equation (3)}$$

Thus, we have accomplished our goal of determining the expected time to traverse a typical cycle. Summing over all cycles gives the total expected initialization time (Equation 2).

# Fixing timeout intervals for lost packet detection in computer communication networks

by ROBERT J. T. MORRIS

Bell Laboratories  
Holmdel, N.J.

## INTRODUCTION

In a packet-switched data communication network which provides internal packet accountability via an end-to-end positive acknowledgment protocol, it is necessary to include a mechanism for detection and retransmission of missing packets. In particular, a decision must be made as to how long a sending element should reasonably wait before declaring an unacknowledged packet lost and initiating a recovery action. This waiting time is one of a class of system parameters which have come to be known as timeout intervals. The choice of a timeout interval is a delicate problem.<sup>1,2</sup> If it is too short, network capacity is wasted by frequent unnecessary actions for packets which are not lost but merely delayed. If the timeout interval is too long, lost packets cause needlessly prolonged delays before recovery is initiated.

Several recent papers have considered this problem. Sunshine<sup>2</sup> considered a retransmission scheme where a packet  $P$  is retransmitted every  $T$  seconds, until an acknowledgment of  $P$  is received. He considered the quantities mean delay including retransmission and mean number of transmissions. He illustrated the analysis by considering an Erlangian delay distribution with a defect representing packet loss. As  $T$  is varied, the curve mean delay versus mean number of transmissions exhibits a definite "knee."

Fayolle, Gelenbe and Pujolle<sup>3</sup> conducted an analysis of a related protocol. A packet  $P$  is retransmitted every  $T$  seconds until an acknowledgment of the last retransmittal of  $P$  is received. They derive individually optimal values of  $T$  for three separate performance measures: buffer throughput (maximized), response time (minimized) and loss rate due to buffer overflow (minimized).

Buttò, Colombo, Taggiasco and Tonietti<sup>4</sup> conducted an analytic and simulation study of a nontrivial network and demonstrated that overall network performance could be severely degraded by employing too short a retransmission timeout interval. They identified the following interesting network phenomenon: if a network reaches a critically busy state, delays may be sufficiently long that timeouts continually occur, resulting in a flooding of the network with retransmission traffic which in turn increases delays, causing unstable traffic growth until network saturation occurs. We

will discuss ways of averting this type of behavior in a later section.

McQuillan and Cerf<sup>5</sup> gave the rule of thumb: the timeout interval should be set equal to the round-trip delay plus a "fudge factor" to account for variance.

The treatment we give here is distinguished by the following features:

1. We begin by identifying what appear to be the performance objectives of major importance in normal network operation. We use a simple model to produce a design method for the timeout interval which *simultaneously* satisfies each objective as well as possible.
2. We are particularly interested in networks using fixed routes or virtual calls. In contrast to References 2 and 3, we do not assume independently distributed packet round-trip times, since a packet and any retransmissions will normally follow the same network path causing highly correlated round-trip times.
3. Despite the inevitably subjective nature of the problem, we defend our design rules by demonstrating the presence of an inherent generality in the approach.
4. We consider the practical implications and *caveats* of the results. Of particular importance are the additional considerations which arise when we allow the possibility of abnormal network conditions caused by faults or congestion. It is shown that in order to obtain satisfactory operation, it is highly desirable that the timeout mechanism be made adaptive in an autonomous manner to the network and connection condition.

## A SIMPLE MODEL

In this section we construct a simple model comprised of a network path characteristic and a rudimentary retransmit protocol. The model serves to identify some important performance issues which should be taken into account when fixing the timeout interval  $T$  in normal network operation.

Consider a path between two nodes  $A$  and  $B$  of a packet-switched network. Packets are transmitted from  $A$  to  $B$ , and  $B$  returns individual acknowledgment packets to  $A$ . Suppose the probability that a packet is not acknowledged (forward

packet or acknowledgment lost) is  $L$  and if the packet is not lost, its round-trip delay (transmission to receipt of acknowledgment) is governed by a continuous distribution  $F$  with finite mean  $\mu$  and complement  $F^c = 1 - F$ .

Next, consider a retransmit protocol wherein a packet  $P$  is retransmitted every  $T$  seconds until an (any) acknowledgment of  $P$  is received.

The main performance issues in choosing  $T$  are as follows:

1.  $T$  should not be so short that frequent "false alarms" occur, i.e., frequent retransmissions of packets which are not lost but merely delayed.
2.  $T$  should not be so long that a lost packet causes an unnecessarily prolonged delay in system recovery. A long recovery delay affects system performance in two ways. Firstly, delayed recovery causes prolonged retention of unacknowledged packets in the retransmit buffer, and consequently a wastage of shared buffer space. Secondly, the delayed eventual packet receipt at node  $B$  caused by a packet loss can cause a delay which is directly apparent to an application such as terminal to host computer interaction.

Other performance issues related to abnormal network conditions are discussed later.

We now quantify the above considerations. Rather than assume that the round-trip delays of a packet and its successive retransmissions are independent random variables, we adopt the following assumption which is appropriate for fixed-route or virtual call paths.

*Assumption A:*

No retransmitted packet will pass an earlier version of the same packet.

Now let

$D$  = time from packet first sent until packet acknowledgment first received, i.e., effective round-trip delay.

$N$  = number of transmissions required to successfully deliver one packet.

$F'$  = maximum round-trip delay of a packet which is not lost =  $\sup\{t: F(t) < 1\}$

$X_i$  denote the  $i^{\text{th}}$  retransmission of packet  $X_0$ ,  $i = 1, 2, \dots$

Then

$$\begin{aligned}
 E(N) &= \sum_{i=1}^{\infty} i \cdot \Pr\{X_0, \dots, X_i \text{ only sent}\} \\
 &= \sum_{i=1}^{\infty} i \cdot \Pr \left[ \bigvee_{j=0}^{i-1} \{X_0, \dots, X_{j-1} \text{ lost}; \right. \\
 &\quad \left. X_j \text{ acknowledged in } [(i-1)T, iT)\} \right], \\
 &\hspace{15em} \text{by Assumption A} \\
 &= \frac{1}{1-L} + \sum_{i=1}^{\infty} F^c(iT) \tag{2.1}
 \end{aligned}$$

and

$$\begin{aligned}
 E(D) &= \sum_{i=0}^{\infty} (\mu + iT) \Pr\{X_i \text{ first to be acknowledged}\} \\
 &= \sum_{i=0}^{\infty} (\mu + iT) \Pr\{X_0, \dots, X_{i-1} \text{ lost}; \\
 &\quad X_i \text{ acknowledged}\}, \\
 &\hspace{15em} \text{by Assumption A} \\
 &= \sum_{i=0}^{\infty} (\mu + iT)L^i(1-L) = \mu + TL/(1-L) \tag{2.2}
 \end{aligned}$$

We now go on to show how  $E(N)$  and  $E(D)$  are related to considerations 1 and 2, stated previously.

Let us define *transmission efficiency*  $\eta$  as the reciprocal of the number of packets transmitted per successfully delivered packet. A lowering of  $\eta$  causes an increase in effective network load which in turn leads to a depletion of the capacity of the network to do useful work. Consideration 1 is embodied in the requirement that  $\eta = E(N)^{-1}$  be kept high. Note that the maximum network "throughput" allowable for a given delay figure will be proportional to  $\eta$ . Thus our first stated objective is to *choose  $T$  to keep  $E(N)$  small*. According to (2.1),  $T$  should be chosen large.

We now turn our attention to consideration 2. First note that  $E(D)$  describes the mean holding time in the sender's retransmit buffer. Assuming that the path throughput is constant, then it follows from Little's results that mean retransmit buffer occupancy is proportional to  $E(D)$ . Attention to mean buffer occupancy is reasonable since buffer space at the sender is shared amongst many independent calls. Next assume (although this can be relaxed) that both packet round-trip delay and loss are approximately equally shared between forward and return paths and that  $L$  is small. Then the mean time to successful receipt of a forward packet is approximately  $E(D)/2$ . Thus both aspects of consideration 2 are taken into account by requiring that  $E(D)$  be kept small. Hence our second stated objective is to *choose  $T$  to keep  $E(D)$  small*. According to (2.2),  $T$  should be chosen small, in conflict with our earlier requirement.

In order to study this demonstrated conflict between the requirements of avoiding false alarms yet retaining short delays in the presence of loss, we examine more closely expressions (2.1) and (2.2).

Assume for simplicity that  $L$  is non-zero and  $F(t)$  is strictly increasing for  $t \leq F'$ . Then  $E(N)$  and  $E(D)$  are shown diagrammatically as  $T$  varies in Figures 1a,b. The "tradeoff curve"  $E(N)$  versus  $E(D)$  is shown in Figure 1c.

Considering the multiobjective optimization problem of minimizing both  $E(N)$  and  $E(D)$  by choice of  $T$ , we see immediately that any choice of  $T \leq F'$  is pareto-optimal (also known as efficient, noninferior, etc.). The specification of an "optimal" value for  $T$  requires precise knowledge about the relative costs of  $E(N)$  and  $E(D)$ . In the absence of any such knowledge, one way of identifying the knee of the tradeoff curve, Figure 1c, is to demand that the operating point be such that the relative degradations of both objec-

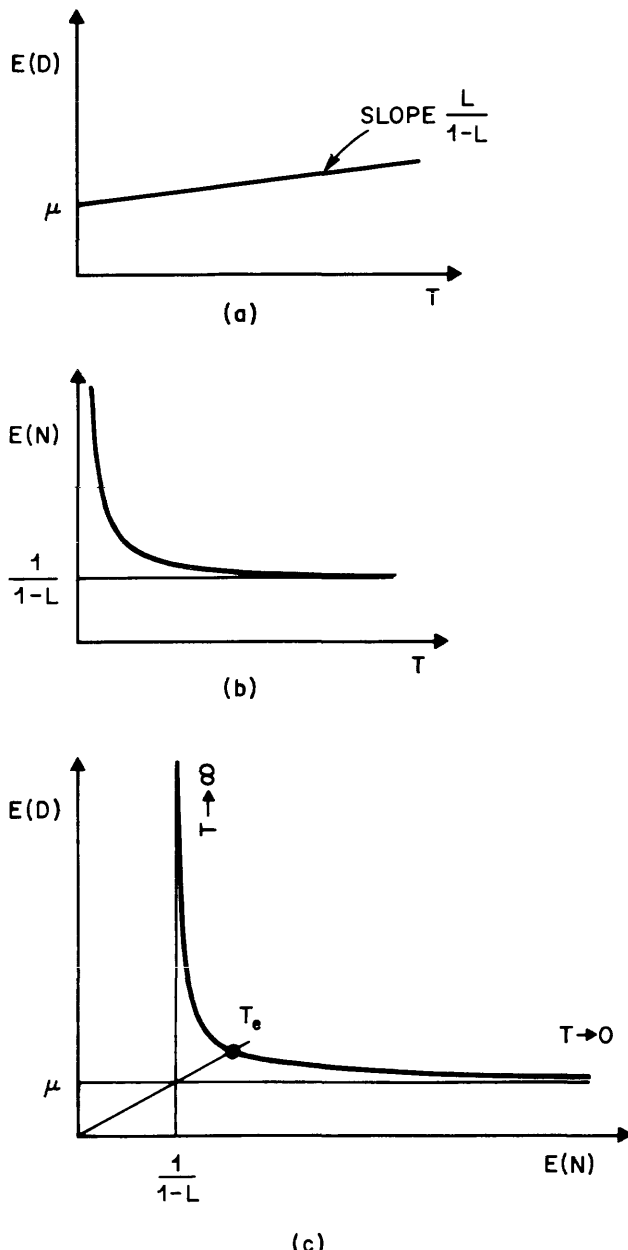

Figure 1

tives from their respective individual optima are equal. Hence we define an equitable value of  $T$  denoted  $T_e$ , by

$$\frac{E(N)_{T_e} - \frac{1}{1-L}}{\frac{1}{1-L}} = \frac{E(D)_{T_e} - \mu}{\mu} \tag{2.3}$$

Substituting from (2.1) and (2.2) yields

$$\frac{L}{1-L} \frac{T_e}{\mu} = (1-L) \sum_{i=1}^{\infty} F^c(iT_e) \tag{2.4}$$

The value of  $T_e$  is shown in Figure 1c and always exists by our assumption that  $F$  is continuous and  $L$  is non-zero.

We will be particularly interested in the case where  $L$  is small, so it is of interest to see what happens to  $T_e$  as  $L$  approaches zero.

Proposition I:

$$\lim_{L \rightarrow 0} T_e(L) = F'$$

Proof:

Assume first that  $F' < \infty$ . Then  $T_e \leq F'$  or else (2.4) would be contradicted. Letting  $L \rightarrow 0$ , the lefthand side of (2.4) approaches zero. The only way for the righthand side of (2.4) to approach zero is for  $T_e$  to approach  $F'$ .

Now consider the case  $F' = \infty$ . Pick  $L_0 \in (0, 1)$ . Then for  $L < L_0$ ,  $T_e(L)$  must be unbounded, for if it were bounded the righthand side of (2.4) would be bounded below, but the lefthand side of (2.4) cannot be bounded below unless  $T_e(L)$  is unbounded. The observation that  $T_e(L)$  increases as  $L \rightarrow 0$  completes the proof.  $\square$

The effectiveness of the design decision  $T = T_e$  naturally depends on the relative importance of the two objectives  $E(N)$  and  $E(D)$  and in turn the considerations 1 and 2. However, if the value of equation (2.4) is small then little improvement of either objective is possible, and then only at the expense of a worsening of the other objective. Thus when the value of equation (2.4) is small it would be difficult to find grounds on which to criticize the choice  $T = T_e$  and for this reason the design can be considered sound.

Hence it is of interest to note that for small loss probability  $L$ , the value of equation (2.4) is also small.

Proposition II:

$$\lim_{L \rightarrow 0} \frac{L}{1-L} \frac{T_e(L)}{\mu} = 0$$

Proof:

Assume first that  $F' < \infty$ . By Proposition I as  $L \rightarrow 0$ ,  $T_e(L) \rightarrow F'$  and the result follows.

If  $F' = \infty$ , then as  $L \rightarrow 0$ ,  $T_e(L) \rightarrow \infty$ . But

$$\sum_{i=1}^{\infty} F^c(iT_e) \leq \frac{1}{T_e} \int_0^{\infty} F^c(t) dt = \frac{\mu}{T_e}$$

which also approaches zero.  $\square$

A natural question which now arises concerns the sensitivity of the performance objectives  $E(D)$  and  $E(N)$  to a variation of  $T$  away from  $T_e$ . We shall answer this question briefly for the case where  $L$  is small. By observation of Figures 1a and 1b, it is seen that if  $T$  is increased above  $T_e$ , the degradation of  $E(D)$  will be negligible (since  $L$  is small) and the improvement of  $E(N)$  slight. On the other hand, if  $T$  is decreased below  $T_e$ , there is a possibility of a serious worsening of  $E(N)$  caused by excessively many false alarms. We consider this possibility further in a later section. An observation of some general value is that for systems with low loss probability, if there is any uncertainty,  $T$  should be made longer rather than shorter.

ALTERNATIVE APPROACH AND COMPARISON

Given a delay distribution and loss probability, we have given a technique for choosing a timeout interval. This technique was based on an examination of overall system objectives. We now develop an alternative approach.

We adopt the same model as in the previous section and continue to employ Assumption A.

Consider the first transmission of a packet. Denote by  $q(t)$  the conditional probability that the packet is lost given that it has not been acknowledged by time  $t$ . Thus

$$q(t) = \frac{L}{L + (1-L)F^c(t)}$$

The curves  $q(t)$  and  $1 - q(t)$  are plotted in Figure 2. The significance of the point  $T_d$  shown on the figure is that

$$\begin{aligned} &Pr\{packet\ is\ lost\ | packet\ not\ acknowledged\ by\ T_d\} \\ &= Pr\{packet\ is\ not\ lost\ | packet\ not\ acknowledged\ by\ T_d\} \end{aligned}$$

and for  $t > T_d$ , presently available information implies that the packet is more likely lost than delayed. Assumption A now implies that if the packet is delayed but not lost, there is nothing to be gained by retransmission.

Thus, in the absence of further information, an appropriate time to declare the packet lost is at  $T_d$ . Note that  $T_d$  satisfies

$$q(T_d) = 1 - q(T_d) \tag{3.1}$$

or

$$F^c(T_d) = L / (1 - L) \tag{3.2}$$

Equation 3.2 always has a solution if  $L \leq \frac{1}{2}$  and  $F$  is continuous and it is clear that  $\lim_{L \rightarrow 0} T_d(L) = F'$ .

The choice  $T = T_d$  is, of course, inherently no less or more arbitrary than the choice  $T = T_e$ . What is of interest is that, as we now show, there is a degree of consistency between the values  $T_e$  and  $T_d$ .

We begin with a numerical example.

Example

Consider the case where  $F$  is an Erlangian distribution with 16 phases and mean  $\mu$ . The values  $T_e$  and  $T_d$  obtained from equations (2.3) and (3.1) are shown as a function of  $L$  in Figure 3.

Figure 2

Figure 3

A reasonable agreement between  $T_e$  and  $T_d$  is observed. Note that for loss probabilities smaller than one percent, the value  $LT_e / (\mu(1-L))$  is sufficiently small that it may be argued that  $T_e$  provides a sound design, in that little improvement of  $E(D)$  or  $E(N)$  is possible with a different decision.

For many delay distributions of interest (e.g., Erlangian, hyperexponential, exponential), it can be shown that

$$\lim_{L \rightarrow 0} \frac{T_e(L)}{T_d(L)} = 1 \tag{3.3}$$

Sufficient conditions for (3.3) to be true are that

- a.  $F$  has density  $f$  satisfying  $\liminf_{t \rightarrow \infty} f(t) / F^c(t) > 0$ .
- b.  $F^c$  is log-asymptotic to a log-concave complementary distribution.<sup>6</sup>

Thus, as well as the reasonable agreement evidenced in the example, it is observed that there is an intrinsic consistency between the two approaches.

It is of interest to observe that if Equation 2.4 is replaced by

$$\frac{1}{1-L} \frac{T_e}{\mu} = a(1-L) \sum_{i=1}^{\infty} F^c(iT_e)$$

where  $a$  is arbitrarily positive, then under the above conditions (3.3) remains true. This implies that the asymptotic (small  $L$ ) behavior of  $T_e$  is independent of the relative costs attributed to the delay and efficiency objectives.

Similarly, if Equation 3.1 is replaced by

$$q(T_d) = b[1 - q(T_d)] \tag{3.4}$$

where  $b$  is positive and allows a solution to (3.4), then under the above conditions, (3.3) also remains true.

ABNORMAL NETWORK CONDITIONS

In the two previous sections we have considered that a network path is characterized by a fixed delay distribution

$F$  and a fixed loss probability  $L$ . While this assumption is reasonable under normal network operation,  $F$  and  $L$  may be considerably altered during periods of network congestion or partial failure. A poor choice of timeout intervals can even contribute to a change in  $F$  and  $L$ .

In the introduction we described an effect where too short a timeout interval  $T$  led to continual retransmission of a packet causing increased traffic load and in turn increased delay. Such an effect can lead to artificially-induced network saturation and it is necessary to incorporate some adaptation into the timeout mechanism to prevent this hazard. The measurement of packet round-trip times by the sender for the purposes of detecting timeouts provides valuable information on the current network condition and  $T$  can be set using the method of the two previous sections, but taking into account recent observations of round-trip delay. However, this does not provide complete protection, since a sudden change in path or network condition could result in a sudden increase in mean round-trip time. A transmitter should interpret the occurrence of a timeout as meaning that a packet has been lost, or, quite possibly, that an increase in round-trip delay has occurred. Thus the transmitter's response to a timeout should include a lengthening of the timeout interval as well as retransmission. This latter mechanism provides an autonomous adaptation to a network condition that does not rely on the receipt of recent round-trip delay information. Automatic deflation of  $T$  occurs when the network problem subsides and round-trip times resume normal values. Similar comments to the above apply in the case where a change in network condition causes an increase in  $L$  (perhaps to unity!); the appropriate action is a lengthening of  $T$ .

Thus we can identify three classes of inputs to an adaptive timeout setting algorithm:

1. *Setup parameters*—Number and type of nodes in path; call priority.
2. *Observational corrections*—Observed round-trip delays; congestion indicators.
3. *Autonomous corrections*—Number of recent timeouts.

One issue which has not been discussed concerns the relationship between timeouts and fault detection strategies. If the occurrence of timeouts is used as an input to a fault detection/diagnosis mechanism, this will provide another reason for not choosing  $T$  too large.

## SUMMARY AND CONCLUSION

In this paper we have tried to isolate some of the most important underlying issues which arise when choosing a timeout interval.

We have observed in the second section the presence of several conflicting goals and that the solution we have proposed should be viewed as a pleasing compromise. It was demonstrated in the next section that our solution yields a result similar to that of a quite different design technique and in fact, that for small loss probabilities the solution is insensitive to the parameter representing the compromise. In the fourth section we have considered how the basic design should be modified to take into account the possibility of abnormal network conditions and to ensure that timeouts themselves cannot act as a source of network problems.

It is likely that any real network and protocol will possess its own features and idiosyncrasies which require additional factors to be included in the timeout strategy. In the author's application,<sup>6</sup> a number of additional objectives and protocol details have been taken into account. For example, an efficient protocol will acknowledge groups of packets rather than individual packets. As a general network strategy, when a timeout occurs it may be desirable for the transmitter to send an inquiry requesting status of the receiver rather than simply retransmitting the original packet. In this case the essence of the model remains valid since these inquiries need to be repeated periodically so that recovery from a short duration fault (e.g., trunk fade) is accomplished automatically. Another modification which can be accommodated in the above analysis arises from the consideration of block retransmit as opposed to the selective retransmit scheme we assume here.

## ACKNOWLEDGMENT

The author is grateful to Jack Holtzman of Bell Laboratories for suggesting a study of this problem and providing many suggestions and comments.

# Comparison of some end-to-end flow control policies in a packet-switching network

by G. PUJOLLE

IRIA-LABORIA  
Le Chesnay, France

## INTRODUCTION

Various techniques may be considered when it comes to setting up a communications system between computers. The "packet-switching" technique described by Davies<sup>1</sup> seems to be one of the best of existing approaches. In the following we consider only such a technique—users of a computer network communicate with each other by the intermediate of a store-and-forward packet-switching network.

The term host has been introduced in the Arpanet literature. It has been used widely, although not always in the very same sense as in Arpanet. We use it here in some loose sense—a host is a source and a sink of packets. A subscriber is an entity which provides to the host the data to be transmitted through the packet-switching network (PSN). The set of subscribers attached to host  $i$  asks on the average the transmission of  $\lambda_i$  packets per second.

It is well known in a system where resources are shared that when the load increases, it is necessary to have a congestion tool to avoid a degradation of performance. Such a phenomenon has been pointed out in PSN.<sup>2,3</sup> Thus tools are necessary to prevent this degradation. They are flow control methods, namely procedures whereby the receiver allocates a potential transmission credit to the sender, no matter what the form may be to specify this credit.

In the second section, we describe several types of specifications in order to compare them in the fifth section. To do this, we shall introduce in the fourth section an unified mathematical model. This model will use a single source destination path taking into account intermediate interarrivals. Two different node transmission procedures, introduced in the third section, will be used in the model.

The main contribution of our paper is that we explicitly take into account most of the elements which characterize a packet-switching network—node-to-node and host-to-host protocol, retransmission policy, finite buffer size in nodes. Three flow controls are examined and their performance compared in detail under several working assumptions.

We show that the maximum throughput allowed by these three types of flow controls are very different and the higher the throughput, the more important it is to control ade-

quately the parameters of the system to avoid a thrashing phenomenon.

## FLOW-CONTROL TECHNIQUES

### *Window flow control*

One of the best known techniques is the isarithmic scheme.<sup>1,2</sup> Under this control, there are a fixed number of credits circulating in the network. A packet is admitted into the network only if it can get hold of a free credit. The packet travels through the network accompanied by its credit. The credit is again free when the packet reaches its destination. Several policies can be followed to re-distribute the free credits. For example, they can be host-dedicated, namely, they return to the originating source when they are released. If they are host-to-host dedicated, the scheme corresponds to a window flow control and the number of credits used for an host-to-host communication corresponds to the value of the window width. Our first flow control is exactly this last one—we shall name it WFC (*Window Flow Control*). We shall assume first a fixed window width, with the possibility to render it variable in a later phase of this study.

### *Rate flow control*

An attractive scheme can work by a limitation of packets entering into the network in the following way. As long as a destination is able to cope with the outgoing packets, there is no need to choke the sending host-sources. However, if there is an excess of traffic, queues will start building up, and will eventually block the nodes. It is convenient to let each host receive from each node the information of the maximum amount of packets it can accept. According to this knowledge, hosts can then limit their transmissions to a "good" number of packets per unit of time. This is an idealized flow control because propagation delay is assumed infinite. However, it is possible to anticipate correctly the

variations of flows in a network by a system of control packets.

In a first step we shall assume a fixed threshold on the number of packets that can enter the network each unit of time. Then this number will vary with the state of the network. We name this technique *the rate flow control (RFC)*.

*Flow control induced by the X25 recommendation*

X25 flow control is negotiated between two subscribers by a virtual channel. At the host level X25 flow control is viewed as a superposition of virtual connections. The flow control for a virtual connection is based upon authorizations from the receiver. The main means for this control is the Receive Ready indication which essentially consists of the sequence number of the last well received packet. For each virtual connection a window size specifies how many packets may be transmitted from the sender host to the receiver host, related to the last correct Receive Ready indication. The difference with the window flow control is the existence of virtual circuits. Virtual circuits need establishment and release. The first packet opens the virtual circuit from the source to the destination and reserves special buffers at each node so that no possible overflow is possible. We shall name this flow control XFC (*X25 flow control*).

**SPECIFICATIONS OF THE PACKET-SWITCHING NETWORK**

Before we develop the mathematical model, it is necessary to define some specifications of the packet-switching network itself. We must define a strategy for dealing with packets rejected because of overflow due to finite buffer size at

the switching nodes. We shall take into account two types of technique:

- The most common technique, here called switch-retransmission (used for example in ARPA) in which if a packet cannot be accepted by a switch, it is retransmitted from a back up copy held in the preceding switch.
- Another technique which we call host-retransmission (used in the Cyclades network) in which the network drops a packet which arrives at a full switch, to be re-sent later by the source host.

In the modeling of store-and-forward communication lines we have to know the behavior of nodes. This behavior is very dependent on the node-to-node transmission procedure. Two types of procedure can be allowed:

1. Without look-ahead (window width=1)
2. With look-ahead (window width>1)

*“Send and wait” procedure*

The “send and wait” (SW) procedure<sup>4</sup> belong to the first category. Before transmitting a new packet, the previous one must be acknowledged. We are going to analyze their behavior. On the time axis of Figure 1 we have represented the state of the sender and of the receiver during the transmission of a packet.

- $\omega_{00}, \omega_{10}$  are due to the task switching and software work of the packet.
- $\omega_{01}, \omega_{11}$  are the software delay of the writing on both systems.

Figure 1—The “send and wait” behavior.

$\omega_{02}, \omega_{12}$  are due to the propagation delay, and depend on the modems used and the line length (overhead due to modems are not negligible).

$L$  is the mean total length of packets to be transmitted.

$l$  is the length of the control packet which returns the acknowledgment.

$v$  is the line capacity.

$\tau$  represents the time that the previous packet if any takes to finish its transmission.

We denote by  $S$  the total time necessary for the transmission of a packet. This mean service time is given by:

$$S = \omega_{00} + \omega_{01} + \omega_{02} + \frac{L}{v} + \omega_{10} + \omega_{11} + \omega_{12} - \frac{l}{v} + \tau$$

For the various overheads we will use the following values measured on the Cyclades network,<sup>5</sup>

$$\omega_{00} = \omega_{10} \approx 5\text{ms}, \quad \omega_{01} = \omega_{11} \approx 3\text{ms}$$

For a 500 km line length  $\omega_{02} = \omega_{12} \approx 3\text{ms}$ . We have to note the variation of  $\tau$  according to the load on the lines. If the load is weak,  $\tau = 0$  almost surely. In heavy traffic on the average  $\tau$  is the transmission time of half a packet length.

In the sequel, we assume a symmetric traffic and we denote by  $\rho$  the load on a line. If  $\rho = 0$  then the service  $S$  is minimum and if  $\rho = 1$  the service time is maximum. We shall adopt a linear variation of the mean service time  $S$  between its maximum and its minimum.

Let  $Ca = 1/v$  and  $Cb = \omega_{00} + \omega_{10} + \omega_{01} + \omega_{11} + \omega_{02} + \omega_{12} + l/v$ . We obtain the following simple expression for  $S$ :

$$S = CaL + Cb + Ca \frac{L}{2} \rho.$$

If the line speed is 48 Kb/s, we have for a 500 km line length:

$$S = 20.8 L + 26 + 10.4 L \rho$$

The quantity  $S$  we have defined is the time necessary to transmit successfully one packet. Now if an error occurs during the transmission or if the packet is rejected by an overflow in the receiver node, a backup copy has to be transmitted after a time-out. We have shown in a previous

paper<sup>6</sup> that the performance of the node-to-node procedure is not sensitive to the probability of packets in error for usual values of this probability. Thus, we assume this probability negligible. Let  $p$  be the probability of overflow of the receiver node.

If we use the switch-retransmission (sr), a backup copy is retransmitted after a time-out  $T$  with the probability  $p$ . So the mean real time for one transmission is (without the retransmission if the packet is lost):

$$S_{sr}^{SW}(\rho) = (CaL + Cb + \frac{CaL}{2} \rho)(1-p) + Tp$$

We assume  $T = 200$  ms for a 48 Kb/s line.

For the host-retransmission (hr) the overflow is detected after the acknowledgment is sent (the overflow is detected by the switch). So the mean time for one transmission is

$$S_{hr}^{SW}(\rho) = CaL + Cb + \frac{CaL}{2} \rho.$$

### HDLC procedure

The HDLC procedure (High-level Data Link Control) which has been accepted as an international standard, belongs to "with look-ahead" node-to-node procedure. Its behavior is shown in Figure 2.

Due to the parallelism of the processes, the effective time required for a transmission is difficult to calculate; it depends on the window width. However, it is shown in Reference 6 that the throughput is only limited by transmission times if the window width is chosen adequately (the window width has to be sufficiently large so that no blocking occurs).

Thus we shall adopt for the mean effective transmission time the following values:

$$S_{sr}^{HDLC}(\rho) = CaL(1-p) + Tp, \text{ or } S_{hr}^{HDLC}(\rho) = CaL.$$

### THE UNIFIED MATHEMATICAL MODEL

In this section, we consider a particular route inside the store-and-forward PSN. Such a route is modeled as a tan-

Figure 2—Behavior of the HDLC protocol.

dem queueing network. The system consists of  $K+1$  queues. A customer (corresponding to a packet) goes through the system joining the  $(i+1)$ -th queue after the  $i$ -th device for  $0 \leq i \leq K-1$ .

The first station 0, corresponding to the host, is assumed to have an infinite number of buffers. We assume that one packet and only one can be contained in one buffer. All the other stations have a finite number  $M_i$  of buffers (there is room for only  $M_i$  packets at station  $i$ ). This finite size corresponds to the storage facility of the output queues of nodes of a route.

This mathematical model is shown in Figure 3. In Figure 3, customers of station C represent the credits. If its queue is empty the host must wait for a credit before transmitting a packet. The number of credits in the packet-switching network is denoted by  $N$ . When a packet leaves the network a credit comes towards the host. It passes through the station R which represents if necessary the return time of the credit (and the positive ACK). When a customer flows from station 0 to station 1 a credit disappears.

Our three flow control policies can be characterized as follows.

In the window flow control, the total number of credits circulating in the PSN represents the window width. We have to note that if this number  $N$  of credits is less than or equal to  $\text{Min}(M_1, M_2, \dots, M_K)$ , there is always a buffer available for a packet entering the network. This corresponds to the X25 flow control. If the total number of credits is greater than the sum  $M_1 + M_2 + \dots + M_K$  and assuming station R does not exist, we have a network without flow control.

Finally, the rate flow control policy will be studied at the same time as the case without flow control because it corresponds to a threshold on the utilization of the server of the host.

In the applications, the mean service time will be chosen to be one of  $S_{sr}^{SW}$ ,  $S_{sr}^{HDLC}$ ,  $S_{hr}^{SW}$ ,  $S_{hr}^{HDLC}$  according to the node-to-node protocol and retransmission strategy chosen.

We shall denote by  $S$  this mean service time when the choice between several policies is possible.

#### *Solution of the unified mathematical model*

Several criteria can be used to evaluate the performance of the models. As we deal with flow control schemes we need an indicator of performance according to which the system is judged. This congestion measure can reasonably be chosen to be the throughput of the system versus the utilization of the server of the host. We have chosen this last parameter because it allows us to compare the different flow control schemes in a unified manner, and it is one the parameters used to control the traffic entering the packet-switching network.

The solution of the unified mathematical model will be carried out in two steps:

1. The model without station C and R.
2. The model with station C and R.

In order to solve this complex model some simplifying assumptions must be made; we describe them now.

In a real PSN each packet maintains its length as it travels from node to node, and service times are not independent. Here we will make the independence assumption of Kleinrock<sup>7</sup> and a new independent packet length will be chosen at each station.

We assume that the distribution of service times of all the stations are identical and the average value is  $S(\rho)$  where  $\rho$  is the utilization of the server of the host. This assumes that all stations have the same utilization rates. This is accurately verified in balanced networks.

Finally, our last assumption is to assume that a customer leaving a queue sees the system in an equilibrium state, namely the probability for a packet to be rejected is taken equal to the probability that the following queue is full. It has been shown<sup>8</sup> that this assumption is quite accurate.

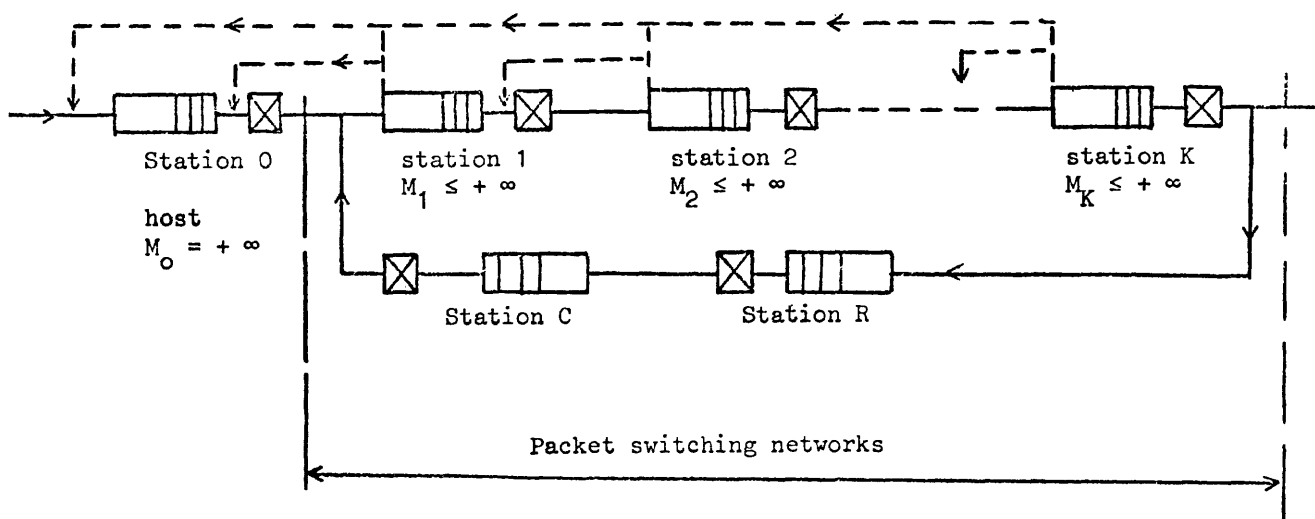

Figure 3—The unified mathematical model.

The explicit computations are introduced in the Appendix. We just give an idea here—from a given utilization of the host  $\rho$ , we compute the probability  $p$  that a customer is rejected by the PSN and comes back into the host. Then the mean transmission time is obtained from  $S(\rho)$  whose value depends on the node-to-node protocol and the retransmission policy. Therefore we obtain the total arrival rate  $\lambda^*$  as  $\lambda^* = \rho/S(\rho)$ . This rate is the sum of external arrivals and recycling packets, therefore the throughput of the system will be:  $\lambda = \lambda^*(1-p)$ .

Though computation can be carried out with a different buffer size at each node, we shall assume  $M_i = M, i=1, \dots, K$ .

RESULTS AND COMPARISONS

For the SW procedure, we have compared the two retransmission policies. In Figure 4, some curves have been drawn representing both the situations of node-retransmission and host-retransmission, for a 48Kbits/sec. line and five or eight buffers at each output line, for six stations in series (one host and five nodes).

It is important to notice (this is true for all the following results) that the maximum throughput is reached for an utilization of the server of the host equal to 1. Namely, a

throughput greater than this value cannot be reached without flow control. This implies that the points corresponding to higher throughput than for  $\rho=1$  are unstable points.

Thus, we see in Figure 4, that without flow control, host-retransmission leads to a better throughput than switch-retransmission. This can be easily explained—when we approach saturation ( $\rho=1$ ) the switch-retransmission policy increases the congestion whereas the host-retransmission policy prevents congestion. This is even more explicit for the HDLC node-to-node procedure (see Figure 5).

We can notice by examining Figures 4 and 5 that if a flow control policy exists and allows us to obtain a throughput near the *optimal* point (the highest point of the curve) switch-retransmission is better than host-retransmission.

Figure 4—Throughput versus the utilization rate of the host. line capacity=48 Kbits/sec. mean packet length=1 Kbit packet length distribution=exponential procedure=SW

Figure 5—Throughput versus utilization rate of the host. capacity=48 Kbits/sec. mean packet length=1 Kbit packet length distribution=exponential procedure=HDLC

Figure 6—Throughput versus the utilization rate of the host.

throughput  
packets/sec

Figure 7—Throughput versus the utilization rate of the host.  
line capacity=48 Kbits/sec.  
mean packet length=300 bits  
packet length distribution=exponential

This can also be easily explained—the optimal point is surely obtained when there are only few retransmissions but when the lines are utilized at the maximum. In this case to come back to the host is worse than to reset from the previous switch.

Since the purpose of this paper is to study and compare flow control methods, we limit ourselves to the switch-retransmission case, which is the best retransmission policy in this case.

Now we allow the packet length and the distribution of the service times to vary in Figures 6, 7 and 8. We have adopted a 48 Kbits/sec line and three or six stations in series, five, eight or 12 buffers per output line, and SW or HDLC protocols.

The degradation predicted is very clear and more important with HDLC than with the SW procedure. As long as there is no degradation (namely the probability of retransmission is negligible) three or six stations in series give the same throughput. Threshing is evidently stronger for six stations than for three stations in series.

The degradation is so much important when mean packet length is short. The degradation is less obvious with constant packet lengths. These three figures give an idea of throughput that can be obtained between two hosts of a PSN.

Rate flow control policy

The rate flow-control policy using a threshold on the number of transmissions per unit time can be studied with the previous results. This threshold corresponds to a value  $\rho^*$  of the activity of the server of the host. In Figures 8, 9 and 10 the maximum throughput is now obtained for the value of the throughput corresponding to  $\rho^*$  and the parts of the curves on the right of  $\rho^*$  cannot be reached.

It is obvious that the quality of this flow control policy depends on the choice of  $\rho^*$ . For the case studied in Figures 6, 7 and 8 it is sufficient to take for  $\rho^*$  the activity of the host corresponding to the optimal value of the throughput. However, in a general network, according to the destination of packets, the line capacities and the sizes of the pools of buffers, the optimal throughput does not correspond to the same limitation. Therefore, an efficient estimation and control system is necessary to adjust the threshold according to the state of the nodes of the PSN. This control leads to high throughput, but the risk of a strong degradation of performance exists as soon as the system is badly controlled. In Cyclades such a flow control is used and the rate defining the threshold varies according to the load of the lines of the system.

In Figures 9 and 10 both the two other flow controls are examined using the solution of the second part of the Ap-

Throughput (packets/sec)

Figure 8—Throughput versus the utilization rate of the host.  
line capacity=48 Kbits/sec.

Figure 9—Throughput versus the utilization of the host for a number of credits  $N$ —six stations in series and five buffers per station. line capacity=48 Kbits/sec. mean packet length=1 Kbit procedure=SW packet length distribution=exponential

Figure 10—Throughput versus utilization of the host, for a number of credits  $N$ —six stations in series and five buffers per station. line capacity=48 Kbits/sec. mean packet length=1 Kbit procedure=HDLC packet length distribution=exponential

pendix to solve the unified mathematical model. We look at the case of 48 Kbits/sec line, six stations in series and five buffers per output line of nodes. Figure 9 corresponds to the SW node-to-node protocol and Figure 10 to HDLC.  $N$  is the number of credits. If  $N=5$ , we obtain the XFC. For example we have a superposition of five virtual circuits between the two hosts with a window width equal to 1. If  $N=25$ , we find again the case without flow control or with RFC if a  $\rho^*$  is given. Now if  $5 < N < 25$  we obtain a WFC. We assume that the queue  $R$  of the mathematical model does not exist.

The advantage of the XFC is that no thrashing phenomenon exists. Above a certain value of the activity of the host, the throughput is practically constant. However, this constant value is far from the maximum value. This assurance is counterbalanced by a low throughput.

The best value for the window width (if it is to be fixed) seems to be  $\bar{N} = (\sum_{i=1}^K M_i + \inf_i(M_i))/2$ . In Figures 9 and 10 this value corresponds to  $N=15$ . In this case the maximum throughput (obtained for  $\rho=1$ ) is intermediate between maximum throughput of RFC and XFC. Performance does not seem to be very sensitive to this parameter setting. Besides, means to regulate the value of the window width are easier than those used to throttle the rate for the RFC policy.

The view of Figures 9 and 10 gives an idea of an efficient dynamical WFC—the use of the upper envelope of the curves. For example on Figure 9, as soon as  $\rho < 0.8$ ,  $N=25$ ;

if  $0.8 < \rho < 0.9$ ,  $N=20$ ; if  $\rho > 0.9$ ,  $N=15$ . When a threshold is exceeded no admittance is allowed until the number of packets in the PSN is above the associated window width.

As a conclusion of this comparison of flow control policies, we have written on the side of Figure 10 the throughput that can be reached by each of the three techniques described previously. We see that the zone corresponding to the RFC goes from the highest to the lowest point. WFC is intermediate. A very precise throughput is associated with XFC.

It has to be noted that the more we want to get high performance, the more the control of parameters must be sophisticated, otherwise the throughput will be very low.

### CONCLUSIONS

First, we have shown that a flow control is necessary in PSNs. Without flow control schemes a thrashing phenomenon occurs when the traffic rate reaches a value close to 1. Several flow-control policies have been modeled and comparisons of the results can be interpreted as follows. The XFC technique allows one to obtain a certain throughput which does not decrease with increasing input traffic even when the system is saturated. We are sure that whatever the traffic conditions, a certain amount of service will always

be rendered. However, the maximum throughput is very low in relation with the throughput obtained by other flow-control policies.

The RFC (rate flow control) policy gives efficient results when it is easy to find accurate rate limitation corresponding to the optimal throughput. If the network is well balanced or very simple, such as a tandem queueing system, the value of the limitation can be obtained. But in a complex network, this rate limitation will have to change with the state of the network. A system of control packets must be created for the host to know the state of the system. The RFC policy will allow us to obtain large throughput; but a necessary condition is the need to have a sophisticated control system. Thrashing can appear here with bad management.

The WFC policy can be considered as an intermediate method. The maximum throughput is not as high as in the previous scheme, but there is no thrashing in saturation conditions. Moreover, the simplicity of this scheme can be a good reason for its implementation.

Finally, the question that can be raised is the accuracy of the previous results. Some validations by simulations of the unified mathematical model results have been done and are available in Reference 9. It is shown that even when the model parameters are somewhat different, the form of the curves is identical and the conclusions of the comparisons are similar.

A more widely available validation can be found in Reference 10 where the predictions of a mathematical model (with the parameters used here) are compared to the results of a measurement campaign on the Cyclades network. The model being a queueing system in tandem, the very good accuracy of the mathematical model prediction is established.

## APPENDIX

### *Computation of the throughput as a function of the activity of the host*

#### The model without station C and R

We recall the assumptions we have taken:

- The independence assumption
- The distributions of service times of all the stations are identical
- A customer leaving a queue sees the system at steady state.

Let  $\mu^{-1}$  and  $K_s$  be the mean and the squared coefficients of variation (SCV) of the service time distribution of each server. We show in Figure A1 the model that we want to study (we have only depicted stations  $n$  and  $n+1$ ). We denote by  $\lambda_n$ ,  $K_{a_n}$  the rate and the SCV of interarrival distribution respectively to station  $n$ , (before rejection which occurs with probability  $p_n$ ).

#### *Analysis of the switch retransmission model*

We will replace each station (for example station  $n$ ) with its retransmission loop, by a simple queue with service time which represents the total time of the first retransmission and all retransmissions of the same packet. Let  $\hat{\mu}_n$  and  $\hat{K}_{s_n}$  determine the distribution of the equivalent service time. Using a convolution product we obtain:

$$\begin{aligned}\hat{\mu}_n &= \mu_n(1-p_{n+}) \\ \hat{K}_{s_n} &= p_{n+1} + K_{s_n}(1-p_{y+})\end{aligned}$$

To compute the two first moments of the interarrival flow we must include all transmissions and retransmissions from station  $n-1$ ; hence  $\lambda_n = \lambda / (1-p_n)$  and  $K_{a_n} = -1 + \rho_{n-1}^2 (K_{s_{n-1}} + 1) + (2\rho_{n-1} + 1 + K_{a_{n-1}})(1-\rho_{n-1})$  where  $\rho_n = \lambda_n / \hat{\mu}_n$ . This last expression is a particular case of the SCV of the interarrival flow in a station computed in Reference 11 from a general network.

To summarize, each station  $n$  is treated as a  $G/G/1/M_n$  system with a service time distribution determined by  $\hat{\mu}_n$  and  $\hat{K}_{s_n}$  and an arrival time distribution by  $\lambda_n$  and  $K_{a_n}$ .

The probability that a packet is refused at this station is computed through a diffusion approximation:<sup>8</sup> it is the probability at steady state that the queue is full.

$$p_n = \frac{\rho_n(1-\rho_n)}{e^{-\gamma_n(M_{n-1})-\rho_n^2}}$$

where

$$\check{\rho}_n = \lambda_n / \hat{\mu}_n$$

$$\gamma_n = 2b_n / a_n$$

$$a_n = \lambda_n K_{a_n} + \hat{\mu}_n \hat{K}_{s_n}$$

Figure A1—The tandem queueing model.

and

$$b_n = \lambda_n - \hat{\mu}_n.$$

Note that  $p_n$  depends on  $p_{n+1}$  by the intermediate of  $\hat{\mu}_n$  and  $Ks_n$ . But if we begin to solve the equations for the last station first, we have  $p_{K+1} = 0$  and so we can compute, one after another, the values of  $p_n$  for  $n=K$  to  $n=1$ .

As we have assumed that the distributions of service times of all the stations are identical, we can suppose the mean service time equal to a time unit. We have to note also that  $p_i$  is an increasing function of  $\lambda$  the normalized arrival rate (mean service time = 1) such that the value of the activity of the host determines a unique value of the external arrival rate  $\lambda$ . Therefore, for a given utilization  $\rho$  of the host, by an iterative method we can compute  $\lambda$  and  $p_i$  (for a given  $\lambda$  we get step by step  $p_n$ ,  $n=K$  to  $n=1$ , thus  $p_i$ ; the exact value of  $\lambda$  is obtained when the equality  $\rho = \lambda / (1 - p_1)$  holds). Now the value of  $S(\rho)$  is derived as:

$$S_{sr}^{SW}(\rho) = (CaL + Cb + \frac{CaL}{2} \rho)(1 - p_1) + Tp_1$$

$$S_{nr}^{HDLC}(\rho) = CaL(1 - p_1) + Tp_1$$

following the retransmission policy.

Therefore, the total arrival rate is  $\lambda^* = \rho / S(\rho)$ . As this rate is the sum of external arrivals and recycling packets, the throughput of the system is

$$\lambda = \lambda^*(1 - p).$$

*Analysis of the host-retransmission scheme*

The arrival rate at station  $n+1$  is  $\lambda_{n+1} = \lambda_n(1 - p_n)$  for  $n=1$  to  $K-1$ ; if we conveniently denote by  $\lambda_{K+1}$  the departure rate from the last station,  $K$ , then the preceding equation is also valid for  $n=K$ .

As we use the host-retransmission only with exponentially distributed service times, we develop the solution only in this particular case. An extension to general service times can be done through a diffusion approximation.

The probability of refusal is obtained through the classical  $M/M/1/M_n$  queue:

$$p_n = \rho_n^{M_n} \frac{1 - \rho_n}{1 - \rho_n^{M_n+1}} \text{ where } \rho_n = \lambda_n / \mu_n$$

We also know that the departure rate from the last station is equal to the external arrival rate into the network, i.e.  $\lambda_{K+1} = \lambda$ . Thus, beginning with the last station, we can compute  $(\lambda_n, p_n)$ , for  $n=K$  to  $n=1$ . The host is a  $M/M/1$  system with service time  $S(\rho)$  and arrival rate  $\lambda^* = \lambda + \sum_{i=1}^K p_i \lambda_i$ .

The service time  $S(\rho)$  depends on the node-to-node protocol:

$$S_{nr}^{SW}(\rho) = CaL + Cb + \frac{CaL}{2}$$

$$S_{nr}^{HDLC}(\rho) = CaL$$

Therefore, for a given utilization rate of the host we obtain the total arrival rate  $\lambda^* = \rho / S(\rho)$ , and the throughput of the system is obtained by an algorithmic method determining  $\lambda$  when the following equality holds:

$$\lambda = \lambda^* - \sum_{i=1}^K p_i \lambda_i.$$

The solution is unique because the  $p_i$ 's are increasing with  $\lambda$ .

**The model with stations R and C**

The model has been shown in Figure 3. We are interested only by the switch-retransmission policy.

Figure A2—The equivalent unified model.

The solution we propose is to use an equivalent station. The closed network representing the model of the PSN itself can be replaced by a single queue with a state dependent rate  $\nu(j)$ ,  $j=1, \dots, N$  ( $N$  is the total number of credits, namely the total number of packets in the PSN plus the free credits). We have to study a closed queueing network with finite buffer size. As no analytical method is available to study such a queueing system, we adopt a simulation just to compute the utilization  $A_K^j$  of the server  $K$ , when there are  $j$  customers in the closed network. We have assumed in this simulation that the service time of the credit queue equals the host service time. The equivalent service rate is obtained as  $\nu(j)=A_K^j$ , assuming the mean service time of each station is a time unit.

The equivalent system is shown in Figure A2.

The rejection probability  $p$  for a customer is always taken as the probability the second queue is full, so:

$$p = \frac{\frac{\rho}{\nu(1)\nu(2)\dots\nu(N)}}{1 + \frac{\rho}{\nu(1)} + \dots + \frac{\rho^N}{\nu(1)\dots\nu(N)}}$$

where  $\rho$  is the utilization of the host.

Now the service time  $S(\rho)$  can be computed and is equal to either  $S_{sr}^{sw}$  or  $S_{sr}^{HDCI}$  following the node-to-node protocol.

The total arrival rate is  $\lambda^* = \rho/S(\rho)$ , and the throughput of the system is

$$\lambda = \lambda^*(1-p).$$

# Alternatives for providing highly reliable access to X.25 networks\*

## INTRODUCTION

Public and private packet-switching networks (PSNs) are being developed or planned throughout the world—for example in Canada (DATAPAC), the U.S. (TELENET), France (TRANSPAC), the U.K. (EPSS), Japan (DDX), Spain, Netherlands and others.<sup>7</sup> Such an explosive development of data communications services is one of the means for attaining the near-perfect availability required from future distributed information processing systems.<sup>9</sup> The reasons for this requirement are the increasing size, complexity and geographic dispersion of information processing systems, and the increasing real-time dependence of users on these critical, distributed systems for the timely and effective operation of their businesses.

As a result, there is a sustained incentive towards improving the reliability and availability of PSNs<sup>11</sup> on the one hand and of information processing systems on the other. Both improvements use similar techniques, namely components of high reliability and redundancy of components. However, the reliability of the *access path* between the information system and the PSN is in some cases the weakest link in the overall reliability of distributed teleprocessing systems.<sup>10</sup> Using the same reliability techniques for the access path (namely redundant, reliable physical circuit *configurations*) is not sufficient as the access path connects two dissimilar logical entities, and the *implementation* of the access protocol governing their inter-communication has to be considered.

This paper is concerned with the reliability of access from synchronous packet-mode Data Terminal Equipments (DTEs) through multiple physical circuits to X.25 packet-switching networks offering virtual circuit services. The techniques discussed in this paper are also generally appli-

cable to the reliable interconnection of X.25 networks via X.75. The reliability of access of asynchronous non-packet terminals using multiple dedicated physical circuits has not been identified as being cost-effective and can be adequately ensured by alternate dial-in facilities; it is not further discussed here.

Each subscriber DTE is connected to the PSN node by a local access circuit or local loop (LL) (see Figure 1). The local loop is typically configured through a number of telephone central offices and is constrained to existing inter-office facilities. User data and control information are exchanged across the interface between the DTE and the DCE (Data Circuit-Terminating Equipment, or the network side) according to the formats and procedures of the X.25 network access protocol, standardized by the International Telephone and Telegraph Consultative Committee (CCITT).<sup>14</sup> The X.25 network interface has been specified as a hierarchical set of three separate functional protocol layers, namely a Level 1 (or the physical level protocol), a Level 2 (or the frame level or link access protocol, LAP), and a Level 3 (or the packet level protocol). It should be noted that X.25 is purely a local interface to the virtual circuit service provided by the network.<sup>13</sup> A virtual circuit service is characterized by the establishment of a logical path and network association between two end-user DTEs for the purpose of exchanging data in the form of a network-maintained sequenced flow of packets. For the purpose of this discussion, no particular hardware or software implementation is assumed for the DTE.

## NEED FOR MULTIPLE PHYSICAL CIRCUITS

Three common user reliability measures are Mean Time Between Failures (MTBF), Availability and Reliability.<sup>4</sup> The Availability parameter (A) gives the probability that at any given time the access path is ready for use, but does not predict for how long it will stay operational. The Reliability

\* This paper is based on work done by R. J. Chung while with the Computer Communications Group of the TransCanada Telephone System in partial fulfilment of the requirements for his M.Sc. (Computer Science) degree from the Université de Montréal.

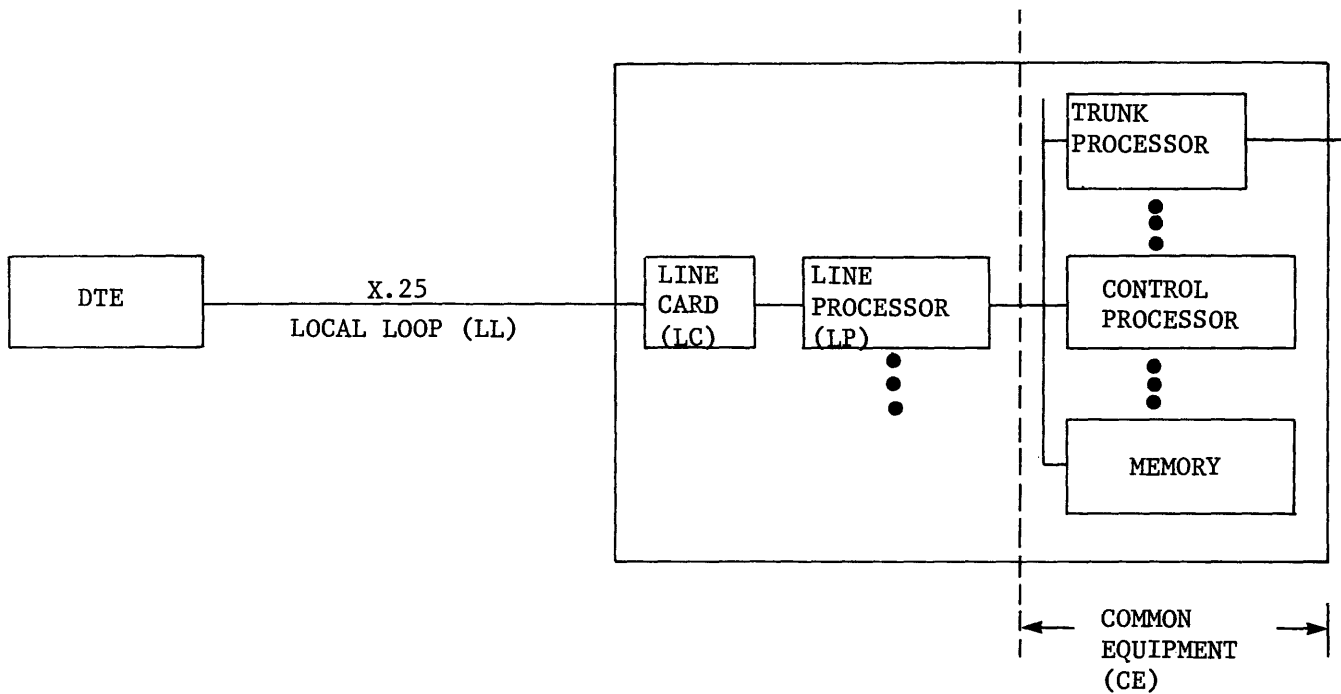

Figure 1—DTE X.25 single-circuit access to a typical packet-switching node.

parameter (R) gives the probability that the access path maintains its correct operation during a selected time period. We note that Availability applies when the access path is to be used (e.g. during X.25 call establishment phase) whereas Reliability applies while the access path is being used (e.g. during X.25 data transfer phase).

Since access circuit failures are not rare events and their probability of occurrence cannot be reduced to a negligible level, we define a third measure of reliability, namely Fault-tolerance, which may express future user concerns about the suitability of a PSN to meet their reliability requirements. The Fault-tolerance parameter gives the probability that the access path continues to provide virtual circuit services without clearing calls and without external assistance in the presence of circuit (also called line) or link failures. Access path Fault-tolerance consists of three components:

1. The probability of loss of virtual circuits during line failures. It is a function of the assignment of virtual circuits to lines, whether the allocation is fixed at subscription time, or dynamically assigned during call establishment, or dynamically switched (i.e. floating) during data transfer phase.
2. The probability of recovery of virtual circuits after line failures. This is a function of the availability of an alternative line and whether a call reconnect capability is implemented.
3. The probability of loss or duplication of data during the recovery of virtual circuits.

Thus, the Fault-tolerance of an access path can be char-

acterized by its capability to maintain or recover virtual circuits automatically, and by its robustness and adaptability against line failures. Whereas the Reliability measure ceases to apply at the first failure, Fault-tolerance recognizes that failures do occur and implies that built-in mechanisms exist in the system allowing it to continue to operate, though in degraded mode, by "tolerating" the fault. It also depends on the implementation of automatic recovery software which may be distributed in different hosts or nodes. The Fault-tolerance parameter is not discussed further here but will be reintroduced in the fifth section where the reliability of a number of implementations are compared.

For some applications, the failure of the telecommunications system during information transfer and the subsequent loss of connection is inconvenient, but acceptable if the user is allowed to reestablish his connection. Examples are time-shared computing, message and reservations systems. Hence, these users put a higher premium on Availability than on Reliability. They can live with short, infrequent disruptions of service provided alternate facilities are readily available. For other applications, the loss of connection or disruption of service during information transfer cannot be tolerated or may have catastrophic results, for example real-time systems like remote process control or pipeline control, or, less critically, bulk data transfer or remote job entry. For such users, Reliability and Fault-tolerance are significant parameters. Availability may not be as critical since the user can try to establish the connection at some other time or to some other place.

To meet user reliability requirements, the packet-switching node to which the X.25 DTE is connected is designed to perform all network functions (e.g. control, switching and

terminal support) while ensuring the highest degree of availability. It is typically a multi-processor (as in DATAPAC,<sup>3</sup> TRANSPAC,<sup>5</sup> TELENET<sup>12</sup>). The multi-processor organization of the DATAPAC SL-10 Network Processor is typical of current switch architectures designed for reliability, flexibility, reconfigurability, and expandability.<sup>3</sup> This organization is illustrated in Figure 1 and is used as the basis for this paper. It consists of at most 15 functionally different and separate processing units, interconnected by a common bus and communicating through a common memory module. Each customer circuit terminates on an individual line interface card (LC). The line processor (LP) has sufficient memory and processing power to control a number of subscriber synchronous and/or asynchronous circuits. The assembly of common memory, control processors, trunk processors and other related hardware is referred to as Common Equipment (CE).

Communication networks and some computer systems are designed with built-in redundancy, bypass switches and fully duplexed components to guarantee an availability of at least 0.998. On the other hand, the access circuit connecting the

two has an average line availability of only 0.98 in the U.S.A.<sup>10</sup> Typical analyses of leased line failures show that half the outages last for more than an hour. Consequently, multiple parallel physical circuits are used to make the reliability of the access path comparable to that of the network and computer system.

ACCESS PATH CONFIGURATIONS

The current access to PSNs through the X.25 packet-mode interface is based on a single circuit using the High-Level Data Link Control (HDLC) procedures,<sup>2</sup> standardized by the International Organization for Standardization (ISO), as the link access procedure. For greater reliability, the *access path* of a packet-mode DTE may consist of a set of circuits. These can be configured as shown in Figure 2, subject to the protocol and implementation considerations discussed in the next section.

In order to develop a quantitative comparison of the reliability of these configurations, we assume a mathematical

CONFIGURATION I: SINGLE CIRCUIT

CONFIGURATION II: TWO CIRCUIT

CONFIGURATION III: TWO-LINK, SINGLE NODE

CONFIGURATION IV: TWO-LINK, TWO NODE

Figure 2—Access path configurations.

model in which physical components fail at random and the number of failures in a given time period depends only on its duration. That is, the probability of having failures in a given time period follows a Poisson distribution, and the probability that the times between failures are a given value follows an exponential distribution. A reliability analysis must consider, in addition to the local data loop (LL), the following components of a packet switch (see Figure 1): the line interface card (LC), the line processor (LP), and the remaining common equipment (CE). A failure of LP will lose all access circuits connected to it while a failure of CE will lose the circuits of all subscribers connected to that node.

As an example of the type of simple calculations which may be useful, we apply classical multiple component reliability theory<sup>6</sup> to the model just outlined to derive the Availability, and the probability of failure-free operation during a given period, of each configuration in Figure 2. We assume all parallel components are identical and independent. The MTBF of LL has a wide variance as a result of the varying types of equipment used, e.g. analog or digital. We have therefore computed the Reliability of the different configurations over a month using a MTBF of 36, 24, 12, or 6 months respectively for the local data loop and typical MTBF figures for the other components. The results are given in Table 1.

The following conclusions can be drawn from analyzing the preceding model:

1. Two-circuits (II) increase the Reliability in a significant way (8-15 percent), especially when the local loop has the highest failure rate.
2. Two-links (III) have a 5 percent better Reliability than Two-circuits (II) independently of the local loop failure rate. This result follows from the fact that the LP has a failure rate comparable to that of LL and LC, and the multi-link only uses independent LPs. We note that connecting Two-links to independent nodes (IV) only increases the Reliability by 1 percent compared to connecting them on the same node (III).
3. The Availability of the local loop reduces the Availability of a single circuit significantly.

The quantitative approach just outlined is adequate for evaluating reliability in most cases; it cannot, however, be used for the design of data communications systems which require extreme reliability. This is because the assumption of identical and independent components, particularly for the local data loop, rarely holds for common carrier equipment.<sup>15</sup> In fact, diversified routing of the access lines is very difficult and costly to obtain. The failures of different data communications lines are highly dependent because of the inherent sharing of the same multi-pair cable for local loops to the telephone central office and of short-haul or long-haul inter-office facilities. For techniques to handle these problems in computing communications system reliability, refer to Reference 15.

## ACCESS PATH IMPLEMENTATIONS

This section outlines the different implementation alternatives possible in an X.25 network to support user access by multiple physical circuits. A DTE is said to be *multi-homed* if it is connected to multiple nodes by multiple autonomous links. A *link* is defined as a set of one or more physical circuits operating according to a single data link control procedure.

For reliability calculations, the only access path parameter of interest is the number of physical circuits available for data transfer. However, in implementing any X.25-based access path, other protocol factors must be considered, including the administration of network addresses for routing during call establishment, and of logical channels for relating packets locally to virtual circuits. Furthermore, the ordering property of the virtual circuit service must be maintained. This sequencing can be achieved by an appropriate switching function at either the physical level/frame level interface or the frame level/packet level interface of X.25. The problem can be avoided by using each physical circuit as an autonomous X.25 link. Thus, the following access path implementations (Figure 3) can be distinguished for the multiple circuit configurations shown in Figure 2:

TABLE I—Reliability Results for Access Path Configurations\*

LOCAL LOOP MTBF (months)	CONFIGURATION I			CONFIGURATION II			CONFIGURATION III			CONFIGURATION IV		
	MTBF (months)	R (month)	A (%)	MTBF (months)	R (month)	A (%)	MTBF (months)	R (month)	A (%)	MTBF (months)	R (month)	A (%)

CONFIGURATION I: SINGLE CIRCUIT LINK

CONFIGURATION II: MULTI-CIRCUIT LINK

CONFIGURATION III: FLOATING MULTI-LINK

CONFIGURATION IV: AUTONOMOUS MULTI-LINK

LAP = X25 FRAME LEVEL (LINK ACCESS PROCEDURE) MODULE

LAPM= MULTI-CIRCUIT LAP MODULE

PL = PACKET-LEVEL MODULE

⊠ = SWITCHING FUNCTION

▮ = RECONNECT FUNCTION

Figure 3—Access path implementations.

1. A multi-circuit link (frame level) implementation of Configuration II.
2. A floating multi-link (packet level) implementation of Configuration III with automatic alternate routing.
3. An autonomous multi-link (packet level) implementation of Configuration IV with an optional reconnect procedure.

Each link of a multi-link implementation (i.e. III or IV in Figure 3) may be a uni-circuit or a multi-circuit link. A major concern of the multi-link packet level is failure recovery,

namely to maintain virtual circuits after a link failure. This function is automatic in the floating multi-link but requires a reconnect procedure in the autonomous multi-link.

*Multi-circuit link implementation*

A multi-circuit link implementation (Figure 3(II)) consists of parallel physical access circuits with the same network address and logical channel set statically assigned at subscription time to all of them. These circuits are attached to

uniquely different line interface cards on the same line processor in the same node. They are administered individually via a line level protocol and operate under a single multi-circuit link protocol.

A line level protocol is required for a multi-circuit link to establish the actual configuration of the link at any time in terms of line status and characteristics. It performs the functions of connecting/opening, disconnecting/closing and supervising a physical circuit individually according to commands from a higher level. Thus, it permits circuits to be removed or added with no disruption to link operation. We note that the line level protocol does not concern itself with data integrity or sequencing. It only provides a mechanism below the X.25 frame level for switching frames onto multiple physical circuits.

The purpose of a multi-circuit link protocol is:

1. To make a set of physical circuits appear as a single full duplex data link for better reliability and efficiency (throughput, delay). Thus, the physical characteristics of the link configuration (such as number of lines, line speeds, propagation delay, transmission media) are transparent to the higher-level protocols; frames are sent on the first circuit that is operational and not busy.
2. To ensure the integrity of the exchange of packets without loss, duplication or out-of-sequence delivery.
3. To detect circuit failures and control the link configuration by a line level protocol discussed above. Circuit failures do not impact the integrity or reliability of the link but only cause a graceful degradation of efficiency.

A multi-circuit link protocol has been used in the experimental French RCP network since 1974, i.e. before the standardization of HDLC by ISO, and is planned for TRAN-SPAC.<sup>5,8</sup> A second possibility would be the use of HDLC over multiple circuits. Both these are currently called multiline procedures. We note that a third possibility, currently being studied, is the addition of a sequencing sublevel on top of a multiple circuit configuration where each circuit is operating under its own data link control procedure.

A multi-circuit link has the properties of variable delay, loss, duplication and out-of-sequence delivery of data. This is the result of the disordering phenomenon inherent in the simultaneous transmission of variable size frames on multiple physical circuits having variable line speeds, propagation delays, and multiplexing delays. Therefore, the main problem is how to maintain a sequenced data flow and its relationship to control, supervisory or out-of-band signals on each virtual circuit<sup>13</sup> multiplexed over the physical circuits. A solution is to use a sequence-preserving link level.

Possible extensions and amendments necessary to the X.25 LAP or HDLC elements of procedure<sup>2</sup> to accommodate multiple physical circuits are outlined below:

1. I-frames (information frames carrying packets) received out-of-sequence should not automatically initiate REJ recovery. Instead, the receiver should buffer out-of-sequence frames and define a new secondary

timer TS (see Figure 4(A)), started on the reception of the first out-of-sequence I-frame. REJ recovery is initiated only at the expiry of TS.

2. The use of the REJ frame is inefficient (Figure 4(B)). A selective retransmission optional facility through a SREJ frame to request retransmission of a single I-frame is more efficient since the secondary has already buffered out-of-sequence frames.
3. To recover from lost I-frames, the primary retransmits its last unacknowledged I-frame after the expiry of primary T1 timer. The most conservative T1 value is twice the transmission time of the longest I-frame on the slowest line plus the transmission time of the longest I-frame on the fastest line. Such a long T1 value would ensure a high throughput but increases the delay in recovering from lost frames. However, this delay is minimized by the use of TS and SREJ at the secondary.
4. When the secondary receives a P-bit set to 1 from the primary (after T1 timeout), it should withhold sending an F-bit set to 1 until its own TS timer expires. Otherwise, after accepting the retransmitted I-frame with P-bit set, the original I-frame may arrive in the next numbering cycle and become an undetected duplicate.
5. The receipt of an invalid NR field should not initiate the resetting procedure because it may be in a late frame.
6. A window size less than the modulus of the sequence numbers minus one may be necessary to avoid ambiguity as to the meaning of NR received from different numbering cycles.
7. An extended numbering system using a modulus of 128 is desirable to ensure high link throughput.
8. To preserve link integrity, when a SARM (or UA) is to be transmitted all I-frames (or supervisory frames) in the process of being transmitted must be aborted. The SARM (or UA) should be transmitted only after the propagation delay of the last transmitted, still unacknowledged I-frame (or supervisory frame). Otherwise, this may cause undetected loss and duplication of frames (Figure 4(C)).

Finally, the following DTE implementation considerations must also be taken into account:

1. It is required that the multi-circuit link protocol be compatible with ISO HDLC procedures and X.25 LAP and LAPB.
2. The investment made by the customer in his development of the X.25 link control software must be protected by minimizing and localizing the impact of software changes.

#### *Floating multi-link implementation*

A floating multi-link implementation (Figure 3(III)) consists of parallel links attached to different line processors on a node. At subscription time, all the links are assigned the same set of network addresses and logical channels. How-

Figure 4—Some problems of multi-circuit HDLC.

ever, the implementation may dynamically switch the logical channels between the links in a disciplined manner. This depends on considerations of virtual circuit integrity, link availability and load balancing. Each link is independent and may use a different data link control procedure.

Logical channels are not statically fixed to links but float over all the links. To transmit a packet, it is queued to the link module on which there is an unacknowledged I-frame containing an outstanding packet for the same logical channel; if no such link exists, then any link can be used. This simple technique maintains virtual circuit integrity, while avoiding packet level resequencing, by using the sequencing property of data link control procedures such as HDLC.

A switching function is required between the packet level module and the various link level modules. Typically, it maintains a table giving the number of outstanding packets for each particular logical channel and the associated link module. This table is incremented when a packet is queued and decremented when an I-frame is acknowledged at the link level. When a link fails, all its unacknowledged I-frames are switched to another link module for initial transmission or retransmission, in the latter case creating duplicate packets.

Thus, after a link failure, the floating multi-link provides automatic alternate routing of virtual circuits but relies on the X.25 error procedures for handling duplicate packets. The maximum number of logical channels which may have to handle duplicate packets is equal to the window size (K) at the link level. There is no packet loss or requirement for extra resynchronization signals and procedures at the packet level.

However, the effects of duplicate packets in X.25 need further study. For example, they can give rise to conflicting situations in which the DTE and the DCE do not agree as to the state of the interface for a particular logical channel.<sup>1</sup> The possibility of deadlock due to out-of-the-blue duplicate packets (when the DTE/DCE interface is in an ambiguous state) is to be considered. These problems do not arise if extensions to HDLC or higher-level protocol procedures (e.g. using logical channel zero) would make it possible to exchange the HDLC receive state variable, VR, values between the DTE and the DCE. An alternative approach is for the transmitter to number every I-frame, independently of the link, to enable the receiver to eliminate duplicates. This would introduce an overhead on every packet compared to an overhead only incurred during recovery in the former approach.

The floating multi-link introduces an additional interaction between the packet level and link level (i.e. the implementation has to keep track of the mapping of packets to links).

#### *Autonomous multi-link reconnect procedure implementation*

An autonomous multi-link implementation (Figure 3(IV)) consists of several autonomous X.25 modules. At subscription time, each X.25 link is assigned its own node, and set of addresses and logical channels.

A link failure in an autonomous multi-link implementation loses its associated virtual circuits. The simplest recovery is by the user establishing new virtual circuits on an alternate link to maintain his end-to-end connections. A potential alternative is a network-provided DTE-to-DTE reconnect procedure proposed to improve the fault-tolerance of an autonomous multi-link by implementing an alternate routing capability over the multiply-connected access path.<sup>16</sup> It refers to the capability to reconnect one end of a virtual circuit on an alternate link on any node. It then resynchronizes both ends of the access path and of the virtual circuit to recover from a link failure.

We note that a reconnect capability only protects against the loss of a virtual circuit (VC) when its associated link fails; it does not guarantee against packet loss or duplication. The recovery process is left to the user as it is a function of the reliability requirements of his application. Hence, PSN administrations may offer the reconnect capability as an optional user facility aimed at increasing the VC-recoverability against access link and node failures.

Virtual circuit reconnection can be accomplished by using a reset or a call packet with a facility field containing a parameter specifying it as a reconnection packet and another parameter identifying the virtual circuit to be reconnected. To identify a virtual circuit, it is sufficient for the ends to exchange their unique identification of the connection, namely a numeric connection identification (CID), when the call is created. Such a CID could consist of the (network address, logical channel identifier) pair which is the network-wide naming space at the DTE/DCE interface for identifying one end of a VC. Thus, Call Request and Call Accepted packets may contain a CID parameter field for the DTE to identify the local end of the virtual circuit. Call Connected, Incoming Call and Reset Indication packets may contain a CID parameter field for the DCE to identify the remote end of the virtual circuit. The CID field of a Call or Reset Request "reconnection" packet will contain a CID for the remote end, and optionally another CID for the DTE to identify the new local end to which the remote end is reconnected. We note that this requires extension of the Call Accepted and Call Connected packet formats of X.25. The simplification of the procedure to use a single CID for both ends of the VC is a subject for further study.

An example of the call "reconnection" procedure in a national call is shown in Figure 5. DTE 1 is connected to the network by link A whilst DTE 2 is connected by autonomous links C and D. A virtual circuit is established through links A and C originally. When DTE 2 detects link C is down, it selects a free logical channel on link D and reestablishes the call by sending a Call Request packet with reconnection facility (REC). When the node servicing link A receives this packet, it checks the facility field. As it refers to the reconnection of a previously established call, the node does not generate an Incoming Call but resets its end of the virtual circuit instead. On completion of the reset, the node will initiate an abort of the process originally serving the remote end (old logical channel). It also returns a confirmation that reconnection is completed to the new process (new logical channel) at the remote end. If the net-

Figure 5—Illustrations of possible reconnect procedures.

work detects that link C is down and knows that there is an alternate link D, it may automatically reconnect as shown in Figure 5(D) on link D.

The reconnect capability may be useful in the following application areas:

1. Whenever fast re-establishment of calls is required. This is essential for real-time traffic or for commercial real-time systems, e.g. digitized voice, airline reservations.
2. Whenever the context of the communication of the end users is to be kept. One example is in facilitating access control to data base systems.
3. Whenever a specified quality of service (e.g. probability that a virtual circuit is not disconnected) is to be maintained. This is particularly relevant to permanent virtual circuits.

#### *Software and addressing considerations*

Having outlined the implementation alternatives, it is important to note that the node software organization and the internal operation of a PSN may impose constraints on the implementation of user access paths. In particular, multi-homing can be easily achieved only by the autonomous multi-link implementation since the other implementations need to coordinate the transfer of packets on the various physical circuits and links, and are restricted to a single node.

Typically, the node control software of a PSN may be designed as a set of high-level subsystems consisting of hierarchically cooperating, functionally separate, and modularly decomposed components. The distribution of the software components to the various physical processing units (i.e. LC, LP, CE) determines the circuit configurations which may be implemented. The line processor (LP) performs at least all link control functions, and its reliability would restrict the reliability of a multi-circuit link.

A floating multi-link implies that packets for the virtual circuits are dynamically switched between links. If both the link and packet levels of X.25 are implemented in the LP, then a floating multi-link must have all its links connected to the same line processor and can be considered as an alternative for a multi-circuit link. However, if only the link level is implemented in the LP, then the links can be connected to different line processors and use the common memory for communication and coordination. Such a software organization permits a floating multi-link with a still better reliability.

An autonomous multi-link may not be constrained by node software structure. If the links are controlled by different LPs, the coordination and resynchronization (i.e. the reconnect procedure) may be accomplished by the common equipment. However, for a multi-homed DTE, the addressing of access points on the network may impose constraints on the implementation.

A network address is a unique identification for an access

point in the network, and is used for routing calls during call establishment and for administrative purposes such as accounting, error reporting and directory listing. A multi-homed DTE is supported by assigning to it an autonomous multi-link with different addresses for the links. The subscriber usually prefers one or more addresses for his DTE independently of the number of links connecting it to the network. The subscriber may request an autonomous multi-link configuration in which the logical channel identifiers (other than zero) are partitioned over all the links for identifying individual conversations uniquely. To the subscriber, a multi-homed DTE with a single address set is a useful reliable configuration. Because of network routing, tariff and accounting problems, the PSN administration may find it difficult to offer such a single address, multi-homed configuration.

In conclusion, each PSN administration will determine which access path implementations to offer depending on the software constraints of the particular switch architecture (i.e. single, dual, multi-processor) used in the network, and constraints due to the subnetwork system design (i.e. addressing, routing, . . .).

## COMPARISON OF ALTERNATIVES

This section contains a comparison of the access path configurations and implementations, described in previous sections, in terms of user reliability parameters, protocol features and implementation requirements. The three alternatives identified in this paper are: 1) multi-circuit link, 2) floating multi-link, and 3) autonomous multi-link reconnect procedure.

#### *Reliability considerations*

The Reliability and Availability of the access path implementations have already been quantitatively compared by referring to their associated configurations. However, we note that the Reliability of any associated virtual circuit depends on the characteristics of the protocol implemented on the configuration in a similar manner as does the Fault-tolerance.

The multi-circuit link implementation has the best Fault-tolerance because its protocol is defined to consider the different physical circuits as a single transmission facility such that the failure of any one physical circuit does not affect any virtual circuit. Virtual circuits are aborted only when all the physical circuits fail. The floating multi-link implementation has comparable Fault-tolerance in that it does not lose virtual circuits after a physical circuit or link failure. However, it requires a local recovery procedure which guarantees the integrity of the information transfer after a link failure.

On the other hand, a link failure in an autonomous multi-link implementation will lose the virtual circuits associated to it. These virtual circuits can be recovered by re-estab-

lishing them on an alternate link. Hence, the autonomous multi-link implementation has an acceptable Fault-tolerance only if the end-to-end reconnect procedure is implemented to resynchronize the virtual circuits in the event of a link failure.

For the highest reliability achievable by multi-homing, the PSN administration may find it advantageous to offer an autonomous multi-link with multiple address sets. It should be stressed that a multi-link, implemented on independent line processors of a single node, with a single address set has slightly worse Reliability than a multi-homed multi-link. Furthermore, the Availability of the single node multi-link is better than that of the network. Thus, multi-homing does not bring any significant gain in overall reliability since the node is usually a multi-processor system. The high correlation between the failures of the different communication lines, connected to the same DTE, and the wide variability of their failure rates (3-4 orders of magnitude are common) would reduce the reliability gain still further. A more reliable and available access to an X.25 network may be better achieved by ensuring that the lines are really diversely routed, and as identical as possible, than by multi-homing.

#### *Protocol and implementation considerations*

To maintain compatibility with ISO, a multi-circuit HDLC protocol may be a desirable alternative for an X.25 interface. Major points left for further study in a multi-circuit HDLC protocol are semantics of SREJ, duration of time-out values and performance considerations.

Two areas to be considered to make the floating multi-link a viable proposal are:

1. Link failure recovery procedures which avoid duplicate packets.
2. Specification of the interaction between the frame and packet levels.

The multi-circuit link and floating multi-link have the advantage of having only local implications, e.g. multi-circuit requires the implementation of a new frame level protocol in both the DTE and the node. On the other hand, multi-link reconnect implies an end-to-end protocol affecting Level 3 of the DTE/DCE interface. This necessitates some implementation changes in the DTE and complex internal resynchronization mechanisms in the network. All these alternatives require the development of appropriate standards.

Multi-homing can be achieved by an autonomous multi-link configuration. Hence, the autonomous multi-link has potentially better flexibility than the multi-circuit or floating multi-link, but it is more attractive only with the provision of a reconnect capability. It is simpler to implement reconnect for recovery from a link or a line processor failure than from a node failure. The implementation of reconnect by a PSN is constrained by its routing scheme and its assignment of network addresses to the multi-link.

## CONCLUSIONS

Users have different reliability requirements depending on their applications. A fault-tolerant data communications service is becoming more economically feasible because of the availability of cheap, reliable hardware components and new programming techniques to master software complexity. There are different multiple circuit configurations to meet these reliability requirements for the access paths between the DTE and the PSN. The implementation of these configurations must take into account existing constraints in both the DTE and the PSN. It is recommended that PSN administrations offer some form of multiple circuit access for DTEs which hides the network operational constraints from the users, e.g. hunt groups or preferably a multi-circuit link. The definition of a multi-circuit capability within HDLC by ISO and CCITT is urgently required. Finally, packet level procedures providing higher virtual circuit reliability should be studied within CCITT.

## ACKNOWLEDGMENTS

R. J. Chung would like to express gratitude to his supervisor at Université de Montréal, Professor Gregor V. Bochmann, for having introduced him to teleprocessing and protocols, and his useful comments on this paper. Also, Professor J. Gecsei was especially helpful with useful advice on the original report. Furthermore, he would like to thank his former colleagues at Computer Communications Group and Bell Northern Research for having provided such a stimulating work environment.

## INTRODUCTION

We are concerned here with the design of an interconnection network for communication between terminals and computers in local distributed computer systems. By a local system, we mean one in which computers and terminals are concentrated in a relatively small area (e.g., with distance between terminals  $< 100$  Km) and interconnected by communication links with relatively large bandwidth (e.g., up to 10 Mb/sec.). By a distributed network, we mean one in which the control of communication network is distributed among the computers and terminals. For our discussions, there is no need to distinguish terminals from computers. Hereafter, we shall refer to them simply as stations.

In recent years, several local networks have been designed and implemented. Among the better known ones are DCS (Distributed Computer System), Mitrix, Spider and Ethernet.<sup>1-4</sup> These networks, designed for different objectives (e.g., different intended applications), illustrate the different approaches taken to provide fast and reliable communication. For example, in both DCS and Ethernet, reliable communication is achieved through the distribution of network access control to the stations in the network. In Ethernet, all stations are interconnected via a passive medium (a high bandwidth low loss bus called Ether.) Broadcast packet switching discipline is used. The DCS is a ring network. A message from a source station addressed to a process residing in another station is placed on the ring and is transmitted in one direction to all stations connected to the ring. A station copies a message only if its interface finds that the destination process name contained in the message matches the name of a process residing in the station. The message is allowed to travel along the ring back to the source station and, there, is removed from the

ring. Spider is a ring network containing several rings. A central switch is used to route packets destined for stations not in the same ring with the source stations. Similar to Spider, Mitrix is also a centralized network in which switching and bandwidth allocation functions are performed by centralized computers.

We consider here a fault tolerant communication network in which multiple-link and subnetwork failures may occur due to natural or intentional damages. Application of fault tolerant networks can be found in shipboard communication systems, and in traffic control and navigation systems where the growing use of digital sensors and computers requires large local fail-safe communication systems. Other application examples include networks linking process control microprocessors, data acquisition terminals, central computers and other facilities in large manufacturing plants, and networks connecting intelligent terminals serving individual users for the purposes of text editing, managing personal data bases, providing controlled access to shared data bases, exchanging messages, etc. In these examples, an interconnection network must provide continuous communication linkage between stations.

Assumptions on the overall local distributed network and our design objectives are summarized in the next section. In the third section, a routing algorithm, which guarantees finding a route from any source and destination pair as long as routes between them exist, is described. A network access protocol is described in the fourth section. The relatively small round-trip propagation delays and wide bandwidth of the links are used in the design of this protocol.

## GENERAL ASSUMPTIONS AND DESIGN OBJECTIVES

In the interconnection network considered here, the communication links are full duplex lines with bandwidths

\* This work was partially supported by Office of Naval Research No. N00014-75-C-0982.

identical to or larger than that required by any communication station. Connecting to the intersections of two or more communication links are switch nodes. The switch nodes resemble outlets in power supply lines. Any station with the appropriate interface may be plugged into any of the switch nodes. Some of the switch nodes, therefore, are not connected to any station. Without a station attached to it, a switch node serves simply as a routing device.

To assure that the stations remain connected with high probability, redundant connections are provided. We consider here the special case when the interconnection network forms a homogeneous array. Examples of such networks are shown in Figure 1. The design of network topology for a given survivability criteria is a well known problem and will not be addressed here. We note that when successful communication between all pairs of communication stations are equally important and switch nodes and links are identical, homogeneous networks are maximally reliable<sup>5</sup> (both in terms of being maximally connected networks and having maximal survivability.) Simulation studies<sup>6</sup> of large arrays show that in terms of the survivability (average fraction of stations which remain connected after damage occurred), a network in which each switch node is

connected to four or more of its nearest neighbors is almost optimal when all routes can be used.

The communication links, switch nodes and stations may fail independently and at random. Moreover, multiply links and switch nodes may fail together due to natural and intentional damages. Changes in the network topology may also be caused by additions to and modifications of the network. However, links in a local network, not being exposed to conditions which affect long distance cables or radio links, are less susceptible to intermittent failures. Hence, we assume here that changes in network topology occur relatively infrequently. In particular, it can be considered as fixed during the routing of a particular message.

It is our objective to design a message routing algorithm so that the delivery of message from a source station to a destination station is guaranteed as long as there exist some paths from the source to the destination. If no such path exists, this fact is detected sooner or later. Because of the relative shortness and wide bandwidth of the communication links, it is not essential that messages be delivered via the shortest routes. We assume that each switch node is aware of the status of the links connecting to it and the status of the adjacent switch nodes. Only such local information on the condition of the network is used by the routing algorithm.

As in the case of store-and-forward networks, a message being transmitted is error-checked by each of the switch nodes enroute. However, to minimize the complexity of the switch nodes, the messages themselves are not stored by the switch nodes. The requirement on the processing capability of these switch nodes is further reduced by carrying out the tasks such as buffering for flow control, message error control, duplication detection, etc., in the network interface inside the stations. (The description of this interface is in the fourth section.)

### ROUTING ALGORITHM IN A HOMOGENEOUS NETWORK

The routing algorithm designed here guarantees the delivery of messages between any pair of stations as long as there exist some paths between them. For the sake of concreteness, we confine our discussions to the case of the endless matrix network shown in Figure 1a. Generalization to other similar homogeneous network topologies is discussed in Reference 7.

#### Basic concepts

A natural set of addresses for the switch nodes in the endless matrix is the set of ordered pairs  $(i,j)$ ,  $i=0, 1, \dots, m-1$  and  $j=0, 1, \dots, n-1$ . Because of the relative shortness of communication links between switch nodes, propagation delay severed by a message can be reasonably measured by the number of switch nodes along the route between its source and destination. The number of switch nodes along a route connecting two nodes is referred to as the distance

Figure 1—Examples of almost homogeneous arrays.

between the two nodes. For an  $m$  by  $n$  network, modulo  $m$  arithmetic for the  $x$  direction and modulo  $n$  arithmetic for the  $y$  direction allow the calculation of distances between switch nodes.

When every switch node and link is operational, a routing algorithm that finds the shortest path can be obtained easily. For example, the shortest route from the switch node  $(i, j)$  to the node  $(i_d, j_d)$  shown in Figure 2 can be found by calculating the distances from row  $j$  to row  $j_d$  along column  $i$  in both directions:  $|j_d - j|$  or  $n - |j - j_d|$  and selecting to send the message in the shorter direction along column  $i$  to node  $(i, j_d)$ . From node  $(i, j_d)$ , the message is forwarded to column  $i_d$  along  $j_d$  in the shorter one of the two directions. We referred to this simple shortest route algorithm as Algorithm P.

However, Algorithm P does not work when some switch nodes and links are down. If there is a switch node or link along the route chosen by Algorithm P fails, a detour around it must be found. To carry out this simple statement for all possible patterns of multiple link and node failures is not as simple as it first seems since switch nodes have only local information. Examples in Figure 3 illustrate some of the difficulties. The bold lines show schematically the links and/or switch nodes that are down, thus forming a "wall." Suppose that the wall forms a trap as shown in Figure 3a. Moreover, suppose that the entrance to the trap is only one row wide. According to Algorithm P, a message from  $S$  to  $D$  is sent from  $S$  to  $A$  and onward to the right. Clearly, the destination  $D$  cannot be reached in this way. As a matter of fact, in order to reach  $D$ , the message must be sent out of the trap, again through  $A$ . That is, the switch node  $A$  must relay the message to its right neighbor the first time but to its left neighbor the second time. Note that in both cases, the local information about the condition of the network for node  $A$  is the same. This fact implies that some

Figure 2—Illustration for the shortest route.

(a)

(b)

(c)

Figure 3—Examples of traps formed by failed lines and nodes.

information in addition to the conditions of its neighboring nodes and links is necessary.

Let us consider also the configuration in Figure 3b. Suppose that a message is sent along the shortest route from  $S$  to  $D$ . When the wall is reached, we may attempt to search for an opening in the wall to reach column  $i_d$ . The search is obviously fruitless since the wall forms a closed loop. (Hereafter, this type of loop is referred to as a type I loop.) However, column  $i_d$  can be reached via the alternate route shown in the figure. On the other hand, the wall may form a loop (referred to as a Type II loop) as shown in Figure 3c. In this case, since there is no way to reach the destination  $D$ , this fact must somehow be detected.

**Wall-touching principle**

To get around the walls, we may use a version of the wall-touching procedure commonly used to find a way out of a maze. That is, one traverses along the wall always keeping the wall to the right (or left). Unless the wall forms a loop, a more desirable position will eventually be reached.

In order to detect the existence of a loop, we need to check if a switch node of reference (say  $A$ ) has been reached more than once. (Selection of the node of reference will be discussed later.) However, checking the position of the switch node reached is not sufficient as illustrated by the example in Figure 4. In this case, the switch node  $A$  is reached twice although the wall does not form a loop. However, it is clear from this example that a loop can be unmistakably detected if we also check the direction in which the message is sent from the switch node  $A$  each

destination that can be reached in each case. ("Left" means the cell to the left of the current position. "Up" means the cell on top of the current cell, etc.).

**Routing algorithm**

The routing algorithm is repeatedly carried out by the switch node enroute until the destination node is reached or the fact that there is no path connecting the source and the destination is ascertained. The routing algorithm is based on the minimal distance algorithm, to be described.

**Minimal distance algorithm**

When no loops are encountered, distance between the current node to destination node is calculated as in Algo-

rithm P. When a Type I loop is encountered, the distance between nodes  $[p,q](i,j)$  and  $[p',q'](i',j')$  in two different cells is given by  $d=(p'-p)m+(i'-i)|+(q'-q)n+(j'-j)|$ .

Let  $d_{cl}^{**}$  denote the shortest distance to the destination from all switch nodes already reached so far. The node  $j$  whose distance to the destination is equal to  $d_{cl}$  is referred to as the closest node. It serves as the reference in detection of loops.

*Minimal Distance Algorithm*

1. Calculate the distance from the current node to the destination,  $d_c$ , and compare with the current value of  $d_{cl}$ .
2. If  $d_c \leq d_{cl}$ , move to the neighboring node that is on the shortest route to the destination determined so far, if possible. Update the record for  $d_{cl}$  and the address of the closest node.

\*\* When there is more than one node with distance to destination equal to  $d_{cl}$ , the closest node is one reached last during routing.

TABLE I—Reachable Virtual Destination

p	q	Basic pattern	Direction for message delivery
0	0		no way
1	0		up
-1	0		down
0	1		left
0	-1		right
$ p = q $			
1	1		left or up
1	-1		up or right
-1	1		left or down
-1	-1		down or right
$ p > q $			
1	1		left
1	-1		right
-1	1		left

(c) Walls forming multi-diagonal division

Figure 7—Division of the network into different regions by the walls.

3. If  $d_c > d_{c1}$  or if  $d_c \leq d_{c1}$  but impossible to reach the neighboring node chosen so far, move according to the wall touching principle. A loop is detected whenever a node is reached twice while traversing in the same direction.

**Description of the routing algorithm**

Starting in Phase 1.

*Phase 1*

1. Repeat the minimal distance algorithm until the destination is reached or a loop is detected.
2. If the destination is reached, or Type II loop is found, terminate.
3. If Type I loop is detected, determine the appropriate virtual destination in the expanded network as given in Table I and go to Phase 2.

*Phase 2*

4. Apply the minimal distance algorithm repeatedly, using the modified distance calculation for destination node until a loop is detected or the destination is reached.
5. If the destination is reached, terminate.
6. If a loop is detected (this loop will always be Type I if the network remains unchanged), change the wall

touching parameter (from left to right or vice versa) and go to (4). If both left and right had been tried, terminate.\*\*\*

The algorithm is illustrated by the example shown in Figure 8. It is written in detail in [7] in a modified version of PASCAL language. Table II lists the information required for routing a message from the source node to the destination node. This information is carried in the message and is updated by the switch nodes enroute. The node address and virtual network address of the closest node is used in the minimal distance algorithm, and also as reference for loop detection. A current virtual address is needed for distinguishing the types of loops and also to calculate the distance in Phase 2. The entry in touch hand specifies whether left wall-touching or right wall-touching is being carried out. Sending direction specifies the direction in which the message was sent when the node is reached. This is used when testing for the existence of a loop. The total number of bits in the case of  $m=n=16$  is 50 bits.

\*\*\* This case occurs when there are two or more Type I loops exist isolating the source from destination.

path as viewed in the expanded network

NETWORK PROTOCOL AND INTERFACE

In the design of network protocol, we make use of the relatively small round-trip propagation delays and large bandwidth of the data links in a local network. Since changes in network topology occur relatively infrequently, a route from a source to a destination, once found, can be used until either it is no longer needed or corruption or disruption of data transmission is detected. Within the network, links which consistently corrupt data are said to be unoperational. A version of an ARQ (Automatic-Repeat-Request) scheme is used for error control. We assume that source stations in the network either contain data buffers or are able to regenerate data as needed.

The switching discipline used here is referred to as call-switching discipline. It resembles the scheme used in the telephone network where a path for audio signals is set up by sending a control signal during the call establishment phase. In our network, whenever a source station wants to communicate with a destination station, a network control message is sent from the source switch node for the purpose of establishing a route from the source to the destination. When a route is found, the destination switch node sends a response message to the source to acknowledge the success of call establishment. Hereafter, messages containing data from this source station to the destination station are sent along this route.

From the viewpoint of the source station, the transmission of a message proceeds according to Figure 9. To establish a route, the source station assembles an addressing control message containing the destination address (switch node address plus device number) and transmits it to the switch node which serves the source device. Without loss of generality, the formats of communication messages are assumed to be as shown in Figure 10. For each addressing control message sent, a response message is received in return. The source station compares the address in the response message with the address of the destination node. When they match, this response is interpreted as an acknowledgment that a working route to the destination is

found. The source station may begin to send data (using the data variant of the communication message format). Again, for each message sent, a response message is received. As long as the address in the response messages remains that of the destination node, data transmission proceeds. A response message containing a node address other than the destination node address is interpreted as a negative acknowledgment. When such a response is received, transmission is restarted beginning with the addressing phase, by the source. To terminate the call, one or more terminator control messages are exchanged. Upon detecting the terminator control messages, switch nodes along the established route may delete routing information used during the call.

The operations of the switch node are a little more complicated. Only the general operation of a node will be explained here. A switch node services many links to other nodes plus zero, one or more (up to d) ports to devices and is capable of receiving messages on all device ports and link ports simultaneously. Upon receiving a message, the switch node either forwards the message toward the destination within the time limit defined for receiver timeouts or returns to the sender a response message containing the switch node's own node address (plus a zero device code). This response message is used either when the node is too busy to issue a proper response in time, or when concurrent traffic makes it impossible to react to an addressing request.

Clearly not all requests for attention of the switch node can be serviced. The addressing mechanism resolves the switch node resource allocation problem. All contentions occur within the addressing phase. When an addressing control message arrives at a switch node where the resources to process it are not available, the node responds to the requestor with a response message containing the

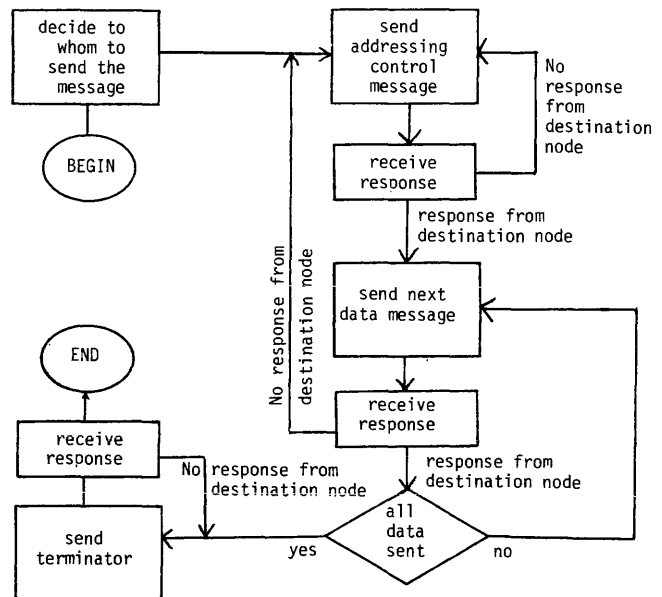

Figure 9

Network control message format

Data message format

## Control code for network control message format

- 00 - addressing control: emitted by the source node as part of the call establishment signalling. The address of the destination node is contained in the word.
- 01 - addressing response: generated by switch nodes and returned to the source node as a response to each addressing control message processed and forwarded. The node address and device port form the address of the destination device address when addressing control message is correctly received and forwarded. The node address contains the address of the switch node when no response is received, or the response is erroneous, or when the switch node or its outgoing links are busy.
- 10 - terminator: emitted by the source node to terminate the call. Node and device address in the word is the address of the destination.

Figure 10—Communication message for stations in the network.

address of the node. The requestor then reissues his addressing request. This process repeats until a working route is found.

After a route to the destination is found, the switch nodes enroute keep track of the outgoing links on which messages to the destination are sent. A switch node acts like a relay point of messages in the network. It passes any messages received directly to outgoing links if the block-sum-check by the switch node does not find the message erroneous. For each message sent out over a link, the switch node expects a response message from the neighboring node in return. No erroneous messages are relayed further. When an erroneous message is received, it is discarded without eliciting a response. If no response arrives, or if the received response is erroneous, the link is deemed unoperational. The switch node informs the source node this fact by sending a response message containing its

own address. Thus, alternate route selection is invoked to find another working route. During addressing phase, when a response message is properly returned to a switch node, it is passed back to the incoming line and is the response which the source device will ultimately see. Thus the source device may monitor the progress made by the addressing message at any time. The whole operation is analogous to remote controlled switching units, where each switch node sets up a connection to relay messages as it processes an addressing message and the connection from source to destination is built up one link at a time.

The communication scheme presented above is distinctly different from packet-switching, and seems capable of supporting the demands of local communication networks. Future work includes (a) The determination of whether the network will behave deterministically. (That is the establishment of one route does not lockout activities over

another.) (b) Performance evaluation to determine the effective bandwidth of the network. (c) The design of addressing scheme and protocol for broadcasting mode. (d) The design of diagnostic aids needed to maintain/repair the network.

# An analysis of a distributed switching network with integrated voice and data in support of command and control

by DANIEL SCHUTZER

*Navalex*

Arlington, Virginia

## INTRODUCTION

The potential for increased transmission efficiency of military tactical command and control data links through voice/data integration has increased in importance in recent years. With the introduction of even more sophisticated and automated weapons systems, the requirement for on-line exchange of data among tactically-embedded military computer systems has risen dramatically. Today we are faced with a proliferation of data link requirements for innumerable military systems that span all the services. An already densely populated electromagnetic environment is faced with still greater demands for its scarce bandwidth resources. Adding to this situation is the fact that these very resources that are in such heavy demand are quite fragile in the face of military electronic warfare measures. And, with few exceptions, the means for countering these electronic warfare measures place still greater demands on the already scarce bandwidth resources. All of the above provide the motivation for exploring new avenues and techniques that achieve greater efficiency of transmission resources. Economically, the revolution in digital componentry makes more viable the consideration of a greater degree of voice/data integration over tactical data links than would have been possible just a few years ago. Namely, competing signal processing techniques—Digital LSI, CCDs and SAWs are pushing the boundaries of technologies and making economically attractive spread spectrum, time division multiple access data link systems and internal multiplexed data distribution techniques which would simplify the integration of voice and data. Finally, with the increased sophistication of military weapon systems, the interrelationships and employment of voice and data in the conduct of war becomes even more intertwined and requires in many cases careful re-evaluation and re-enumeration.

Although there has been much analysis and study in recent years concerning the advantages and disadvantages of integrating voice and data over commercial and military strategic switching networks and long-haul data transmission systems, there has not been much analysis to date that has studied similar trade-offs for tactical data links. Tactical data

links can be thought of as a distributed form of switching where multiple users share a common transmission facility and where the associated multiplexing (time and frequency sharing), addressing and routing functions, rather than being implemented on separate multiplexers, concentrators and switches, are implemented directly in the data link terminal design. Two quite different examples of such a data link are the JTIDS<sup>1</sup> and the Fleet SATCOM TSCIXS links.<sup>4</sup>

Interestingly enough, recent advances in the interconnection of loosely coupled heterogeneous intra-nodal computer systems (systems co-located on a single platform or site) have resulted in bussing and networking schemes (such as the Farber ring, the experimental distributed processor (XDP), the Shipboard Data Multiplex System (SDMS), the Xerox Ethernet, the LCS net at MIT, and the Shipboard Integrated Processor and Display System (SHINPADS)) which can also exploit the advantages of voice/data integration.

In fact, there are distinct advantages to designing the intra-nodal and the inter-nodal networking protocols to be as similar as possible. This is discussed in more detail in the following section.

## VOICE/DATA INTERRELATIONSHIPS

All command and control information is communicated either in the form of voice, data, narrative message or graphics. From these communications, data is extracted and information derived. In the past, messages and the data extracted from these messages were filed in storage cabinets, clipboards, etc. for later retrieval and for message accountability. They were filed based upon content and were often cross-indexed on more than one subject. They were associated with one another in terms of the categories they were filed under and in terms of the data extracted and the information derived from the message. The data was retrieved, summarized and in some cases plotted. Although the media and the techniques have changed, the basic processes remain the same even in the computer-to-computer case.

Fundamentally, command and control involves the ex-

change, storage, retrieval and manipulation of information to support command decision-making with respect to military plans, objectives, resource allocations and assignment, conflict resolution and combat direction and management. Consider the following two examples.

At the National Command Authority level and the Fleet Command, or component command level, messages summarizing such information as the combat readiness, local weather and hostile units are prepared by the responsible organizations for electronic transmission, generally in formatted message form, to the appropriate Command authorities. There the messages are received and validated by computers. If validated, the entire message and/or the pertinent data is logged, indexed and filed in digital computers by categories such as date-time-group and unit identity. Likewise, orders, plans and warnings are also prepared in formatted message form for electronic transmittal to the responsible authorities. The stored data and formatted messages are later retrieved, sometimes with supporting computations based upon the retrieved data (information), to aid in situation assessment and command decision-making. On the other end of the spectrum, sensors (generally analog) are automatically processed and reduced to digitally formatted sensor contact reports which are then, where possible, automatically associated with earlier sensor reports to identify targets with sufficient location accuracy for assignment to an appropriate weapon system. These target assessments are transmitted directly to the appropriate weapon direction computer systems and there input automatically to the appropriate fire control solution. Human interaction is restricted to ambiguity resolution, validation and override types of activities. In all of these cases we find that the process can still be modelled by a basic message handling (message preparation, distribution and routing, validation, storage, retrieval and manipulation and presentation) operation/system.

In fact, all command and control inter-process data can be modelled as an  $n$ -ary relation,  $R$ , which has the properties:

1. Each row represents an  $n$ -tuple of  $R$ .
2. The ordering of the rows is immaterial.
3. All rows are distinct.
4. The ordering of the columns is significant—it corresponds to the ordering  $S_1, S_2, \dots, S_n$ , of the domains on which  $R$  is defined.
5. The significance of each column is partially conveyed by labelling it with the name of the corresponding domains. The example in Figure 1 illustrates a relation of degree 4, called "position report," which reflects the location and status of a unit in a task force commander.

POSITION REPORT	(Identification)	Location in LAT-LONG	Status	Time of Report
	1	63-50	10	0900
	5	67-71	2	1400

Figure 1—A relation of degree 4.

A relation whose domains are all simple can be represented in storage by a two-dimensional column-homogeneous array of the kind just discussed. Some more complicated data structure is necessary for a relation with one or more non-simple domains.

Consider, for example, the collection of relations exhibited in Figure 2. "Signature" is a non-simple domain of the relation "sensor report." The tree in Figure 2 shows these interrelationships of the non-simple domains.

These more complicated relationships can, however, be normalized to a multiple relation over simple domains. Figure 3 is an illustration of a normalized form of Figure 2.

The simplicity of the array representation which becomes feasible when all relations are cast in normalized format is not only an advantage for storage purposes but also for communication of data between systems which use widely different representations of the data. The communication form would be a suitable compressed version of the array representation and would have the following advantages:

1. It would be devoid of pointers (address-valued or displacement-valued).
2. It would avoid all dependence on hash addressing schemes.
3. It would contain no indices on ordering lists.

All inter-process communications could then be placed in either an informal narrative message format, or a formatted message in a normalized relational form. Similarly, all storage retrieval, computations and correlation of the received data can be shown to be defined in terms of operations on these relations and their domains.

For example, correlation involves a matching operation on the sensor report relations ID, signature and location domains. Thus, the basic  $C^2$  processes of data dissemination, analysis, storage/retrieval and presentation can all be expressed in terms of message handling.

There are advantages to viewing the command control process in this manner. They are briefly summarized below:

1. The message-handling process is fairly well understood with an extensive theoretical foundation<sup>2,3,5,6</sup> and supporting analyses and simulations. Platforms and nodes can be quantitatively characterized in terms of their message-handling capabilities.

SENSOR REPORT			
Sensor name	Report ID	Location (LOC)	Signature
			Waveform Class
			Pulse Repetition Interval (PRI)
Sensor report (Name, Report ID, Location, Signature)			
Signature (Waveform class, PRI)			

Figure 2—Unnormalized set.

---

Sensor report' (Name, Report ID, Loc)  
Signature' (Report ID, Waveform class, PRI)

---

Figure 3—Normalized set.

2. The message distribution and routing process forms a *natural partitioning* upon which the interface and communication among command and control processes can be based.
3. Requiring the command and control process to communicate exclusively by means of man-readable message exchanges allows for *ease of human intervention and take-over* of any command and control process. Of course, a degradation in processing time would be experienced under manual take-over.
4. Inter-connecting command and control processes exclusively by means of asynchronous variable length message exchanges simplifies the interfacing among processes, allowing for a generalized approach to process interfacing which does not distinguish whether the interfacing processes are program modules on the same processor, on different processors in the same local node, or are processors remote from one another. This results in a *design flexibility* which can easily accommodate the addition and deletion of processors, new functions and capabilities, and which permits the dynamic remoting of functions. This enhances the practicality of implementing a survivable nodeless reconfigurable system. It also serves to isolate and, thus, insulate the main portion of the application design from the particulars of any specific message format or structure.
5. The asynchronous, variable length nature of the message exchanges allows the system to work independently of the reporting rates and the available communications bandwidth. This allows one to reduce the reporting rate and/or the message content in response to decreases in available system processing capacity and in available communications capacity. Thus, a loss or denial of facilities (processing or communications) and/or a manual override can be accommodated with a *graceful system* degradation rather than an abrupt loss of capability.
6. Restricting the communication between processes in a distributed processor network to a message exchange format should *ease the control and scheduling* of these processes. Several systems have already been built and operate on these principles, the ARPANET and its associated TENEX services being a notable example. Recent research trends in distributed processor network operating systems also appear to support these notions.<sup>7</sup>
7. By couching the command and control process in message-handling terms, there is the *potential for capitalization* of the software and concepts available from such rapidly growing *commercial application areas* as word processing, office automation and electronic mail.

On the negative side, there will be, of course, a loss of computer efficiency resulting from the requirement that all process-to-process communication be in man-readable message form and not through such mechanisms as common addressable blocks of memory or other such more tightly coupled program module inter-communication. But available computer processing capacity and memory is now a relatively abundant commodity, and to achieve computer efficiency at the sacrifice of other now scarcer resources such as manpower is the last thing we should do.

It should be noted, however, that the restriction of process-to-process communications via man-readable message format should not be misconstrued as prohibiting the compression and compaction of this message prior to its physical transmission over the communications media and its subsequent decoding and decompaction upon its reception at the other end. This operation is transparent to the process involved, is conservative of communications bandwidth, which is a relatively scarce resource, and is an acceptable, indeed, a preferred approach.

Such a model of the command and control process encourages the ease with which voice and data can be integrated. In this model, voice and data are recognized as merely two different medias to support Command and Control message (information) exchange and manipulation. Whereas voice requires greater bandwidth and exhibits less efficient information compression, it has the advantages of allowing for a rather informal, highly interactive and natural means for human communication. Data, on the other hand, exhibits more efficient use of communications bandwidth, and is a more natural medium for computer entry and for message storage, retrieval and manipulation. Both media are needed, and in fact, the employment of one over the other is highly dependent upon the situation. If the situation calls for complex team problem-solving, or is highly manual, informal voice is preferred. If the situation stresses conservation of bandwidth or communication with a highly automated weapon system, then data is preferred. Since the military situation is highly dynamic where systems fail, are jammed and destroyed, the ability for easy and effective control and reallocation of the voice/data mix is desirable. A distributed switching network over which voice and data are integrated would greatly facilitate and enhance such a capability. In addition, there is a definite advantage performance-wise in such an integration of voice and data. This is addressed in the following sections.

## PROBLEM FORMULATION

The basic issue to be addressed can be reduced to the following question:

Given a fixed available bandwidth, is it preferable (e.g. more efficient) to (1) Allocate this bandwidth among two or more radios on a relatively fixed basis with voice traffic restricted to some pre-selected portion of the total number of available radios and data traffic restricted to the remaining portion? (2) Share the entire available spectrum among both

types of services, voice and data, on a totally demand basis? or (3) Allocate along some hybrid scheme (partial dedicated, partial shared on a demand basis)?

Furthermore, for the demand assignment model, is it preferable to allocate on a voice silence, call-by-call, message-by-message basis or on a less dynamic reservation type of basis?

The problem can be analyzed by studying the two statistical models illustrated in Figure 4 where  $\lambda_1$  equals the average number of voice calls per second (the voice arrival rate),  $\lambda_2$  equals the average number of data messages or packets sent per second, and  $\mu_1, \mu_2$  represent the average service rates associated with a single voice-equivalent channel, and  $n$  and  $m$  refer to the number of voice-equivalent channels available for voice and data respectively. The arrivals and servicing of the calls and data are assumed to be probabilistic (random variables) and not to be fixed constants. The service rate for voice is inversely proportional to the average length of a phone conversation, or speaking period (depends on integration approach). The service rate for data is directly related to the bandwidth (capacity) of the voice channel and inversely related to the message length.

Voice calls and data messages arriving at a faster rate than they can be serviced will experience occasions when there is no available channel. In the case of voice, the attempted call is assumed aborted (or interrupted) and the caller is required to try again (or repeat). In the case of data, the data message is assumed to be stored or queued in a waiting state until a channel that can service it is freed up.

Case 1 is rather self-explanatory and straightforward. Voice traffic of average arrival rate  $\lambda_1$  and service rate ( $1/\text{average holding time}$ )  $\mu_1$  is allocated  $n$  voice-equivalent channels.

Accordingly, the grade of service (GOS) or the probability of a lost call is given by the Erlang  $B$  distribution; equation 1 of Figure 4 where:

$$B\left(\frac{n, \lambda_1}{\mu_1}\right) = \frac{\left(\frac{\lambda_1}{\mu_1}\right)^n}{\sum_{x=0}^n \frac{\left(\frac{\lambda_1}{\mu_1}\right)^x}{x!}} \quad (5)$$

Data traffic of average arrival rate  $\lambda_2$  is allocated  $m$  voice-equivalent channels. The service rate is equal to the channel bandwidth (measured in bits-per-second) divided by the average message length (measured in bits). Accordingly, the average delay (seconds) is given by Equation 2 in Figure 4.

Case 2 models an integrated voice/data system as a single server system which provides real-time, uninterrupted transmission service for voice, and data transmission service with a lower preemptable priority. Figure 4 illustrates this model. Assumptions for this model are:

1. Voice signals and data packets arrive in a Poisson fashion with mean arrival rates  $\lambda_1$ , and  $\lambda_2$  respectively.
2. No queueing is permitted for voice because of its real-time nature (i.e., as soon as a voice signal arrives, it

preempts the use of a server for its immediate transmission).

3. A data packet which was being served for its transmission and is preempted by the arrival of the voice signal will stand temporarily in front of the queue station of data packets until it is re-served (the whole packet is retransmitted). An exponentially distributed service time with a mean service time of  $1/\mu_2$  is assumed.
4. Service time for the voice signal is also exponentially distributed with mean service time of  $1/\mu_1$  seconds. In this case, the mean service time is not necessarily equal to the mean call holding time. It can be considerably less if a call is broken-up into talking and silent periods and the data packets sent during silent periods.

This model was analyzed in Reference 2 and the results are shown in Figure 4 with Equations 3 for the voice grade of service, and 4 for the average data packet delay. Because voice is treated as a preemptive priority class of arrivals, it is assumed to be represented by the same Erlang  $B$  distribution, Equation 5, used for Case 1.

Using Equations 1 through 5, Tables I-IV were computed.

## RESULTS

From Tables I-IV it can be seen that it is generally more efficient for voice and data traffic to share voice-equivalent channels on a statistical contention basis than for voice and data to operate over separate dedicated data link voice-equivalent channels.

More specifically, for example, two voice-equivalent channels available for dynamic sharing by both voice and data on a statistical contention basis (with voice served on a preemptive priority basis) results in the following performance enhancements:

For a voice traffic intensity equal to or less than .1 second of voiced periods for every available second of channel time (.1 erlangs), the "grade of service" improves from .09 to .005, and the data traffic responsiveness is enhanced over the dedicated or non-integrated channel scheme up to data traffic utilizations (throughputs) in excess of 70 percent.

If the voice traffic density increases to  $\frac{1}{2}$  second of voiced periods for every available second of channel time (.5 erlangs), an improvement in voice "grade of service" (probability of a blocked call) from .34 to .08 results from this

voice/data integration and an accompanying increase (enhancement) in data traffic responsiveness is still experienced if the data traffic throughput (for this example) does not exceed 30 percent channel utilization, or:

- a. 24 message packets/sec per channel for 200-bit average message length, and 16 kbps voice-equivalent channel.
- b. 1.2 message packets/sec per channel for 200-bit average message length and 2.4 kbps voice-equivalent channel.

TABLE IV.—Probability of Blocked Voice Call

$$B(n, \rho_1) = \frac{\frac{\rho_1^n}{n!}}{\sum_{x=0}^n \frac{\rho_1^x}{x!}} \quad (8)$$

$\rho_1$  = traffic intensity in erlangs  
 $n$  = # trunks

# Trunks $n$	$\rho_1$

1	.09	.24	.34	.41	.49
2	.005	.03	.08	.13	.17

The contention scheme just analyzed requires the capability for data to be interleaved with voice by transmitting only over quiet (unvoiced) periods in a voice conversation. If the interleaving is only done on a completed call basis, then Table III applies, call-holding times on the order of 1/2 hour result, and the resulting data packet delay becomes prohibitively large.

The sensitivity of achievable data traffic throughput to data packet length is illustrated by noting that there is a tremendous loss in the efficiency (throughput) of the data traffic as one increases the length of the packet to be interleaved with voice signals over a common channel. Specifically in Table II (2 sec average voice holding time) for a voice signal of .5 erlang traffic intensity over 16 kbps voice-equivalent channel, the data traffic throughput is 2.4 messages/sec for 200-bit packets, and only .8 messages/sec for 2000-bit packets. This represents a 300 percent improvement in data throughput efficiency when one interleaves on a 200-bit basis as opposed to a 2000-bit basis.

Based on this sensitivity of data traffic throughput to data packet length, it is clear that if voice/data integration is desirable (which it is) then word or short-packet (200 bit or less) interleaving is preferred and this interleaving should be done on a voice silent period basis rather than on a completed call basis.

The above analysis was based upon a scheme which as-

sumed that if a voice signal occurs during a data transmission, the data transmission will be preempted by the voice signal and queued for later retransmission. This was required because of the real-time nature of voice; voice signals cannot be randomly stored and forwarded without degrading its intelligibility.

For some military applications, it is conceivable that there will be classes of message traffic for which it is preferable to interrupt a voice conversation and to allow for a real-time message delivery (no or negligible queue time). Such a capability can be easily implemented. Although its impact on total system performance is not completely analyzed in this paper, it is clear that if this preferred class of messages appears sufficiently infrequently, this special message class can be accommodated with preferential preemption treatment, and performance advantages will still result over a wide practical range of traffic mixes for both voice and for lower-priority message traffic. For example, the impact on the performance of voice and lower priority messages, when practicing preferential preemption treatment for a select class of messages that represent less than one percent of the total channel capacity, can be approximated by increasing the traffic intensity,  $\rho_1$ , in Equations 4 and 5 by 1 percent, i.e., .11 worth of traffic will look like  $\rho_1 = .11$  worth of traffic.

If one wishes, a hybrid scheme could be adopted where a thin-line capability is reserved for a special class of data and/or voice and where the remainder supports an integrated voice-data operation. The reserved channels can be dynamically increased or decreased in response to channel fluctuations in such a way as to guarantee a minimum acceptable threshold of performance. One such scheme, analyzed in Reference 3 for a circuit-switched network, is reformulated in the context of the tactical data link situation, and is now summarized.

## RESERVATION SCHEME

It is desired to guarantee that for a select class of data messages, their delivery time will not exceed a maximum allowable value. One way this guaranteed performance can be achieved is by the originating data terminal transmitting this select class of data messages as packets, over pseudo-dedicated channels, previously reserved and connected to the destination data terminal processor. The originating data terminal may reject messages/packets over a critical length as the pseudo-dedicated line utilization reaches a pre-determined threshold. Upon reaching this threshold, the data terminal must reserve additional voice-equivalent channels on a multi-channel basis if the guaranteed performance is to be maintained.

Let us now determine how one may compute the value of the threshold at which the data terminal must reserve additional voice-equivalent channels in order to keep the maximum message delay below some allowable value. This threshold is related to the maximum acceptable delivery time as expressed by Equation 9.

$$T_D = (Q_I + 1 + Q_0)t_{tr} \quad (9)$$

where  $T_D$  = maximum acceptable delivery time

$Q_I$  = input queue to originating data terminal  
expressed in packets

$Q_0$  = output queue to the destination data  
terminal expressed in packets

$t_{tr}$  = packet transmission time in seconds/packet

Equation 9 can be rewritten as

$$-1 + \frac{T_D}{t_{tr}} = Q_C \quad (10)$$

where

$$Q_C = Q_I + Q_0. \quad (11)$$

If the average packet length is  $\ell$  bits, and a single voice-equivalent channel represents  $b_0$  kbps, and if we reserve  $n$  voice-equivalent channels at a time, and if  $m$  pseudo-dedicated lines have already been reserved between the originating and destination data terminals, then the average packet transmission time  $t_{tr}$ , is at that instant of time

$$t_{tr} = \frac{\ell}{mnb_0} \quad (12)$$

Substituting Equations 11 and 12 into Equation 9, we obtain the relationship that

$$\frac{mnb_0 T_D}{\ell} - 1 = Q_C. \quad (13)$$

This tells us that if:

$$Q_T = Q_C - t_c(\lambda_0 - \mu_0) \quad (14)$$

where  $\lambda_0$  = maximum arrival rate

$\mu_0$  = maximum service rate

$Q_T$  = threshold queue

$t_c$  = connect time

then combining equations 13 and 14, we obtain

$$Q_T = \frac{mnb_0}{\ell} T_D - t_c(\lambda_0 - \mu_0) \quad (15)$$

The maximum resulting queue for which buffer space must be provided is  $Q_{MAX}$ , where

$$Q_T + t_c(\lambda_0 - \mu_0) \leq Q_{MAX} \quad (16)$$

The basic theory underlying the hybrid network then is to reserve an additional  $n$  voice-equivalent channels when the queue approaches some critical value,  $Q_T$ .

As an example, consider that the output and input queues are equal.

$$Q_0 = Q_I,$$

then from Equation 9

$$T_D = (2Q_0 + 1)t_{tr} \quad (17)$$

Then for the maximum capacity queue,  $Q_0 = Q_{MAX}$ , and

$$\frac{T_D/t_{tr}}{2} - 1 = Q_{MAX} \quad (18)$$

From Equation 12,  $t_{tr} = 0.125$ , for  $\ell = 2000$  bits average message length,  $b_0 = 16$  kbps,  $n = 1$ , and  $m = 1$ .

From Equation 18, a maximum queue of seven packets ( $Q_{MAX} \leq 7$  packets) results for a  $t_{tr} = 0.125$  and a maximum allowable  $T_D$  of 2 seconds. This technique for maintaining a maximum allowable  $T_D$  is to monitor the queues,  $Q_0$  and  $Q_I$ . As  $Q_0 + Q_I$  approaches  $Q_T$ , one reserves more channels, thus increasing the capacity and reducing  $T_D$ .

The general conclusions to be made from the analysis presented in this section is that this reservation scheme is practical over a wide range of realistic values. More specifically, for messages of length 2000 bits or less, it is practical to maintain a delivery time under a pre-established allowable maximum of two seconds by adding more channel capacity on a reserve basis when a queue threshold less than seven packets, or 14,000 bits, is reached.

# The exploratory system control model multi-loop network

by DANIEL J. PAULISH

*Burroughs Corporation*  
Paoli, Pennsylvania

## PURPOSE

The Exploratory Systems Control Model (ESM) Multiloop Network consists of the original three-loop ESM network delivered in 1977 and the fourth Exploratory Systems Control Model Development (ESMD) loop delivered in 1978. The ESM also includes a fifth loop supplied under the Modular System Control Development Model (MSCDM) project. The ESM provides a flexible tool for simulating and comparing a wide range of system control architectures and their related procedures and protocols. The ESM has been designed to model the class of the system control architectures that have the characteristics of decentralized operation, modularity, easy modification and upgrade capability, high reliability, high survivability and fail-soft operation.

## BACKGROUND

The Defense Communications System (DCS) is a global, multiple-user system composed of leased and government-owned transmission media, relay stations and switching centers deployed in support of the National Command Authorities and the services, including command and control, intelligence and early-warning, as well as administrative and logistical communications. In order to increase the reliability and availability of these DCS services, it is essential to improve the responsiveness and robustness of the System Control (SYSCON) process as much as possible. This requirement demands a DCS SYSCON subsystem possessing such design features as modularity and "fail-soft" operation. Modularity implies a subsystem that is capable of being upgraded, modified and reconfigured easily, and "fail-soft" implies a subsystem that tolerates partial failures, yet is relatively immune to total collapse. To afford these capabilities, the future DCS SYSCON subsystem is expected to consist of many semi-autonomous, mutually-supportive, geographically-dispersed control centers.

During FY 75, Burroughs Corporation began development of an Exploratory System Control Model (ESM) which capitalized upon the inherent flexibility of multiple, interconnected data transmission rings and microprocessor-based host/ring interface nodes to provide an initial capability for experimental validation of various candidate SYSCON subsystem architectures characterized by distributed control

and graceful degradation under stress. This capability to model apparently dissimilar architectures is a consequence of the universal physical connectivity provided by the ring structure coupled with flexible protocols that permit definition of different logical connectivities through selective routing of transmitted data.

In the broader context of the DCS SYSCON Program, the longer-term joint purpose of this effort and the separate-but-related "Modular System Control Architecture Study and Feasibility Development Model" is to provide DCEC with the necessary integrated means to evaluate through hybrid simulation a variety of candidate SYSCON subsystem the architecture(s) thereby identified as being suitable for implementation. The technical and performance information obtained from the unified hybrid simulation model will ultimately be used in the preparation of performance specifications for the future DCS SYSCON subsystem.

## LOOP OR RING COMMUNICATIONS SYSTEMS

### *General operation*

A communications loop is a closed, ring-connected set of nodes providing data flow unidirectionally from one node to the next. Each link between nodes is a single twisted pair of wires carrying a serial data stream in a self-clocking code. Full connectivity is achieved by associating a destination address with each packet of data carried on the loop. A node to whom a packet of data is not addressed acts simply as a "delayed repeater," having no effect on that data other than introducing some delay. The concept of a data exchange loop has been described extensively in the literature of computer communications by Reames,<sup>1</sup> Jafari<sup>2</sup> et al. Loops may be distributed such that each node contains its own power supply and cabinet and is located near the equipment it interfaces or locally such that all nodes are connected within a single cabinet with cable connections to interfaced equipment.

A functional block diagram of a communication loop node is given in Figure 1. The Loop Interface Unit (LIU) is responsible for reading data addressed to the node and writing data on the loop. The Control and Interface Processor (CIP) is a microcomputer that provides a data communications interface to the external device. The memory is used

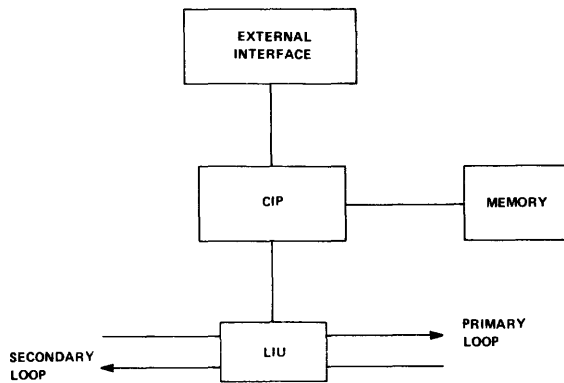

Figure 1—Communication loop node.

for program storage, routing tables and intransit queue storage. The external interface provides a hardware connection to the external equipment to be connected to the loop.

#### Modularity-adaptability features

The basic Burroughs loop node is a module made up of the LIU, microprocessor CIP, memory and external interface. The nodes are identical except for the external interface and the external device interface software used to handle the protocol between the microprocessor and the external device. In the ESM external devices include processors (PDP11/40, PDP11/70, B776), terminals (TD802, TD832), gateways (between the multiple rings) and data communication interfaces (SDLC, AUTODIN II, TCCF). The nodal external device interface software provides code conversion, flow control, intransit queueing, logical attachment capability and emulation of various communications protocols for the devices. The interfacing capability of the nodal modules provides communication capability between devices in the heterogeneous system.

When a module fails, the loop will recognize the failure and cut the failed module out of the system by forced loop-back from the module's nearest neighbors. The module may then be replaced and the loop will return to normal operation. In the meantime, the other modules will still be in operation so that degradation will be graceful in that only the operation of the failed module will have been lost.

#### Loop throughput capability

Loop throughput (total number of message units that can be sent over the loop per unit time without undue message delay to the receiving modules) is a function of line speed, loop discipline and the definition of "undue" message delay. Various loop disciplines have been developed and compared.

The Newhall loop which uses a special control packet called a Write Token can transmit only one message on the loop at a time and has the lowest throughput but has the advantage of simplicity and cannot be clogged by misdi-

rected messages. It also shows some advantage in ease of detection and deletion of certain types of faults.

The Pierce loop which uses fixed size slots in which data packets can be placed can transmit multiple messages, but the small fixed packet size causes greater overhead than in the DLCN loop.<sup>1</sup> The DLCN loop uses queues within each LIU that can expand or contract to hold upstream messages in temporary storage. This allows packets of variable size to be transmitted and allows multiple transmissions. Loop clogging is possible in both cases, however, and special means must be employed to "declog" the loops under certain error conditions. Loop clogging is the deadlock situation when packets cannot be written onto the loop until previously written packets are removed.

The Jafari loop<sup>2</sup> is a double loop, one used for control and the other for data. The data loop is segmented such that a switched point-to-point circuit is set up when requests for communication are issued on the control loop.

The ESM uses a Newhall protocol at a loop frequency of one mega-baud. Simulation studies and queueing analyses<sup>3</sup> indicate that this loop can support a throughput in excess of 750K baud without undue delay. The Pierce, DLCN and Jafari throughputs can be even higher, due to simultaneous conversations.

Suppose the average node writes 15 packets of 2000 bits each per second for a total of 30,000 bits/second. At that rate a Newhall loop can support 25 nodes. The worst-case time that a node will have to wait for a write token is given by

$$T_{WT} = \frac{MP}{C_L} \quad (\text{Eq. 1})$$

where  $M$  is the number of nodes=25,  $P$  is the packet size—2000 bits, and  $C_L$  is the loop frequency of  $1M$  bits/sec. Thus  $T_{WT}$  is 50 msec. The average wait for a write token is given by

$$T = \frac{\rho}{2} T_{WT} \quad (\text{Eq.2})$$

where  $\rho$  is the loop utilization=0.75 for our example, thus  $T=19$  msec.

#### Multiple loops—addressing schemes

The ESM system has proved the capability for providing multiple loop systems and has acted as a vehicle for testing multiple loop addressing schemes. Figure 2 exemplifies a multiple loop system. Three loops are shown connected via gateway nodes. Gateway 2 of Loop 1 connects to Gateway 1 of Loop 2 via a hard-wire connection independent of the loops. Similarly, Loop 1 connects to Loop 3 and Loop 3 connects to Loop 2 via gateways. Each loop is independent of the other loops.

The small boxes are nodes and the numbers within the boxes represent the "functional address" of the node. The functional address (FAD) is the local address unique within the loop. In addition, each node has a "logical identifier" (LID) unique within the system.

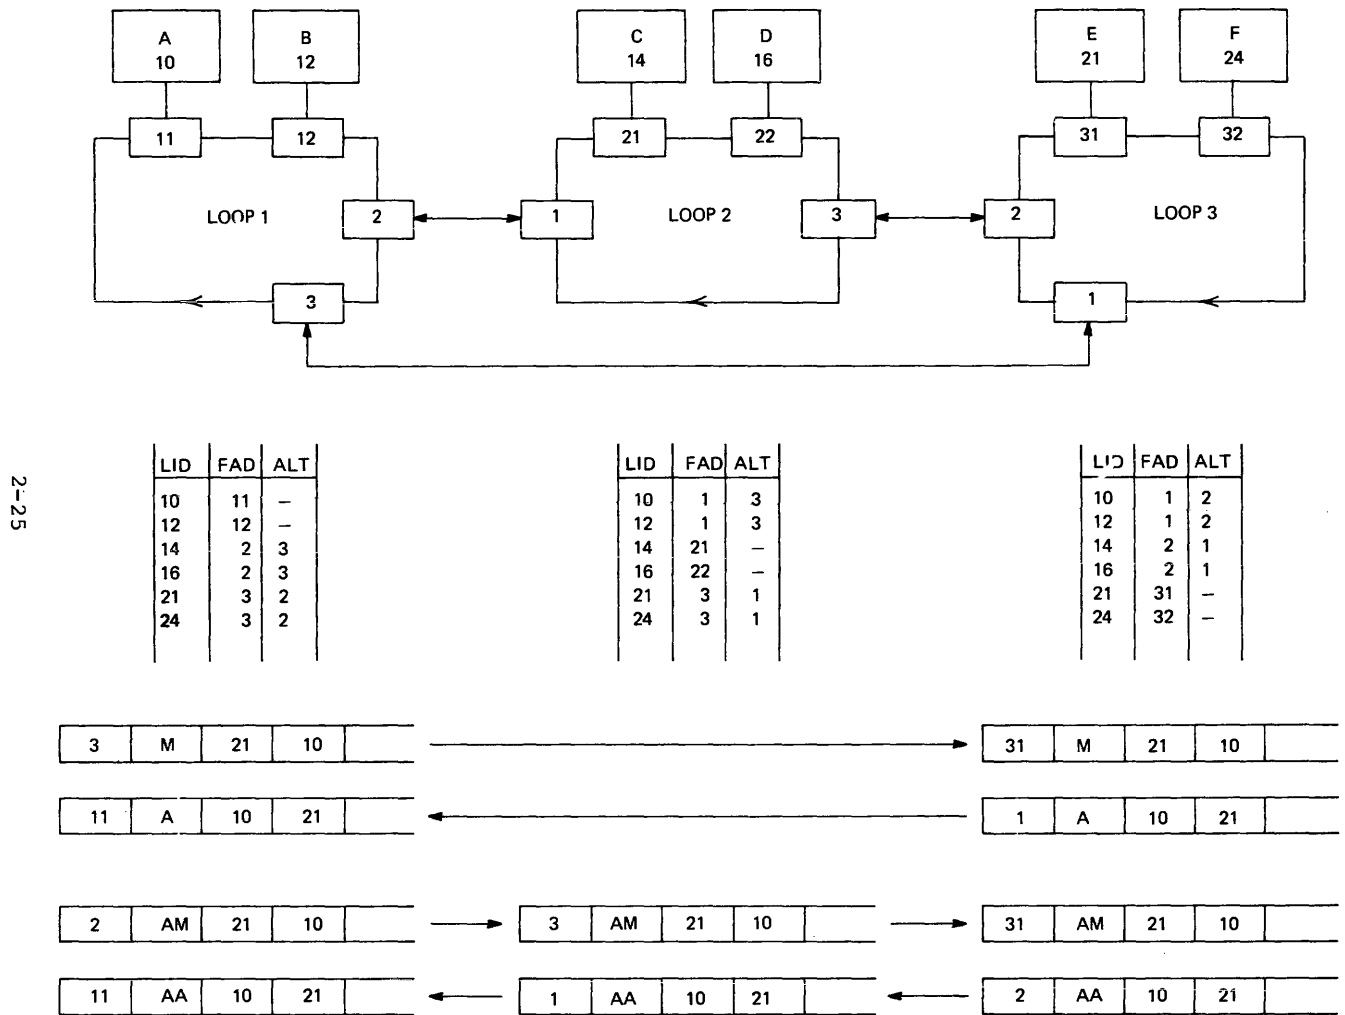

Figure 2—Indirect method of addressing.

An example of how alternate routing is implemented with a multi-loop architecture using indirect addressing is given in Figure 2. Let us assume that Host Processor A on Loop 1 wishes to send a message to System Process 21. Host A sends a packet to its CIP with 21 as the destination LID and 10 as its source LID. The CIP formats a packet using an FAD or loop address equal to 3. The packet is sent out onto the loop, bypasses Nodes 12 and 2 and is read by Gateway Node 3. Gateway Node 3 sends the information part of the packet across the 1-3 link. Gateway 1 in Loop 3 formats a packet having Loop Address 31. The packet bypasses Node 2 and Node 31 reads the packet. An ACK packet is sent out on the loop using LID 10, and the packet is linked to the input queue for deliverance to Host A.

If Node 11 had not received an ACK message after a specified number of retransmissions, it would utilize alternate routing. It would do this by marking the packet indicating that alternate routing was used and changing the loop read address (FAD) from 3 to 2. Gateway Node 2 in Loop 1 would read the packet and send it across the 1-2 link.

Gateway Node 1 in Loop 2 would use an FAD of 3. The packet would bypass Nodes 21 and 22 and be read by gateway Node 3. The packet would be sent across the 2-3 link and gateway Node 2 in Loop 3 would use an FAD of 31. The acknowledgment message would be sent via the alternate route.

Node 11 would also report to one or more network control processors who could remove the 1-3 link from service for repair. This would involve sending special broadcast control packets to Loops 1 and 3 so that Link 1-3 would not be used.

The above method of indirect addressing can be used for resource allocation such that processes could be moved around the network so that spare or less utilized processors can be utilized. For example, let us say that Host E is brought down for service and thus Process 21 is to be moved to another processor. Let us say that it is determined (possibly by some bid-quotation scheme) that Host D of Loop 2 is to handle Process 21. In order to move the process, control packets would be broadcast in each loop.

ESM/ESMD IMPLEMENTATION

System elements and connectivity

The ESM is a communications system used to interconnect devices (e.g., terminals, host processors, data communications lines) so that each device can interface with any other device for information transfer. To accomplish this, each ring is supplied with nodes that act as interfaces from ring to device and from ring to ring. The ring-to-ring nodes are called "gateway" nodes. Each node is the same physically as any other node except for a small amount of special separable hardware for each type of node. The major difference between nodes is in the software of the nodes. The nodes provide all the necessary communications functions of queueing, parity checking, ACKing, NAKing, retransmitting, alternate routing, etc. The hosts and terminals need only supply the data processing functions and need not be concerned with the communications functions.

The gateway node interchanges are via cables in the ESM configuration, but in principle can be via any communications medium such as telephone, microwave relay, optical transmission or satellite relay.

The terms "loop" and "ring" are interchangeable. Each loop is housed in a separate cabinet in this implementation, but this is not a necessity. A loop could, as easily, extend throughout a building or facility.

The ESM Multiloop Network is illustrated in Figure 3. Loops 1, 2 and 3 were delivered in 1977 as part of the ESM Contract.<sup>4</sup> Loop 4 was delivered as part of the ESMD Contract in 1978.<sup>5</sup> Loop 5 was delivered as part of the MSCDM Contract in 1979.

Features of the ESM

The ESM is designed to be transparent to the user. Regardless of the CRT used and the host on which a particular activity takes place, the activity will take place for the CRT that calls for it. When a message is transmitted from a CRT, suitable control bytes are added to the message by the CRT node and directed to the node of a nearby host. When the host receives the message, it will either handle the message completely if it can or it will pass it on to another host, via the ESM, for cooperative handling of the message. This is done under program control using the content of the CRT message and the added control bytes. The CRT will then receive a response from one of the hosts. A CRT can "ATTACH" itself to any node in the network via user command.<sup>6</sup>

Responses will generally be part of the "user language" which is designed to provide directions for further dialog as well as replies to previous messages. The language is designed to be modular so that it can be easily updated and

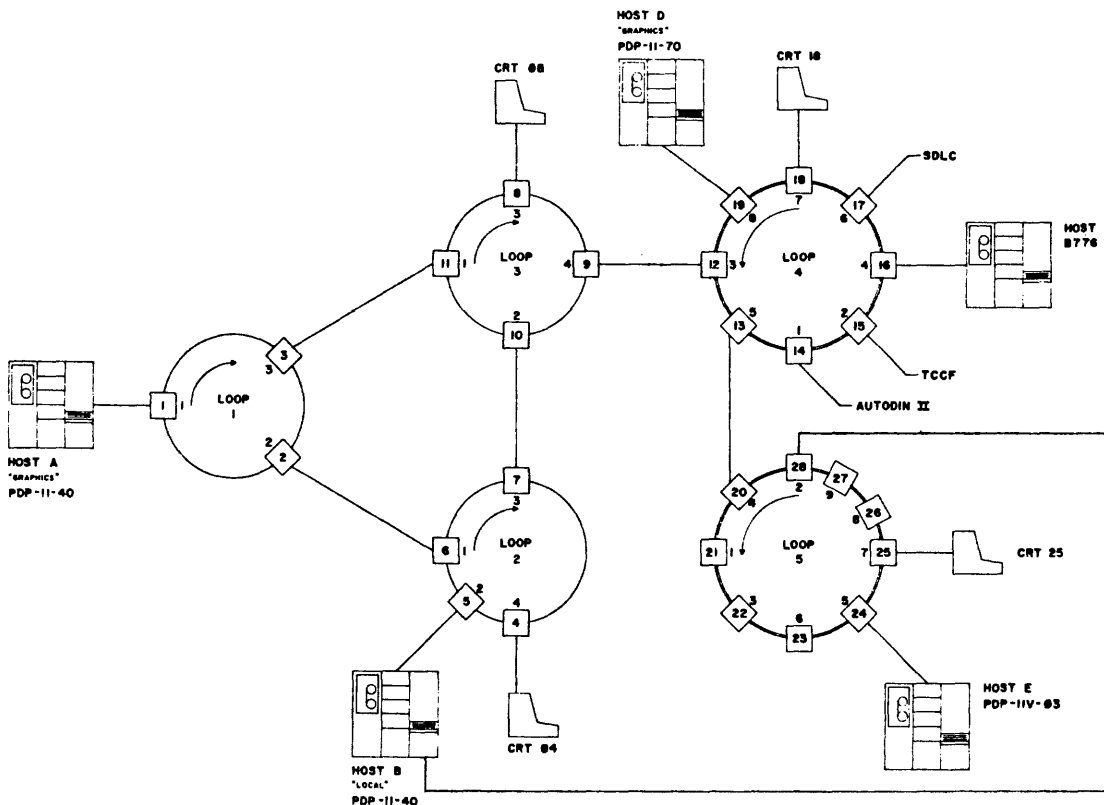

Figure 3—ESM multi-loop network.

enhanced. In addition CRTs can communicate directly with the operating system of the particular processor as if it were a local terminal.

Messages are sent in the form of packets of length not greater than 256 bytes. As each packet is sent, the sending node holds it for acknowledgment (ACK) from the receiving node. When an ACK is received by the sending node, it frees the packet space.

If a non-acknowledgment (NAK) is received, the message is resent or sent by an alternate route. Absence of an ACK or NAK after a timeout period is considered to be a NAK. After a suitable number of resends without an ACK, the message may be reported "not sent." Nodes automatically provide input and output queueing for the external device. Sufficient extra memory space is provided in each node to permit receipt of system control commands from the loop and to act on these commands. This is done to prevent a deadly embrace condition within the node. If the input queue (from the loop to the external device) is full, new input messages are rejected. Room always exists for the receipt of ACKs and NAKs and other control messages. These are acted upon with dispatch so that they do not reside in data memory for a long period. If the output queue is full, the external device is prevented from sending to the node.

The loop protocols are designed to be non-blocking and self-polling. Each node in the loop has its turn to write onto the loop and if any noise exists on the loop from prior transmissions, it is overwritten by the new transmission. Nodes share the polling activity and any loss of polling is restarted automatically.

ACKs and NAKs are generated by end-user nodes when they receive packets. Each packet is tested against cyclic redundancy bytes in the packet. A good check results in an ACK and a bad check results in a NAK.

### *Examples of use*

The ESM Multiloop Network is part of DCA's Hybrid Simulation Facility (HSF). The ESM provides DCA with a System Control Simulation Facility. The uses of the system are to be outlined. The various applications are in different stages of development; some of the system uses are a direct result of the original implementation, others require additional modeling application and demonstration software.

### **User language**

The User Language provides the human interface to the system and demonstrates many of its modeling capabilities. The User Language is an application program running on the various Host processors in the network. All loop connected terminals can communicate with the User Language on any processor.

The User Language consists of four major modes of operation. The first mode, CRT-to-CRT, provides users with the capability to send messages to each other. This simulates communication between System Controllers at different

sites who must talk to each other in order to isolate certain faults. Mode 2, System Inquiry, allows the user to examine the nodal configuration tables; the tables are monitored on disk on a host computer. Mode 3, System Control, allows the user to modify the nodal configuration tables; this feature provides the capability to model different network architectures. Mode 4 implements a distributed data base on the PDP 11/40s. The TOTAL Data Base Management System is used to distribute records of files on the two processors. The data base appears to the user to reside completely on one machine.

### **File transfer**

A file transfer utility has been written to transfer files between host processors. The program allows peripheral sharing by providing a capability to send files to another machine's disk, printer, or tape. Files can be obtained from another machine's disk. In addition, terminals can be AT-TACHed to the various host processors in the system.

### **Fail-soft operation**

The system is designed to tolerate partial failures. LIU failures result in automatic loop-back performed to remove the failure from the network. The failure is detected by the nodes and reported to a System Control Monitor node. Alternate routing is automatically performed when a node in another loop fails to ACK a packet after a specified number of retries. Failure to ACK a packet is reported to the Monitor node. Queue overflows are also reported to the Monitor; a queue overflow results from the failure of an external device to respond to the node.

### **Security**

A demonstration of the use of a Security Monitor node is performed using Loop 4. A CRT-B776 conversation is monitored by a PDP 11/70 to detect an invalid password. The node connected to the PDP 11/70 is commanded such that it does a non-destructive read on packets addressed to the B776. Thus the data sent by the CRT is read by both the B776 and the PDP 11/70. The PDP 11/70 monitors the CRT-B776 conversation. When a bad password is detected, the Security node sends control packets to the nodes directly upstream and downstream from the CRT node to perform loop-around, resulting in the CRT node being removed from the network.

### **Network architecture**

The ESM can be used to study System Control network architectures. Since the logical connectivity of the network is maintained by the modifiable nodal tables, the system can be used to model other network architectures. Network

control problems such as automatic channel reconfiguration can be studied.

#### Response time

Since each loop frequency is independently modifiable, response-time studies can be done on the system. The loop rates are modifiable via switches on the clock generator cards. In addition for Loops 4 and 5, an external clock generator can be connected to drive the loop.

#### Software development

The ESM can be used as a general software development facility. Since each loop-connected terminal can ATTACH to any processor, software can be written on a variety of machines with different operating systems and different language compilers. In addition, since files may be transferred between machines via the network, duplicate copies of files can be kept on different machines. Processors without certain resources (e.g. line printers) can utilize the resources of other machines via the network.

#### APPLICATION TO SYSTEM CONTROL

The ESM Multiloop Network will be used as a DCS System Control Simulation Facility. DCS System Control must accomplish the following functions<sup>7</sup>:

- *Network control*—Transmission and switched network configuration control, which includes network and extension supervision, reconstitution, restoral and satellite configuration control.
- *Traffic control*—Control of traffic routing and traffic flow.

- *Performance assessment* of the DCS and status monitoring of the DCS resources.
- *Technical control*—Includes quality assurance and monitoring, patching, testing, coordinating, restoring and reporting functions necessary for effective technical supervision and control over trunks and circuits traversing or terminating in a facility.

#### ACKNOWLEDGMENT

I wish to acknowledge that this work was supported in part by the Defense Communications Agency under Contracts DCA100-75-C-0054 and DCA100-76-0081. I also wish to acknowledge the contributions of personnel associated with the project at the System Control Group at the Defense Communications Engineering Center and the Advanced Development Organization of the Burroughs Corporation—in particular, the guidance given by D. Schutzer, O. Halpeny, J. Lynch and A. Meyerhoff.

# Software reliability measures applied to system engineering

by JOHN D. MUSA

*Bell Laboratories*  
Whippany, New Jersey

## INTRODUCTION

Boehm, Brown, and Lipow<sup>1</sup> have characterized the multi-dimensional nature of software quality in terms of a hierarchy of attributes. One of the high-level attributes is reliability, which they define qualitatively as the satisfactory performance of intended functions. This definition may be refined to the quantitative statement "probability of failure-free operation in a specified environment for a specified time." A "failure" is an unacceptable departure of program operation from program requirements, where, as in the case of hardware, "unacceptable" must ultimately be defined by the user. The term "fault" will be used to indicate the program defect that causes the failure.

Several trends have recently combined to escalate the importance of quantitative software reliability measures:

1. The large and growing number of real-time and interactive systems has increased the operational and cost impacts of failures.
2. The increasing number, size, and complexity of computer networks and distributed processing systems have multiplied the risk and effects of failure.
3. The explosive growth of personal computing has created a demand for relatively foolproof software for unsophisticated users.

Measurement is seen to be important as soon as one recognizes that in software as in hardware there can be too much as well as too little reliability. Improvement of reliability, of course, costs money, and usually impacts development schedules and system performance (in the case of software, through increased memory, processing time, and peripherals requirements). The system engineer and the manager have to make design tradeoffs among the foregoing factors and it is best that this be done in quantitative terms. The need for a quantitative reliability measure continues throughout the development process, particularly during test, since reliability is a valuable indicator of system status. Finally, reliability or mean-time-to-failure (MTTF) is a useful metric for characterizing system operation and for controlling change during the maintenance phase. This paper will focus on the system engineering application, but it will

also touch on monitoring the system test phase and controlling change during maintenance.

## EXECUTION TIME THEORY OF SOFTWARE RELIABILITY

Software failures are caused by design or coding faults, while the hardware failures dealt with by hardware reliability theory are caused by physical deterioration. However, software and hardware reliabilities are mathematically very similar. Thus they may be manipulated in similar fashion and they may be combined to yield system reliability.

The basic concept of the execution time theory<sup>2,3</sup> is that execution (processor or CPU) time is the best practical measure for characterizing the failure-inducing stress placed on software. Execution time and calendar time can be related because the relationship between the two is characteristically paced at any given time by one of the resources failure identification (test team) personnel, failure correction (debugging) personnel, or computer time.

The execution time theory is based on assumptions that appear to be satisfactorily met by most executable programs and most development projects, assuming that testing is representative of the operational environment and that failures are observed.

A number of fundamental equations relating failures experienced, present MTTF, cumulative execution time, objective MTTF, failures to be experienced to reach the MTTF objective established for the project, and execution and calendar times required to meet the objective have been derived<sup>2</sup> and summarized.<sup>3</sup>

The equations mentioned above depend on four classes of parameters (described in detail in Reference 3, Section VI): program, planned, debug environment, and test environment. The two program parameters, the total failures expected during the maintained life of the software and the mean time to failure at the start of test, can be statistically reestimated (Reference 3, p. 436) as testing progresses.

A portable FORTRAN program<sup>4,5</sup> has been developed to re-estimate the program parameters and compute status quantities significant to the manager. The program requires as input the execution time intervals between failures experienced, the MTTF objective, and the test environment

parameter. The debug environment and planned parameters are required only if it is desired to predict the test completion date.

The program computes confidence intervals for the quantities it estimates. The 75 percent confidence interval has been found to be the most useful; it represents a good compromise between high confidence and a narrow range of estimation. A sample report generated for an actual project is shown in Figure 1. The lower and upper confidence bounds are sandwiched around the "most likely" (maximum likelihood) estimates. Note that "999999" indicates "no upper limit." For the project illustrated on 10/6/77, the most likely present MTTF is 66.7 hr and the 75 percent confidence interval for present MTTF is 36.3 hr or greater. The most likely date on which the 5000 hr MTTF objective will be reached is 11/22/77 and the 75 percent confidence interval for reaching the objective is sometime between now (10/6/77) and 12/23/77.

SYSTEM ENGINEERING

The use of the execution time theory in system engineering can be illustrated by looking at the tradeoffs that can be made between MTTF, cost, and schedules. These tradeoffs are made for the system test phase of the project. It is assumed that MTTF improvement is obtained by more extensive testing, which of course affects costs and schedules. Costs and schedules for other phases are assumed to be constant. This assumption is reasonable; reliability improvement techniques such as structured programming, design reviews, etc. are commonly implemented on a "yes-no" basis dependent on their cost effectiveness. One does not ordinarily trade off the degree to which structured programming is employed with MTTF.

The procedures and formulas used for computing system test duration and cost will be described, since these two computations are central to the system studies to which the execution time theory of software reliability can be applied. An example of a system study will then be presented to suggest some of the kinds of questions that can be answered.

System test duration

Estimates of system test duration (excluding the test planning effort) may be made *before testing begins* as follows. The total inherent faults  $N_0$  is estimated from data on faults per source instruction at the start of system test. The total expected failures  $M_0$  may be equated to  $N_0$  unless the ratio of faults corrected to failures detected departs appreciably from 1 (in this case, a correction must be made—see Reference 3, pp. 447-8). Data taken by the author and by Akiyama<sup>6</sup> and Endres<sup>7</sup> give a range of 3.36 to 7.98 faults per thousand source instructions for assembly language programs at the start of system test; the weighted (by number of instructions) mean is 5.43 faults per thousand instructions. It is likely that these numbers are also applicable to higher-order languages, although the author does not currently have data on this.

The initial MTTF  $T_0$  is estimated from

$$T_0 = \frac{1}{fKN_0} \tag{1}$$

where  $f$  is the linear execution frequency of the program (the average object instruction execution rate divided by the number of object instructions in the program),  $K$  is a fault exposure ratio, and  $N_0$  is the total number of faults in the program. The fault exposure ratio relates fault exposure frequency to "fault velocity." The fault velocity is the rate at which faults in the program would pass by if the program were executed linearly. The fault exposure ratio accounts for:

- Code is not "straight line" but has many loops and branches, except in very trivial cases, and
- The machine state varies, and hence the fault associated with an instruction may or may not be exposed at one particular execution of the instruction.

At present,  $K$  must be determined from a similar program. It may be possible in the future to relate  $K$  to program structure in some way. On six projects for which data is available,  $K$  ranges from  $1.54 \times 10^{-7}$  to  $2.99 \times 10^{-7}$ .

The calendar time interval  $t$  consists of the sum of one to three periods. In each period, a different resource (indicated by the value of the index  $k$ : C—computer time, F—failure correction personnel, I—failure identification personnel) is *limiting* or produces the maximum ratio of calendar time to execution time for that period. Thus the duration of each period is computed separately based on its limiting resource, and then the durations are summed. We have

$$t = \sum_k \frac{\Delta X_k}{P_k \rho_k} \tag{2}$$

where  $\Delta X_k$  is the limiting resource requirement for the *period* (e.g., 100 person days),  $P_k$  is the limiting resource quantity *available* (e.g., 5 persons), and  $\rho_k$  is the limiting resource utilization factor. The resource utilization factor reflects the possibility [particularly for failure correction personnel (see Reference 3, pp. 432-3)] that all of an available resource cannot be usefully employed.

Each resource requirement during its limiting *period* is given by

$$\Delta\chi_k = \theta_k \Delta\tau_k + \mu_k \Delta m_k, \quad (3)$$

where  $\theta_k$  is the resource expenditure per unit execution time,  $\mu_k$  is the resource expenditure per error,  $\Delta\tau_k$  is the execution time interval for the *period*, and  $\Delta m_k$  is the number of failures experienced in the *period*.

The number of failures experienced in the period is given by

$$\Delta m_k = M_0 T_0 \left[ \frac{1}{T_{k_1}} - \frac{1}{T_{k_2}} \right], \quad (4)$$

The execution time interval may be determined from

$$\Delta\tau_k = \frac{M_0 T_0}{C} \ln \frac{T_{k_2}}{T_{k_1}}, \quad (5)$$

where  $C$  is the testing compression factor\* and  $T_{k_1}$  and  $T_{k_2}$  represent the MTTFs at the boundaries of the limiting resource period.

The boundaries of the different resource-limited periods  $T_{k_1}$  and  $T_{k_2}$  are the present and objective MTTFs and the transition points

$$T_{kk'} = \frac{C(P_k \mu_{k'} \rho_k - P_{k'} \mu_k \rho_{k'})}{P_{k'} \rho_{k'} \theta_{k'} - P_k \rho_k \theta_k}, \quad (6)$$

that lie within that range, where  $(k, k')$  have the values  $(C, F)$ ,  $(F, I)$ , and  $(I, C)$ . One must determine which resource-limited periods actually occur from an examination of the boundaries and a determination of the maximum calendar time/execution time ratio for each period. The maximum calendar time/execution time ratio for each period is given by

$$\left. \frac{dt}{d\tau} \right|_{\max} = \max \left[ \frac{\theta_k T + C \mu_k}{P_k \rho_k T} \right], \quad (7)$$

where  $T$  is any MTTF in the range  $[T_{k_1}, T_{k_2}]$ .

#### System test cost

Estimates of system test cost are made as follows. Determine the number of failures

$$m = M_0 \left( 1 - \frac{T_0}{T_F} \right) \quad (8)$$

that must be experienced and the associated execution time

$$\tau = \frac{M_0 T_0}{C} \ln \left( \frac{T_F}{T_0} \right) \quad (9)$$

\* The testing compression factor  $C$  depends on the test environment and its relationship to the actual operating environment of the program. More specifically, its value is related to the extent to which redundancy due to runs being made under identical conditions during the operation of the program is removed during the test phase. There is some indication that  $C$  is reasonably stable across similar test environments, but data from more projects is needed to verify this. The quantity  $C$  may be computed for a project after a sufficient period of operation has occurred following the test phase so that the operational phase initial MTTF can be accurately estimated. If there is no good way of estimating  $C$  for a particular project, it is probably best to be conservative and take  $C=1$ .

to increase the MTTF from  $T_0$  to the MTTF objective  $T_F$ . Each of the three *total* resource expenditures  $\chi_j$  is given by

$$\chi_j = \theta_j \tau + \mu_j m, \quad (10)$$

where  $j$  has the values  $C, F$ , and  $I$ . The  $\chi_j$  are multiplied by cost rates and the results totaled to yield overall cost.

The foregoing approach implicitly assumes that idle time for all resources during the project can be profitably employed in other activities and should not be charged as a cost. If this is not true for any resource, the cost for that resource should be determined by multiplying  $t$  from (2) by the total number of personnel (or dedicated computers) and the resource rate.

#### Sensitivity of results to parameter accuracy

The reader may be concerned about the accuracy with which parameters on a particular project can be estimated. If this is a problem, one should note that inaccuracies usually affect absolute rather than relative values. Many and perhaps most system engineering decisions are concerned with relative values of alternatives. In any case, calculations can be performed with different values of a parameter to determine the sensitivity of a decision to a parameter inaccuracy. As experience is gained and more data is available, it should be possible to determine parameters more accurately and hence improve the *absolute* accuracy with which costs, schedules, etc. can be estimated.

#### Example

Consider a cost optimization problem to illustrate the application of the foregoing concepts. An online system is being planned to process orders received by a business, generate bills, break down the work involved into tasks and write work orders on those tasks, order materials, etc. It is desired to establish the mean-time-to-failure (MTTF) objective for the system that will minimize total system cost over an estimated lifetime of two years. Faults are not to be corrected in the field for this system; they will be fixed at the next release. Assume for simplicity that the hardware components of the system are much more reliable than the software and hence may be neglected in this analysis. Also, for simplicity, assume that the entire system test period is failure-correction-personnel limited. The system is expected to operate 250 days/yr, 8 hr/day. The average total cost impact of a failure (in terms of reduced efficiency, extra supervisory time and other work required to "straighten out the mess," etc.) is \$10,000. The software consists of 100,000 source (400,000 object) instructions. Programmer loaded salary is \$30/hr and computer (CPU) time is \$1000/hr. The system test team has eight members and there are 40 program designers available for debugging. The utilization factor for failure correction personnel is 0.138 (computed from Reference 3, Equation (10), using a probability of 0.9 and a queue length of 3). Average instruction execution rate is one million instructions per second. On similar projects, a value

of fault exposure ratio  $K=2.4 \times 10^{-7}$  has been experienced and the average fault rate has been 6.25 faults per thousand instructions. Data taken in similar environments indicates that six person hours are required for failure correction per failure and that this effort is independent of amount of execution time. Similarly, four person hours of system test team effort and one hour of chargeable computer time are required per hour of execution time and two person hours of system test team effort and one-half hour of computer time are required per failure. Assume a testing compression factor  $C$  of one.

We compute a value of  $M_o=N_o=625$ , using the program size and average fault rate. The linear execution frequency, determined by dividing object instruction execution rate by number of object instructions is  $2.5 \text{ sec}^{-1}$  or  $9000 \text{ hr}^{-1}$ . Hence from (1) we obtain  $T_o=0.741 \text{ hr}$ . Using (8) and (9) we find

$$m=625 - \frac{463}{T_F} \quad (11)$$

and

$$\tau=463 \ln \frac{T_F}{0.741}. \quad (12)$$

Substituting the resource expenditure rates and (11) and (12) in (10) for each resource we obtain

$$\chi_c=313 - \frac{232}{T_F} + 463 \ln \frac{T_F}{0.741}, \quad (13)$$

$$\chi_f=3750 - \frac{2778}{T_F}, \quad \text{and} \quad (14)$$

$$\chi_i=1250 - \frac{926}{T_F} + 1852 \ln \frac{T_F}{0.741}. \quad (15)$$

The cost of system test will be

$$\begin{aligned} \$1000 \chi_c + \$30(\chi_f + \chi_i) &= \$463,000 - \frac{\$343,000}{T_F} \\ &+ \$519,000 \ln \frac{T_F}{0.741}. \end{aligned} \quad (16)$$

The number of failures during operation will be the total operating lifetime divided by MTTF, or  $\frac{4000}{T_F}$ . Hence the cost of failures will be  $\frac{\$40,000,000}{T_F}$ . The expression for the sum of these costs,

$$\$463,000 + \frac{\$39,700,000}{T_F} + \$519,000 \ln \frac{T_F}{0.741}, \quad (17)$$

is of the form

$$a + \frac{b}{T_F} + c \ln \frac{T_F}{T_o}. \quad (18)$$

A simple minimization using calculus yields

$$T_{F|MIN} = \frac{b}{c}. \quad (19)$$

Thus we obtain a value of 76.5 hr for the MTTF objective

that minimizes system life cycle costs. The cost of system test and operational failures for this value is \$3,389,000

To determine the duration of system test, note that since there is only one limiting resource period, (2) becomes

$$t = \frac{\chi_f}{P_F \rho_F}, \quad (20)$$

where  $\chi_f$  is the resource expenditure for the entire system test period and is given by (10). Hence, using (14) in (20), along with the number of failure correction personnel and their utilization factor, we obtain

$$t=679 - \frac{503}{T_F}. \quad (21)$$

At the minimum cost point, the system test period will require 672 hr or 84 eight-hr days.

Sensitivity analyses can be conducted for each of the quantities involved in the calculation. For example, let  $K$  be  $1.6 \times 10^{-7}$  rather than  $2.4 \times 10^{-7}$ . Repeating the calculations outlined above yields a value of 50.8 hr for the MTTF objective that minimizes system life cycle costs.

Another useful technique is to vary parameters that are under the control of the manager to determine the effects on schedules and costs. For example, suppose that the length of the system test period is unsatisfactory. Let us examine the effect of staffing with 60 rather than 40 programmers for debugging. This will reduce the failure correction personnel utilization factor to 0.121 (from Reference 3, Equation (10), using a probability of 0.9 and a queue length of 3). Equation (21) now becomes

$$t=517 - \frac{383}{T_F}. \quad (22)$$

The costs will remain unchanged, since the total resource expenditure required to reach a given MTTF remains the same. Thus minimum cost will still occur at the same value of  $T_F$ . However, the *time* required for system test is reduced to 512 hr (64 days).

The reader might suggest increasing the debugging staff still further to improve schedules. In actuality, possible improvement is restricted. We have oversimplified the example for explanatory purposes by dealing with only one limiting resource period. The other periods would come into play and limit further reduction in system test duration.

The reliability of the software for one day (eight hours of operation), assuming the MTTF objective of 76.5 hr is attained, is given by

$$R = \exp\left(-\frac{\tau}{T}\right) = 0.90, \quad (23)$$

where  $\tau$  is the period of operation and  $T$  is the MTTF. This figure can be combined with reliabilities of hardware components to give overall system reliability (Reference 3, pp. 439-442).

## MONITORING TEST PROGRESS AND RE-ENGINEERING THE SYSTEM

Recall that status estimates like those shown in Figure 1 can be obtained throughout the system test period. One can therefore continually track present MTTF and its confidence bounds. The number of failures, execution time, and calendar time required to reach the MTTF objective are also computed. By use of (10) and cost rates, remaining system test cost can be computed. The estimates are usually better than those made before test, and they generally improve in quality as testing proceeds.

The effects of changing the MTTF objective or various resources can be investigated if schedule or costs are unsatisfactory.<sup>8</sup> Consequently the manager can not only determine the present status of his system test effort in terms of a parameter (MTTF) directly related to operational requirements, but he can explore alternatives for accomplishing his objective or the effects of altering it. Thus the techniques we have discussed can be decision-making aids.<sup>8</sup> Many of the decisions represent a system re-engineering.

A plot of MTTF history for an actual project is given in Figure 2. The dot-dashed center curve is the maximum likelihood estimate and the solid outer curves delineate the bounds of the 75 percent confidence interval. Note the general upward progress with some downward swings. Although there may be some statistical variation, the downward swings have usually been found to be correlated with

Figure 2—Present MTTF history for Project 1.

design changes or the introduction of new code. The present MTTF is very sensitive to remaining errors when only a few remain; hence its upper confidence limit can be noisy.

## SOFTWARE MAINTENANCE

Failures continue to occur (and usually, be corrected) for virtually all software systems of any size during the operational phase. They may occur at increasing intervals, but in many cases, the MTTF of a system exhibits a general stability about some value over the long term, although there are many swings about this value. This behavior is generally due to the periodic installation of design changes (with a resultant drop in MTTF) followed by periods of error removal, during which the MTTF improves. It is particularly true of operating systems and other software provided in computation centers;<sup>9</sup> this is illustrated in Figure 3.

If the MTTF can be tracked and plotted as illustrated and if service objectives can be set for the system, a quantitatively-based mechanism for change control can be established. When MTTF falls below the service objective, the system is frozen until improvement occurs. The manager may use the amount of margin above the service objective as a guide to the size of the change he will permit at any given time.

Figure 3—Typical computation center software in operational phase.

## CONCLUSIONS

The theory outlined in this paper has proved to be a good framework for understanding, measuring, and predicting the reliability of computer programs. It constitutes an approach that is compatible with hardware reliability theory as to combination of components and thus permits reliability analysis of hardware-software systems. The theory has been applied to several software development projects of different kinds and several operational systems.<sup>3-9</sup> Substantial experience has been gained in its use. It can be used in system engineering, test monitoring, and change control of operational software. As more data is collected from various projects, it should be possible to improve the estimates of some of the parameters, due to added insight into how they vary with program environment factors. This would result in further improvement in the estimation of status quantities, particularly completion date. Experience in application of the theory should lead to its further refinement and broadening, resulting in greater accuracy and wider utility.

## ACKNOWLEDGMENT

The author is indebted to R. E. Archer, Jr., D. T. Chai, J. P. Collins, and T. R. Peters for their helpful comments and suggestions.

# Verification procedures supporting software systems development

by GRUIA-CATALIN ROMAN

Washington University  
St. Louis, Missouri

## INTRODUCTION

Particularly in the context of large software systems, prevention and early detection of errors during product development are critical factors in controlling cost and quality. Top-down design, structured programming, informal program verifications, and code inspection are some of the tools presently being used in order to reduce the probability of error. However, current methodologies fail to provide a systematic, comprehensive and well formalized error-detection strategy. In response to this need, a new software development methodology is proposed. The approach, described in the next section, incorporates a cohesive set of verification procedures that enables the validation of each development stage, from requirements definition through individual program implementation. The description of the verification procedures is part of the third section, while the fourth section deals with some managerial aspects related to the practical implementation of the advocated techniques in an industrial environment. A summary and conclusions are presented in the fifth section.

The approach described in this paper has already been adopted as standard practice by the MIS Department of the Monsanto Company of Saint Louis with the anticipation of considerable savings in software development and maintenance costs. Preliminary data already indicate widespread acceptance and significant qualitative improvements. However, quantitative data that would allow for a complete evaluation of the methodology will not be available for quite a while due to the considerable development time required by most systems currently being built at Monsanto. A detailed evaluation of the sociologic and economic impact of the method will be made public at a later date.

## THE METHODOLOGY

The development of a software system typically has five stages:

- Requirements definition
- System architecture design
- Program design

- Program implementation and testing
- System integration and testing

The high level of convergence on the basic issues is reflected in a wide variety of approaches. Differences in managerial procedures, company standards, specification techniques, and design strategies make each methodology unique (e.g., References 6, 8, 10 and 11). The methodology proposed here distinguishes itself by the strong emphasis it places on verifiability, not on originality of design and specification techniques, which are described in the remainder of this section. The verification procedures will be presented separately in the next section.

The *requirements definition* stage establishes what functions are to be implemented by the target system. The functions reflect the user's needs and are the basis for the implementation. The requirements definition stage consists of a data-gathering phase (interviews with the user), a synthesis phase (formulation of a functional model) and an evaluation phase (study of feasibility, profits, user environment impact, resources, scheduling, etc.). The functional model supports the design process by providing a complete, precise, relevant and easy-to-access description of the problem at hand. Elements that relate to possible implementations rather than the problem description ought not to be included.

The formalism chosen to specify the functional model is a set of top-down functional diagrams. Each diagram, whose graphic symbols are explained in Figure 1, results from the decomposition of a single function present on an immediately higher level of abstraction. The "permanent record" symbol is used to indicate explicitly the memorization function while "external input" signifies an interaction with the outside environment. The only interdependence that can be expressed between functions is the relation "function F1 provides information I12 to function F2." It was found that this particular relation is the only relevant one since it suffices both for the purpose of designing the system and for establishing its correctness. Figure 2 contains a sample functional model. Although an English narrative is required to accompany each diagram and to explain its items in order, the narrative was omitted for the sake of brevity.

It is usually necessary to break down complex functional models into several parts describing related subsystems. The

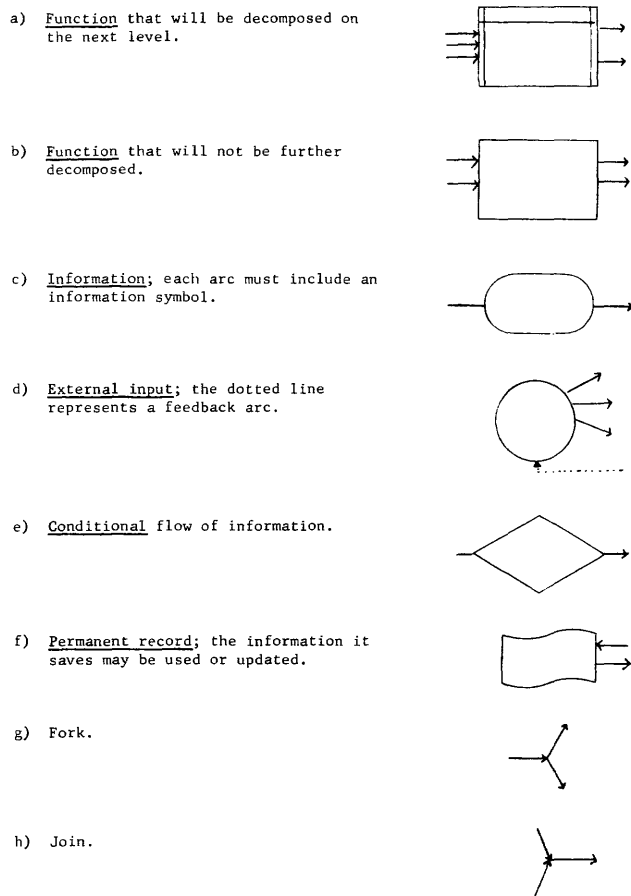

Figure 1—Functional diagrams symbolism.

criteria listed below can assist in the selection of groups of functions that are to establish the requirements for each subsystem:

- Parts of the functional model that are independent, having no connections, could represent separate subsystems.
- Functions that must be present concurrently on-line or satisfy other temporal and spacial relations should be part of the same subsystem.
- Logically-related functions should be associated together.
- Subsystems that are too large are difficult and costly to develop, while those that are too small may be wasteful.
- Few, simple and stable interfaces between subsystems assure a better chance for success.
- The selection of subsystems should assure that the potential new links between functions (due to changes in specifications) either are confined to one subsystem at a time or may be achieved by a minimum number of changes in, preferably, one interface.

The list given above is by no means complete. Furthermore, caution needs to be exercised in achieving a proper tradeoff among conflicting criteria.

During the *system architecture design* stage, programs, flow of control, input-output devices, and relations between programs and data are identified. The system architecture specifies the manner in which the functions considered in the requirements definition stage are to be implemented. Top-down stepwise refinement was selected in order to generate a set of top-down *flow diagrams* expressing the system architecture. The building blocks for the flow diagrams are shown in Figure 3, and examples of flow diagrams are provided in Figure 4. The flow diagrams and the narrative that is required to accompany them cannot completely specify the system architecture; a detailed design of the data structures needs to be included as a separate document. The relation between functional and flow diagrams will be identified better in the section to come; however, it must be pointed out that the top-down nature and labeling conventions of the functional diagrams assure quick access to requirements information, which is critical for a fast and error-free design of the system. As the need for more detailed flow diagrams arises during design, additional decomposition of the functional diagrams has to be carried out based on new interview data.

It is necessary to split the development of large and complex systems into several stages which can be implemented serially or in parallel. (The method is highly advisable for smaller systems as well.) There are two basic ways to carry out this multi-staged development:

1. *Parallel development* (also called system modularization). Parallel development is advisable primarily when working on a very tight timetable and should not be overused. The approach consists of dividing the system into several subsystems which are then developed in parallel. The key to success is to assure minimal need for communication and coordination between teams working on different subsystems. Therefore, in selecting the various subsystems one should assure that:

- The subsystems have very few interfaces.
- The interfaces are simple in nature and unlikely to change.
- The subsystems are conceptually independent and can be independently tested.

2. *Iterative development or system growth*. A more effective and safer approach to constructing large systems is the iterative method. This technique consists of developing an initial incomplete system which is later augmented by incorporating new features. Selecting the initial system, called the core, is the critical aspect of this method. Here are the basic guidelines to be used in choosing the core system:

- The core system must be general and highly flexible.
- The core system should allow for extensive growth at very low cost.
- Additions should not change the core (they may expand it) and should not affect its functions.

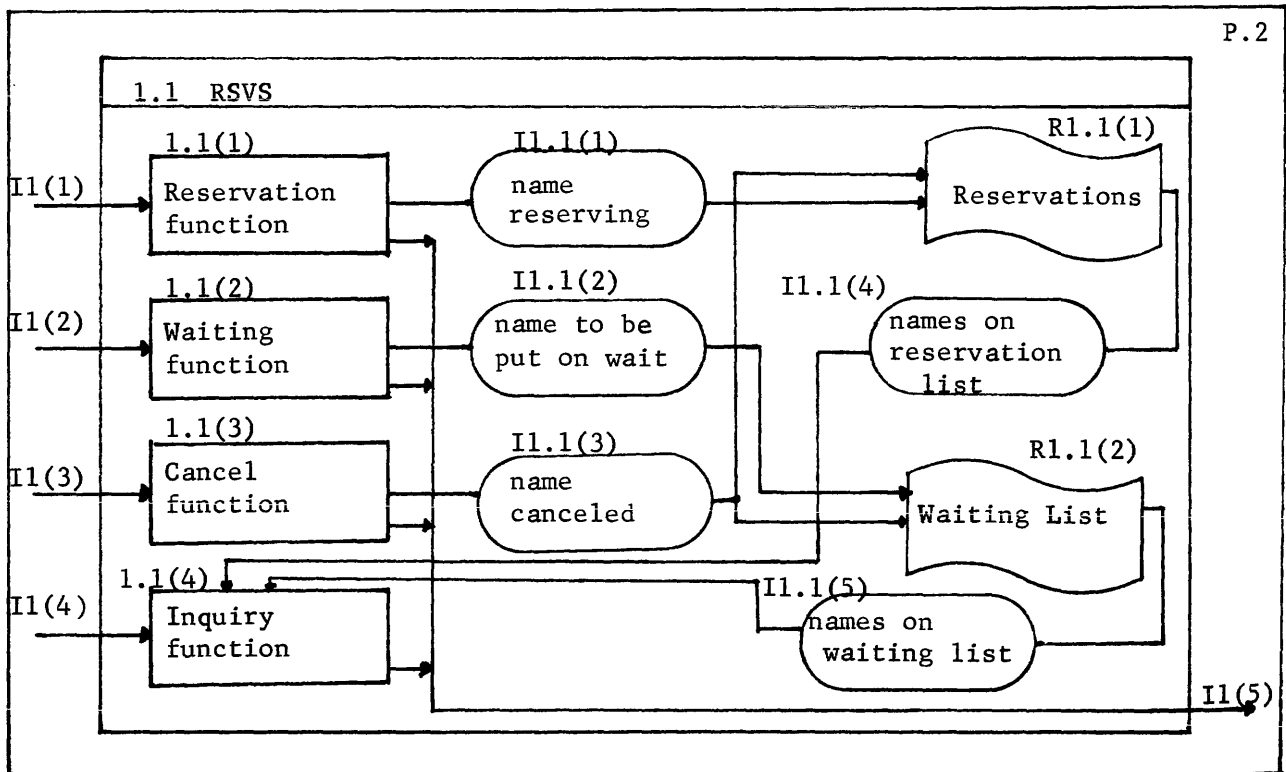

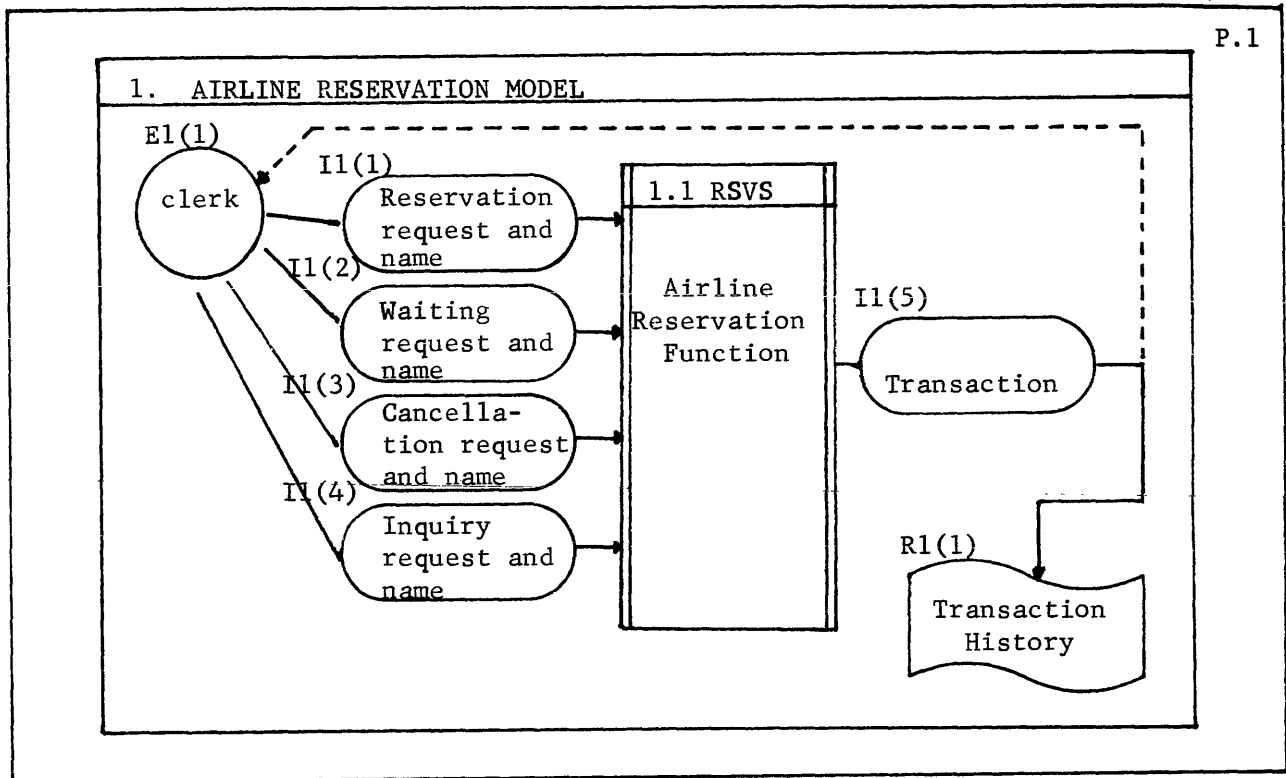

Figure 2—Requirements definition (function diagrams).

a) System component that needs to be further decomposed.

b) Program (will not be decomposed any further).

c) Devices (scope, card-reader, printer, tape, disk, etc.).

d) Human decision or clock signal enabling a certain flow of control.

e) Flow of control.

f) Program call.

Figure 3—Flow diagrams symbolism.

- The growth should not severely impact the performance of the system.
- Growth should be achieved primarily by creating or implementing new *outgoing* interfaces.
- The number of "not yet implemented" incoming interfaces should be minimal.
- The core system should implement several key func-

tions which would allow for its early installation and/or convincing demonstrations.

When the *program design* stage is entered, the various programs that make up the system have already been identified and the detailed design of their inputs and outputs has been completed. During this stage the selection of the major

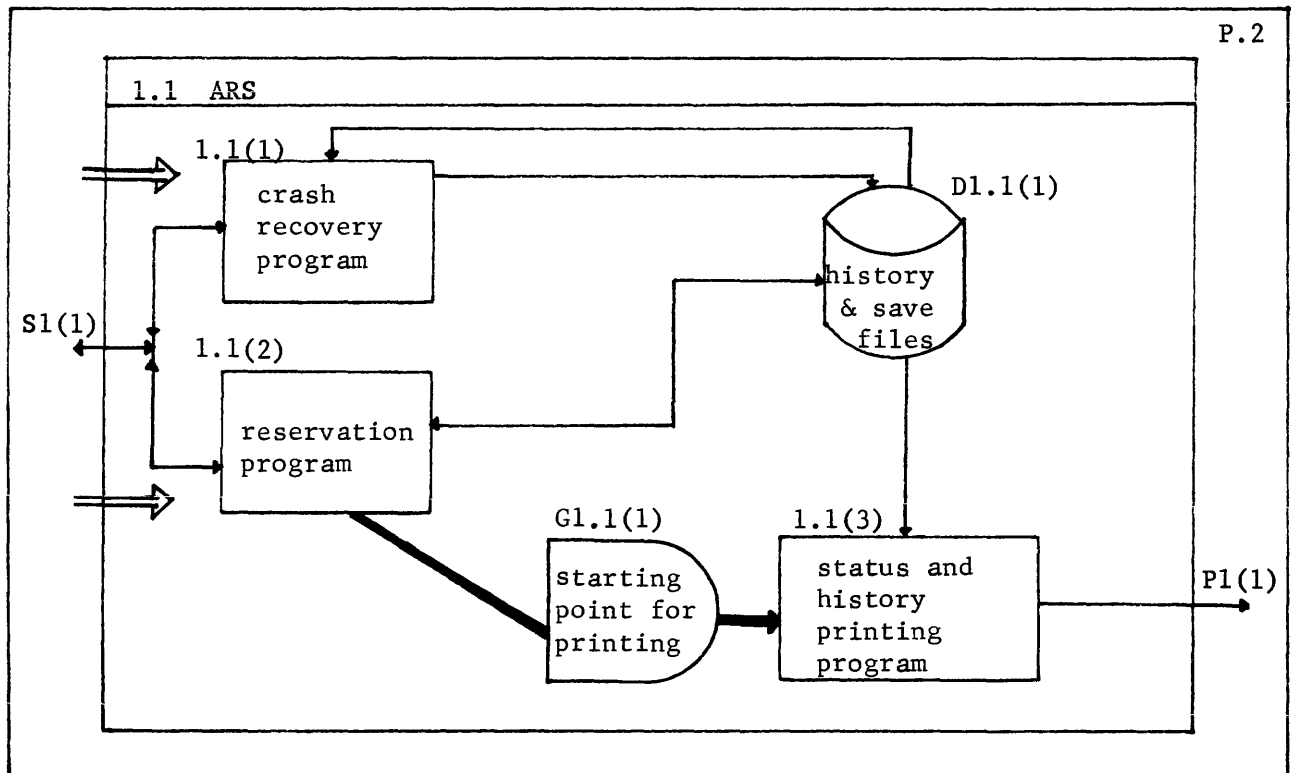

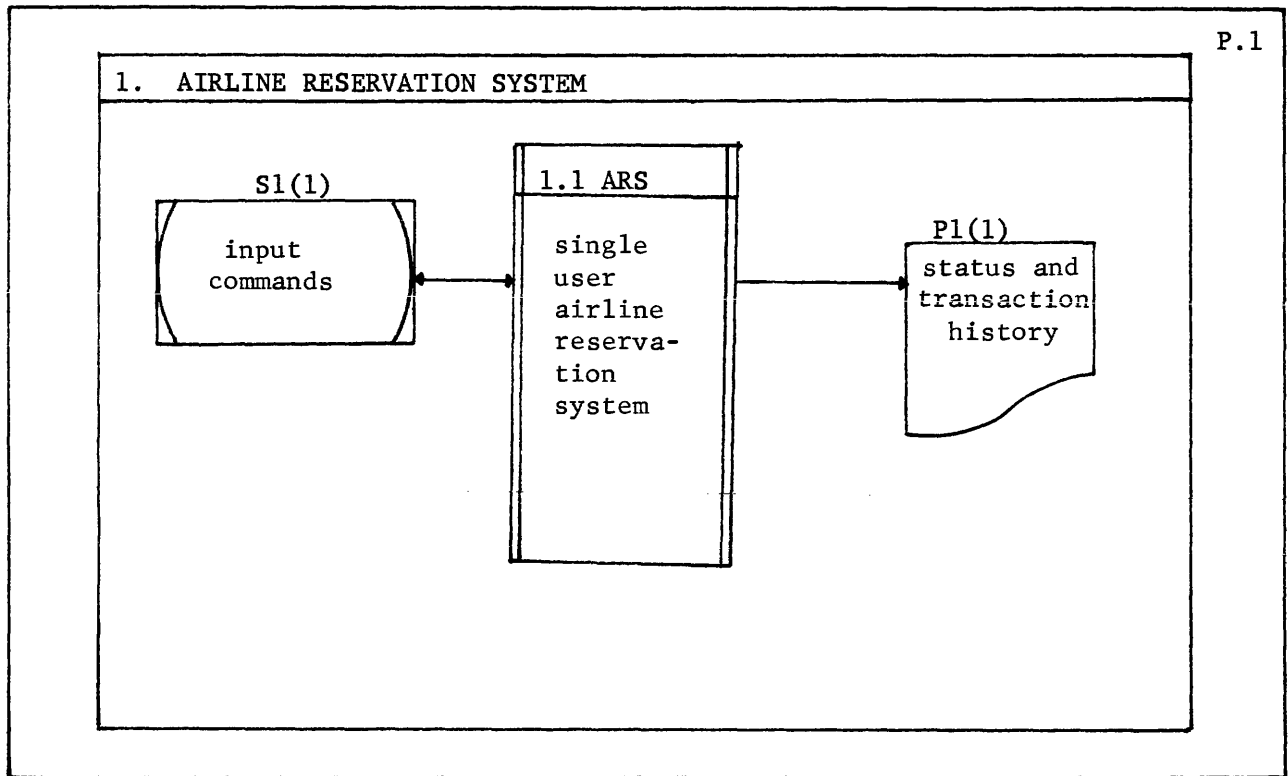

Figure 4—System architecture (flow diagram).

PROGRAM NAME: 1.1(2) RESERVE

MODULE NAME: 1. CONTROL

REMARKS: This is the top module of program RESERVE and is strictly an initialization and driver module.

ACCESS: COMMAND, WAITLIST, RSVLIST. (These data structures are initialized here.)

KEYWORDS: None.

INPUT ASSERTION: COMMAND, WAITLIST, AND RSVLIST are initially empty. The file "SAVE" indicates which names have reservations and which ones are waiting. The "HISTORY" file is empty.

Load WAITLIST and RSVLIST from the "SAVE" file.

ASSERTION: WAITLIST and RSVLIST have been restored to their last known values.

DO

Read next command into COMMAND and put it on the "HISTORY" file.

CASE

<u>WHEN</u> (print command)	<u>INVOKE</u> (1.1(3) PRINT).
<u>WHEN</u> (reserve command)	<u>CALL</u> (1.1) RSV to put name in RSVLIST.
<u>WHEN</u> (wait command)	<u>CALL</u> (1.2) WAIT to put name in WAITLIST.
<u>WHEN</u> (cancel command)	<u>CALL</u> (1.3) CANCEL to remove name from RSVLIST and WAITLIST.
<u>WHEN</u> (save command)	<u>CALL</u> (1.4) SAVE to save current RSVLIST and WAITLIST.
<u>WHEN</u> (inquire command)	<u>CALL</u> (1.5) INQ to print status of the name.
<u>WHEN</u> (halt command)	<u>BREAK</u>
<u>WHEN</u> ( )	print error--command not recognized.

ENDCASE

ASSERTION: A single command was fully processed.

OD

ASSERTION: A halt command was detected.

CALL(1.4) SAVE to save the current RSVLIST and WAITLIST in file "SAVE" and to clear "HISTORY."

OUTPUT ASSERTION: The last state of the reservation and waiting lists has been saved on the "SAVE" file. The "HISTORY" file is empty.

Figure 5—Program design (pseudocode).

program data structures and the algorithms that act upon them takes place. The program design is done top-down following generally accepted structured programming practices. Pseudocode is used to formalize the flow of control. The data structures are described separately. A program is made up of several program modules or subroutines hier-

archically organized. The entry and exit points of each program module must include input and output assertions showing what is assumed to be true at the beginning of, and what should be true upon return from, the module. The assertions are important not only in understanding the algorithms but also in the process of establishing the correctness of the

design. For example, the reader is directed to Figure 5 which shows the design for the top module of a program identified in Figure 4.

*Program implementation and testing* is perceived as a single process that is carried out top-down in the tradition of structured programming. The program design is used as the basis for implementation and testing. If the program was carefully designed, if a good set of implementation standards was selected, and if the design was shown to be correct, then the actual implementation and testing should require little effort.

In its final form the program should exactly mirror the program design. One should be able to identify clearly the modules and the various levels of the top-down design. Each module should *at all times* be consistent with its design specifications. If, when coding, the need for changes in the design becomes apparent, the design should be altered and reverified. Only then should one proceed to recode or modify the module. Upon coding each module, one should verify that the module is in agreement with all implementation standards, and its correctness should be established by mental simulation before any testing takes place.

The *system integration* stage will not be discussed here as it is outside the scope of this paper.

## VERIFICATION PROCEDURES

In the context of the methodology presented above, the term "verification" needs to be understood as meaning nothing more than a convincing demonstration that a certain formalization describes, implements, or computes the subject of that formalization, e.g., the agreement between the functional model and the user's needs. One would want to prove that the formalization is correct but, since such an approach is unrealistic at the present time, informal methods need to be used instead. The immediate objectives of the verification are to provide guidelines for the various stages of the development and to allow for effective and systematic reviews at preselected checkpoints. Ultimately, these procedures establish a unique design and error detection strategy capable of significant impact upon the overall system development productivity. This being the case, some methodological details that have been omitted in the previous section will become apparent as the verification techniques are discussed.

The number of checkpoints that one selects depends upon the personnel and the project involved. Nevertheless, there are four checkpoints that need be considered every time: (a) after the requirements definition is completed, (b) when the system architecture is entirely selected, (c) when the program design is finished, and last, (d) when the program is fully implemented. More checkpoints may be added in between, if the size of the project makes them necessary, without modification of the verification techniques. At every checkpoint one must verify that the formalization produced thus far is self-consistent and in accordance with the standards. Furthermore, one needs to establish the consistency between the formalization being reviewed (e.g., flow dia-

grams) and the formalization that preceded it (e.g., functional diagrams) which, in part, describes the correctness criteria. Let us next discuss each checkpoint in detail.

- **Requirements Definition Checkpoint**—At this checkpoint the verification is carried out in three distinct steps. First, the self-consistency of the functional diagrams is checked. This step includes both syntactic (form) and semantic (content) analysis. Second, one must verify the fact that the functional diagrams indeed correctly reflect the analyst's understanding of the business environment which is being modeled. Last, it is necessary to assure that the model meets the customer's approval.

**Self-consistency check**—It proceeds top-down starting at the root of the tree formed by the functional diagrams.

1. Start with the top level functional diagram.
2. Make sure that:
  - a. The diagram is syntactically correct.
  - b. One single function appears in the top diagram, call it  $F_o$ .
  - c. All external inputs to the model are present and necessary.
  - d. All externally visible permanent records generated by the model are present and necessary.
  - e. Given the information available on the incoming arcs, the function  $F_o$  can generate the information described on the outgoing arcs.
  - f. All information coming in from the external inputs is necessary.
3. Move one level down.
4. Consider the next not yet verified diagram on the current level. (Assume that (1) the diagram contains functions  $F_i$  with incoming information  $IN_{ip}$  and outgoing information  $OUT_{iq}$  and (2) the diagram is a refinement of the function  $F_k$  whose incoming and outgoing information are referred to as  $IN_{km}$  and  $OUT_{kn}$ , respectively.)
5. Make sure that:
  - a. The diagram is syntactically correct and its incoming and outgoing information are in agreement with the description of the function  $F_k$  which is being refined.
  - b. Given the corresponding incoming information, each function  $F_i$  can generate the corresponding outgoing information.
  - c. The information provided for each function  $F_i$  is indeed necessary.
  - d. Each permanent record introduced in the current diagram contains the information that will be required from it and nothing else.
  - e. The current diagram is correct with respect to  $F_k$ , i.e., it is a correct refinement of the function  $F_k$ .
6. If there is a not yet verified diagram on this level, go to 4.
7. If there is a next level, go to 3.

**Completeness and accuracy check**—The functional diagrams are constructed based upon the information that has been obtained from the user or customer during re-

peated interviewing sessions. Therefore, it is important to determine the fact that all that information, to the extent to which it can be incorporated into the functional diagrams, was included. This may be verified by selecting, one by one, the functions identified during the interviews and searching for their presence in the flow diagrams—the top-down organization considerably reduces the search effort.

**User agreement**—Regardless of the correctness of the requirements definition, its value is limited unless the user's agreement is secured. Since the user may not be sophisticated enough to follow and understand the functional diagrams, a simplified document, verified to be fully consistent with the functional diagrams, may need to be created and passed on to the user for approval.

- *Case Study for the Reader.*—Let us consider a user that needs a small airline reservation system. From interviews it becomes apparent that the system is to be accessed by a single reservation clerk that can make reservations, put passengers on "wait," cancel their names from the reservation or waiting list, and request information about either one of the two lists. Furthermore, the user specifies that a written record of all transactions needs to be saved. Based upon all these data the functional diagrams of Figure 2 may be conceived. As a simple exercise, the reader may want to verify the functional diagrams by employing the first two verification procedures.

Consider, for instance, Step 2 of the first procedure:

- a. Diagram 1 is correctly constructed (standard symbols are used, on each arc there is an information box, etc.).
- b. The diagram contains a single function, RSVS.
- c. A single external input was specified by the user, the reservation clerk.
- d. The only visible permanent record is the transaction history. The reservation and waiting lists are internal to the RSVS function and need not be introduced yet.
- e. Trivial.
- f. All information coming in is necessary, e.g., reservation request and name to be entered on the reservation list are needed in order to reserve.

Similarly, Step 5 of the first procedure may be used to verify Diagram 1.1.

In carrying out the second procedure, one establishes the "coverage" relation between the interview data and the functional diagrams: each function identified in the interviews is covered by a subset of the functional diagrams. For instance, the canceling function is covered by function 1.1(3) from Diagram 1.1 (in conjunction with the information boxes I1(3), I1.1(3) and I1(5)). In general, the coverage relation is not necessarily one to one, but the verification is easier if that is the case.

- *System Architecture Checkpoint*—The system architec-

ture poses for the designer a much more complex and varied set of problems. While the requirements definition involved mostly the formalization of amorphous information, the conception of the system architecture is a complex creative process which must result in a product that possesses a large set of attributes, often in conflict with each other. The result is a more complex set of verification procedures, each reflecting the concern with specific system architecture viewpoints. Thus, besides establishing self-consistency, correctness with respect to the requirements definition and user approval, one must also evaluate the system architecture from the point of view of fault tolerance, hardware compatibility and anticipated performance. However, discussion will be restricted to self-consistency and correctness, which form the main subject of this paper.

#### Self-consistency check.

1. Start with the top-level diagram.
2. Make sure that:
  - a. Only one system component is included.
  - b. Each external input from the top functional diagram is covered by one or more devices.
  - c. Each permanent record present in the top functional diagram is covered by some storage or output device.
  - d. Any other files present in the diagram (preferably on the lower side) are created and used by the system component and are important enough as to be identified at the top level.
  - e. All inputs are necessary.
  - f. All outputs are required and can be produced from the available inputs.

(NOTE: This step assures that the top-level flow diagram covers the top-level functional diagram. This relation is not necessarily true for any subsequent levels.)
3. Move one level down.
4. Consider the next not-yet-verified flow diagram from the current level. (Assume that the diagram contains the system components  $C_i$  with the inputs  $INPUT_{ip}$  and outputs  $OUTPUT_{iq}$  and is a refinement of component  $C_k$  with inputs  $INPUT_{km}$  and outputs  $OUTPUT_{kn}$ .)
5. Make sure that:
  - a. The diagram is syntactically correct and its inputs and outputs are in agreement with the description of the component  $C_k$  which is being refined.
  - b. Given its inputs, each component  $C_i$  can compute its outputs.
  - c. No unnecessary inputs are provided.
  - d. Each file is created by some component and the data is all there before being used.
  - e. There are no unwanted loops in the flow of control.
  - f. Each component that is marked as not being further decomposed can be implemented as a single program, (based on previous experience with problems of similar complexity).
  - g. Every arc that indicates a call has associated with it a description of the global data being shared between the two programs.

- h. The diagram faithfully implements  $C_k$ .
- 6. If there is a not yet verified diagram on this level, go to 4.
- 7. If there is a next level, go to 3.

**Correctness check**—The system architecture is correct if it implements the model defined by the functional diagrams. The verification procedure will determine the coverage relation, thus indicating what was left out as unimplemented.

1. Show that all external inputs are covered by some input devices.
2. Show that each permanent record is covered by output devices, one or more files, or by being internal to some program.
3. Show that each function, regardless of its position in the functional diagrams, is covered.
4. Show that all key relationships between functions are preserved by the system architecture.
  - *Case Study for the Reader*—Figure 4 does not provide enough information so as to allow for a conclusive verification of the self-consistency and correctness of the system architecture. The missing data is to be found in the narrative that must accompany each diagram and explain each item in the diagram, and in the detailed design of program interfaces (D1.1(1) and G1.1(1)). The relatively simple nature of the system described in Figure 4 allows the reader to supply the missing details. It may also be an interesting exercise to see under which assumptions the verification is successful and when it is not.

However, before going any further, some interesting facts should be pointed out. First, when trying to establish the correctness of the system, the coverage relation is bound to point out that the crash recovery program does not cover any function appearing in the functional diagrams. The justification for introducing that program is not in the problem being solved but in the means by which it is solved, the architecture. If the program had not been included, the fault-tolerance studies would have signaled the fragility of the system. Secondly, the reservation program covers more than one function, actually four, and also two permanent records. Such complicated coverage relations are by no means unusual and further point out the great distinction between functional and flow diagrams.

Lastly, let us observe more closely the connection between self-consistency and correctness. Self-consistency is a conclusive demonstration of the fact that the architecture is a viable one, could be actually implemented, and carries out the basic intent expressed in the top level functional diagram, but is not necessarily a true realization of the requirements definition. In contrast, the correctness check tries to identify the level to which the intent of the requirements definition is reproduced under the assumption of self-consistency. Therefore, one can see that self-consistency is only a stepping stone, a weaker condition to be verified first.

- *Program Design Checkpoint*—It is intended that the program design checkpoint determines the correctness

of the program before the actual coding is started. The detailed design of its interfaces (accomplished during the system architecture design) in combination with a program abstract that indicates the input/output relation represent the criteria against which the program design is to be judged. The presence of assertions facilitates the verification and helps in the understanding. However, the informal (and incomplete) nature of the assertions prohibits one from carrying out a formal proof of correctness. Therefore, as in previous steps, the procedure employed is informal and does not represent any guarantee that all errors have been eliminated.

The verification ought to establish that:

1. The program design paper is in agreement with the program design standards (the pseudocode is correctly used, the format and organization standard, the level of detail adequate, etc.)
2. The data structures have been designed properly.
3. Each program module is correct with respect to its input and output assertions.
4. The interfaces between program modules have been correctly designed and provide all the data required by each module. Also, there is agreement in the communication signals.
5. The program always terminates (if termination is desired).
6. The proper relation between inputs and outputs is achieved.
7. Adequate performance is to be anticipated.
8. The overall design will result in a maintainable program.
- *Implementation Checkpoint*—In the verification scheme proposed here, the last check takes place at the time when the program is being coded and tested. This code inspection (the term seems to have caught on lately) is designed to investigate four distinct problems:
  1. Compliance with the implementation standards.
  2. Consistency between the code and the design paper.
  3. Correctness of data structures implementation.
  4. Reevaluation of the correctness problem to a new level of detail.
  5. Proper trade-off between efficiency and maintainability.

Particular mention needs to be made of the fact that the process of establishing program correctness could benefit significantly from already available theoretical results. While it is doubtful that the average programmer could be asked to formally verify his product, informal use of formal techniques is bound to prove itself highly effective. Furthermore, informal correctness proving should not be very difficult to teach.

## IMPLEMENTING THE VERIFICATION PROCEDURES

The existence of a well defined and systematic set of verification procedures plays a fundamental role not only in

the discovery of errors but also in the avoidance of them in the first place. The verification may be conceived of as more than a post-factum investigation, which has its own merits. It may be carried out as an integral part of the design itself. Since most verification procedures involve a top-down analysis, it is only natural for the designer to employ them as the design progresses top-down. Furthermore, familiarity with the verification procedures and the prospect of an imminent check are bound to generate questions in the designer's mind that otherwise would have passed unattended.

Like any other methodology, the proposed verification scheme is worthless if it is not strongly enforced. The methodology as a whole was developed in such a way as to assure that auditing be economically feasible and humanly possible: a uniform approach to design including great emphasis on standardization makes the documentation readable, the consistent top-down approach assures fast access to information and a good organization of the material, and the verification procedures provide uniform and relatively precise evaluation criteria. Nevertheless, a very strong commitment of the management is absolutely necessary in order to overcome the initial resistance to such a novel approach. At the same time people need to be convinced that the audit is not going to be used as a means of evaluating personnel, but rather of evaluating or improving products. If this philosophy is truly implemented, supervisors should not be part of the team auditing the products of those under their authority.

The solution that was finally adopted during the first implementation of this methodology is an audit team including one of the authors of the document being reviewed, persons familiar with the project but not involved in that particular design aspect and complete outsiders to the project. Each member of the audit team is to carry out the verification independently and to reveal his finding during group discussions following the author's oral defense of the material. The task of the audit team could be simplified significantly by providing some adequate software support that would analyze the documentation, enforce the standards, ease the search for information and its retrieval, and perform some primitive self-consistency and correctness checks. Such a system is presently under consideration.

## SUMMARY AND CONCLUSIONS

A relatively straightforward methodology for software systems development augmented by a systematic error discovery strategy, a set of verification procedures, was proposed and justified. It was also argued that the informal character of the verification procedures makes them both practical and effective. The discussion emphasized the role played by the verification procedures during software development.

At the present time one large company has adopted the approach as standard practice due to the realization that the cost of carrying out the verification (especially when projects tend to extend over three to five years) represents only

a very small financial investment compared with the significant benefits of early error detection. However, the reader is advised that more work needs to be done. First, the full impact of the methodology has to be established, which in turn should result in improvements to the verification procedures as well as the audit methods. Second, the development of software supporting the enforcement of the methodology and the verification process is needed to further increase their effectiveness while decreasing the time spent during auditing. Third, research needs to be directed toward the development of more formal methods that would support partially-automated consistency and correctness checks.

## ACKNOWLEDGMENT

This research was supported through a contract between the Management Information and Systems (MIS) Department of the Monsanto Company and the Computer Science Department of Washington University. The author extends his thanks to David R. Wilson and Edgar J. Kline of Monsanto for reviewing the material and contributing ideas and for the efforts involved in introducing the approach to the MIS community.

# A language for distributed processing

by RONALD J. PRICE

Perkin-Elmer Data Systems Group  
Tinton Falls, New Jersey

## INTRODUCTION

The main question being addressed here is, what is a good way to program a multiple processor system (whether tightly or loosely coupled) to accomplish an integral distributed processing application? Writing concurrent programs for a uniprocessor is tough enough, but writing programs which interact and operate simultaneously in parallel can be a most difficult and frustrating experience. Opportunities abound for operational failures due to race conditions, for time-dependent bugs and for deadlock situations.

Help is on the scene, though, in the form of new concurrent languages as typified by Concurrent Pascal.<sup>4</sup> The new software technology embodied by these languages can be applied to multiple processor problems as a methodology regardless of the implementation mechanisms.<sup>23,25</sup> Nevertheless, the utility of having an effective language is beyond question, even if only as a design tool.

A key feature of Concurrent Pascal is the *monitor* construct that protects critical data regions shared among co-operating sequential processes. With a mutual exclusion mechanism, only a single process is permitted to access the critical region at any given time. This notion was first suggested by Dijkstra,<sup>11</sup> formalized by Hoare,<sup>13</sup> and implemented by Brinch Hansen in Concurrent Pascal. Monitors, or an equivalent construct or capability, have since been incorporated in many other languages.

Although different linguistic variations are possible, Concurrent Pascal was selected as a base for implementing distributed processing programs because of its track record and extensive documentation. The language has proved to be a powerful and effective tool in practice for building structured concurrent programs.<sup>5</sup> Brinch Hansen recorded improvement in programmer productivity while building a complete operating system with his language,<sup>6</sup> and the utility of the language has been tested for many diverse applications.<sup>29</sup>

There has been some criticism of the language, however. For one thing, it depends on a run-time kernel facility that is invariant and built with a different language.<sup>20</sup> For another, critical system design decisions have been assumed by the language.<sup>24</sup> Researchers are also actively pursuing improved language constructs, most notably the *manager* concept,<sup>18,27</sup> which ultimately may lead to simpler and even more reliable concurrent programming concepts.

The purpose of this report is to propose two fundamental modifications to Concurrent Pascal that not only will alleviate many of the above concerns, but more importantly, will extend the language's applicability to distributed system environments.

In many respects, the proposed changes are adaptations of principles incorporated in Wirth's real-time language Modula.<sup>31</sup> As presented in the next two sections, they would enable the kernel and system control operators (i.e., the lowest levels of an operating system) to be written in the language itself and would enable partitions of a global, distributed multiprocessing program to be mapped to physical processors, but yet represented as an integral program.

The last section of the paper summarizes the proposed concepts and applies them as a methodology for constructing systems—from kernels, across processor boundaries, and up through application programs. As such, the extended language is a *systems description language* in that it can be employed to describe the algorithmic behavior of a multiple processor system (not to be confused with a hardware description language that prescribes physical circuits). It offers the systems designer a tool for:

- Synthesis
- Documentation
- Modeling
- Simulation
- Verification

and implementation if used directly as an implementation language.

Although the emphasis of this report is on distributed processing, the proposed extensions increase the power of the language for solving complex operating system problems irrespective of the multiprocessing issues. For example, the following problem areas are difficult under Concurrent Pascal as defined, but are quite amenable with the modified language:

- Data communications
- Process creation
- On-line system generation
- Dynamic software restructuring

The main intent of this paper is to justify and to explain

the benefits of the proposal, not to specify the language nor to suggest a method of implementation. Semantic details and the mechanics of integrating the new constructs within the language need further study and exposure to actual practice.

The level of presentation assumes the reader is familiar with Concurrent Pascal, but the definition of a few items might be useful. A *program* that can be described by the language is called a *concurrent program*. It consists of system (or program) *components* defined as *process* types and *monitor* types (and *class* types not mentioned here); redefinition of the monitor type and the definition of a *task* component as a partition of a concurrent program are described. A Concurrent Pascal program includes a programmable initial process that directs the initialization of the components in the program. The interpretation of *concurrency* is the execution of multiple processes overlapped in time, either by multiplexing periods of execution on a single machine or by simultaneous execution on multiple machines. When important, the latter connotation of true concurrency (i.e., parallelism) will be explicitly denoted in context; multiprocessing implies parallelism, for example.

#### CONCURRENT PASCAL WITH A PROGRAMMABLE KERNEL

As represented by Figure 1, Concurrent Pascal is based on a virtual machine kernel that implements process switch-

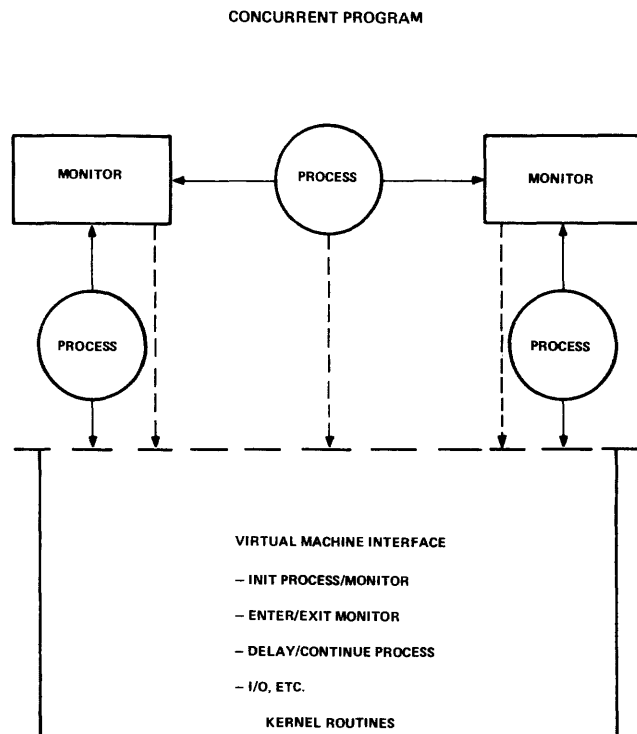

Figure 1—Concurrent Pascal system.

Note: The arrows in Figure 1 and in the following figures that depict a concurrent program represent access rights as defined in Concurrent Pascal, and not the flow of data. Further, circles represent processes and boxes represent monitors.

ing, mutual exclusion on access to monitors, and the various control operators (DELAY, CONTINUE, etc.). The definition of the virtual machine interface can be a problem for system builders interested in different kernel features and/or in multiple machine operations. The problem is that the virtual machine has been abstracted away from the systems programmer to the point of existing literally in another world as defined by its unique language (typically assembly). Moreover, the line between the real and virtual machine might not be optimum for a given application. There are simply too many variables, parameters, factors and extenuating circumstances to consider in general.

In some situations, the programmer of the concurrent program would like to have an influence on the design of one or more of the virtual machine modules, sometimes even to interact with the internal machine dynamically. A prime example of this is programming interrupt service routines. Interrupt handling (typically for I/O processing) is related more to an application than to central general purpose kernel routines; this is clearly so in dedicated systems.

The handling of interrupts has historically caused untold grief and frustration for system programmers. The interrupt is an indeterminate and irreproducible happening. Contemporary systems researchers recommend against using it as a synchronization mechanism and avoid preemption in general. The notion of an interrupt does not even exist in Concurrent Pascal. Instead, synchronizing primitives are provided (DELAY and CONTINUE) that allow system programs to be designed with so-called cooperating sequential processes.

Unfortunately, the processes embodied by most peripheral devices on even modern computers cannot be considered cooperative. Modula was designed to handle them.<sup>32</sup> But even if we stopped using the interrupt as a synchronizing mechanism, we still need it as a signal with which to measure time and to build real-time functions.

So although we might want to hide the interrupt in some abstract way, we still have to deal with it. Today this is generally accomplished through the kernel. However, not only is the interrupt hidden by the kernel, it is also typically inaccessible to the high-level software in a direct manner. Brinch Hansen and Hoare point out that scheduling cannot rely solely on built-in abstractions and that high-level software should be in control of response times at the lowest level.<sup>3</sup> Indeed, the interrupt is the simplest form of low-level scheduling for machines that can switch an instruction stream automatically upon recognizing an external signal. (Some machines provide multiple priority states where an interrupt level may be interrupted by yet another level, but for purposes of discussion, a single level is assumed here.)

The ability to dispatch programmable service routines in rapid response to external signals and to manage them in a disciplined manner could be afforded to Concurrent Pascal by extending the language with a new construct that allows procedures to be called with interrupts disabled. To allow controlled sharing of the uninterruptable procedures and their data structures, they could be treated much like the ordinary "virtual-time" (i.e., interruptible) monitors. This new construct could then take the form of another system

type in the language—a “real-time” monitor (for want of a better name). Generally speaking, the idea being presented here is to incorporate the real-time principles of Modula within the framework of Concurrent Pascal. Actually, we need not add a new system type to the language, but only have to redefine the monitor to include statements that execute in real-time.

The use of “real-time” monitors for interrupt handling is illustrated in Figure 2. Different delay (wait-on signal) and

continue (send-signal) operators would be needed that are consistent with the real-time environment. With appropriate entry and exit mechanisms, processes could communicate directly with interrupt service routines without going through pre-defined intermediary kernel routines; even interrupt service handlers could directly intercommunicate.

The “real-time” monitor construct would have far more application than just for programming interrupt handlers. For example, when multiprogramming a single machine,

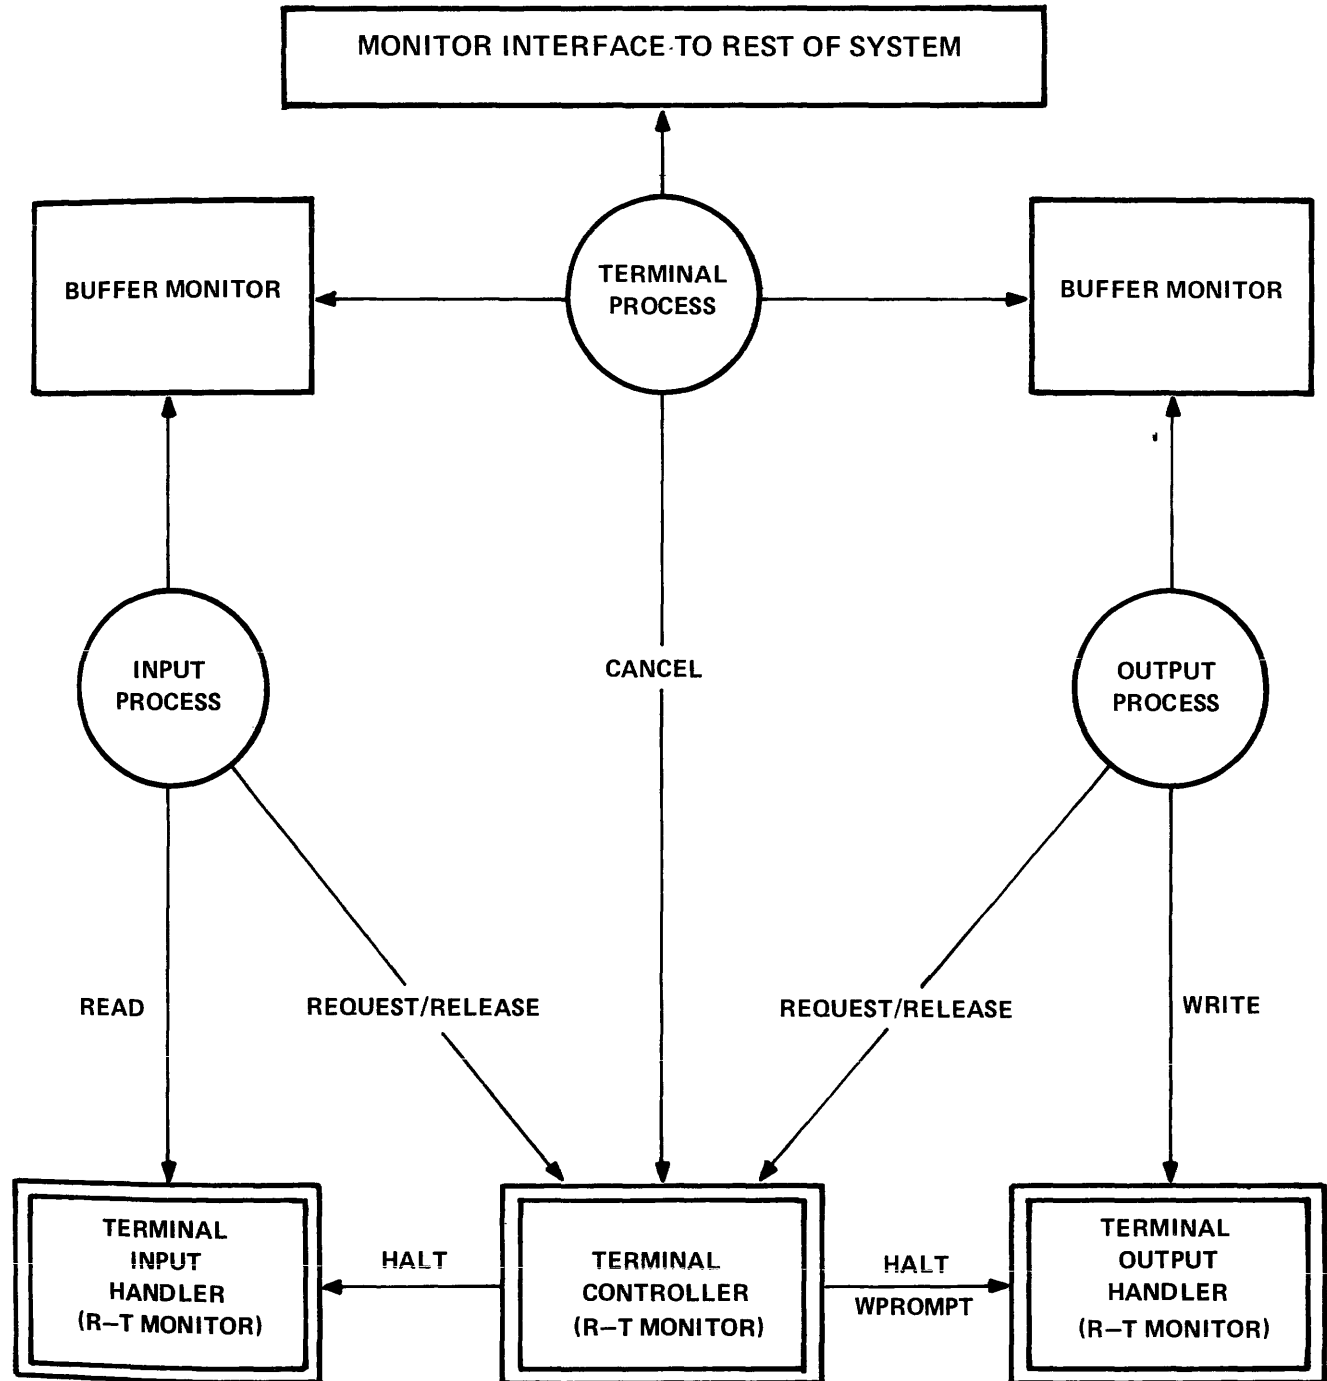

Figure 2—Concurrent program with real-time monitors for terminal I/O handling.

mutual exclusion on access to a monitor is assured simply by having interrupts disabled. In fact, there can be no busy queuing of processes on a "real-time" monitor. Consequently, they could be used in certain situations as a more efficient substitute for the ordinary "virtual-time" monitors in Concurrent Pascal.

Moreover, since the procedures in "real-time" monitors represent indivisible operations to their using program components, they can be employed to implement Concurrent Pascal's "virtual-time" monitors with the language itself. That is, in Concurrent Pascal a process does not directly call a monitor procedure. The call is actually intercepted by a kernel routine to perform mutual exclusion and busy queuing if necessary. This kernel intervention is installed by the compiler in a transparent manner to the programmer. Under the proposed language, this kernel routine would be programmed explicitly and not automatically installed by the compiler (except possibly by default as an implementation-dependent feature).

The various monitor operators and, for that matter, any kernel-like function the systems builder needs would also be programmed in a direct manner. Even conditional critical regions with different scheduling algorithms (guarded regions<sup>8</sup>) can be implemented with this "real-time" construct. In other words, the "real-time" monitor is a means for implementing explicit kernel routines, although the compiler could still support standard implicit kernel calls in a transparent manner.

Figure 3 is an extension of Figure 2 with kernel modules illustrated. An important aspect of this viewpoint is that the full power of the language can be brought to bear on the construction of the lower-level software when it is included as an integral part of the entire system. Such capability is important for embedded systems, process control environments, and data communications applications.

Kernel-like functions could be "hidden" through levels of abstraction, but this would be up to the systems builder and not a condition of the language. In fact, no run-time program, nor a pre-defined kernel definition, is required to support the proposed language.

The kernel can be treated as a concurrent program in its own right,<sup>19</sup> and Figure 3 also illustrates this point. The Genesis process interacts with external processes in peripheral equipment through real-time monitors. It also performs system initialization and takes on the role of the initial process of a concurrent program as per Concurrent Pascal, including in this case the explicit creation of the high-level abstracted user processes. The Kernel Services real-time monitor in this example provides the standard *Enter*, *Exit*, *Delay*, *Continue*, etc., procedures and a *Dispatch* procedure for multiplexing processes. The kernel might control private devices as illustrated, but interrupt handling for the higher-level software would also be supported (typically with considerable hardware assist) for dispatching processes in real-time monitors in response to interrupt signals.

The Genesis process selects high-level processes to execute with the *Dispatch* procedure and executes them much like a subroutine with interrupts enabled. So the high-level abstracted processes are in reality still the Genesis process

in disguise. When the Genesis process recognizes an interrupt signal (presumably with hardware assist), it enters Kernel Services (with interrupts disabled) and takes appropriate action. In the event this action results in activating a waiting process, the Genesis process can decide whether to preempt (reschedule) the current running process or to schedule the waiting process. Typically, the action in response to an interrupt signal would be to dispatch the recipient process immediately in its real-time monitor which in turn would initiate scheduling actions as required.

Many of these low-level functions could be implemented in hardware or firmware. Nevertheless, they can be accurately represented and programmed with the "real-time" monitor construct.

Incorporating the real-time feature does not make the proposed language machine-dependent. From a language point of view, the new proposed construct simply represents the sequential state of the machine. However, escape mechanisms would have to be provided in the compiler for programming machine-dependent features in the low-level software modules; or provide machine-dependent statements as an adjunct to the high-level machine-independent language.

## A MULTITASKING CONCURRENT PASCAL

The representation of a kernel as a concurrent program becomes more important when we consider a multiple processor system. Figure 4 is an example expansion on Figure 3 to illustrate kernels for a three-processor system; the surrounding higher-level software is not illustrated. The Inter-Kernel Communication (IKC) monitors are real-time monitors designed for exchanging information between kernels.

As should be evident from the previous discussion, the Genesis process together with the support modules in each kernel's partition is actually a sequential program running on a sequential machine; parallelism is just an illusion to the higher-levels of software. Even in Saxena's verification of the monitor concept,<sup>26</sup> he had to represent the idle state of multiple physical processors with an idle process for each processor, the equivalent of the Genesis process. Consequently, in order to represent true concurrency (i.e., parallelism) we need a mechanism for representing the multiple processors, or at least the actions of their kernels.

Even if we were to assume the prior existence of a collection of cooperating kernels on multiple machines that form a virtual multiple instruction, multiple data path machine on which we somehow apply the high-level concurrent program, we still could not take full advantage of the parallel machine with Concurrent Pascal as defined. Loading and initialization of the program, for example, must take place sequentially, either on a single processor or in sequential phases on multiple processors because the initial process of the concurrent program is really the Genesis process of a single kernel.

So we need a way of dividing the global concurrent program into logical partitions that can be delegated to separate processors for initiation and execution. Indeed, we have no viable alternative but to divide the program into physical

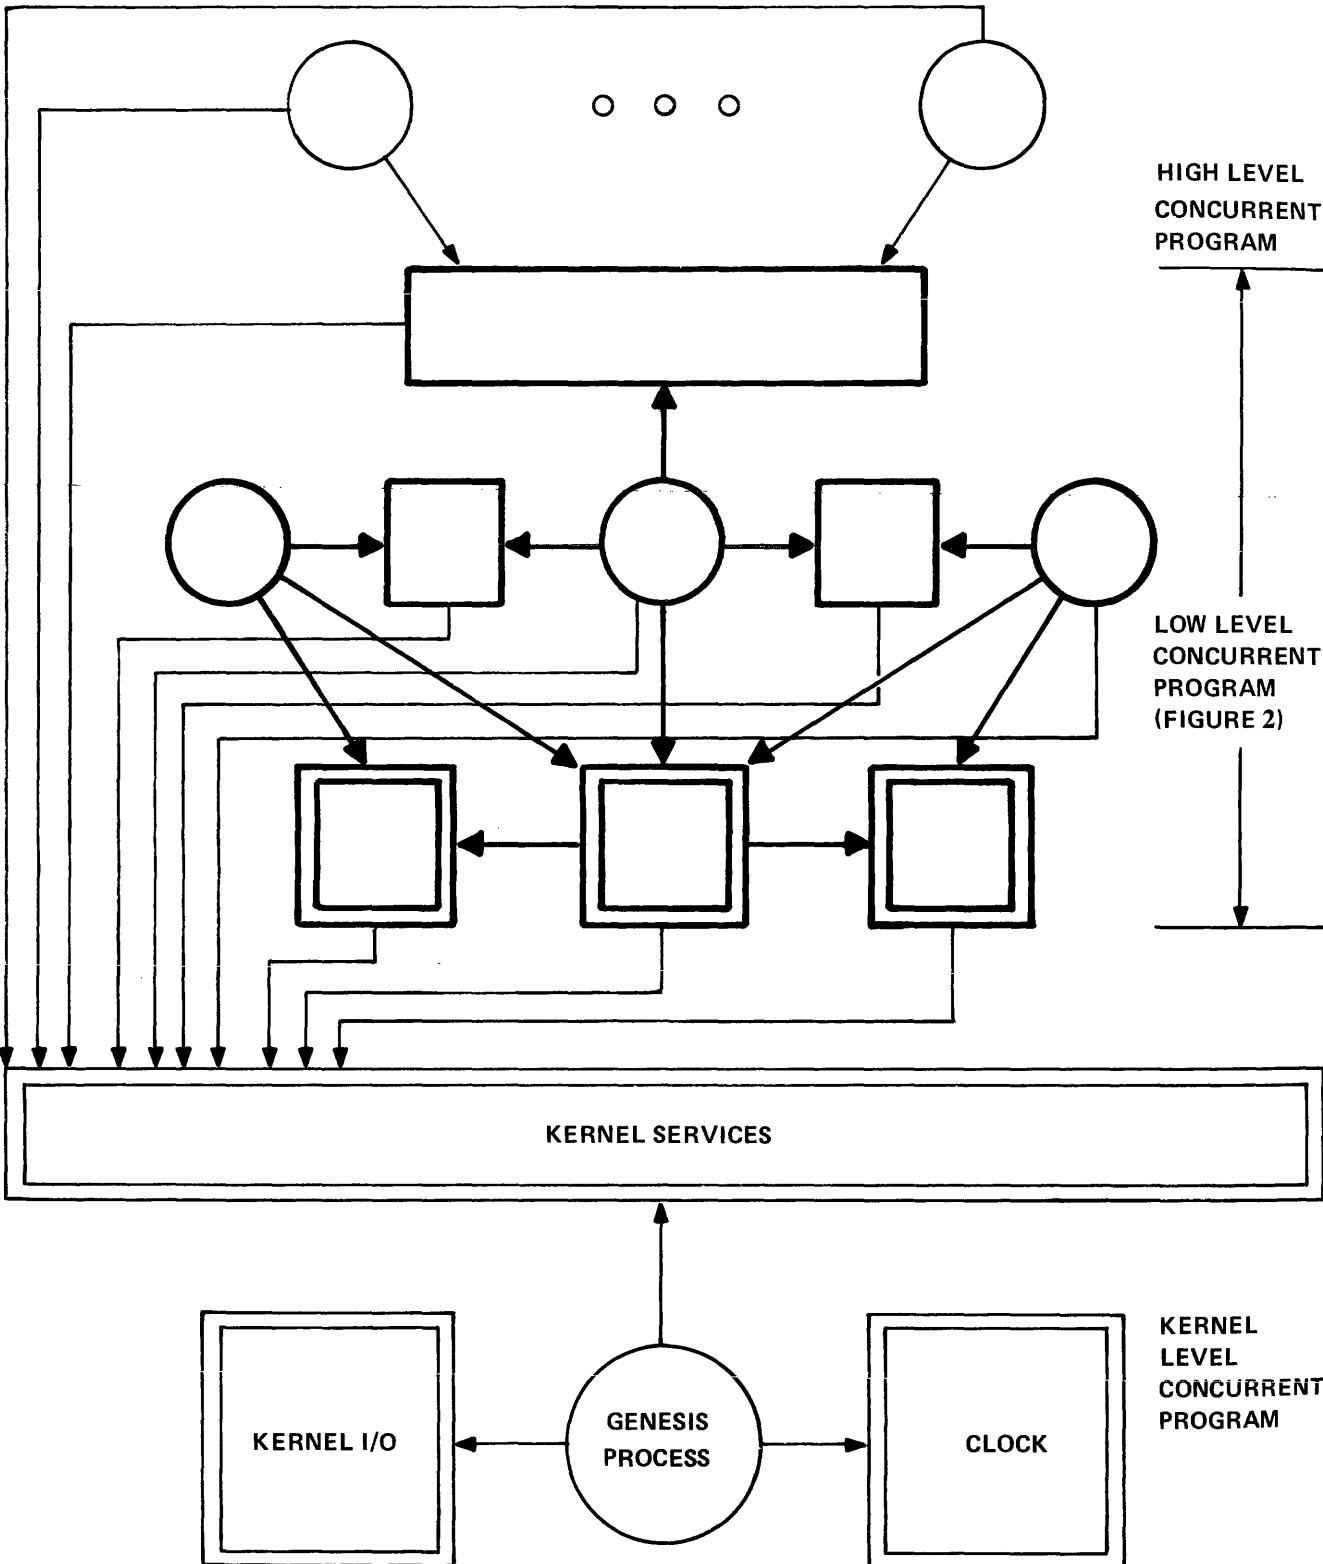

Figure 3—Multiple levels of a concurrent system program.

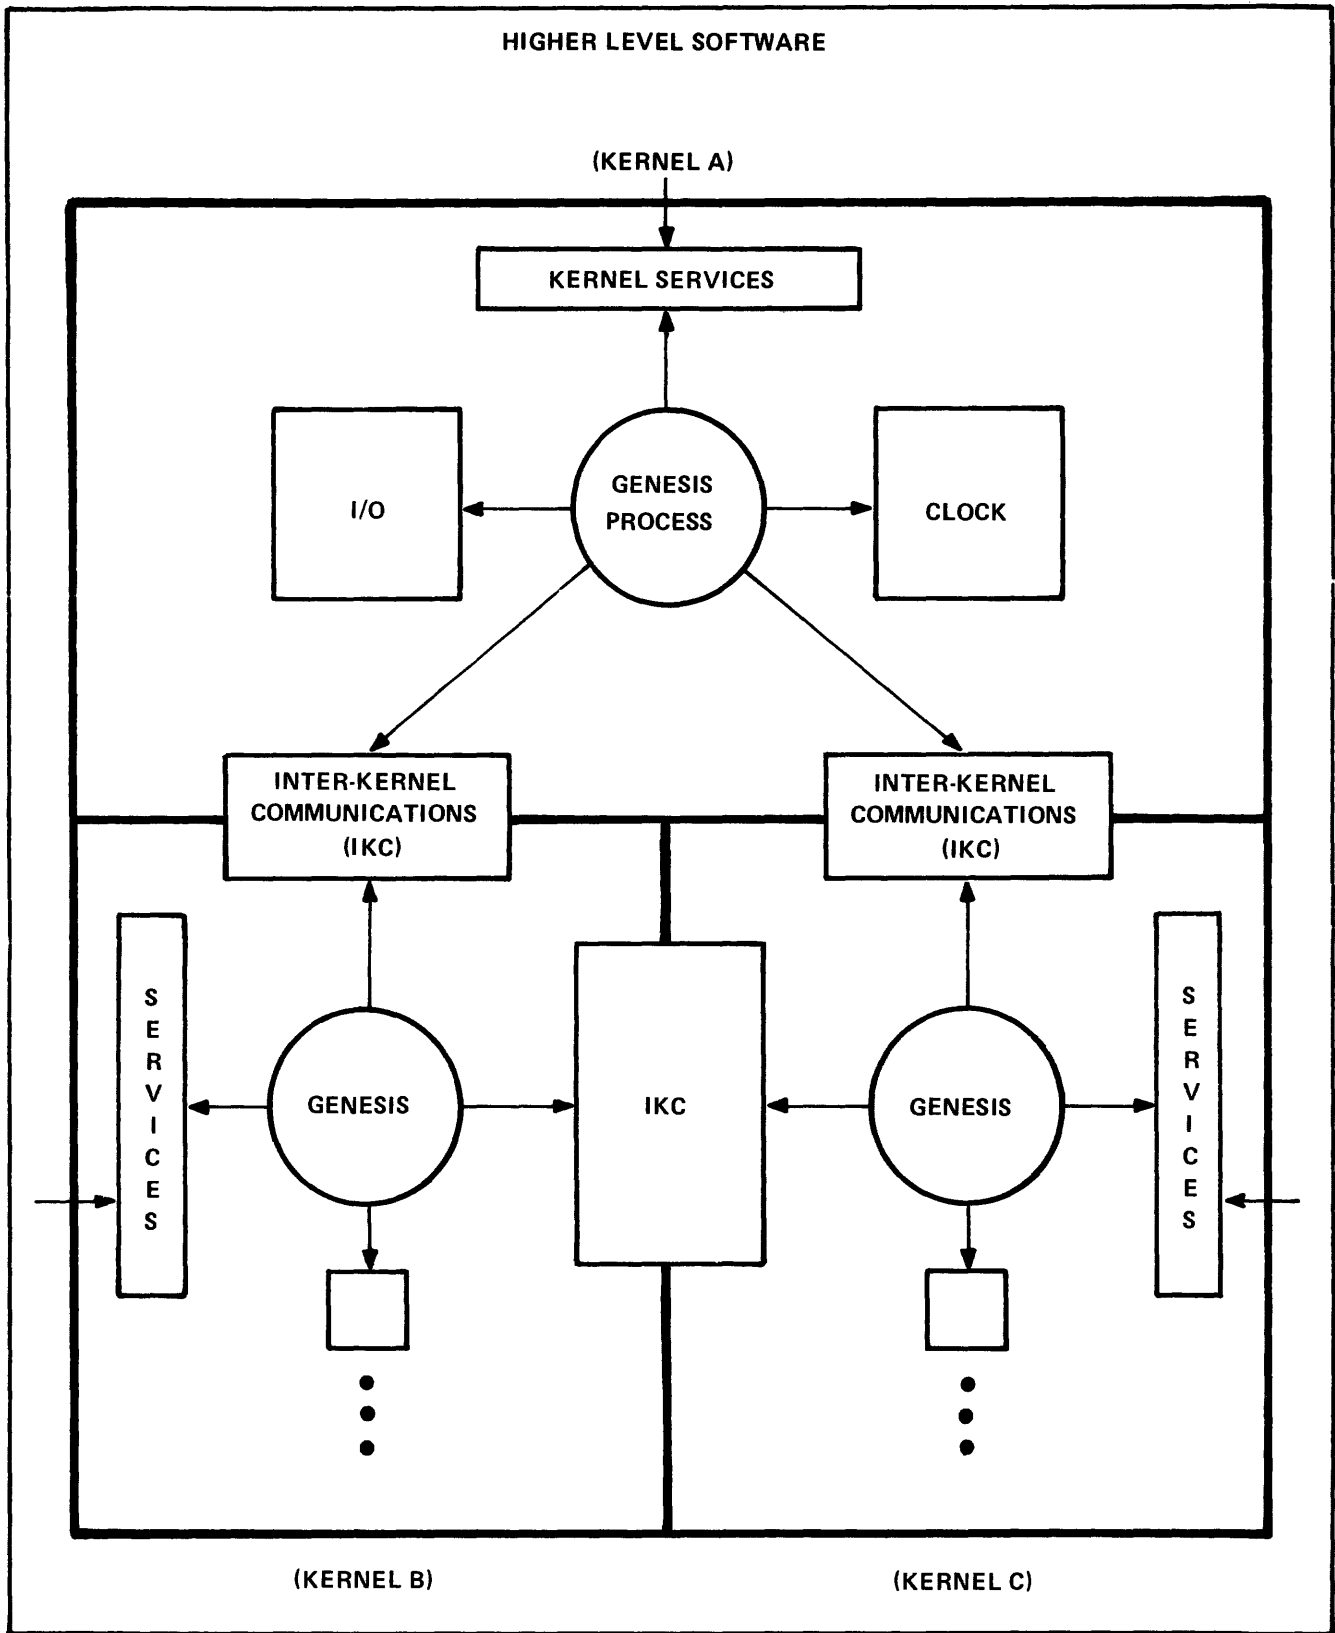

Figure 4—Multiprocessing kernels.

partitions if it is going to be run on a loosely-coupled configuration that does not share memory.

The partitioning mechanism proposed here is to extend Concurrent Pascal with a *task* block structure somewhat analogous to *module* in Modula. The task construct, however, defines a concurrent system component that contains a collection of processes and monitors. It specifically includes an initial process for initializing the task. And tasks cannot be nested. A multiple task program represents parallelism in that different tasks, via their initial processes can be dispatched and executed simultaneously by separate processors. In other words, a multiprocessing program can include multiple initial processes which represent abstracted extensions of multiple kernels.

Each kernel in Figure 4 would be represented by a separate task, and each would be dedicated to a specific processor. The higher-level software could be implemented as extensions of each kernel or as separate tasks. As one or more tasks on a tightly-coupled system, the high-level modules need not be dedicated to specific machines and could be dispatched by any of the three kernels.

Each task is, in essence, an independent concurrent program and can be compiled into a separate load module. Tasks are linked at run-time to form a global system.

The correctness of the system can be tested with an integral compilation where the tasks interact through monitors at the interface of the task boundaries. The compilation of any given task, however, need only include its predecessor tasks in the system and not any task outside its view of the system.

Regardless of the issue of being able to express parallelism in the language, the task construct is a tool for partitioning a multiprocessing system program. Access rights as implemented in Concurrent Pascal will assure a structured design.

We can divide a concurrent program into sections by taking advantage of the isolation property of monitors. That is, processes intercommunicate and synchronize their operations through monitors, and consequently, they need not know anything about each other—even their existence. For example, in Figure 5 the User\_B process need not know of the presence of the User\_A process when calling the Buff\_2 monitor, nor for that matter, even if multiple job processes interface the Buff\_2 monitor. Therefore, we can safely cut the program between monitors and processes as illustrated. The trick is to keep the access right arrows pointing in the same direction across the task boundary. (Whether task initialization is performed by a separate initial process or one of the application processes in each task is not relevant to this example.)

Note that the system structure and hierarchical order of the program components, as required by Concurrent Pascal, is preserved if we define and initiate Task A before Task B, even if one physical processor dispatches Task A and another processor dispatches Task B. This would not be the case, however, if the Job\_3 process were included in the Task A partition because then each task would have access rights to each other in a cycle.

Sometimes the initial layout of a concurrent program does not lend itself to partitioning. For example, if we tried to

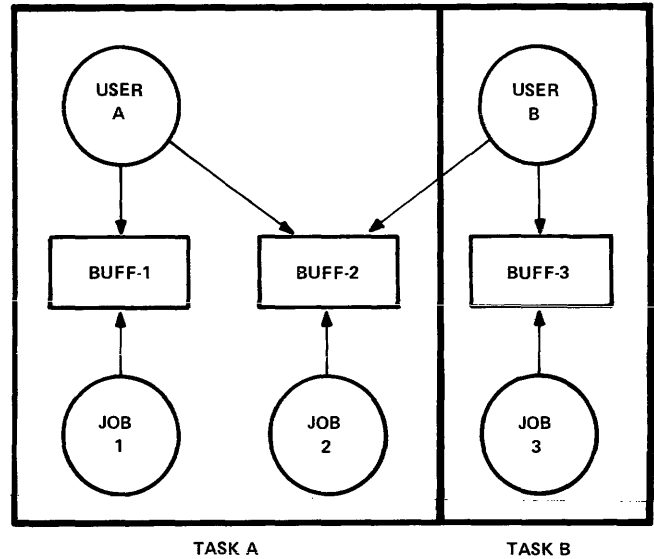

Figure 5—Partitioning a concurrent program.

apply the tasks in Figure 6 to two different machines, the multiprocessing program could easily crash when started (even if one task is initiated before the other) because the design does not guarantee that the monitors will be initialized before being called. But then the program might not crash; the problem is a time-dependent race condition.

Start-up is only part of the problem. We also need orderly ways of stopping a multiprocessing program, and more importantly, mechanisms for detecting error situations across processor boundaries and recovering from them. This is what partitioning is about.

Figure 7 shows how we can take advantage of the insertion property of monitors to resolve this task layout problem. Here, a message exchange monitor and server process are inserted in the User\_A process access path. This gets the arrows pointing in the same direction across the task bound-

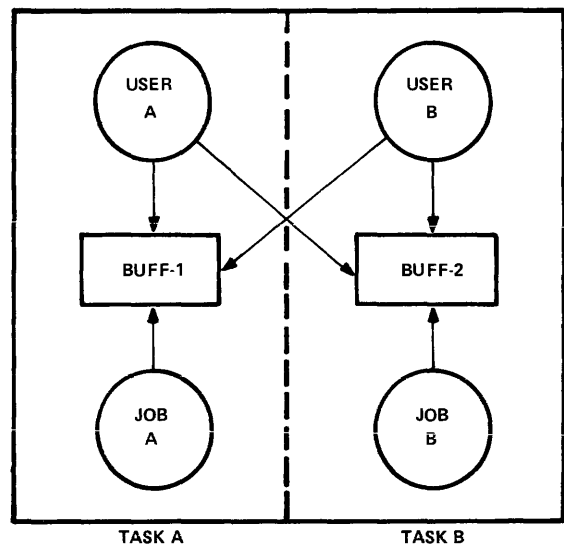

Figure 6—Invalid task partitioning.

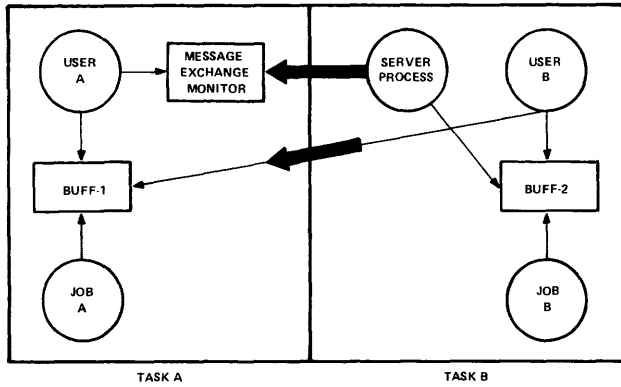

Figure 7—Partitioning with insertion.

ary. The server process acts in behalf of the User\_A process in the Task B partition.

A correct way to partition a multiprocessing program is to group logically-related processes and monitors into separate tasks in such a manner that their access rights point in the same direction across the task boundaries and by arranging the tasks in a hierarchy such that tasks which access other tasks are ranked below their predecessors, as in Figure 8. This ranking assures an orderly initialization (and termination) and eliminates race conditions and deadlock situations that otherwise might occur with a cyclic control structure.

In some arrangements, tasks, such as Task C in Figure 8, can be literally removed and brought back on-line without disturbing the rest of the system. The status of Task A does have to be known to Tasks B and C, however. In essence, the kernel tasks (not illustrated) and Task A form a virtual machine for Tasks B and C. This capability allows a system program to be generated and restructured dynamically.

Figure 8—Hierarchical structuring of multiprocessing programs.

### DISTRIBUTED PASCAL

A key feature of this proposal for implementing distributed programs is the ability to describe interface monitors between processors. The characteristics of a given interface can be programmed with the "real-time" monitor construct. Parallel kernels can then be described with the task block structure where the legality of their interface monitors is tested with an integral compilation. Higher-level tasks are built on top of the kernel tasks.

Interface monitors can be implemented in shared memory employing "thick-wire" communication techniques or in shared "thin-wire" I/O facilities. Mutual exclusion between machines is achieved by mutual cooperation in adhering to a protocol.

In the thick-wire case, permission to access the data structures is achieved by locking the monitor with a *read-modify-write* operation (e.g., Test and Set instruction) and then the data structures are manipulated in place. The logic for manipulating the data (i.e., the monitor's program code) can also be located along with the data if the hardware configuration allows code to be executed out of shared memory, or otherwise the logic can be replicated in the private memory of each processor.<sup>9,25</sup>

In the thin-wire case, data are physically copied from one location to another. Although Concurrent Pascal's monitors cannot be directly supported across a thin-wire boundary, an abstracted user's environment illustrated by Figure 9a could be supported by an underlying message communications system as depicted by Figure 9b. This software message system is conceptually the same thing implemented in hardware to support shared memory; however, the flexibility of a thick-wire emulation in software has to be highly constrained because of the limited bandwidth and long response times of the communication facilities.

A good case can be made for adopting a standard thin-wire communication technique for multiple processor systems which is adaptable to networks as well as to tightly-coupled architectures.<sup>15,22,30</sup> The overhead normally associated with a message-based system can be ameliorated by implementing message exchange facilities in hardware.<sup>16,28</sup>

Special languages have been proposed for message systems,<sup>1,21</sup> but Concurrent Pascal is a very suitable language

Figure 9a—Message-based concurrent program

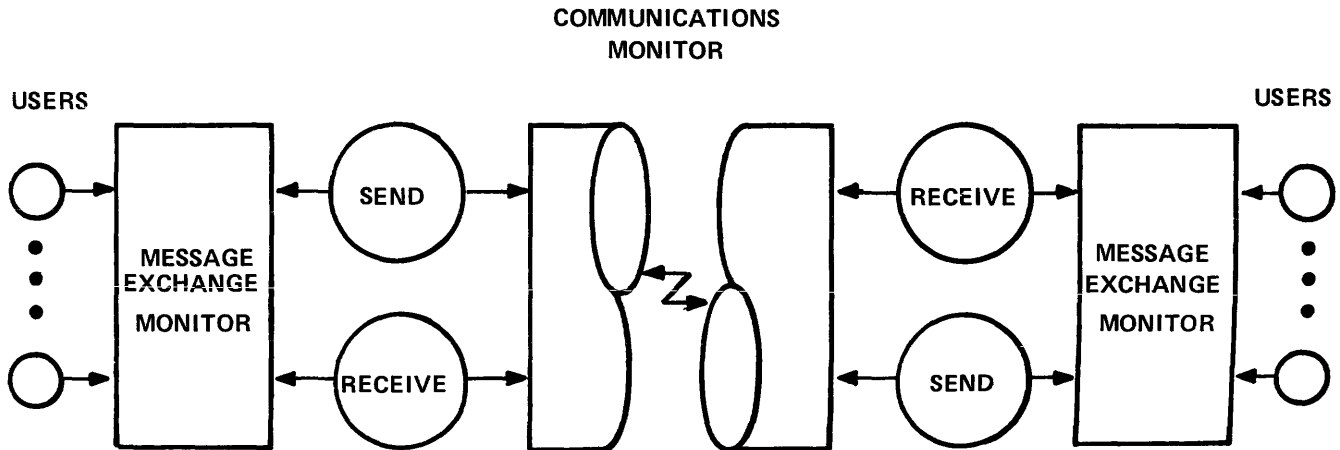

Figure 9b—System implementation of message communications.

for expressing networked systems,<sup>7</sup> including the communications protocol.<sup>2,9</sup> Moreover, the language offers the flexibility of general monitor designs where appropriate in addition to any built-in message exchange monitors of the communications system.

In any case, Concurrent Pascal as proposed to be modified is open-ended in the sense that both communication approaches can be accommodated. For example, if an operating system built with the language establishes a message-based inter-process communications protocol for conventional system use, the underlying implementation can still be based on thick-wire techniques where appropriate and more efficient.

Figure 10 depicts a multiple-task, multiple-processor system employing both thick-wire and thin-wire communications. The kernels dedicated to the processors in each tightly-coupled dual processor complex interface through multiple real-time monitors in shared memory, whereas the two complexes interface through a single real-time monitor over a communications channel. Kernels are represented by tasks and form the lower levels of the system. Higher-level tasks in the global system intercommunicate through monitors in a hierarchical fashion, as well. It is important to note that the different levels do not necessarily imply physical levels; that is, virtual kernels that emulate process switching, interrupts, etc., on top of real kernels is not a requirement to support high-level concurrent programs.

The point being made here is that this total system can be described with a single program (although part of it might be implemented in hardware). The program consists of a set of cohesive routines (program components) that implement the behavior of the global system. Indeed, the whole system operates as a harmonious confederation of cooperating sequential processes, some of which may run in parallel.

Even if the language is used only as a modeling tool, it can help us to design reliable systems by applying computer programming technology to their construction. This is so because Concurrent Pascal is based on proven software engineering techniques.

When building the "THE" multiprogramming system, Dijkstra suggested employing hierarchical levels of abstraction as a methodology for dealing with the complexity of operating systems;<sup>10</sup> that is, modules are built on top of others with well defined interfaces and interactions. This technique, actually a formal method of structured programming, is an invaluable aid for proving program correctness and is an inherent capability of Concurrent Pascal.

The axiomatic definition of Pascal<sup>12</sup> and the treatment of critical regions (e.g., monitors of Concurrent Pascal) and other research efforts have led to many proofs of program correctness relevant to concurrent programming (e.g., References 8, 14, 17, 26). These principles are now being applied in attempts to discover simpler, more flexible and more reliable techniques for constructing monitors and by enlisting the aid of the compiler itself.

The fact that formal constructs can lead to provably-correct programs may sound academic in reality. However, they actually do in practice lead to rapid program synthesis and to program correctness by inspection. Testing becomes much more systematic and takes on more of a verification role than a debugging operation. Modification and maintenance are also assisted.

By maintaining the consanguinity of Concurrent Pascal as proposed, we can apply these formal constructs to the construction of distributed systems. The language serves as a synthesis aid by enabling the system designer to decompose a system in terms of task components which in turn are decomposed into logically-related processes and monitor components; this can be illustrated in diagrammatical form. Moreover, the language allows a system to be designed in incremental stages, and it can be used to simulate and to evaluate different implementation strategies. In particular, the system designer can describe proposed solutions as models that accurately represent the physical environment and that can be demonstrated to run correctly. The language can also serve as a vehicle for documentation and testing. Finally, it becomes a piece-part of the end product where it is employed as an implementation language.

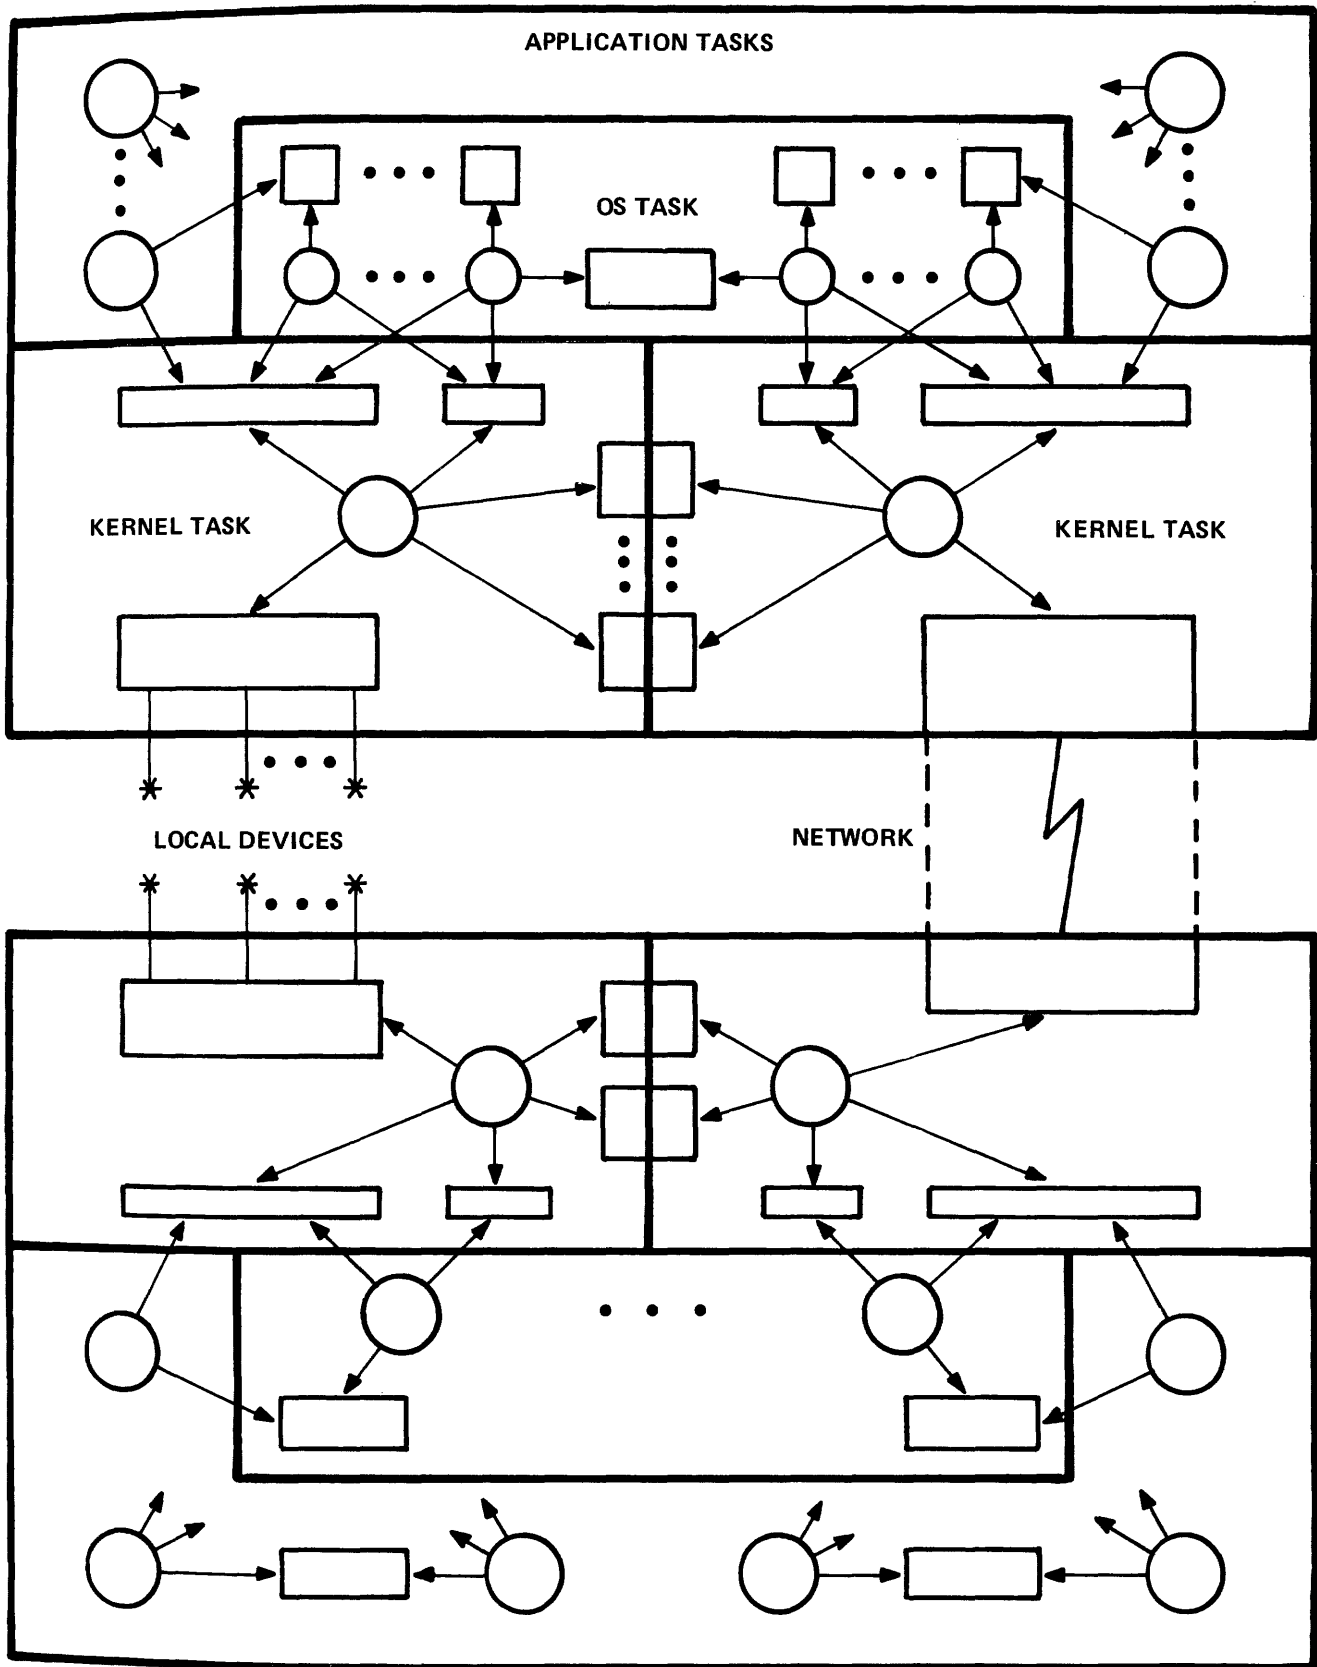

Figure 10—Distributed processing system.

## CONCLUSION

Changes to the language Concurrent Pascal are proposed that enable it to be used to:

1. Describe the algorithmic behavior of the physical system.
2. Express the physical parallelism of a distributed multiprocessing program.

As such, the new language acquires the connotation of Distributed Pascal.

## ACKNOWLEDGMENT

Mr. Gary Anderson and Mr. Tom Kibler are thanked for their helpful contributions and review.

# Automatic program transformations for virtual memory computers\*

by W. ABU-SUFAH, D. KUCK and D. LAWRIE

University of Illinois at Urbana-Champaign  
Urbana, Illinois

## INTRODUCTION

Improving the behavior of virtual memory systems is a popular subject, as evidenced by the vast number of papers in the literature. Typically, attempts to improve behavior fall into two areas—those which accept existing locality properties of programs and attempt to modify system parameters (e.g., memory allocated, window size for the working set policy, etc.), and those which attempt to reorganize programs in some way. The first approach treats programs behavioristically, i.e., without any attempt to change the original behavior of the program. This type of research generally attempts to deal with space allocation policies and replacement algorithms in order to improve the performance of the system, given the original behavior of the programs. The work of Denning,<sup>12,13</sup> Belady,<sup>8</sup> Chu and Opderbeck,<sup>9</sup> Smith,<sup>21</sup> Trivedi<sup>22</sup> and many others has contributed greatly to the evolution of operating systems and hardware for virtual memory systems.

Yet the second approach promises even more significant improvement. Early work in this area<sup>11</sup> indicated the importance of program reorganization, and more recent research (e.g., References 17 and 15) has borne out this promise. Our work belongs to this latter group, but with an important difference. We reorganize programs—automatically—by examining their structure at the source code level where more information about the program is available. The papers by Elshoff<sup>14</sup> and Trivedi<sup>23</sup> describe some similar techniques but left the restructuring to the programmer.

In the next section of this paper we present a brief description of our program transformations. By detailed analysis of the program, we reorganize the loop structure of programs in an attempt to ensure that once a page is used, as much computation as possible is done on that page before it is discarded and replaced by a new page. The result of our transformations is a program whose locality is better controlled. Our presentation will be through examples. For a formal description of the transformations, implementation problems and theorems related to the correctness of the transformations see References 3 and 1.

\* This work was supported in part by the National Science Foundation under Grant Nos. MCS76-81686 and MCS77-27910, and the Department of Computer Science, University of Illinois at Urbana-Champaign.

In the third section we present a summary of some preliminary experimental results which we obtained by applying our transformations to a collection of FORTRAN programs. As we will describe in that section, we have obtained good results so far in our work. We have seen more improvement in space-time product over standard paging from our source level transformations than we see in going from a nonpaging system to paging.

In the final section we will present some concluding remarks.

## BRIEF DESCRIPTION OF THE TRANSFORMATION

Throughout this paper we will be concerned only with data paging. Moreover, we will ignore references to scalar variables. Similar assumptions were made by other researchers.<sup>6,5</sup> The storage of each array will start on a page boundary. Moreover, we are primarily concerned with scientific programs; it is usually the programs with large arrays which cause serious problems for virtual memory computers.<sup>14</sup>

One of our principal transformations is *distribution* of DO-loop control. In order to see how this improves paging behavior, consider Program 1.

```
Program 1
DO 1 I=1, N
  A(I) = B(I) + C(I)
  X(I) = A(I) * X(I-1) + D(I)
1   E(I) = 2 * X(I) + F(I)
```

Consider first a non-paged versus a paged machine. If allotted seven data pages, this loop will run completely through each of seven array partitions between page fault bursts. If each array occupied a total of  $p$  pages, then about  $7p$  page faults would be generated in total, whereas a nonvirtual memory machine would have to allot a total of  $7pz$  words of memory to its execution ( $z$  is the page size, in words). Thus, the memory-saving due to paging is a factor of  $p$ . Generally, however, paging will increase the I/O activities over a non-paged system, because some pages may be re-fetched several times. Note that in programs containing sev-

eral loops, the same space can be used for each loop so the total space saved by standard paging is proportional to the product of  $p$  and the number of loops in the program (assuming that distinct loops reference distinct pages).

*Program 2*

```

DO 1 I=1, N
1   A(I)=B(I)+C(I)
DO 2 I=1, N
2   X(I)=A(I)*X(I-1)+D(I)
DO 3 I=1, N
3   E(I)=2*X(I)+F(I)

```

Suppose that Program 1 is rewritten as Program 2 by loop control distribution. This version can be run with an allotment of only three pages and still not generate page faults, except at the end of processing each set of pages. Note that in this case loop control can be distributed down to the level of individual statements.

*Program 3*

```

DO 1 I=1, N
   X(I)=Y(I-1)+A(I)
1   Y(I)=X(I)*Y(I-1)+B(I)

```

In general, loop distribution is possible down to the level of cyclic data dependence graphs (called  $\pi$ -blocks<sup>19</sup>) for individual loops. The nodes of a cyclic data dependence graph (each node representing a statement) are connected by directed arcs which form a cycle. An arc is drawn from one node to another if, at some instance, the statement represented by the first node must be executed before the statement of the second node. Thus, the loop of Program 3 cannot be further distributed since its two statements form a data dependence cycle and hence constitute a single  $\pi$ -block. Since such cycles seldom contain more than two statements in practice, the improvement in memory space of this method over standard paging is a factor proportional to the number of statements in the longest loop in a program. Note that in practice this may be comparable to the improvement obtained by standard paging over non-paged memory schemes, although I/O activities may increase in general.

In the past, a great deal of work has been done on the problem of extracting array operations from standard programs for purposes of compiling for high-speed array machines.<sup>18</sup> Based on this, we have implemented a comprehensive FORTRAN program analyzer for speeding up FORTRAN programs, and have found that a very high percentage of FORTRAN loops can be broken into array expressions and linear recurrences by loop distribution (as in Program 2). An important key to our success has been in obtaining very accurate data dependence tests for subscripted variables inside loops. While a number of earlier attempts to solve this problem used only array names or simple subscript tests, we now use tests that in most cases are exact,<sup>7</sup> i.e., we have necessary and sufficient tests for the data dependence of one subscripted variable on another, subject to a loop index set. This allows us to obtain a data dependence graph that has many fewer arcs (and more  $\pi$ -

blocks) than would be obtained by more naive tests and, in particular, allows the breaking of many false cycles. Thus, control in most graphs can be distributed to the level of individual assignment statements.

An outline of the complete transformation algorithm is shown in Figure 1. The first step, analysis, is done automatically by the FORTRAN program analyzer. During this step, data dependences are determined, and certain simplifying transformations are performed (e.g., DO-loop initial value and bound normalization).

Following analysis, statements are *clustered* depending on common data elements. Consider, for example, Program 4. Statements  $S_1$  and  $S_3$  are clustered together because array  $B$  is common to both statements. Clustering is done only within a loop however, so statement  $S_4$  is not clustered with  $S_2$  (yet) because they belong to different loops. Each cluster is called a *name partition* (NP). Loops are now distributed over NPs, as shown in Program 5. Notice that the loop could have been further distributed over the NP( $S_1, S_3$ ). However, while this would reduce the space requirement for each loop, it would increase the page faulting since each page of  $B$  would have to be fetched twice.

Following clustering, an attempt is made to *fuse* different loops together. Observe that the data in  $S_4$  of Program 5 is a subset of the data of  $S_2$ . Thus, these two loops can be fused (as shown in Program 6) without increasing the space required in the loop, but allowing a decrease in the total number of page faults.

*Program 4*

```

DO S3 I=1, N
S1   A(I)=B(I)+C(I)
S2   D(I)=E(I)+F(I)+X(I)
S3   G(I)=B(I)+H(I)
DO S4 J=1, N
S4   E(J)=D(J)*F(J)
      ↓ Clustering

```

*Program 5*

```

DO S3 I=1, N
S1   A(I)=B(I)+C(I)
S3   G(I)=B(I)+H(I)
DO S2 I=1, N
S2   D(I)=E(I)+F(I)+X(I)
DO S4 J=1, N
S4   E(J)=D(J)*F(J)
      ↓ Fusion

```

*Program 6*

```

DO S3 I=1, N
S1   A(I)=B(I)+C(I)
S3   G(I)=B(I)+H(I)
DO S4 I=1, N
S2   D(I)=E(I)+F(I)+X(I)
S4   E(I)=D(I)*F(I)

```

Since eventually we will distribute the loop control of an NP on its  $\pi$ -blocks, our next step is to simplify the data dependence graph of each NP by breaking any dependence

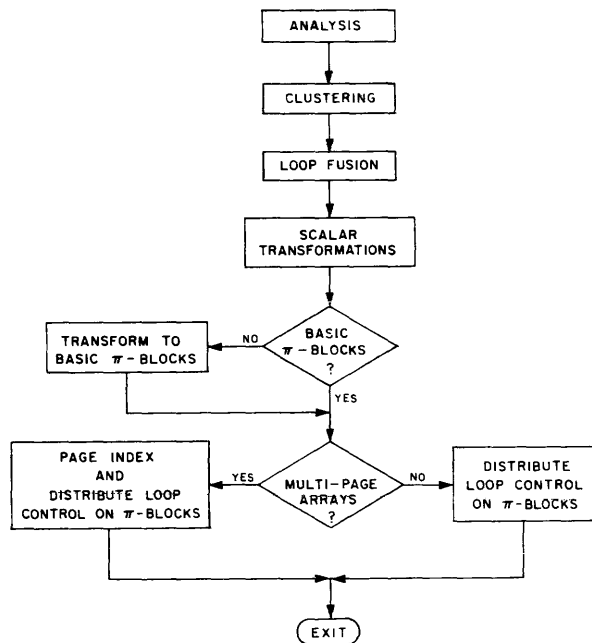

Figure 1—Flowchart of the transformation process.

arcs due to assignment statements to scalar variables. We use one of two techniques to handle such assignment statements—*forward-substitution* or *scalar expansion*. As an example, consider Program 7a.

#### Program 7a

```

DO S3 I=1, N
S1 T = (A(I)*C(I))/2
S2 D(I) = D(I)**2 - T**5
S3 F(I) = T*(A(I) - C(I)) + F(I)/C(I)

```

Because of  $S_1$ , the data dependence graph of this NP is cyclic and there is one  $\pi$ -block. For this NP, the amount of memory allotment needed to obtain minimum I/O activity is four page frames. By substituting the right-hand side expression of  $S_1$  in  $S_2$  and  $S_3$ , we can eliminate  $S_1$  and we will have two  $\pi$ -blocks:  $\pi_1 = S_2$  and  $\pi_2 = S_3$ . Note that the memory needed for each of these  $\pi$ -blocks is three page frames. Thus the space requirement of Program 7a can be dropped by a factor of  $\frac{4}{3}$  by forward-substitution and then distributing the control on the  $\pi$ -blocks as in Program 7b.

#### Program 7b

```

DO S2 I=1, N
S2 D(I) = D(I)**2 - ((A(I)*C(I))/2)**5
DO S3 I=1, N
S3 F(I) = ((A(I)*C(I))/2)*(A(I) - C(I))
          + F(I)/C(I).

```

In other situations, forward-substitution might be impossible or undesirable (e.g., if it increases the space requirement of the program). In such cases, we use scalar expansion as shown in Program 8.

#### Program 8a

```

DO S3 I=1, N
S1 T = T + A(I)*E(I)
S2 A(I) = B(I)*C(I)
S3 B(I) = T + F(I)/D(I)

```

↓ Scalar expansion and  
loop distribution

#### Program 8b

```

DO S1 I=1, N
S1 T'(I) = T'(I-1) + A(I)*E(I)
DO S2 I=1, N
S2 A(I) = B(I)*C(I)
DO S3 I=1, N
S3 B(I) = T'(I) + F(I)/D(I)

```

Note that for Program 8a the memory requirement is six page frames while for Program 8b it is four (the maximum of the space requirement of the three  $\pi$ -blocks). Rules to be used in choosing between forward-substitution and scalar expansion (when both are possible) are discussed in Reference 3.

As mentioned earlier, distributing the control of an NP on its  $\pi$ -blocks will increase the page fault rate if the arrays referenced are multi-page arrays. To prevent this from happening, we apply the *page indexing* transformation to such loops. Program 8c shows the page-indexed distributed version of Program 8a. Basically, this transformation ensures that a page that is referenced in different  $\pi$ -blocks of an NP will not be removed from memory until it is used by all relevant  $\pi$ -blocks. (Additionally, by page-indexing we have reduced the size of the scalar expansion array in Program 8c to only  $z$  words instead of  $N$ .)

#### Program 8c

```

DO S3 IP=1, [N/Z]
  ILB = 1 + (IP-1)*Z
  IUB = MINIMUM(IP*Z, N)
DO S1 I=ILB, IUB
S1 T'(I MOD(Z)+1) = T'(I MOD(Z))
      + A(I)*E(I)
DO S2 I=ILB, IUB
S2 A(I) = B(I)*C(I)
DO S3 I=ILB, IUB
S3 B(I) = T'(I MOD(Z)+1) + F(I)/D(I)

```

Page indexing can be applied only to NPs which have basic  $\pi$ -blocks. A *basic  $\pi$ -block* is one with all of its statements at the same loop nesting depth. However, we have an algorithm for transforming non-basic  $\pi$ -blocks into basic  $\pi$ -blocks.<sup>3</sup> After this is done, page-indexing is applied as before. Program 9a is a non-basic  $\pi$ -block (this is a Gaussian elimination program). In Program 9b, it is transformed to a basic  $\pi$ -block. Page-indexing is applied as shown in Program 9c. We use the same storage scheme for all multidimensional arrays of a program, the submatrix storage scheme.<sup>10</sup> This is because this storage scheme has inherent advantages over the row or column-wise storage schemes as was shown in 10. We have developed tests to check the correctness of the

page-indexing transformation.<sup>3</sup> Currently, we are looking into storing arrays using different schemes when the arrays are referenced in different uniform ways in the program.

*Program 9a*

```

DO S2   I1=1, N-1
DO S1   I2=(I1+1), N
S1     A(I2, I1) =A(I2, I1)/A(I1, I1)
DO S2   I3=(I1+1), N
DO S2   I4=(I1+1), N
S2     A(I4, I3) =A(I4, I3)
           -A(I4, I1)*A(I1, I3)
           ↓
           Non-basic to basic
           π-block

```

           -A(I, K)*A(K, J)

```

## PRELIMINARY RESULTS

We define performance in terms of three criteria—space ( $m$ ), time (measured in terms of page faults,  $f(m)$ ), and space-time product ( $f(m)m$ ). Notice that for simplicity we assume that computation time is negligible relative to the time for a page fault, so we can measure time in terms of

the number of page faults. In fact, our transformations do increase the CPU time for a program due to increased loop control overhead, redundancy (from forward-substitution of scalars), etc. However, much of this is invisible due to control-execution overlap, and the total increase in CPU time is generally negligible when compared to disk access time.

We define  $m_r$  to be the amount of memory required by a program in order to produce the minimum space-time product. More specifically, for the untransformed program this value is  $m_o$ , and for the transformed program it is  $m_t$ . Our choice of a memory allotment that minimizes space-time product is somewhat arbitrary, but is based on the intuitive idea that this will lead to maximum throughput and minimum turnaround in a multiprogrammed environment. In such a system, throughput and turnaround time are related by

$$\text{Throughput} = \frac{\text{average number of jobs present}}{\text{average job turnaround time}}$$

Roughly speaking, reducing page allotments as much as possible maximizes the average number of jobs present. Since reducing each job's page faults reduces the average job turnaround time, the transformations we carry out tend also to maximize throughput. Thus, for the fixed memory allotment case discussed above, our techniques improve both turnaround and throughput. In fact, however,  $m_r$  does not always lead to minimum page faulting as we shall see. Thus, in an I/O bound system,  $m_r$  may not produce optimal results. We shall discuss this problem in more detail later.

Regarding space, it is intuitively clear that if one can transform a program into a form that contains a set of  $\pi$ -block computations, then each of these  $\pi$ -block computations can be broken into a sequence of page-sized loops (using the page indexing transformation). The net effect would be to reduce the necessary page allotment for an entire transformed program to that required for the largest  $\pi$ -block computation in the program,  $m_t$ . The simplest  $\pi$ -blocks might be expected to contain one or two distinct arrays, while the maximum number per  $\pi$ -block in a program might be six or eight. Thus if one were successful, perhaps any program could be run with a data page allotment of at most eight pages.

Another important program characteristic is page faulting and how it would be affected by such transformations. For any given program loop, the number of page faults per iteration equals the number of arrays referenced in the loop, unless *all* pages are left in main memory for the entire loop execution, in which case page faulting occurs only after a number of iterations proportional to the page size. In this case the page allotment for the original program,  $m_o$ , would at best be equal to the largest number of arrays referenced in any loop in the program, in contrast to the  $m_t$  for the largest  $\pi$ -block obtained above. At worst, many more pages than array names would be required. For example, a matrix multiplication loop has three array names but needs an entire row and column of pages. Thus, one would expect that the number of required pages for any program to run well would be less for a transformed program, i.e.,  $m_t < m_o$ .

By a combination of automatic and manual transformations, as well as a tracing program that handles FORTRAN programs compiled for the IBM/360, 370, we have obtained preliminary statistics for 17 FORTRAN programs, comprising a total of almost 1600 cards (excluding comments). These were selected from about 300 programs we have collected for various studies. The 17 programs contained a total of 200 DO-loops whose limits were supplied by users. The program generated over 1.4 million array element references. Most of the programs are numerical in nature but they are drawn from diverse application areas. One important criterion in our selection process was that the programs not contain too many statements, as our analysis procedures were rather time-consuming.

We have observed average values of  $m_o=25$  and  $m_t=4$ . Thus, a space-saving of greater than six could be expected for these programs. However, since page faulting does increase somewhat for the transformed programs, the space-time product improvement is only about three or four (the mean is four and the median is three). Nevertheless, this implies a potential increase in throughput of a factor of three or four for a multiprogrammed system. Furthermore, for our programs the average space-time product improvement of standard paging over a non-paged main memory (one that allocates sufficient space for all arrays) was only a factor of about 2.5 (mean and median). Thus, the performance increase of our transformations over standard paging is comparable to (in fact, greater than) the performance increase of standard paging over a non-paged system.

It is important to realize that our  $m_o$  values were obtained by direct observation of the space-time product of our sample programs over a wide range of memory allotments. The difficulty of directly observing  $m_o$  (say, by compiler measurement) has been discussed in Reference 20, where possible correlation with the number of array names in a loop was rejected as impossible in practice. On the other hand, for our transformed programs there is a strong correlation between the number of array names and  $m_t$ ; the two are almost equal in most  $\pi$ -blocks.

In Figure 2 and Figure 3 we show typical page fault versus memory allotment and space-time product versus memory allotment curves, respectively. Note that both page fault curves approach approximately the same low level of page faulting. The transformed program approaches this low level much earlier than the original program. This, in turn, causes the space-time product of the transformed program to be substantially less than that of the original program over a wide range of memory allotments. Note that the transformed program's space-time product decreases monotonically to a minimum at  $m_t$ , then increases to meet the minimum for the original program at  $m_o$  and then both increase together as useless memory is allotted. However, the space-time products of original programs usually vary a great deal between one page and  $m_o$ , thus making the operating system's (OS) page allotment job nearly impossible unless  $m_o$  pages are allotted (the difficulty of knowing  $m_o$  was discussed above). Of course, allotting each program an efficient amount of space would also complicate the overall scheduling job of the OS. However, the transformed programs are much bet-

Figure 2—Page faults vs. memory allotment.

ter behaved, and any allotment in the region of  $m_t$ , say from four to eight pages will give a reasonably good space-time product for any of the programs we observed.

To compare averages using ideal memory allotments ( $m_o$  and  $m_t$ ) is rather pointless because of the difficulty of achieving  $m_o$  allotments in practice. More realistic is a comparison of the performance of the original and transformed programs given fixed allotments,  $m_a$ , which are not necessarily optimal. This reflects the situation where space is allotted by an OS that does not know the optimal allocation. (Note, however, that it may be easier for a compiler to estimate  $m_t$  even though estimation of  $m_o$  is known to be difficult.) We have tabulated the ratio  $m_a f_o(m_a) / 6 \cdot f_t(6)$ , for  $16 \leq m_a \leq 48$  with  $m_a$  increasing by increments of four. For  $m_a=16$  the space-time product of transformed programs is improved over untransformed programs for all but one of the 17 programs (where it drops by a factor of .75), with an average improvement by a factor of 8.8. Fur-

Figure 3—Space-time product vs. memory allotment.

thermore, in all but three cases, both space and page faults decrease (in two of these the page faults increase very slightly). As  $m_a$  increases, several other programs reach  $m_o$  and need no more pages, but averaging over those that need 28 pages (14 programs), the average space-time product improvement reaches a maximum of 12.9 with a median of seven. In fact, over the entire range of  $m_a$  and using four, six, or eight pages for the transformed programs, we achieve an average space-time product improvement over untransformed programs in the range of seven to over 12. Thus, we feel safe in concluding that by using our transformations, operating systems that use fixed memory allotments can achieve a decimal order of magnitude improvement in space-time product over standard paging techniques for the data of ordinary FORTRAN programs.

The above studies assumed a fixed memory allocation and a least-recently-used (LRU) page replacement algorithm. We have done similar studies assuming paging is done according to the working set policy, WS. For transformed programs, there was no difference between the cost of execution under LRU and WS. Moreover, several programs exhibited the working set anomalies.<sup>16</sup> For more discussion on the results under WS, see References 3 and 1. For detailed measurements of the working set anomalies in FORTRAN programs, see Reference 2.

## CONCLUSION

In this paper we presented an overview of compiler transformations which are aimed at the enhancement of the locality property of programs. Moreover, we presented a summary of preliminary experimental results which show that our techniques have good potential for achieving their goals. These results indicate that transformed programs are cheaper to execute, easier to manage, and simpler to model.<sup>4</sup> For example, using simple and practical memory management policies, we observe a factor of 10 improvement in space-time cost over untransformed programs.

# Analysis of data flow models using the SARA graph model of behavior\*

by W. RUGGIERO\*\*, G. ESTRIN, R. FENCHEL, R. RAZOUK, D. SCHWABE and M. VERNON

University of California at Los Angeles  
Los Angeles, California

A number of investigators have continued to discuss application of asynchronous techniques to improve the computational power of computing systems.<sup>2,12,5,9</sup> In fact the need for asynchronous design techniques arose in the earliest machines<sup>26,6,20</sup> which introduced parallel handling of bits in a number and overlapping of independent operations. The concept of distributed autonomous concurrent processors was essential to the visionary architecture proposed by Holland<sup>16</sup> to support "operating programs floating in a sea of hardware." The importance of such concurrent and asynchronous systems has increased recently because of the availability of entire processing units on one or a few chips and the potential cost reduction of those units. Moreover, it is expected that work on VLSI technology will permit even more complex systems to be reduced to silicon if their design and market analysis have been validated sufficiently to justify the cost. The need for validation prior to costly physical implementation has increased the value of methods and tools which support modeling and analysis.

SARA (System ARchitectures Apprentice) is such a supported methodology particularly applicable to multilevel modeling of concurrent systems. Dennis has proposed computation structures for concurrent system design which have aroused considerable interest. This work shows how SARA tools may be used to analyze data flow models utilizing Dennis' computation structure. This work refers to the latter as the Dennis Data Flow (DDF) Model.

In the first part of this paper we establish relationships between primitives of two models—the Dennis Data Flow Model and the SARA Graph Model of Behavior (GMB). The second part of the paper presents an example showing how SARA tools can be used to construct and simulate a data flow model. The discussion and the example should help to increase the reader's understanding of both models.

This opens the way for application of supported multilevel design methodologies, like that supported by SARA,<sup>8</sup> to higher-level design of systems incorporating devices which implement data flow primitives.

## RELATIONSHIP BETWEEN DDF AND GMB

### *Token flow models*

The Graph Model of Behavior (GMB)<sup>11</sup> and the Dennis Data Flow (DDF) Model<sup>5</sup> can be considered token flow models which were invented to help synthesize asynchronous concurrent systems. A token flow model uses a directed graph composed of nodes and arcs to describe the static component of a system behavior. Tokens, which are initially placed on the arcs, flow through the graph, activating and deactivating nodes. In this way, selected dynamic behavior of a system can be modeled and observed. Such models are most suitable for describing the behavior of concurrent and asynchronous systems in which some events may occur concurrently, but those occurrences must be controlled to satisfy constraints, i.e. precedence and frequency.

The GMB was developed in a search for a natural, simple and powerful method for describing and analyzing the flow of data and control in systems. The GMB was derived from the bigraph model of computation (GMC)<sup>13</sup> which formalized earlier work at UCLA.<sup>7,18</sup> The GMB was influenced by the LOGOS work at Case Western Reserve.<sup>24</sup>

A simple data flow model was studied in the basic work by Karp and Miller.<sup>17</sup> Dennis and Rodriguez<sup>23</sup> developed program graphs which were later revised and analyzed as a form of parallel program schema. A chain of investigators in Dennis' information structure group has continued exploration of fundamental data flow primitives and architectures. In this paper we concentrate on the data flow model developed by Dennis. Other noteworthy data flow models have been reported in the work of Adams,<sup>1</sup> Arvind - Gostelow,<sup>15</sup> Bahrs<sup>3</sup> and Kosinski.<sup>19</sup>

### *Dennis' data flow primitives*<sup>5</sup>

A data flow language is a machine language for expressing computations in which an instruction executes when and only when all operands needed for that instruction become available. The instructions, at whatever level they might exist, are purely functions and produce no side effects. Dennis' data flow language seeks to define a scheme of repre-

sensation that exposes concurrency while maintaining a guarantee of determinacy. This language considers only programs that compute a set of output values from a given set of input values and that define the functional dependence of output values on input values.

An elementary data flow program can be represented as a bipartite directed graph where the two types of nodes are called links and actors. The arcs of a data flow program should be regarded as channels through which tokens flow carrying data values. A data flow token is a primitive concept. It is better described as a pair  $\langle e_r, v \rangle$ ;  $e_r$  is an enable flag and  $v$  is a data value. The enable flag signals the presence of the token which carries a data value to be used in the computation.

A DDF link cannot have more than one incident arc, whereas it may have more than one emanating arc. A distinguished input link is one that has no incident arcs; a distinguished output link has no emanating arcs. There are two kinds of link nodes—data link and control link. Figure 1 shows the kinds of actor nodes from which elementary data flow programs are constructed. The *T*-gate, *F*-gate and Merge actors are called control actors. The Or, And and Not actors are called boolean actors.

The execution of a data flow program is described by a sequence of snapshots; each snapshot shows the data flow

Figure 1—DDF nodes.

Figure 2—Firing rules for link nodes.

program with tokens and associated values placed on some arcs. In the case of control arcs, the associated values are of the type  $truth = \{true, false\}$ ; for data arcs, the values are of the types  $integer, real$  or  $string$ . Execution of a data flow program advances from one snapshot to the next through the firing of some randomly selected link or actor that is enabled in the earlier snapshot. Except for the Merge actor, a node is enabled when all input arcs have a token and there is no token on any output arc. The Merge actor is enabled if there is no token on the output arc and *either* it has a token with value true on the input control arc and a token on the true arc input *or* it has a token with value false on the input control arc and a token on the false arc input. When a node fires it removes all enabling tokens from its input arcs and places tokens on its output arcs. An exception is made for the *T*-gate and *F*-gate. If the token value on the input control arc of a *T*-gate is False, the token on the input data arc is removed but no token will be placed on the output data arc. The same happens with an *F*-gate and a True value on the input control arc.

The value associated with an output token is a function of the values of the enabling input tokens. Firing an Operator applies the function denoted by the symbol written in the Operator to the set of values associated with the tokens on the input arcs and associates the resulting value with the

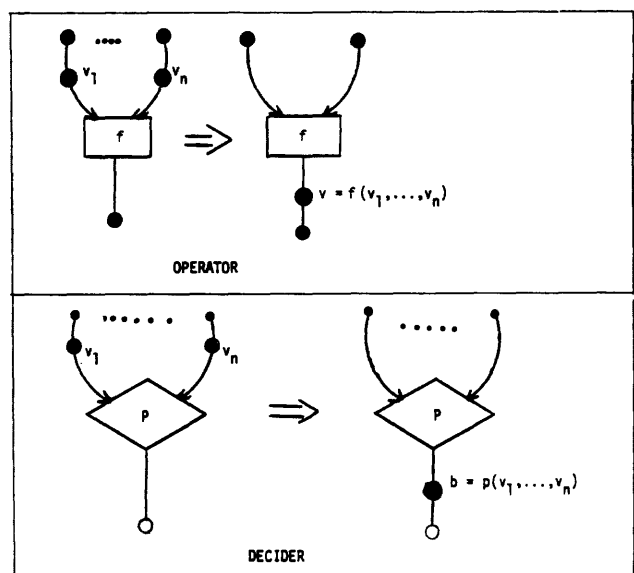

Figure 3—Firing rules for operators and deciders.

token placed on the output arc. Firing a Decider has a similar effect, but the symbol in the Decider denotes a predicate and a control value is associated with the output token. Figures 2, 3 and 4 show the effects of firing.

### Relating the two models

In the most general terms, information processing systems can be considered as flow and transformation systems. Basically, there are two commodities which flow during a processing activity in those systems—one is the control over resources and data and the other is the data itself.

The Graph Model of Behavior (GMB)<sup>10,21,22</sup> is a fundamental model incorporated in the SARA (System ARchitects Apprentice) methodology<sup>8</sup> for multilevel design of concurrent systems. The GMB tools provide languages for modeling the behavior of a digital system in three related domains—control, data and interpretation.

The control domain is concerned only with the control flow aspects of the system. It utilizes a directed graph (called the control-graph) where nodes model steps in the computation and arcs model precedence. Tokens flowing through the control graph establish activation conditions for control nodes. A node is activated if a simple function (a combination of +, \* and a weight) holds for the tokens on the incoming arcs. Activation amounts to removing the activat-

ing tokens and, upon completion of the activated process, adding tokens to the outgoing arcs according to a similar simple function.

The data domain describes flow of data and access capability constraints. A directed bipartite graph (called the data graph) is used to show how input data streams can flow through the system and where they are transformed (processed) in order to generate output data streams. The data graph describes the organization of data places (called data sets) and computation points (called processors). Data arcs describe allowable directed data paths between processors and data-sets.

The third domain, the interpretation, defines the format of data-sets, the format of data which flows along the data-arcs and the specific procedures to be carried out by activated processors. The current implementation of the GMB simulator uses an interpretation language which is an extension of PL/1 (called PLIP), but different interpretation languages could be introduced to enhance flexibility.

The three domains are associated as follows: Each control node is associated with at most one controlled processor in the data graph. Each controlled processor is associated with a unique (non-empty) set of control nodes in the control graph. The activation of a control node implies the non-preemptable activation of the associated controlled processor (if any). All concurrent activations of control nodes that are associated with the same controlled processor imply a sequence of activations of that controlled processor. The order of these activations is random. Segments of interpretation define the data structure associated with each data arc and the specific computation that is executed by each controlled or uncontrolled processor.

The GMB operates as follows: The "token machine" activates enabled nodes in the control graph. Control nodes activate controlled processors in the data graph while changes in the distinguished inputs activate uncontrolled processors in the data graph. The controlled and uncontrolled processors cause execution of code segments in the interpretation domain. The code segments cause data transfers (possibly with transformations) between data sets. Controlled processors may feed information back to the control domain to determine choice of output branching of the associated control nodes. The GMB can be used in a flexible way for the following purposes: a designer may choose to explicate more or less control flow; a designer may choose to vary the amount of data flow abstraction; a designer may choose to utilize different interpretation languages offering different powers of abstraction. Tables 1 and 2 tersely summarize properties of the current set of structural and behavioral modeling primitives. Table 3 summarizes properties of proposed extended primitives.<sup>25</sup> The SL1, GMB and PLIP languages (which support multi-level modeling) and a simulator (which supports analysis) are implemented at both UCLA and MIT-MULTICS.

In order to illustrate and make more meaningful comparison between the two models, let us first express the data flow primitives in terms of GMB primitives. Subsequently, some GMB constructs are expressed in terms of data flow primitives.

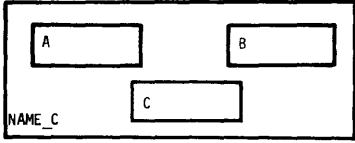

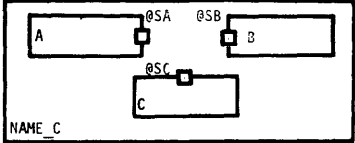

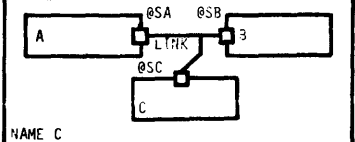

Figure 4—Firing rules for control actors.

TABLE I.—Modeling Primitives

STRUCTURAL PRIMITIVES	TYPE	GRAPHICAL	MACHINE PROCESSABLE
A NAMED MODULE REPRESENTS AN OBJECT WHOSE INTERNAL, FULLY-NESTED STRUCTURE IS HIDDEN FROM THE OUTSIDE. A MODULE'S ONLY POSSIBLE COMMUNICATION WITH THE OUTSIDE IS THROUGH A SOCKET. OTHERWISE, A MODULE'S NAME IS KNOWN ONLY TO THE STRUCTURE WITHIN WHICH IT IS NESTED.			NAME_C (A,B,C)
A NAMED SOCKET IS PART OF A MODULE BUT THE SOCKET'S NAME IS KNOWN BOTH INSIDE AND OUTSIDE OF ITS HOST MODULE.			NAME_C (A<@SA>, B<@SB>, C<@SC>)
A NAMED INTERCONNECTION IS A STRUCTURE WHICH CONNECTS TWO OR MORE SOCKETS.			NAME_C (A<@SA>, B<@SB>, C<@SC>, LINK : A@SA-B@SB-C@SC)

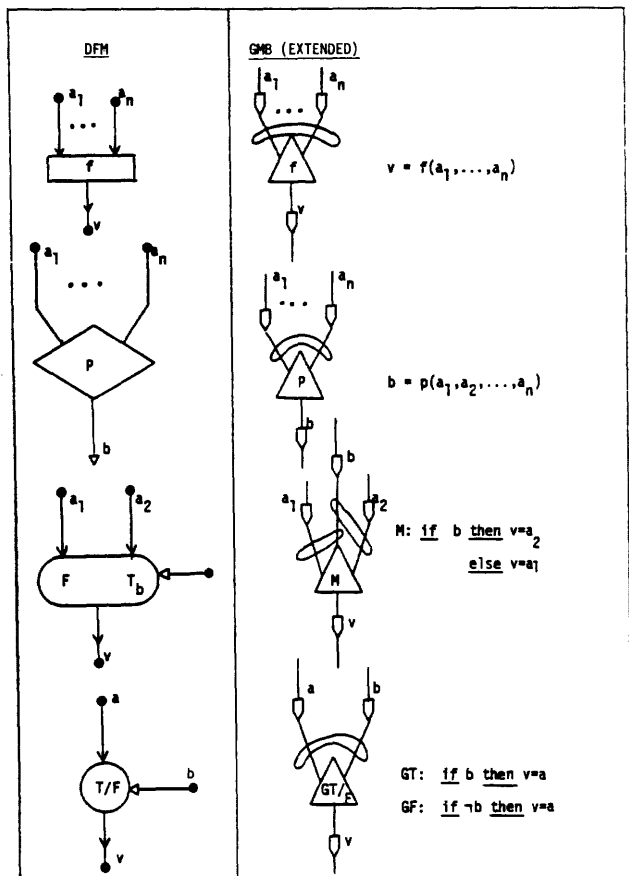

Figure 5—DDF to GMB using uncontrolled processors and data links.

Expressing data flow primitives in terms of GMB primitives

In general, any DDF can be abstracted into an uncontrolled processor where the interpretation of this processor

TABLE II.—Behavioral Modeling Primitives

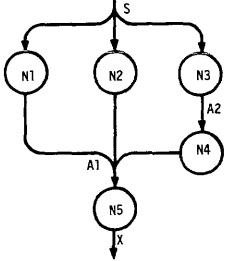

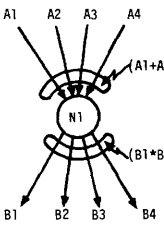

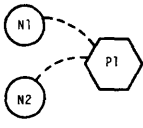

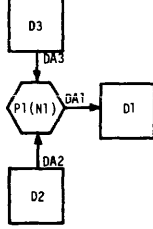

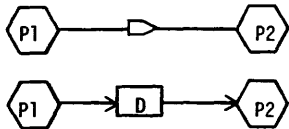

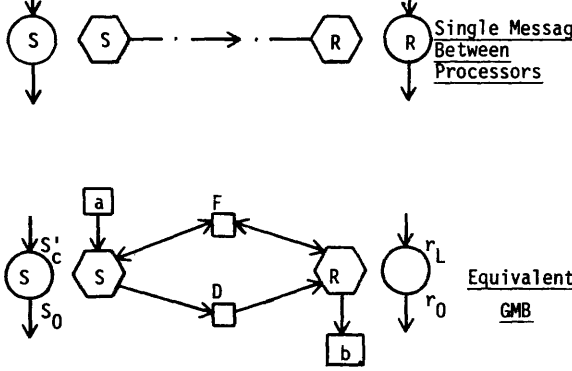

BEHAVIORAL PRIMITIVES	TYPE	GRAPHICAL	MACHINE PROCESSABLE
<p>A NAMED CONTROL NODE REPRESENTS A STEP IN A PROCESS BEING MODELED. A CONTROLLED DATA PROCESSOR (SEE BELOW) MAY BE ASSOCIATED WITH A NODE TO PROVIDE INTERPRETATION OF THE PROCESS.</p> <p>EXAMPLE: A NODE N1 HAS A SINGLE ENTRY ARC S AND A SINGLE EXIT ARC X.</p>		<pre>@CONTROL_GRAPH; @NODES N1; @ARCS S,X; N1 (S:X); @END;</pre>	
<p>A NAMED DIRECTED CONTROL ARC REPRESENTS NON-VOLATILE PRECEDENCE RELATIONS BETWEEN SETS OF NODES. IF THERE IS MORE THAN ONE SOURCE OR DESTINATION NODE THE ARC IS CALLED COMPLEX; OTHERWISE IT IS CALLED SIMPLE. AN ENABLING TOKEN IS PLACED ON AN ARC EITHER AS A STARTING STATE OR UPON TERMINATION OF ANY OF ITS SOURCE NODES. WHEN A NODE IS INITIATED, ITS ENABLING TOKENS ARE ABSORBED.</p> <p>EXAMPLE: A2 AND X ARE SIMPLE CONTROL ARCS. A1 IS A COMPLEX CONTROL ARC WHOSE SOURCE SET IS NODES N1, N2 AND N4 AND WHOSE DESTINATION SET IS N5. S IS AN INCOMING COMPLEX ARC WHOSE DESTINATION SET IS N1, N2, AND N3. IF THERE WERE AN INITIAL TOKEN ON S, THE TOKEN MACHINE MECHANISM WOULD NON-DETERMINISTICALLY ENABLE N1 OR N2 OR N3 AND THE TOKEN WOULD BE ABSORBED.</p>		<pre>@CONTROL_GRAPH; @NODES N1,N2,N3,N4,N5; @ARCS S,A1,A2,X; N1 (S:A1); N2 (S:A1); N3 (S:A2); N4 (A2:A1); N5 (A1:X); @END;</pre>	
<p><b>INPUT CONTROL LOGIC</b></p> <p>A LOGICAL RELATION AMONG THE INPUT ARCS TO A NODE SPECIFIES THE PRECEDENCE CONDITIONS THAT MUST BE SATISFIED BY TOKEN STATES FOR THE NODE TO BE INITIATED. TOKENS FROM THE INITIATING ARCS WHICH SATISFY THE INPUT RELATIONS ARE ABSORBED BY THE TOKEN MACHINE. TOKENS ARE ABSORBED FROM ONE OF AN INITIATING ARC SET GOVERNED BY AN OR RELATION IN A MANNER ESTABLISHED IN THE TOKEN MACHINE AND FROM ALL MEMBERS OF AN INITIATING ARC SET GOVERNED BY AN AND RELATION.</p> <p>EXAMPLE: IF ENABLING TOKENS EXIST ON EITHER A1 OR A2 AND ON EITHER A3 OR A4 THEN N1 CAN BE INITIATED.</p> <p><b>OUTPUT CONTROL LOGIC</b></p> <p>A LOGICAL RELATION AMONG THE OUTPUT ARCS SPECIFIES WHICH ARCS HAVE TOKENS PLACED UPON THEM WHEN A CONTROL NODE IS TERMINATED. WHEN AN EXCLUSIVE OR OUTPUT RELATION HOLDS, A DATA PROCESSOR INTERPRETATION MUST DECIDE WHICH ARC RECEIVES A TOKEN. WHEN AN AND RELATION HOLDS ALL OUTPUT ARCS RECEIVE TOKENS.</p> <p>EXAMPLE: WHEN N1 TERMINATES, ITS ASSOCIATED CONTROLLED DATA PROCESSOR WILL HAVE DECIDED WHETHER TOKENS ARE TO BE PLACED ON B1 AND B2 OR ON B3 AND B4.</p>		<pre>INPUT: OUTPUT CONTROL LOGIC @CONTROL_GRAPH; @NODES N1; @ARCS A1,A2,A3,A4,B1,B2,B3,B4; N1((A1+A2) * (A3+A4); (B1+B2) * (B3+B4)); @END;</pre>	
<p>A NAMED CONTROLLED DATA PROCESSOR REPRESENTS A DATA TRANSFORMATION OBJECT WHICH IS ACTIVATED WHEN AN ASSOCIATED CONTROL NODE IS INITIATED. E.G., PROCESSOR P1 IS INITIATED WHENEVER EITHER N1 OR N2 IS INITIATED. WHEN PROCESSOR P1 TERMINATES IT CAUSES TOKENS TO BE PLACED ON OUTPUT ARCS OF THE CONTROL NODE WHICH INITIATED IT. AN INTERPRETATION OF THE DATA TRANSFORMATION AND OTHER PARAMETERS SUCH AS THE DELAY OR RESOURCE REQUIREMENTS CAN BE ASSOCIATED WITH THE DATA PROCESSOR.</p> <p>EXAMPLE: PROCESSOR P1 HAS A RANDOM DELAY ASSOCIATED WITH IT. IRAND IS A BUILT-IN FUNCTION. THE CONTROL GRAPH CARRIES THE BURDEN OF GUARANTEEING THAT N1 AND N2 ARE ENABLED IN A DESIRED SEQUENCE. OTHERWISE THEY WILL BE ACTIVATED IN A NON-DETERMINISTIC ORDER AND THE SIMULATOR WILL SHOW POSSIBLE CONTENTION.</p>		<pre>@DATA_GRAPH; @PROCESSOR P1 (N1,N2); @END;</pre> <p><b>PLIP INTERPRETATION</b></p> <pre>@PROCESSOR P1; DCL IRAND ENTRY(FIXED BIN(31))RETURNS (FIXED BIN(31)); /*RANDOM # GENERATOR*/ DCL NUMBER FIXED BIN(31); NUMBER=IRAND(1,2) /*PICK AN INTEGER: 1 OR 2*/ IF NUMBER=1 THEN @OUTPUT_ARCS= 'B1,B2'; ELSE @OUTPUT_ARCS='B3,B4'; @DELAY=IRAND (10,100); /*PICK RANDOM DELAY FROM 10 TO 100*/ @ENDPROCESSOR;</pre>	
<p>A NAMED UNCONTROLLED DATA PROCESSOR REPRESENTS A DATA TRANSFORMER WHICH PROVIDES, AT ITS OUTPUT, STATED FUNCTIONS OF ITS INPUTS INDEPENDENT OF CONTROL NODE STATES. IN THE DATA GRAPH AN UNCONTROLLED PROCESSOR IS IDENTIFIED BY PROVIDING AN EXPLICIT DECLARATION. AN INTERPRETATION OF THE DATA TRANSFORMATIONS AND OTHER PARAMETERS MAY BE ASSOCIATED WITH IT IN AN IDENTICAL MANNER TO THE CONTROLLED PROCESSOR.</p>		<pre>@DATA_GRAPH; @UNCONTROLLED_PROCESSORS U1; @END;</pre>	
<p>A NAMED DATA SET REPRESENTS A PASSIVE COLLECTION OF DATA. DATA STRUCTURE MAY BE ASSOCIATED WITH A DATASET. ALL PL/I DECLARATIONS NOT CONTAINING SCOPE OR STORAGE CLASS ATTRIBUTES ARE ACCEPTED AS DEFINITIONS OF DATA SETS. CHARACTER STRINGS CANNOT HAVE THE VARYING ATTRIBUTE.</p> <p>EXAMPLE: THE DATASET D1 IS A SIX-DECIMAL-DIGIT COMPLEX FLOATING POINT NUMBER.</p>		<pre>@DATA_GRAPH; @DATASETS D1; @END;</pre> <p><b>PLIP INTERPRETATION</b></p> <pre>@TEMPLATE (1) D1 COMPLEX FLOAT DECIMAL(6);</pre>	
<p>A NAMED DATA ARC STATICALLY BINDS DATA PROCESSORS AND DATASETS. TABLE III.—Extended GMB Primitives

DESCRIPTION	GRAPHICAL
<p>A <u>data link</u> is a directed path between structured processors. A structured processor <b>WRITES</b> to a data link only immediately before its termination and <b>READS</b> from a data link only immediately after its activation. A data link may be used to build a connection between two structured processors by connecting a data link followed by a dataset followed by a data link. We refer to the composite as also being a data link between processors.</p>	 <p><u>Data Link Between Processors</u></p> <p><u>Equivalent D.G.</u></p> <p>P1: WRITE D; END P1;</p> <p>P2: READ D1; END P2;</p>
<p>A <u>message link</u> is a directed path between two processors that provides a fully interlocked mechanism to exchange messages. The processors are able to synchronize control and to exchange data. A message link is said to be active whenever the two processors are synchronized and ready to exchange data. A message link can be viewed as an input/output part for the involved processors. <u>Only processors that can be active at the same time can be connected through message links.</u></p> <p><u>single instantiation:</u> involves only one message link, two processors</p> <p><u>complex instantiation:</u> involves several message links at same time; requires arbitration. See [RUGG78] for more details of this model.</p>	 <p><u>Single Message Between Processors</u></p> <p><u>Equivalent GMB</u></p> <p>S: D:=a; F:=TRUE; while F do endwhile;</p> <p>R: while F do endwhile; b:=D; F:=False;</p>

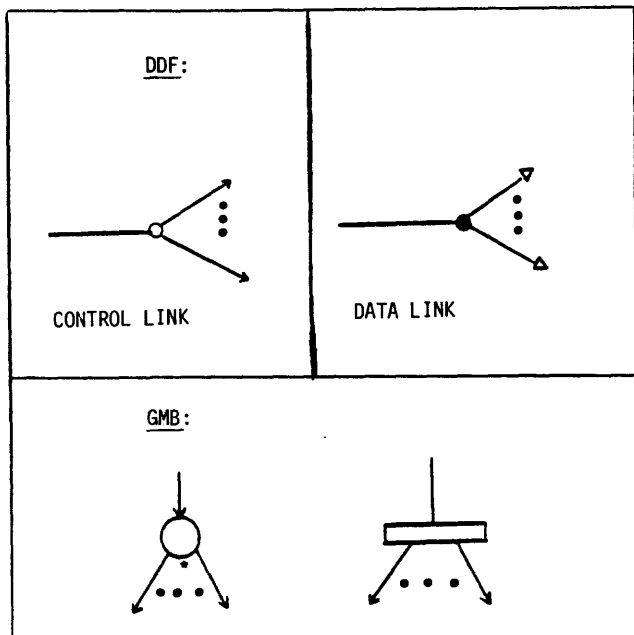

Figure 7—GMB representation of data and control links

is the data flow program. The behavior described by this data flow interpretation can be immediately translated into the GMB Control Graph (CG) and Data Graph (DG).

One approach is to define extended primitives to express data flow behavior only in the DG using for example, un-

Figure 8—Explicit acknowledge tokens.

Figure 9—GMB representation of an elementary actor.

controlled processors and data links (see definitions in Tables 2, 3) as shown in Figure 5. The GMB data links have internal storage, are written into just before termination of a processor and are read from only immediately after initiation. Another approach is to describe the data flow behavior by separating the control and the data parts into a GMB CG and a GMB DG respectively. For the rest of this section we assume the latter approach because it gives more insight into the properties of the two models. For practical purposes, a data graph-oriented description of a DDF is usually preferable, (and is used in the demonstration example of Part B); however, the control-oriented description is more suitable for analysis purposes. In a data flow program the flow of control and the flow of data are shown together in the same graph.

As shown in Figure 6, the DDF enabling flag,  $e_r$ , is, in GMB terms, an input token for a node  $n$  in the control graph. It signals the presence of a data value  $v$  in a data-set  $d$ . A controlled processor  $pn$  associated with a control node  $n$  then has read access to the data-set  $d$ .

Let us consider, in a data flow program a link node  $l$  with one input arc and  $m$  output arcs (Figure 7). The equivalent

Figure 14—DDF representation of GMB switch construct.

Figure 13—DDF representation of GMB join construct.

Figure 15—DDF representation of GMB union construct.

representation in GMB will have

- A data set  $d$  with one input data arc and  $m$  distinct output data arcs.
- A control node  $n$  with one input control arc and  $m$  output control arcs related by an "\*" operator in the output logic expression of  $n$ .
- If  $m$  is equal to "1," node  $n$  does not need to exist. It is reduced to just a control arc.
- The control node  $n$  does not have any controlled processor associated with it in the data graph.

Except for control actors, all elementary DDF primitives can be represented in GMB using only one control node and one controlled processor. The DDF control actors represent more complex computations.

The DDF interpreter requires an elaborate operation to decide which node to activate next. It needs some kind of acknowledge token which flows internally in the interpreter. In order to effect the same behavior in GMB, the acknowledge tokens may be shown explicitly in the control graph (see Figure 8), may be included in every GMB processor interpretation or may be placed as a burden on the token

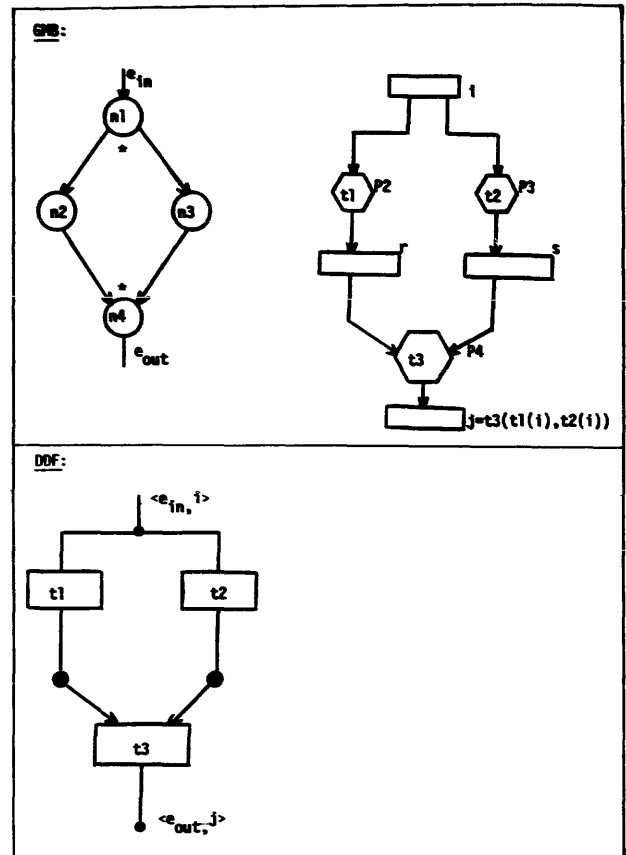

Figure 17—DDF representation of GMB Parbegin\_Parend construct.

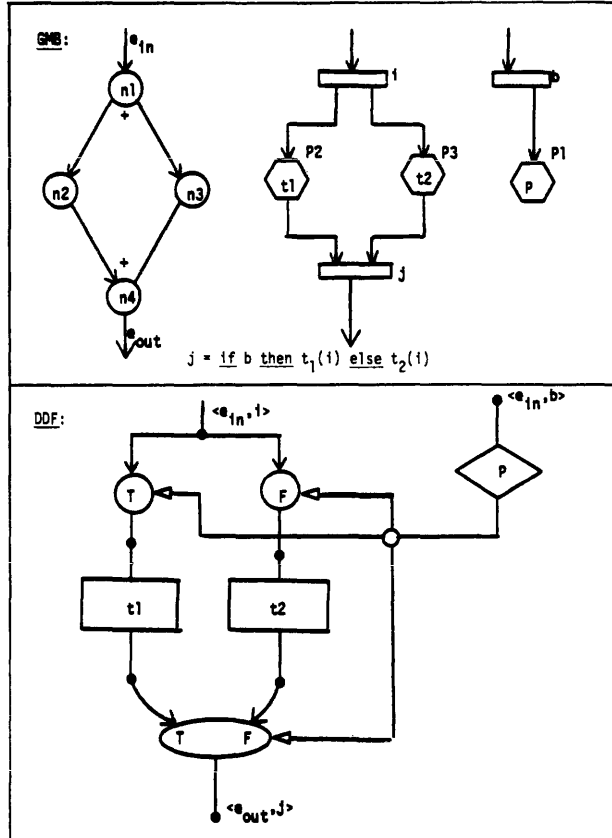

Figure 16—DDF representation of GMB If\_Then\_Else construct.

machine. The last approach would make the token machine equivalent to the DDF interpreter.

The use of explicit acknowledge tokens in a GMB makes the description much less readable. In the remainder of this section, we neglect the acknowledge tokens required in the GMB equivalent expression of the DDF primitives so as to focus attention on the relationship between the two models. Figure 9 shows how actors, except for control actors, are represented in GMB. Figures 10 and 11 show the representation of Gate and Merge control actors respectively.

The GMB representation of a Gate actor shows clearly (Figure 10) that this primitive has a control flow description which is not properly terminating.<sup>13</sup> In GMB terms, the Gate actor is not considered "well behaved" and its presence may complicate the verification of a DDF model.

Finally, we should observe that there is no need to distinguish between data for different data types (boolean and numeric) in a GMB model.

#### Expressing some GMB constructs in terms of DDF primitives

We do not attempt the expression of non-deterministic GMB constructs in terms of DDF primitives because the set

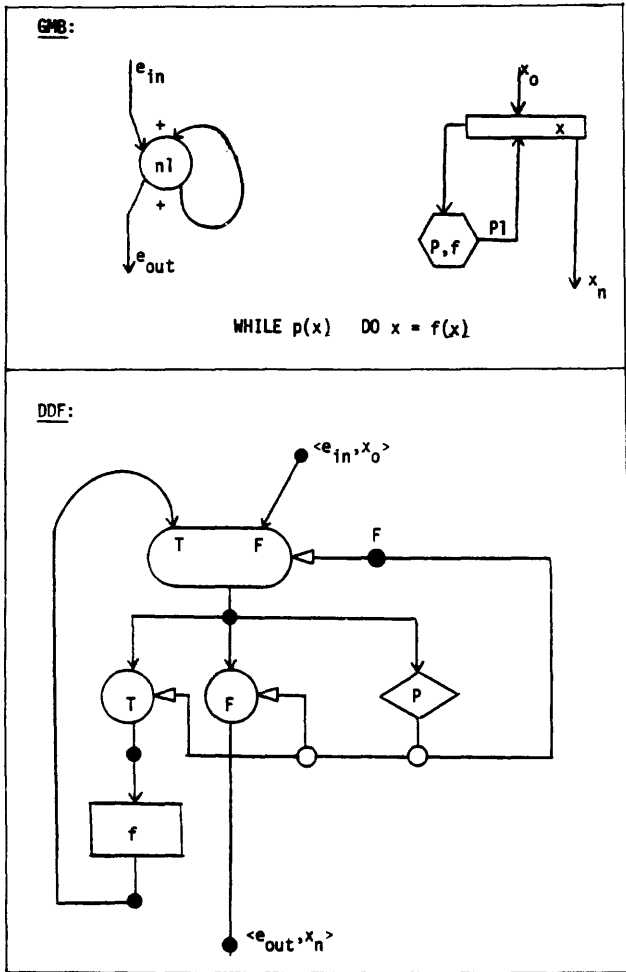

Figure 18—DDF representation of GMB Do\_While construct.

Figure 19—GMB solution of the root of  $f$  by Newton approximation,  $x_{i+1} = x_i - f(x_i) / f'(x_i)$ .

of programs intended to be expressed by the DDF language includes only deterministic programs. But, we should point out here, that the lack of non-determinism is one of the main weaknesses of DDF language when applied in a real-time programming environment. Some important problems in real-time processing such as mutual exclusion, synchronization and resource management, are in essence non-deterministic problems. The complex control arc is the general form of expressing non-determinism in a GMB program.

Now let us see the equivalent expression, using DDF primitives, of some deterministic GMB constructs. Figures 12-18 show respectively the Fork, Join, Switch, Union, If\_Then\_Else, Parbegin\_Parend and Do\_While constructs in terms of DDF primitives.

The equivalent expression of the Union construct (Figure 15) (which is another form of non-determinism in GMB) presented a problem when described in DDF terms—namely the control input of the Merge actor was not defined. This does not seem to be a problem in deterministic programs, because this construct should be used as shown in the If\_Then\_Else and Do\_While constructs (Figures 16 and 18).

Looking at Figure 18, where a sequential construct is presented, we note flexibility of the GMB program in including all the sequential processing inside of a controlled processor. To describe this purely sequential construct in DDF we need the full DDF interpreter mechanism, which was designed to handle concurrent operations. The capability to embody segments of sequential code in elementary primitives, without involving the elaborated mechanisms of the token machine, represents a great advantage for GMB programs. The programmer may specify the use of an extra processor only when the problem really requires it, i.e., when there are some concurrent operations to be performed.

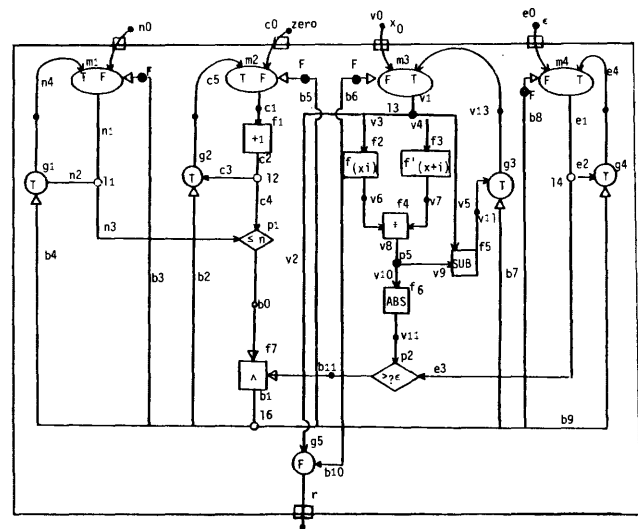

Figure 20—DDF solution of the root of  $f$  by Newton approximation,  $x_{i+1} = x_i - f(x_i) / f'(x_i)$ .

## DEMONSTRATION EXAMPLE

*A deterministic program in GMB and DDF*

In this section we present the solution of a simple computation expressed in GMB and in DDF languages. The problem to be used as an example is the calculation of a root

of a function  $f$  by the NEWTON-RAPHSON approximation.<sup>4</sup> This method involves the successive calculation of

$$x_{i+1} = x_i - f(x_i) / f'(x_i),$$

given the initial value  $x_0$ , the maximum number of iterations  $n$  and the precision  $\epsilon$  to be achieved.

Models of the solutions were designed trying to express

The following is a sample of a session with the SARA system. The system is a set of design and modelling tools which are implemented on the MIT-Multics computer system. This demonstration is intended to acquaint all interested persons with the state of implementation of the SARA system. All the demonstrated tools are available to any user with access to the MIT-Multics system.

The example shown here is a GMB model simulating Arvind and Gostelow's [GOST75] data-flow model for the calculation of the roots of a function by Newton-Raphson approximation.

In the session, all user input is preceded by the SARA system prompt ">"; all other information is output by the SARA system (except where otherwise noted). Several comments are included to describe the session, they are surrounded by "/\*" and "\*/".

The SARA commands are generally divided into two categories:

- 1 System Commands (preceded by &)  
These are commands available at any level of input and within all tools. They allow the user to alter the SARA input/output environment and additionally to request assistance (&help).
- 2 SARA Commands (preceded by @)  
All non-System commands are preceded by @. This is a standard observed by all SARA tools, as well as the tool Selector.

In addition to the above commands, a "?" may be entered at any point of input (including at the end of an incomplete input line) to receive assistance in several of the SARA tools, including the Selector.

/\* The following Multics command must be entered to \*/  
/\* begin a SARA session. It is often abbreviated \*/  
/\* "SARA" by use of Multics abbreviation facilities \*/

the parallelism existent in the problem. Figure 19 presents the GMB model and Figure 20 represents the DDF model. Both models should be viewed as if they were part of a SARA closed design universe, i.e., the model of the system to be designed is enclosed by a module structure and can

interact with other modules only through specified sockets. It is assumed that outputs from other modules initialize the model and provide the four inputs at the top of the figure. It is assumed that the outputs at the bottom are received by other modules and possibly tested for error.

control graph. Templates for PLIP interpretations were used to make each uncontrolled processor behave like the corresponding DDF primitive. The resulting GMB description representing the DDF model was then translated and simulated by SARA at MIT-MULTICS via the ARPANET. The dialogue between user and SARA was captured and is incorporated in Figure 21 to complete the body of this section. In the interest of space, some details have been removed and comments have been added to notify the reader.

## CONCLUSIONS

This paper has attempted to describe two token models which have been used to explore architectures taking advantage of concurrency. The primitives of the Dennis Data Flow Model and the SARA Graph Model of Behavior have been described and further understanding of their relationships was obtained by expressing one set of primitives in terms of the other. It was then demonstrated that data flow architectures could be explored making use of existing SARA tools. In particular, some investigators have found that developing a DDF model is very much like low-level design of a hardware system. The multi-level modeling supported in SARA gives some hope of expressing functions at a high level and refining them systematically.

# Software metrics for aiding program development and debugging

by N. F. SCHNEIDEWIND

Naval Postgraduate School  
Monterey, California

## INTRODUCTION

Computer program graphs have proven very useful because they illuminate the structural characteristics of a program. Structural characteristics, as a representation of program complexity, have been shown to be strongly related to program development time, program quality and difficulty of debugging.<sup>1-3</sup> The use of graphs for these purposes is not widely known or understood in the data processing community. It is the aim of this paper to provide an introduction to graphs as they apply to program representation and to show examples of their use in program design and debugging.

## GRAPH DEFINITIONS AND PROPERTIES DEFINITIONS

The following definitions are due to Chan:<sup>4</sup>

### *Graph*

A graph is a set of line segments called edges ( $e_j$ ) and points called vertices ( $v_i$ ) which are the end-points of the edges, interconnecting in such a way that the edges are connected only to the vertices. A non-directed graph has no orientation of the edges; a directed graph does have edge orientation in the form of arrows. Figure 1a shows a directed graph  $G$ .

### *Degree of a vertex*

The degree of a vertex is the number of edges incident with that vertex. The degree of  $v_6$  of  $G$  is 3.

### *Sub-graph*

A portion of a graph, containing a subset of the edges and vertices of the graph is called a sub-graph. Two sub-graphs of  $G$ ,  $G_1$  and  $G_2$ , are shown in Figure 1b.

### *Path*

If a set of edges  $e_1, e_2, \dots, e_i$  can be ordered in the form  $e_1(v_1, v_2), e_2(v_2, v_3), \dots, e_i(v_i, v_{i+1})$ , where  $v_1$  and  $v_{i+1}$  are the terminal vertices and all vertices are distinct, then the set of edges forms a path. In  $G$ , the set of edges  $a, d, e$  forms a path. It is important to note that by this definition vertices may not be revisited. Thus, the sequence of edges  $a, b, c, d$  in  $G$  is not a path because  $v_2$  appears twice in the edge sequence. In graph theory this sequence is called a walk. However, since iteration is an important characteristic of computer programs, we will modify the above definition of path to include walks in order to avoid using two terms when describing a program graph. When the edges of a path have consistent orientations, the path is directed. The above paths are directed.

### *Circuits*

If the two terminal vertices of a path coincide and the remaining vertices are distinct, this path is a circuit. A directed circuit has all edges with the same (clockwise or counter-clockwise) orientation. Thus  $G_1$  and  $G_2$  are circuits but only  $G_1$  is directed.

### *Connected graph*

A graph is connected if there is at least one path between every pair of vertices.  $G$ ,  $G_1$  and  $G_2$  are connected.

### *Tree*

A tree  $T$  of a connected graph is a connected sub-graph that contains all vertices of the graph but no circuits. The edges contained in a tree are called branches. The complement set of edges  $T'$ ; that is the remaining edges of the graph, are called chords. One of the trees of  $G$  is shown in Figure 1c, where  $T=(a, b, d, e, f, g, h, i, k)$  and  $T'=(c,$

Figure 1a—Graph G.

$j, l, m$ ) are the branch set and chord set, respectively. If we let  $E$  and  $V$  represent the number of edges and number of vertices, respectively, the number of branches and chords is equal to  $V-1$  and  $E-V+1$ , respectively.

Figure 1b—Sub-graphs  $G_1$  and  $G_2$ .

MATRIX PROPERTIES

Adjacency matrix

The adjacency matrix  $X=[x_{ij}]$  of a directed graph with  $V$  vertices is a  $V \cdot V$  matrix consisting of 0, 1 elements, where  $X_{ij}=1$  if there is an edge directed from  $v_i$  to  $v_j$ , and 0 otherwise.<sup>5</sup> The  $r$ th power of the adjacency matrix  $X^r$  is equal to the number of directed paths of length  $r$  edges between each pair of vertices  $v_i$  and  $v_j$ . Shown in Figures 2a, 2b and 2c are  $X, X^2$  and  $X^3$  of  $G$ , respectively. Thus Figure 2b shows that there are two paths of length 2 from  $v_6$  to  $v_9$ ; these consist of edges  $g$  and  $i$  and  $h$  and  $j$  (see Figure 1a). A directed path of length 3 from  $v_1$  to  $v_{10}$  is indicated in Figure 2c; this is a path from start to terminal vertices consisting of edges  $a, d$  and  $l$ . If  $v_i$  designates the terminal node of a graph and recognizing that the maximum possible path length is  $r=E$  edges, the matrices  $X, \dots, X^E$  with non-zero entries in the  $1, t$  cells will enumerate all of the paths which start at  $v_1$  and terminate at  $v_t$ .

Fundamental circuit matrix

A fundamental circuit matrix,<sup>4</sup> with respect to a tree  $T$  of a graph  $G$  of  $V$  vertices and  $E$  edges, is the matrix  $B_f$  of

Figure 1c—Tree  $T$ .

order  $(E - V + 1) \cdot E$  with each row identified by a fundamental circuit  $c_i$  (with respect to  $T$ ) and each column by an edge  $e_j$ , where  $b_{ij} = 1$  if  $e_j$  is in  $c_i$  and has the same orientation as chord in  $c_i$ ,  $b_{ij} = -1$  if  $e_j$  is in  $c_i$  and has opposite orientation of chord in  $c_i$ ,  $b_{ij} = 0$  if  $c_i$  is not in  $c_i$ . The  $B_f$  for

Figure 2c—Cube of adjacency matrix.

$G$  is shown in Figure 3. The chord set  $T' = (c, j, l, m)$  forms a unit matrix on the left. The branches of  $T$  are on the right. Circuits are formed by adding one chord at a time to  $T$ . Thus the circuits are:  $bc$ ,  $ghij$ ,  $efgikl$  and  $adefgikm$ , corresponding to  $c_1$ ,  $c_2$ ,  $c_3$  and  $c_4$ , respectively, where  $c_1$  and  $c_4$  are directed circuits. Fundamental circuits have the property that no circuit in the set can be obtained by a linear combination of other circuits in the set. The number of fundamental circuits in a graph is given by  $E - V + 1$ , the number of chords. Once  $B_f$  has been determined, all circuits in a graph, comprising the circuit matrix  $B_a$ , can be generated by performing all possible sum (Exclusive OR) operations indicated by  $(\oplus)$  on the rows

Figure 4—Reachability matrix  $R$  of  $G$  (with no edge from 10 to 1).

of  $B_f$ , if the negative signs in  $B_f$  are ignored. A ring sum operation on two rows of  $B_f$  will generate either another circuit in  $G$ , whose edges are either in one of the original circuits but not in both, or an edge disjoint union of circuits:<sup>5</sup> the latter are ignored. Thus from Figure 3,  $C_2 \oplus C_3$  will generate circuit  $e f h j k l$  and  $C_2 \oplus C_4$  will generate circuit  $a d e f h j k m$ . Program constructs, which will be described later, are shown on the diagram.

#### Reachability matrix

The reachability matrix  $R=[r_{ij}]$  has a value  $r_{ij}=1$  if a directed path exists between  $v_i$  and  $v_j$  and 0 otherwise [6]. The  $R$  matrix for  $G$  is shown in Figure 4. This matrix does not include the edge  $m$ , because this would result in  $R$  having all ones, a special case where each vertex can be reached from every other vertex (strongly connected graph).

## APPLICATION OF GRAPHS TO PROGRAM DEVELOPMENT AND TESTING

### Directed graph representation of computer programs

The use of a directed graph to represent a program will now be demonstrated. In fact, the connected graph  $G$  which has been discussed in the examples is the graph of the ALGOL procedure in Figure 5. The circled numbers in this figure correspond to the vertex numbers in Figure 1a; edges correspond to ALGOL statements between vertices. The program constructs (e.g. *If Then Else*) of this procedure are shown in Figure 6. The four constructs (*While Do*, *If Then Else*, *If Then* and *Main Line*) are connected sub-graphs. The part of the procedure corresponding to no iterations and the satisfaction of all true conditions is called the *Main Line*. Each of the constructs can be obtained from the tree in Figure 6 by adding a chord to the tree. These chords are  $c$  for *While Do*,  $j$  for *If Then Else*,  $l$  for *If Then* and  $m$  for *Main Line*. Each of the constructs is an independent circuit as previously defined. Edge  $m$  is an artificial edge which has been added to the graph for the purpose of obtaining the *Main Line* construct as an independent circuit; it is not part of the ALGOL procedure. Using *Main Line* allows edges  $a$  and  $d$ , which do not appear in the other three constructs, to be represented in the set of independent circuits. The independent circuits in matrix form ( $B_f$ ) are shown in Figure 3. The extent of branching at a vertex is given by the degree of the vertex. For example the beginning of the *If Then Else* construct is at  $v_6$ . This vertex has degree 3, corresponding

        END;
   END TEST_CONDITIONS;

```

Figure 5—ALGOL procedure corresponding to graph of Figure 1a.

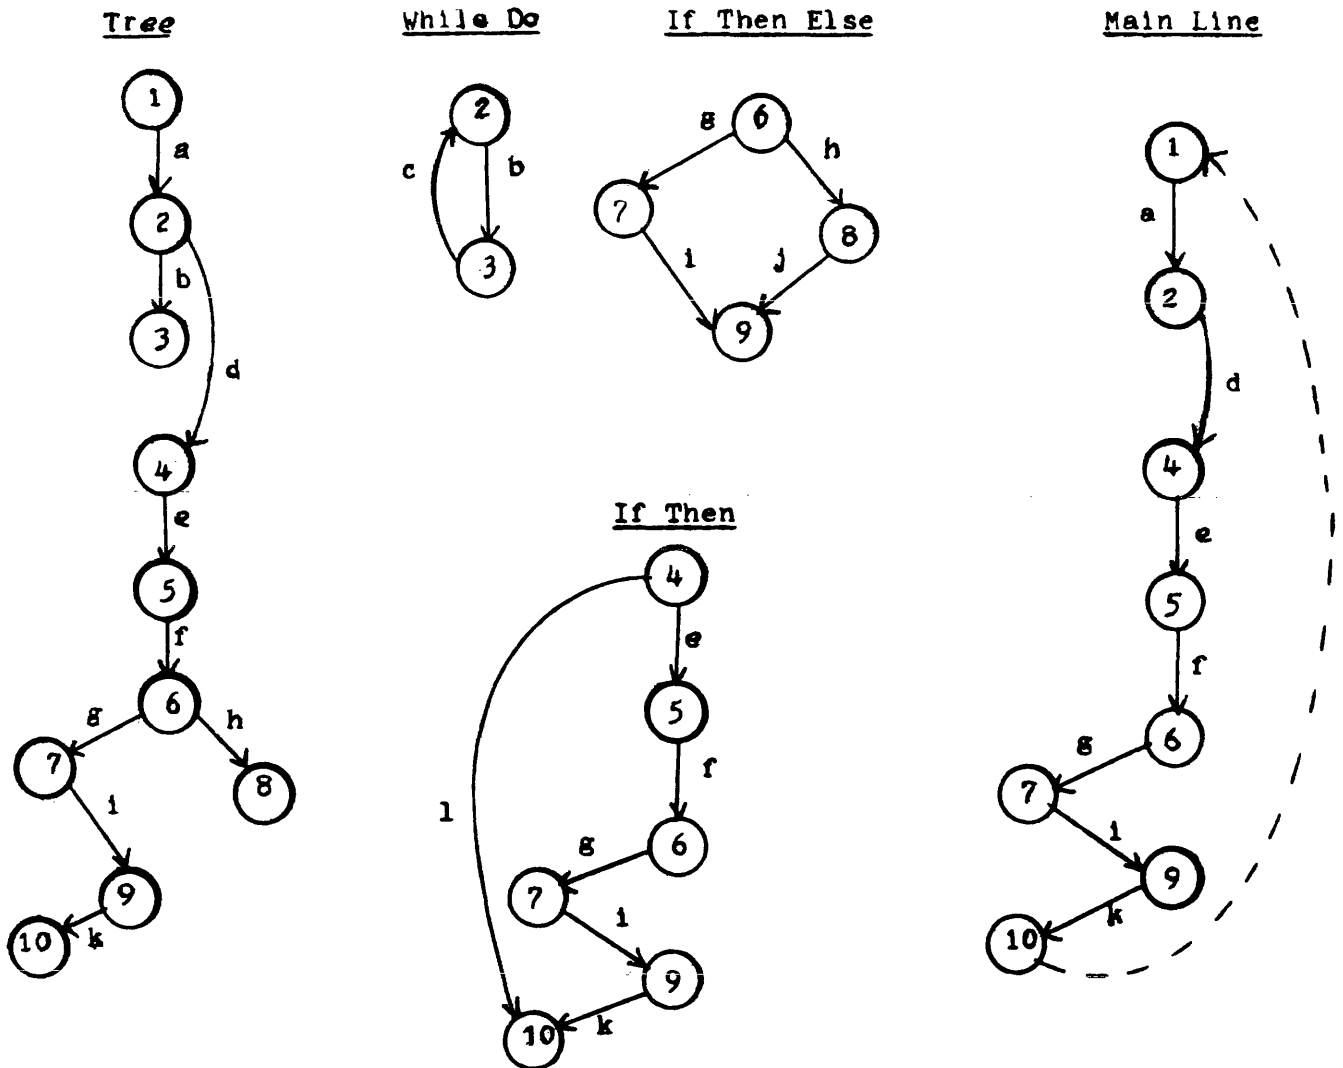

Figure 6—Decomposition of Figure 1a structure.

to the entry, *Then* and *Else* branches. Vertex degree is one indicator of program complexity.

*Implications of graph properties for program development and testing*

**Program constructs**

A program graph can be partitioned into its constructs by first identifying a tree and then adding a chord at a time as shown in Figure 6. Each construct is a basic unit of a program which must be tested. The number of constructs or independent circuits is called the cyclomatic number. This was previously given as  $E - V + 1$ . This quantity has been shown to be highly related to difficulty of debugging.<sup>1,3</sup>

**Program paths**

The Adjacency Matrix and its derivatives provide program path information. This information can be used to identify

the various paths whose correct execution should be verified. Two elementary program paths are given by Figure 2b, where it is shown that there are two paths of length 2 from  $v_6$  to  $v_9$ ; these correspond to the *If Then* and *If Then Else* branches. It should be noted that path length as used in Figure 2 refers to number of edges and not to number of source statements.

Complete paths from  $v_1$  to  $v_{10}$  can be obtained by performing ring sum operations on the independent circuits of matrix  $B_f$ , as explained previously. The six possible paths so obtained are

- a d e f g i k
- a d e f h j k
- a d l
- a b c d e f g i k
- a b c d e f h j k
- a b c d l

These are paths from start vertex to terminal vertex which should be tested.

### Code reachability

The reachability matrix can be used to ascertain whether any program code is not used. This would be indicated by one or more zero rows in  $R$ . The relative importance of vertices can also be ascertained by examining  $R$  and noting the number of ways a given vertex can reach other vertices. A high number indicates that the vertex and the edges comprising the paths to the other vertices are relatively important for correct execution of the program and should be accorded corresponding emphasis in testing;  $v_2$  is such a vertex in Figure 4.

Reachability may also be defined as the summation, over all vertices, of the number of ways in which a vertex can be reached. Average reachability can be obtained by dividing this figure by number of vertices. This is the way reachability was calculated in Table I, which will be described subsequently.

To make the use of directed graphs practical for program representation and complexity measurement, it is necessary to significantly automate the production of the various matrices and complexity measures from a definition of the program graph. Even the latter can be generated, if the problem has been put in the form of a decision table. Several automated tools exist for directed graph manipulation.

### PROGRAM COMPLEXITY MEASURES OBTAINED FROM DIRECTED GRAPHS

The data in Table I show the results of an experiment conducted at the Naval Postgraduate School involving four ALGOL programming projects, where average values of four complexity measures were computed for programs with and without detected errors [3]. Three of the measures (cyclomatic number, number of paths and reachability) were obtained from directed graphs and were discussed previously in this paper. Complexity measure values were significantly lower for the no-error case, suggesting a set of quantitative measures for program quality control and error avoidance.

TABLE I—Software Error Experiment  
Complexity Measure Comparison  
Procedures With No Errors vs. Procedures With Errors

	No Errors		Errors	
	Mean Value	Number of Procedures	Mean Value	Number of Procedures
Cyclomatic Number	1.699	83	4.74	31
Number of Source Statements	9.361	83	27.23	31
Number of Paths	2.671	82	27.1	20
Reachability	10.1	82	120.3	20

### SUMMARY

Several directed graph properties which are useful for program representation and complexity measurement were described. These were then applied to a small ALGOL program. Evidence was then presented suggesting that directed graph properties can provide quantitative measures of program quality.

# A measure of software complexity

by NED CHAPIN

InfoSci Inc.  
Menlo Park, California

## IMPORTANCE OF COMPLEXITY

In recounting the copious reasons or excuses for our traditional problems in developing and maintaining computer software, many authorities have mentioned complexity (e.g., References 2, 8, 15). The complexity pointed to sometimes is the inherent complexity of the jobs the computer is to do; sometimes it is the complexity of the systems or programs that direct the computer to do the jobs.

Yet thoughtful observers have also long noticed that the inherent complexity of jobs may differ greatly from the apparent complexity of the software for those same jobs (e.g., References 26, 29). Anyone who has had the opportunity to study the diversity of approaches, designs, and codes resulting when different people independently produce software for the same job, keenly senses the difference between apparent software complexity and inherent job complexity (e.g., Reference 25).

Intuition and common sense generally agree that software which appears simple is superior to software that appears complex, whatever the inherent complexity of the job (e.g., Reference 20). This position is in fact incorporated in the appraisal guidelines of structured design as "simplicity."<sup>23,24</sup> But applying intuition and common sense is not really sufficient to obtain consistently simple software. What is needed is objective, quantitative, reliable, valid and convenient ways of measuring either the complexity or the simplicity in software. To that end, a number of proposals have been advanced.<sup>1,7,11,12,17,19,21,22,26,32</sup>

This paper proposes an alternative measure of software complexity. The background of the measure is briefly given, and its computational procedure described. Then it is applied to a given software design of a small modular structured program. Afterward, the measure is compared with other alternative measures and with programmer ratings of the program. The paper closes with a discussion of the validity of the proposed measure of software complexity.

## BASIS OF MEASURE

The proposed measure of software complexity,  $Q$ , is an index of the difficulty people have in understanding the function implemented by the software. The proposed meas-

ure is quantitative, highly reliable, shows reasonable validity and is easily computed from system and program documentation. Since source code is not required, the measure can be applied to designs before writing the source code, as long as they display some modularization.

The theoretical basis for the proposed  $Q$  measure springs from the set theoretic definition of function. The function is what the software is to direct the computer to do. Briefly put, a function is a correspondence between sets of input data of specified domains, and sets of output data of specified ranges. Hence, any difference in functions must be expressed as differences in the input or in the output or both.

These differences may take two forms—differences in the membership in the sets, or differences in the domains and ranges. Changes in domains—that is, the legal, allowable values the input may take for which the function is defined—and in ranges, are usually of smaller impact in the specification of a function than are changes in the component sets of the input or output. Thus, expanding the domain of a function such as "find a square root" from a domain of one- and two-digit positive integers to a domain of one-, two- and three-digit positive integers is usually a minor matter. But changing the components of the input or output to include a new variable, such as the natural log of the root as an additional output, usually makes a non-trivial change in the function of the software. At the loss of some validity, the proposed measure of software complexity ignores domains and ranges, and concentrates on the components of the sets of input and output.

A listing of the sets of input and output define the function coarsely. A more refined specification is possible if the role of the data is recognized.<sup>5</sup> Some input data are needed for processing (role "P" data)—that is, for the production of output data. The data changed, created, or modified (role "M" data) in value or identity by the performance of the function are the output data. The data used to select or decide which functions to perform serve in a controlling role (role "C" data). Or, data may pass through (role "T" data) a function unchanged in value and identity, when a function of the software is to communicate data from one part of the software to another part, as from one module to another.

To improve the validity of the proposed measure, data roles are recognized in it. Data in a  $C$  or control role contribute the most complexity. Data in an  $M$  or modified role are major contributors. Data in the  $P$  or processing role

contribute some complexity. The *T* role data that are only passed through contribute the least to software complexity.

The modules or segments of the software can be visualized as communicating data among themselves.<sup>20</sup> Such intermodule data exhibit a simple life history. They start as *M* role data in one module, become *T* role data as they are communicated through other modules, and then terminate as *C* role or *P* role data in a using module.<sup>5</sup> If only two modules are involved in the communication, then the data skip the *T* role. But the more modules involved in communicating any item of data, the higher is the apparent complexity of the software.

The data communication among modules may be further complicated by the presence of iteration. In modularized programs and systems, the iteration control is observed to be the psychologically most difficult aspect of the "interior" complexity.<sup>30</sup> Modularization can reduce most kinds of "interior" complexity, but makes no reduction in iteration complexity when more than one module is involved.<sup>18,19</sup>

If the duration or extent of iteration is determined by *C* or control role data arising outside of the loop exit module, the complexity of the software increases, but not in a linear manner. This non-linearity at first is of little importance, but becomes critical as the number and arrangement of the *C* role data become larger and more diverse. This is approximated in the computation of the proposed *Q* measure by a conversion formula involving the square of one-third of a weighted count.

In review, the proposed *Q* measure appears, because of its stress on function, to reflect the "exterior" rather than the "interior" complexity. This appearance is deceptive for several reasons. First, as Halstead has pointed out with his " $n_2^*$ ," the externals place a lower limit on the potential interior complexity of a module.<sup>11</sup> Second, assuming the presence in the module of an algorithm that avoids work redundant and extraneous to the function within the module, the data (as noted in the input-output table) with their associated domains and ranges, place an upper limit on the interior complexity of a module. And third, the process of identifying modules, apportioning the interior complexity of a system into the programs' component modules, and their interrelationships. Both what is apportioned where, and the interrelationships, are described by the data flow among the modules, and are reflected in the proposed *Q* measure of complexity because of its stress on function.

## COMPUTATION OF MEASURE

The high reliability of the proposed measure arises from the simple computational procedure used on the documentation for the program or system. A measure is reliable when different people using the same computational procedure consistently come to the same result.<sup>28</sup>

The ten steps in the computational procedure for the proposed measure *Q* are:

1. For each module, count in the input-output table<sup>5</sup> or the equivalent, the number of data items shown in *C*,

*P*, or *T* roles as input, and in *M* or *T* roles as output. When one data item appears in multiple roles or has multiple sources or destinations, each is to be counted. Data serving as program-wide or system-wide constants or literals are not counted. The reason for distinguishing the roles of data was described earlier.

2. Multiply for each module the total count for each role by the appropriate weighting factor *W*, as follows: 3 for *C*, 2 for *M*, 1 for *P*, and  $\frac{1}{2}$  for *T*. The reason for the weights was described earlier.
3. Sum the weighted counts by module.
4. Assign an initial *E* of 0 to all modules. Then examine the documentation to determine which modules are to contain the exit tests for iterations where subordinate modules are part of the iteratively-invoked loop body. The tree structure chart usually shows this most conveniently.<sup>4,20</sup> The loops or iterations are ignored when they are to be performed entirely within a module with no subordinate modules iteratively invoked. The reason for the concern with iteration control was described earlier.
5. For each iteration-exit module identified in Step #4, examine the *C* items to determine which are to serve in the exit test for the iteration of the subordinate modules that comprise the loop body. Determine where these *C* data come from. If they come from within this module only, or are constants, add 0 to *E* for each such *C* data item. If they come from within the subordinate loop body, add 1 to *E* for each such *C* data item. If they come from outside of the loop body, add 2 to *E* for each such *C* data item. An example (starting with *E* as 0) is an item of data which is initialized to a starting value outside of the loop (add 2 to *E*), and also modified within the loop body (add 1 to *E* to total 3). Note that *E* for any one module cannot exceed three times the count of the number of data items serving in a *C* role for determining the exit from iteration.
6. Convert *E* for each module into a repetition factor *R* by adding 1 to the square of one-third of *E*. For example, if *E* is 6, then one-third of *E* is 2, and 2 squared is 4, 4 plus 1 is 5. Hence *R* is 5. The reason for this formula was described earlier. *R* values for common *E* counts are: *E* of 0 gives *R* of 1.00; *E* of 1 gives *R* of 1.11; *E* of 2 gives *R* of 1.44; *E* of 3 gives *R* of 2.00; *E* of 4 gives *R* of 2.78; *E* of 5 gives *R* of 3.78; *E* of 6 gives *R* of 5.00; and *E* of 7 gives *R* of 6.44.
7. Multiply the sum of the weighted counts from Step 3 by the modules' respective *R* values.
8. Find the square root of the products from Step #7. This is *Q*, the index of module complexity. The computation in this step is easily done on most pocket calculators, and effectively is a computation of the geometric mean of the total weighted counts and the inter-module iteration control.
9. Calculate the *Q* of the program by finding the arithmetic mean (average) of the component modules. This is a simple averaging computation.

10. Calculate the  $Q$  of the system by finding the arithmetic mean of the component modules within the component programs, or by weighting the programs'  $Q$  from Step #9 by the relative sizes (in terms of modules) of the programs. Note that if in execution a system will iterate the execution of a program, then the  $E$  of the module containing the loop exit control is rarely zero.

The practical lower bound on module complexity is 1.0. The exception with a lower bound of zero is a module that has no  $C$ ,  $P$ ,  $T$ , or  $M$  role data—a module that does no function! However, in some delayed-time software, such modules may appear as the root of a system implemented at the root (top) level with JCL (Job Control Language). No upper bound exists for  $Q$ , but values beyond 11.0 are uncommon with structured programming and structured design.

#### EXAMPLE OF COMPUTATION

Figure 1 provides a tree structure chart of a program designed with structured programming techniques. The input-output tables are shown in Figure 2. The computation of module  $Q$  and program  $Q$  are summarized later. Figure 3 lists in its leftmost column, the identifications of the module.

The numbered paragraphs to follow refer to the step numbers described previously.

1. The counts from the input-output (I-O) tables are shown in the second through fifth column of Figure 3. Thus, for instance, Module S-4 has one  $C$  item, one  $P$  item, two  $M$  items, and two  $T$  items of data shown in Figure 2. These counts are the "raw counts" entries for line S-4 in Figure 3.
2. The raw counts are multiplied by the weights. Thus, for S-4, the count of 2 for  $M$  is multiplied by the weight  $W$  of 2 to give 4.
3. The sum of the weighted counts is shown as W-TOT in Figure 3. Thus, for Module S-4, the total of 9 is the sum of the weighted counts of 3+1+4+1.
4. A review of Figure 1 shows Modules S-3, S-4 and S-7 to contain iteration exits. The broken ring flags them. If the documentation were less specific, other clues would have to be used to locate repeated functions, such as the reading or writing of records.
5. In S-3, iteration exit items as flagged by a dot in the input-output table are the Record Key East, Record Key West, and Out of Sort. In S-4, it is a Bad End Switch. In S-7, no evidence appears from the input-output table about what the iteration control might

Figure 2—Input-output tables for example.

be. It probably is internal within this S-7 module. Care should be taken in such non-appearances to verify them to be reasonable, and not oversights in preparing the input-output tables. In the case of S-7, since the validation appears to be done in S-7 itself, no explicit loop exit data appears reasonable. Hence, *E* is 1 for all modules except S-3 and S-4.

In S-3, each of the three *C* items identified comes from a subordinate module which is within the loop body (hence, *E* is 3). But one *C* item (Out-of-Sort) also comes from outside the loop. Hence, *E* totals to 5 for the module S-3. In S-4, the Bad End Switch comes from the subordinate (loop body) module. Hence, *E* is 1 for S-4.

- The *E* to *R* conversion for all modules is very easy for all but two modules. Since *E* is 0, *R* is 1.0. For module S-3, it is 3.78, and for S-4, it is 1.11, by applying the formula.
- The column PROD is the product of the entries in the W-TOT column times the corresponding entry in the *R* column. Thus, for row S-4, the product of 9 times 1.1 is 9.9.
- The square roots of the entries in the PROD column are entered in the *Q* column. Thus, the square root of 9.9 is 3.1, which is the *Q* entry for module S-4. The *Q* entry is the complexity index for a module.
- The sum of the *Q* entries for the modules is 35.2, which when divided by 12, the number of modules, yields a program complexity index of 2.9.
- Since this example system consists of one program, the system index of complexity *Q* is also 2.9.

The interpretation of the *Q* measure is easy. Low-complexity is indicated by a low *Q*. But also, a relatively even distribution of the complexity is desirable among the modules. Software prepared using the ideas of both structured design and structured programming show low complexity compared to traditionally prepared software. The highest complexity in the structured software is usually along the main branches of the tree-like structure. But even there, the *Q* rarely exceeds 11. Leaf modules rarely exceed a *Q* of 5.

Traditionally prepared software usually shows a higher average complexity. If the software is modular in design, the *Q* can be fairly easily determined. If it is not modular, two alternatives are open. When source code is available, the modules may be taken to be equivalent to the lexical units used to group code, such as paragraph, section, subroutine, procedure, block, etc. Or when no source code is available, the design documentation may be examined, broken arbitrarily into pieces, and input-output tables prepared. This is rarely an easy process if done in an attempt to highlight and separately recognize functions jumbled together in skimpily-documented traditional designs.

### COMPARISON OF COMPLEXITY MEASURES

Five major measures of software complexity have been proposed. McCabe has offered a graph-theoretic measure,<sup>13</sup> which others have elaborated.<sup>7,12,22,31</sup> An application of it to the same example presented earlier in this paper is given in the McCabe column in Figure 4. McClure has offered a carefully-thought-out and well tested measure.<sup>18,19</sup> An application of it is given in the McClure column in Figure 4. Myers has given a basis for the measurement of software quality.<sup>23,24</sup> While not labeling it a complexity measure, his connectivity matrix measure can be not unreasonably interpreted in that way. An application of it is given in the Myers column in Figure 4. A group of entropy-based measures have been proposed<sup>1,9,11,26</sup> but are not shown in Figure 4. The Zolnowski measure has been claimed by Zolnowski to be not applicable to an individual program and to individual modules as it has been presented thus far.<sup>32</sup> An adaptation

Program complexity index 2.9

Figure 3—Computation of proposed complexity index  $Q$  for the example shown in Figures 1 and 2.

of it to modules and programs by McTap<sup>21</sup> is shown in the  $M \times Z$  column in Figure 4. The  $Q$  column in Figure 4 is the measure proposed in this paper.

A comparison of these other measures with the measure proposed here reveals both similarities and differences, as well as supports the validity of the proposed measure. All of the measures provide an overall indicator of software complexity suitable for making complexity comparisons between systems, programs and modules. But each measure requires a different interpretation.

The McCabe graph-theoretic has 1.0 as a lower bound, but has no upper bound, and grows faster than the number of modules, because a module never adds less than 1 to the total. The Zolnowski measure shows no consistent relationship to program or system size. The Myers connectivity matrix measure can not exceed 1.0 in value. In practice, for structured programs and systems, the Myers measure typically declines as program or system size increases. The proposed  $Q$  measure has a lower bound (zero), no upper bound, and shows a tendency to increase slowly as program or system size increases.

The McClure measure has well defined limits, depending on the number of control variables ( $C$  role data items). But as system or program size increases, larger numbers can be expected. This is intuitively reasonable (the growth generally is less than in the McCabe graph-theoretic measure), but a measure that gave "complexity density" would probably be more useful than just "complexity extent." The proposed  $Q$  measure does do this.

At the module level, all the measures are suitable for making comparisons between modules from different programs and systems. The McCabe graph-theoretic measure reflects primarily the amount of logic expressible as conditional transfers in the flow of control. In any modular approach, this is a useful type of complexity to control during design, implementation and maintenance.

The McTap-Zolnowski features-measure of complexity depends for its interpretation on the particular features included. A high measure indicates that some of the features are present to an important degree.

The Myers connectivity-matrix measure reflects the relative dependence of the modules. The higher the measure,

MODULE	McCABE	McTAP - ZOLNOWSKI	McCLURE	MYERS	Q	GROUP
S-1	7	6.5	2.20	0.70	3.2	2
S-2	1	0.0	0.55	0.70	2.4	5

PROG	24	5.5	1.25	0.58	2.9	--

Figure 4—Comparison for the example of some measures of complexity.

the more interdependent are the modules. But a high measure may also reflect functional variety and code packaging.

The proposed  $Q$  measure reflects what will take the form of actual code complexity in implementation because the more data that are used and produced, the more likely is the processing to be complex. Complexity is harder to achieve with only a few items of data going in and out!

The McClure measure is the most sensitive to the use of data for directing the flow of control. Historically, this has been the source of the toughest bugs in our software. And the McClure measure reflects well the complexity of the patterns of use and value-assignment for the data serving for control.

All of the measures can be used with modular designs characterized by properly nested functions. The Zolnowski measure does not require it. The McClure measure requires it, making provision for only one exception, the equivalent of the job abort. The Myers connectivity matrix and the proposed measures do not require it, but are enhanced by it. More significant for both of them is the size of the module. Both work best for relatively small (less than about 60 imperative instructions expected for the implementing code) and fairly even-sized modules. The McCabe graph-theoretic measure is comparatively independent of the design and

implementation philosophy and practice. In fact, it can be used to limit the size of modules for the aid of the other measures (such as not more than an expected 10 measure and only rarely over an expected 8 measure for the modules).

Some usage difficulties and conveniences distinguish the measures of complexity. For the Zolnowski measure, they depend upon the features selected. The entropy and McCabe graph-theoretic measures are almost always an understatement of the ultimate complexity until the design has been carried fully to debugged code.<sup>9,11</sup> But by then, it is usually too late to take much corrective action. This can be offset by a tight early discipline in design, but few designers welcome it.

The preparation of the Myers connectivity matrix is a separate additional step—not a normal by-product of design. With experience the matrix preparation can be done fairly rapidly, and it does not require either source code or detailed charts to be available. A tree-structure chart<sup>4</sup> may be sufficient, but the availability of input-output tables<sup>5</sup> strengthens the preparation of the connectivity matrix.

To use the McClure measure takes the same detailed review of the design as needed for the Myers connectivity matrix. But the factors looked for are far more objective in

the McClure measure than in the Myers measure. Yet the McClure measure, like the McCabe measure, is a retrospective measure of the complexity already present in the design. By contrast, the proposed  $Q$  measure can be used on-the-fly during design, implementation and maintenance. It does not require source code. It rarely misstates the final complexity of the software as coded if the input-output tables were conscientiously prepared.

A more serious limitation for the McClure measure and to a lesser extent the Myers connectivity matrix measure, is a failure to define data usage consistently. Use of the input-output tables helps reduce the problem but lacking good definition, the effect is to understate the complexity for all of these measures. The McClure measure requires a full and precise anticipation of the  $C$  and  $M$  roles in every module of every item of data used anywhere for control. The proposed  $Q$  method requires that any item of data to be accessed or assigned a value in any module be separately identified, such as a record and the key field within that record. But this is only a statement in data terms of the function of the module. And that is knowledge available to the designer.

The complexity measures differ considerably in computational convenience. The most difficult is the Zolnowski measure because it requires extensive data gathering, computation, measurement and further computation. Somewhat easier is the McClure measure because it involves fewer operations to gather the needed data and fewer computational steps. The next easiest is the Myers connectivity matrix. While the arithmetic is easy, the estimates of strength and coupling involve significant human judgments. Some of the entropy measures, such as the Halstead, are as easy to compute, and are free of the need for such extensive judgments. The McCabe graph-theoretic is still easier, and would be the easiest were it not for the difficulty in obtaining firm counts for the lines, the nodes and branches. The proposed  $Q$  method is clearly the easiest of all to use if input-output tables<sup>5</sup> or the equivalent, or code, or Chapin charts,<sup>6</sup> be available, since simple objective counts and simple arithmetic then yield the proposed  $Q$  measure. HIPO<sup>14</sup> can be used but adjustments are needed since a HIPO detail chart is not limited in its view to a single module except at the leaf position in the tree. When input-output tables are available from the design effort, the proposed  $Q$  measure can be calculated by someone without even a knowledge of computers or data processing.

## DISCUSSION

The validity of any proposed measure of software complexity cannot be assessed with precision. As Zolnowski has well pointed out,<sup>32</sup> people view software differently and see its complexity differently. In general, an index is said to be valid if it measures what it purports to measure.<sup>28</sup> Thus, changes in what it purports to measure should be reflected faithfully in the measure. The validity of some measures is open to question or left unaddressed.<sup>10,16,27,31</sup>

Comparing the proposed  $Q$  measure against four of the

other measures cited offers a measure of validity, as shown in Figure 4. On that basis the proposed measure seems as good as any of the others in terms of validity. The column in Figure 4 identified as GROUP represents the rank of the average rankings of the modules in the example by 206 programmers and analysts who had access to a full set of documentation. A rank of 1 represents the most complex, and of 12 the least complex. A ranking does not discriminate the extent of the differences in complexity. Thus, modules S-10 and S-11 were ranked virtually identically. The module S-1 includes a four-way CASE structure which some people regarded as complex. Module S-1 nearly tied for second place with module S-3 in the rankings. No ranking was made of the program overall.

It is surprising that the theory of computational complexity, long a part of the mathematical side of computer science, has contributed so little to measuring software complexity.<sup>3,13</sup> Perhaps in the future, some contribution will be forthcoming to help assess the validity of measures of software complexity. In the meantime, field experience can help evaluate the contribution in the development and maintenance of systems and programs, of the use of measures of complexity.

*Bell Telephone Laboratories*  
Murray Hill, New Jersey

## MOTIVATION

It is no longer a surprise that program maintenance dominates the total cost of a large software system over its lifetime. In response to these costs, the emphasis in program design has largely shifted from the time and space issues of machine efficiency to issues of clear and flexible program structures that can be easily maintained.

The goal of this project is to identify measurable program properties that influence maintainability. More precisely, we examine the effect of various program characteristics on the subsequent frequency and magnitude of program errors.

## PROGRAM MAINTAINABILITY

This paper presents a study of 123 PL/I program modules from a business data processing application. The modules fall roughly into three categories: high-level control, numerical and data base management. The maintenance record of each module was followed for approximately one year.

We characterize the maintenance performance of a program module by two values—the total maintenance time spent on the module and the number of maintenance changes made to the module. We considered a module in “maintenance” from the time it left the development programmer and entered system testing. The maintenance performance data came from two sources:

1. Informal (and incomplete) time records, recorded by hand, that include time spent on and cause of maintenance activities.
2. A formal (and complete) maintenance activity data base, recorded automatically when a program is changed, that does not include time spent per activity.

In this paper we present an analysis based upon the informal time records, chiefly:

- The number of errors per program module.
- The total time spent repairing those errors.

## PROGRAM MEASURES

Our starting hypothesis was that maintenance performance for a program depends upon:

- The complexity of the algorithm coded.
- The clarity of the coding.

(It is beyond the current scope of this work to consider influences on performance beyond the program itself, such as frequency of execution or instability of user requirements.)

Based upon previous work<sup>1,4,17</sup> and upon programming folklore we compiled a set of program properties for which the qualifiers complex and clear might have meaning. The list includes:

- Complexity of program control flow.
- Clarity of program control structure.
- Clarity of program data usage.

The next step was to develop measures to quantify these properties. Two primary criteria were adhered to in developing the measures:

1. Each measure should be largely language-independent.
2. Each measure should be noncoercible.

A measure is language-independent if:

- It can be meaningfully and consistently applied to programs written in several programming languages.
- The ordering the measure assigns to a set of algorithms

remains roughly constant when the algorithms are coded across languages of similar power.

One language-dependent measure that has been used to characterize programs is a count of the GOTO statements appearing in a module.<sup>1,13</sup> Counting GOTO statements is language-dependent because the practical meaning of GOTO changes as control structures change across languages. One language may require a GOTO to implement an innate control structure of another language.

A measure is noncoercible if it in fact measures the underlying program property of interest. Identifying program characteristics that may coincidentally vary with a fundamental property tells us little about the property.

Coercible measures that have been used to characterize programs include calculating the mean length of variable names as a measure of name meaningfulness,<sup>13</sup> and counting the number and length of comment blocks as an indicator of program documentation.<sup>13,15</sup> We have called these measures coercible since they can (quite easily) be influenced without any corresponding effect on the property they seek to measure.

#### Measuring the complexity of program control flow

Program control flow was characterized by measurements taken from the control flow graph for each program. A control flow graph is a directed graph with nodes corresponding to the simple clauses of a program and arcs indicating the sequence of control. The graph is connected, unreachable clauses are ignored. And the graph is single-entrance-single-exit—an entry node points to all entry points and an exit node is pointed to by all exit points (Figure 1).

Two simple graph measures were included for study:

- A count of the nodes in the graph.
- The ratio of binary decisions embedded in the graph to total nodes. (The number of binary decisions at a node is one less than the number of outgoing arcs from the node.)

Two other graph measures, sensitive to the configuration of the graph, were also studied:

- A count of the possible paths through the graph.
- The mean number of decisions per path through the graph.

We define a path through a graph to be a sequence of nodes, from the entrance node to the exit, such that no cycle is repeated. Even with this restriction the number of paths through a typical graph can be very great. For the more complex programs the total path count was estimated by a lower bound, and the mean path length was estimated from a sampling of the paths.

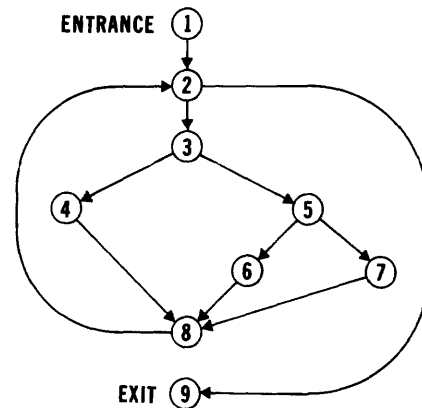

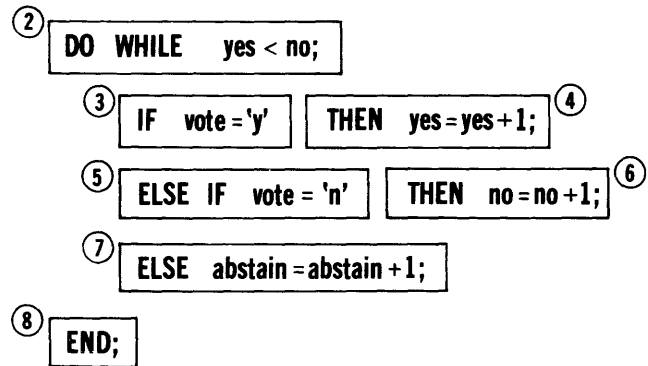

Figure 1—A control flow graph.

#### Measuring the clarity of program control structure

Structured programming has evolved as a guide to writing more easily understood programs. It is generally agreed that well structured code is composed from blocks, each with a single entrance and a single exit. In the strictest sense, the lowest level block can be taken to be a simple clause in a program, a node in the control flow graph. A simple reduction rule exists to collapse graphs of strictly well structured programs to a single node:

1. Choose a node  $n$  that has at most one incoming arc and at most one outgoing arc.
2. Replace  $n$  by an arc, preserving direction, that connects  $n$ 's neighbors ( $m$  is a neighbor of  $n$  if there is an arc between  $m$  and  $n$ ).
3. Remove any redundant arcs:
  - Two arcs in the same direction between the same nodes is a redundancy.
  - An arc from a node to itself is a redundancy.

The three steps are repeatedly applied until they are no longer applicable (Figure 2).

After applying the reduction rule to a graph, some subgraph will remain. The subgraph will be a single node for

**REDUCTION RULE**

**STEP A: COLLAPSE ANY NODE THAT HAS AT MOST ONE INCOMING ARC AND AT MOST ONE OUTGOING ARC**

**STEP B: REMOVE ANY EXTRANEIOUS ARCS**

REPEATEDLY APPLY EACH STEP UNTIL NEITHER IS APPLICABLE

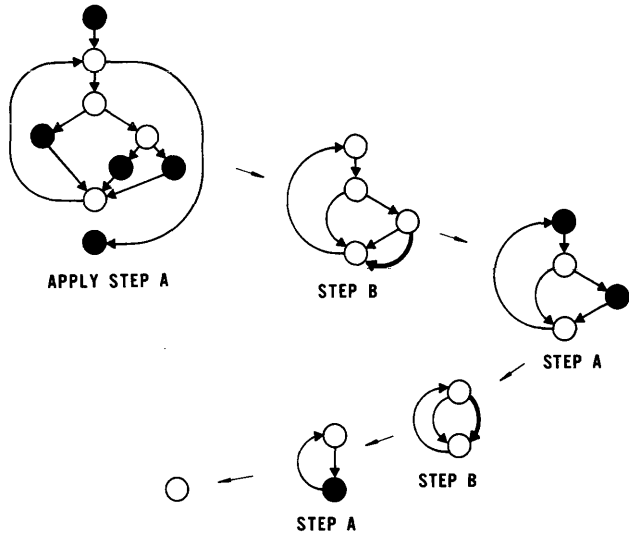

Figure 2—Reducing a Graph.

strictly well structured programs; the subgraph will be more complex for other programs. We characterize the degree to which a graph can be reduced by the ratio of binary decisions embedded in the subgraph to binary decisions embedded in the original graph.

*Measuring the clarity of program data usage*

One characteristic of data usage is the degree to which variable use has been localized. Measuring the span of a variable is one indicator of localization. A span of a variable is one plus the number of intervening statement clauses between two successive references to the variable. The average span of a variable is the sum of all spans for the variable divided by the number of spans. The variable span for a program is the sum of average variable spans for all the variables within the program (Figure 3).

*Software science measures*

The field of software science is attempting to establish meaningful relationships among the primitive components of algorithms—operators and operands (Figure 4). Work by others<sup>10,16</sup> has indicated that some of the software science variables suggested by Halstead<sup>9</sup> may reliably characterize the overall complexity of a program.

In our analysis we studied six software science variables.

All can be derived from counts of: Unique operators ( $n1$ ), unique operands ( $n2$ ), instances of operators ( $N1$ ), and instances of operands ( $N2$ ).

- *Length*— $N1 + N2$ . *Length* is a program size measure of finer granularity than a count of program statements or clauses. A virtue of *length* is that it is largely insensitive to horizontal (deeply-nested expressions) versus vertical (simple expressions) programming style.
- *Expected length*— $(n1 \log_2 n1)(n2 \log_2 n2)$ . Empirical studies have shown *expected length* and *length* correlate highly for published, hence presumably well polished, programs.<sup>2,8</sup> We used the calculation  $(length - expected\ length) / length$  to indicate the agreement between *length* and *expected length*.
- *Volume*— $Length \log_2(n1 + n2)$ . *Volume* is an estimate of the minimum number of bits needed to represent the executable statements of a program.
- *Level*— $(2/n1)(n2/N2)$ . *Level* is a measure of the match between the operations performed by a program and the primitive operators and functions used by the program. In a program at the highest *level* the operation performed is implemented by a single operator.
- *Effort*— $Volume / level$ . Intuitively, *effort* is a function of the quantity of information represented by a program and the power of the statements with which the information is encoded. *Effort* rises with increasing information content and with decreasing statement power.

**DATA ANALYSIS**

An analysis of 12 carriers, or independent variables, and two responses, or dependent variables, is presented here.<sup>14</sup> Figure 5 summarizes the range of values for each of the carriers.

The carriers were first studied singly and in pairs. Normal quantile-quantile plots<sup>6</sup> for each carrier revealed that most had non-normal, asymmetric distributions. Transformations (usually the natural logarithm) were carried out which rendered the distributions approximately normal and symmetric. We used the carrier *node count* as a simple measure of module size. Scatter plots of the eleven other carriers versus *node count* revealed that seven were highly correlated with module size and four were not (Figure 5).

In order to determine whether there was a significant stratification of the modules according to size, the hierarchical clustering algorithm of Johnson, using Manhattan distance and the complete linkage method,<sup>5,10</sup> was used for the 123 modules according to the eight standardized size-related carriers. A dendrogram of the result is shown in Figure 6. The figure shows strong clustering. If the tree is cut at a distance of 9.0, there appear to be six clusters.

An attempt was next made to relate the response *time to repair errors* to module size. Program maintenance data showed that there were a total of 124 errors on 45 modules. The 124 errors were classified into six groups according to the assignment of the modules with errors to the six size

clusters. Average *node count* was calculated for each group, and the *times to repair* (in quarter-hour units) were plotted versus average *node count* (Figure 7). (A random normal deviate from  $N(0, \epsilon)$  was added to each of the  $x$  and  $y$  coordinates of every point so that the density of points in each

group could be seen.) A striking dependency can be seen; the spread of *time to repair* increases with *node count*.

Actually, since at *node counts* of 50, 100 and 220 there appear to be one or two points quite separated from the rest (the observation of 15 hours at *node count* 220 is not a

Figure 5—Carrier summary.

mistake), it is not unreasonable to hypothesize two mechanisms in operation here. Figure 7 suggests a model for such a phenomenon superimposed on the data. The model says that there are two types of errors that occur, easy-to-repair and difficult-to-repair. The easy-to-repair errors occur with large probability and the difficult-to-repair with small prob-

ability. Points that might have come from the difficult-to-repair distribution have been circled in Figure 7. An exponential fit was estimated for these points, but this estimate may be very unreliable because of the small number of points. Nevertheless, the model does provide an interesting framework to study the dependency of *time to repair* on module size.

An important question addressed next in the analysis was whether there might be some residual or second-order effect of the seven size-related carriers other than *node count* on the responses. Size-adjusted variables were created for the seven carriers by performing simple linear regressions of the log carrier on log *node count*. Simple linear regression appeared to be adequate for each case. The seven sets of residuals about regression formed new adjusted carriers that were relatively free of *node count*.

A hierarchical clustering of the 123 modules according to the standardized residual carriers was conducted using Manhattan distance and the complete linkage method. A dendrogram is shown in Figure 8. The dendrogram appears to show reasonably strong clustering. If the tree is cut at a distance equal to 8.5, 13 clusters result. As a check, clusterings using different methods and different metrics were tried. It was seen that modules combined in the tree at different heights and in slightly different orders, but the basic grouping remained stable. In the analysis that follows, only the response *error density* will be considered. *Error*

Figure 6—Clustering of eight standardized log carriers using manhattan distance.

Figure 7—Time to repair versus node count for six size clusters.

*density* is defined as the total number of errors for a group of modules divided by the number of modules in the group which contain errors.

The seven residual carriers were next investigated for multi-collinearity. A principal components analysis of the correlation matrix<sup>7</sup> of these carriers revealed that only three of the seven carriers were not collinear since the first three principal axes accounted for 99% of the total variability. Before proceeding further, the multi-collinearity of the carriers was removed. Weighted (by reciprocal variance) averages of residual *length* and *volume* and residual *path count* and *average path length* were taken, thereby reducing the number of carriers to five. Next, the first and fourth carriers of the five-carrier set were eliminated. These carriers had the lowest simple correlation with the response *error density*. This leaves as carriers residual *level*, residual *expected length*, and a weighted average of residual *path count* and residual *average path length*. A principal components analysis for these three variables showed no singularity.

One approach to relating the *error density* to the carriers is to group the modules with errors according to the 13 clusters found previously, calculate average *error density* for each group, and regress these averages on representative

values of the adjusted carriers for each group. The representative value for each group was taken to be the centroid of the final three adjusted carriers. Since each group has a different number of modules with errors, the average responses are based on differing numbers of items and weighted regression is appropriate. In carrying out this grouping-averaging process, regression analysis was used in its classical sense of estimating the mean of the conditional distribution of the response, conditional on values of the carriers. There was a large amount of inherent variability in the original data, in part because the data was not collected as part of a designed experiment. The averaging carried out above reduced this variability and allowed the marginal effects of an adjusted carrier to be seen more clearly.

Next we formed a regression model of *error density* and our three-carrier set. However, it might be possible for the carriers to affect the response interactively. To account for this, we included cross-product terms in the regression model. When this is done, six carriers result (Figure 9).

In order to select usable models containing combinations of the six carriers, the  $C_p$  statistic<sup>3</sup> was calculated for each possible regression containing the carriers. These statistics were plotted against  $p$ , the number of terms in each regres-

Figure 8—Clustering of standardized residuals from regression on node count using manhattan distance.

sion, and are shown in Figure 10. Here the maximum  $p$  equals seven because a constant term was added in each regression. The line  $C_p=p$  was added in order to indicate good results. Any combination of variables that lie on this line are good models for the regression. A dashed line was drawn to show reasonable models for the data. We considered a model reasonable if it had a mean square error at least as small as the model with all the terms in it. All the models include variable 1, residual *level*, which by itself almost provides a reasonable model for the data. Notice that some of the candidate models include interaction terms without containing the corresponding main effects; such models were not considered acceptable. One of the best and most plausible models comprises the terms 1, 2, 3, and 4. These are residual *level*, residual *expected length*, their interaction and the residual *path carrier*. The result of this analysis shows that there is an apparent residual effect of three of the seven original carriers.

- 
- 1. Residual *level*
  - 2. Residual *expected length*
  - 3. Weighted average of residual *path count* and residual *mean path length*
  - 4. Cross product of carriers 1 and 2
  - 5. Cross product of carriers 1 and 3
  - 6. Cross product of carriers 2 and 3
- 

Figure 9—Reduced Carrier Set

The regressions for models that were considered reasonable were all significant at the  $\alpha=.01$  level but are not strong enough for accurate prediction (the multiple  $R^2$  is less than .40 for regressions performed on the raw, unaveraged data). However, they do provide ideas for future experiments and food for thought.

#### SUMMARY OF FINDINGS

Both the data collection and analysis are at an early stage; yet a few results are evident.

1. Most of the variables we studied have a large size component.
2. Module size, by itself, appears to be a good indicator of maintenance performance for the module, though we have not studied the tradeoff of many small modules versus fewer large modules.
3. When adjusted for size, *level* appears to be a fair indicator as to how a group of modules will perform.

While we do not expect to predict the maintenance performance of a single module based upon a static analysis as presented here, we do expect to find program properties characteristic of poor performance. Such properties would

Figure 10—Cp plot for error density.

lead us to firmer ground for establishing guidelines of good programming practice.

# Program forms and program form analysers for high-level structured design\*

by JAYASHREE RAMANATHAN

University of Houston  
Houston, Texas

and

MEERA BLATTNER

Rice University  
Houston, Texas

## INTRODUCTION

Structured programming is the single most important technique currently used in developing software which is both reliable and inexpensive.<sup>11,27</sup> It has been observed by various researchers that programmer productivity can be vastly improved if the development of software is split into two, equally important phases.

1. The design phase, and
2. The implementation phase.

In this paper we present PSEUDO LANGUAGE (PL)—a program design tool enforcing the functional programming concept discussed in References 4, 10, 13, 17, 21, 22 and 28. A PSEUDO LANGUAGE PROCESSOR (PLP) is also described. The PLP is a translator which examines source programs in PL and provides a listing of these programs together with a variety of messages. These messages can be used by the programmer both during the design and the implementation phase.

A PL program is a *program form* which represents a broad class of possible implementations in any of the standard programming languages. PL program forms resemble pidgin English and are therefore very readable. It is easy to program in PL since the programmer can ignore the messy details necessitated by actual implementation languages (FORTRAN, PASCAL, PL1, COBOL, etc.). An important characteristic of the PL design language is that it requires the programmer to explicitly identify the functional components of the programming task at hand. The implementation details of these functional components may be ignored by the programmer. Instead the programmer can concentrate on the logical interaction between these components. PL is designed to enforce structured programming techniques. A PL program can serve as the documentation for

the implementation version of the program. The advantages of PL mentioned above should also result in better communications between programmers in a team and contribute towards increased programmer productivity.

The PLP described here is constructed realizing that it is cheapest to correct errors during the earlier stages of software development. This is mainly due to the fact that fewer corrective changes have to be made to debug a design program. The messages generated by the PLP indicate errors in the PL program forms and list the functional components in the program form which have already been implemented. In order for the PLP to provide these messages, the PL program forms must have a recognizable structure. The definition of PL given here attempts to strike a balance between allowing program forms with too little syntactic structure and too much syntactic structure (as in implementation language programs).

Existing design tools for structured programming can be generally categorized as a variation of flowcharting (for examples refer to References 6, 8, 9 and 26) or as English sentences with keywords which identify the control flow in the program.<sup>7</sup> Both types of design tools concentrate on the control logic of the programming task. PL programs also contain fixed control structures and in addition restrict the English sentences to "commands." This restriction on the English sentences forces the programmer to identify the functional components of the programming problem. At the same time, this restriction allows the PLP to employ algorithms for validating PL programs. PLP performs extensive static analysis on PL program forms and uses this analysis to print out messages that can be used by the programmer for validating and debugging the program forms.

The next section introduces the syntax for PL, and the third section discusses how PL enforces structured programming. PLP functions are outlined in the fourth section and the final section presents conclusions and suggestions for future work.

\* This research was supported in part by NSF Grant Number MCS77-02470.

DEFINITION OF PSEUDO LANGUAGE (PL)

PL requires that the declarations precede the "executable" statements as in FORTRAN or PASCAL. Using somewhat informal syntax notation we have

- a. <program> → <introduction> <body>
- b. <introduction> → <directives to PLP> <title>  
                   INPUT PARAMETERS: <noun list>  
                   OUTPUT PARAMETERS: <noun list>  
                   READ INTO: <noun list>  
                   PRINT FROM: <noun list>  
                   DICTIONARY: <noun description list>
- c. <noun list> → <noun list>, <noun>  
                   / <noun>
- d. <noun description> → <noun>  
                   / <noun> ATTRIBUTES: <attribute list>  
                   / <noun> ATTRIBUTES: <attribute list>  
                   INITIAL VALUE: <constant list>
- e. <noun description list> → <noun description list>;  
                   <noun description>  
                   / <noun description>  
                   / <empty>
- f. <noun> → <identifier>  
                   / <subscripted identifier>  
                   / <structured noun>  
                   / <empty>
- g. <structured noun> → <structured noun> <constant> <identifier>  
                   / <constant> <identifier>
- h. <attribute list> → <attribute list>, <attribute>  
                   / <attribute>

The syntax of the introduction may be modified to allow declarations for general data types.<sup>20,21</sup> We now give an example of an <introduction> for a Bubble Sort program. Comments on any line are preceded by a double slash (//).

*Example*

```
//introduction
SORT IN ASCENDING ORDER
INPUT PARAMETERS: SIZE_OF_TABLE, TABLE
OUTPUT PARAMETERS: TABLE
READ INTO:
PRINT FROM:
DICTIONARY:
SIZE_OF_TABLE    ATTRIBUTE: INTEGER;
NO_INTERCHANGE  ATTRIBUTE: FLAG
                  INITIAL: 1;
FIRST_ITEM       ATTRIBUTE: POINTER; // TO
                  TABLE
SECOND_ITEM      ATTRIBUTE: POINTER; // TO
                  TABLE
TABLE            ATTRIBUTE: ARRAY;
EACH_PAIR
```

As illustrated in the previous example, <directives to PLP> can be empty. ATTRIBUTES: can be followed by any number of words describing the noun. The syntax for <constant list>, <identifier> and <constant> are as in standard programming languages. The syntax for the <body> of a PL program

follows. We shall think of the body as being composed of statement forms which specify the control flow in the implementation program and statement forms which specify the executable, functional components of the implementation program. We shall loosely say that the body of the program form is executable.

- i. <body> → BEGIN <statement list> END
- j. <statement list> → <statement list>; <statement list>  
                   / <statement list>
- k. <statement> → <assignment>  
                   / <compound statement>  
                   / <if statement>  
                   / <case statement>  
                   / <while statement>  
                   / <repeat statement>  
                   / <for statement>  
                   / <cycle statement>  
                   / <with statement>  
                   / <cobegin-coend statement>  
                   / <I/O statement>  
                   / <expression>  
                   / <command>

The fundamental executable components of a program

form are assignments, commands and expressions. The control structures specify the manner in which the fundamental components are to be executed. The non-terminal <statement> goes to the fundamental components and to the control structures containing sequences of fundamental components. Standard (PASCAL-like) syntax details of the control structures are given in the appendix. It should be noted that concurrent execution of statements may be specified by PL. Hence PL allows the design of program forms for a wide variety of applications. In fact, <statement> may be sent to any of the structures supported by the various languages currently in use. Syntax for exit statements, GOTOs and labels may be easily added to the above grammar but this is not done in the grammar presented here.

The fundamental executable component of interest is the command. The following productions give its syntax.

```

<comments> <noun>
:
<comments> <noun>
/ <verb> <comments> <noun>
<comments> <noun>
:
<comments> <noun>
RETURN
<comments> <noun>
:
<comments> <noun>

```

<verb> is to be semantically interpreted as any English language verb. The non-terminal <comments> is to be interpreted as a sequence of English language words (usually prepositions and conjunctions) which add to the readability of the command. Finally, <noun> is to be interpreted as a data structure declared in the introduction of the program form. The body of the SORT program form introduced earlier is given in the following example.

1. <command> <verb>  
/ <verb> <comments> <noun>

*Example PL program form for SORT*

```

//<body>
BEGIN
    IF      SIZE_OF_TABLE>1
    THEN
        WHILE NO_INTERCHANGE
        DO     NO_INTERCHANGE=0
              FOR EACH_PAIR=1 TO SIZE_OF_TABLE-1
                //<command>
                DO  GET FIRST_ITEM IN TABLE;
                  //<command>
                  GET SECOND_ITEM IN TABLE;
                  IF FIRST_ITEM IN TABLE>SECOND_
                     ITEM IN TABLE
                THEN
                    BEGIN
                        //<command>
                        INTERCHANGE FIRST_ITEM IN TABLE AND
                        SECOND ITEM IN TABLE;
                        NO_INTERCHANGE=1
                    END
                OD
            OD
        PRINT TABLE
END

```

Examine the first command GET FIRST\_ITEM IN TABLE. This command begins with the verb GET and it operates on the nouns FIRST\_ITEM and TABLE. The word IN functions as a comment which makes the command easier to read. Similarly, INTERCHANGE is the verb in the last command of the above program. INTERCHANGE operates on the nouns FIRST\_ITEM, SECOND\_ITEM and TABLE. More specifically,

```

//<verb>      <noun>      <comment>
INTERCHANGE  FIRST_ITEM  IN
              //<noun>    <comment>
              TABLE     AND
              //<noun>    <comment> <noun>
              SECOND_ITEM IN  TABLE

```

INTERCHANGE is the abstraction of a routine which has as inputs FIRST\_ITEM, TABLE, and SECOND\_ITEM.

The actual FORTRAN implementation for even the simple sort program is much harder to read. The FORTRAN subroutine is given below.

*Example*

```

SUBROUTINE SORT (ISIZE, TABLE)
DIMENSION TABLE (100)
IF (ISIZE.LE.1) GO TO 99
2  INTER=0
   DO 20 I=1, ISIZE-1
     IF (TABLE(I).LE.TABLE(I+1))GO TO 20
     INTER=1
     TEMP=TABLE (I)
     TABLE (I)=TABLE (I+1)
     TABLE (I)=TEMP
20  CONTINUE
   IF (INTER. EQ. 1) GO TO 2
99  WRITE (6, 30) (TABLE (I), I=1, ISIZE)
30  FORMAT (5×2, 10 (F8.3, 2×))
STOP
END

```

Note the PL program form for the above SORT given in the next example suppresses the details of TABLE, INTERCHANGE, GET and PRINT.

*Example*

```

SORT IN ASCENDING ORDER
INPUT PARAMETERS:  SIZE_OF_TABLE, TABLE
OUTPUT PARAMETERS: TABLE
PRINT FROM:       TABLE
DICTIONARY:       SIZE_OF_TABLE; NO_INTERCHANGE;
                  FIRST_ITEM; SECOND_ITEM; TABLE;
                  EACH_PAIR

BEGIN
  IF      SIZE_OF_TABLE>1
  THEN   WHILE NO_INTERCHANGE
        DO    NO_INTERCHANGE=0
              FOR EACH_PAIR=1 TO SIZE_OF_TABLE-1
              DO  GET FIRST_ITEM IN TABLE;
                  GET SECOND_ITEM IN TABLE;
                  IF FIRST_ITEM IN TABLE>
                     SECOND_ITEM IN TABLE
                  THEN BEGIN
                     INTERCHANGE FIRST_ITEM IN
                     TABLE AND SECOND_ITEM IN TABLE;
                     NO_INTERCHANGE=1
                  END
              OD
        OD
  PRINT TABLE
END

```

#### STRUCTURED PROGRAMMING USING PSEUDO LANGUAGE

Note that the PL SORT program form implies the hierarchical structure of Figure 1. The PL program form is not

concerned with the details of TABLE or its elements. In an implementation, the TABLE may be a file and its elements may be employee records. Also, GET and INTERCHANGE may be complicated, machine-dependent subroutines. Here again the PL SORT program form is not concerned about

Figure 1

the details of algorithms implementing the functions GET and INTERCHANGE. SORT is written assuming GET and INTERCHANGE work. The logic of the SORT program form is easy to check out. Therefore, if GET and INTERCHANGE work reliably, then SORT works reliably. To reiterate, SORT TABLE might be the main goal. This goal is refined by the PL SORT program form which in turn calls for two functions, GET and INTERCHANGE. The data structures (or nouns) on which the two functions operate are completely specified in the commands in which they appear in the SORT program.

PL forces the programmer to identify the verbs (or functional components) of the program during the design phase. This ensures the program form can be implemented. Design languages which allow flexible English language statements cannot ensure that the design algorithm can in fact be implemented by a process. Another feature that PL has in common with the existing design tools is that control structures must be identified.

The functional components in the PL SORT program form may themselves be implemented by other PL program forms calling on still other functions (verbs). This stepwise refinement can continue until a level is reached where all the verbs are implemented in a desired implementation language. It is easy to see that the resulting implementation program should be well structured.

PSEUDO LANGUAGE PROCESSOR (PLP)

PL syntax is designed so that PL programs are amenable to both structural and symbolic (static) analysis. The PLP

currently being implemented is divided into three logical components—the scanner, the structure analyser and the message generator. PLP is designed to generate a variety of messages. The classes of messages generated are listed below together with a brief discussion of how the messages in each class are generated.

- *Messages detecting violations of standard design practices*—The structural analysis of the PL program, by the parser, detects omissions in the introduction and improper use of control structures in the body.<sup>1,27</sup>
- *Cross-reference tables*—Tables indicating variable usage are determined during the three PLP phases and printed out appropriately.
- *Global references are listed*—All nouns in the introduction which have a global attribute are listed. This allows uses of critical, global resources to be monitored.
- *Messages indicating anomalies in the use of variables*—PLP uses various current techniques of high-level data flow analysis techniques on the parse tree to detect anomalies in the use of variables.<sup>2,5,12,14-16,18,19,24,25</sup> The appearance of a variable in the introduction identifies it as a noun. This information is used by the semantic routines to distinguish the nouns in a command from other words which serve as comments. The first word in a command is always a verb. If a noun follows the keyword RETURN it is taken to be defined in the subprocess named by the verb. See Figure 2 for an illustration.
- *A list of possible sub-processes from the PLP library which may be used by the programmer*—An elementary component of the PL program is the command. Each command is a directive to the computer to operate on some nouns (data structures). The verb contained in the command must be implemented by a routine supplied either by the programmer or provided by the PLP library. Consider the PL statement

```

IF      FIRST_ITEM IN TABLE > SECOND_ITEM IN TABLE
THEN    <verb>      <noun>
        INTERCHANGE FIRST_ITEM
        <noun>      <noun>
        IN TABLE AND SECOND_ITEM
        <noun>
        IN TABLE
  
```

Suppose the verb INTERCHANGE is already implemented by a FORTRAN (or PASCAL) or even another PL routine in the PLP library. PLP will list INTERCHANGE as a possible implementation of the verb. The programmer can examine a copy of INTERCHANGE. After an examination, if the programmer so directs, the library implementation of INTERCHANGE can be used as shown below. PLP library implementation of INTERCHANGE may contain the statements

```

TEMP=FIRST_ARGUMENT
FIRST_ARGUMENT=SECOND_ARGUMENT
SECOND_ARGUMENT=TEMP
  
```

Based on the programmer's directive, INTERCHANGE in the PL statement above will be considered as a call to the library routine called INTERCHANGE and the resulting statement synthesized will be

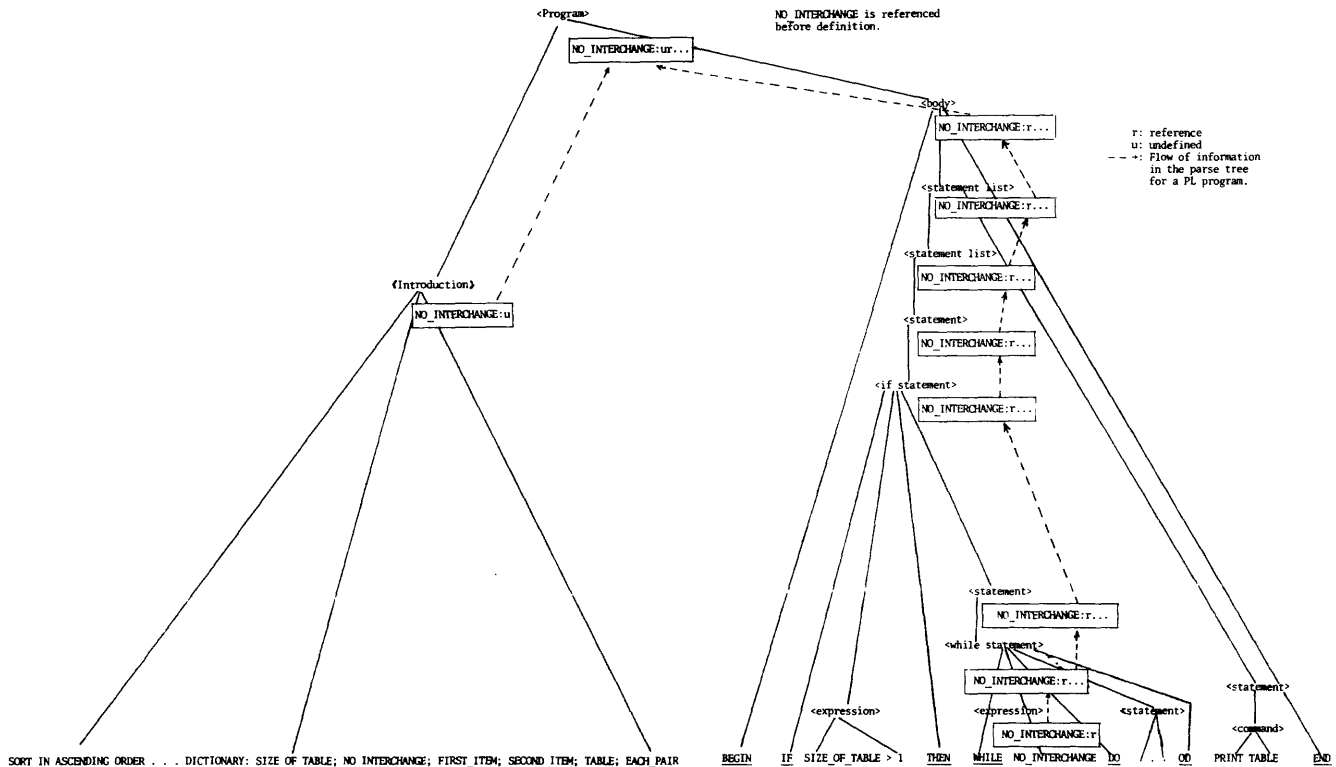

Figure 2

```

IF      FIRST_ITEM IN TABLE>SECOND_ITEM IN TABLE
THEN   CALL INTERCHANGE
        (TABLE(FIRST_ITEM),
         TABLE(SECOND_ITEM))
    
```

The PLP facility just discussed is especially useful when the verbs are implemented by complicated routines. In such cases considerable programming effort is saved and the program itself is more structured. A drawback of this PLP facility is that the programmer may use a verb which is implemented and contained in the PLP library under a different name. To overcome this, a document containing the implemented verbs may be provided to the programmers.

- *Messages on the misuse of a sub-process*—The introduction of each sub-process provides a detailed description of the input parameters and the output parameters of the sub-process. When PLP links together sub-processes or when it recommends (or uses) a particular implementation of a verb, it will check to see whether the actual parameters in the calling sub-process are compatible with the formal parameters in the definition of the sub-process. At the same time PLP will check access rights of each sub-process. These checks will be made semantically by examining the introduction of the two sub-processes involved.<sup>3</sup>

The last two PLP capabilities listed are currently being designed. The remaining capabilities are being implemented.

Finally, PLP uses the structural analysis of a PL program for creating an output listing with proper indentations.

### CONCLUSIONS

A design language called PSEUDO LANGUAGE (PL) has been presented. Programs written in PL are called program forms. Program forms avoid implementation details and are therefore easily readable and understandable. PL also forces the programmer to identify the control structures as well as the functional components of the program system during the design phase.

The cost of finding an error in software increases as the software development comes nearer to completion. Errors found during specification are relatively inexpensive to correct as compared with errors found during total system integration.<sup>23</sup> The PSEUDO LANGUAGE PROCESSOR (PLP), currently being implemented, is an automatic tool for analysing specifications written in PL and printing out messages that indicate

- Violations of good design practices
- Errors

- Incorrect interfacing between programs
- Existing, potentially useful sub-processes that the programmer can use

Current research involves developing the theoretical framework for modeling the translation of PL program forms to implementation programs. Work is also proposed on the PL syntax. There may be many different implementations of a verb in the PLP library. Therefore, the syntax should allow a verb to be further qualified. For example, BUBBLE.SORT implementation would differ from MERGE.SORT. PLP can be designed as an interactive system which aids program form validation and implementation program synthesis. Valuable statistics on the usage of verb implementations can be obtained by the PLP. This would point to verbs that perhaps could be implemented by hardware.

# First-year results from a research program on human factors in software engineering

by SYLVIA B. SHEPPARD, BILL CURTIS, PHIL MILLIMAN, M. A. BORST, and TOM LOVE

*General Electric Company  
Arlington, Virginia*

## INTRODUCTION

For the past two years the Software Management Research Unit at General Electric has been investigating several areas of human factors in software engineering with support from Engineering Psychology Programs of the Office of Naval Research. There have been two major thrusts in this research. The first thrust investigated the effects of several modern programming practices on programmer efficiency. The second thrust investigated the prediction of programmer performance from software complexity metrics such as those proposed by Halstead and McCabe. This research program consisted of separate experiments on the understanding, modification, debugging, and construction of software, each using professional programmers. Each experiment investigated both the effects of experimentally manipulated programming practices, and the values of complexity metrics computed from the programs employed.

Structured coding techniques, mnemonic variable names and commenting are programming practices which supposedly reduce the complexity of software. Dijkstra<sup>4</sup> contended that program construction should proceed in a structured, top-down fashion. By limiting the control structures allowed, he assumed that the simplified control flow would make functions performed by the program easier to trace. Mnemonic variable names supposedly simplify the cognitive task of understanding a program by reducing the memory load on a programmer. The inclusion of comments purportedly simplifies modification tasks, although there are different methods of commenting. Global comments preceding a program summarize what objectives are accomplished, while in-line comments delineate how and where the objectives are fulfilled.

In 1972 Halstead first published his theory of software physics (renamed software science) stating that algorithms have measurable characteristics analogous to physical laws. These characteristics provide one assessment of program complexity. According to Halstead,<sup>13,14,16,18</sup> the amount of mental effort required to generate a program can be calculated from simple counts of distinct operators and operands and the total frequencies of operators and operands. From these four quantities Halstead derives the number of mental comparisons required to generate a program. Correlations

often greater than .90<sup>8</sup> have been reported between Halstead's metrics and such dependent measures as the number of bugs in a program,<sup>2,7,9</sup> programming time,<sup>11,17</sup> and the quality of programs.<sup>1,6,15</sup>

More recently, McCabe<sup>21</sup> developed a definition of complexity based on the decision structure of a program. McCabe's complexity metric is the classical graph-theory cyclomatic number which represents the number of regions in a graph, or in the current usage, the number of linearly independent control paths comprising a program. Simply stated, McCabe counts the number of elementary control path segments. When combined these segments generate every possible path through the program.

This paper reports results from the experiments on understanding and modification conducted during the first year of this research program. The first experiment investigated the effect of structured coding and mnemonic variable names on program comprehensibility. The second experiment studied the effects of structured coding and global versus in-line comments on modification tasks.

## METHOD

### *Participants*

In each experiment 36 programmers were tested in several General Electric locations. Participants in Experiment 1 had working knowledge of FORTRAN and averaged 6.8 years of professional programming experience ( $SD = 5.8$ ). In Experiment 2 the participants had an average of 5.9 years of professional programming experience ( $SD = 4.0$ ), a working knowledge of FORTRAN, and none had participated in the previous experiment. The majority of participants came from an engineering background.

### *Procedure*

In both experiments a packet of materials was prepared for each participant with written instructions on the experimental tasks. As a preliminary exercise, all participants were presented the same short FORTRAN program and a

brief description of its purpose. In Experiment 1 they studied this program for 10 minutes and were then given 15 minutes to reconstruct a functionally equivalent program from memory. In Experiment 2 all participants were asked to modify the same short FORTRAN program. They were given a brief description of its purpose and were allowed unlimited time to complete a specified modification. This introductory program provided a common basis for comparing the skills of participants and diminished learning effects prior to the experimental tasks. This latter point is important since a pilot study<sup>24</sup> indicated that learning may occur during this type of task.

Following the initial exercise, participants were presented in turn with three separate programs comprising their experimental tasks. In Experiment 1 they were allowed 25 minutes to study each program, during which they were permitted to make notes or draw flowcharts. At the end of the study period, the original program and all scrap paper were collected. Each participant was then given 20 minutes to reconstruct a functional equivalent of the program from memory on a blank sheet of paper, but was not required to reproduce the comment section. In Experiment 2 one modification was requested for each of the three programs and was described on a sheet accompanying the program listing. Participants worked at their own pace, taking as much time as needed to implement the modification. A break of 15 minutes occurred before the last program was presented in each experiment.

#### *Independent variables*

*Program class.* Three general classes of programs were used in Experiment 1: engineering, statistical, and non-numerical. Three programs were employed from each class with lengths varying from 36 to 57 statements. These nine programs were selected from among many solicited from programmers at several locations and were considered representative of programs actually encountered by practicing programmers. All experimental programs were compiled and executed using appropriate test data. Experiment 2 used three of the nine programs from Experiment 1.

*Complexity of control flow.* Three control flow structures were defined for each program in both experiments. Structured control flow was generally consistent with the tenets of structured programming described by Dijkstra.<sup>4</sup> When the rules for structured programming are applied rigorously, awkward constructions may occur in standard FORTRAN such as DO loops with dummy indices.<sup>25</sup> In a second version of each program, these awkward constructions were largely eliminated with a more naturally structured control flow. These conventions included multiple returns, exits from DO loops, and judiciously used backward GO TO's. In the unstructured version of each program, the control flow was not straightforward. Expanded DO loops, arithmetic IF's, and unrestricted use of GO TO's were allowed.

*Variable name mnemonicity.* In Experiment 1 three levels of mnemonicity for variable names were developed. The

programs were shown to several non-participants who were asked to assign names to the variables. The names chosen most frequently were used in the most mnemonic condition. The medium mnemonic level consisted of less frequently chosen names. In the least mnemonic condition, names consisted of one or two randomly chosen alphanumeric characters.

*Comments.* Three levels of commenting were tested in Experiment 2: global, in-line, and none. Global comments provided an overview of the function of the program and identified the primary variables. In-line comments were interspersed throughout the program and described the specific functions of small sections of code.

*Modifications.* Three types of modifications were selected for each program in Experiment 2 as typical changes a programmer might be expected to implement. The level of difficulty for seven of the nine modifications increased as more lines had to be added to the original code, and the hardest modifications for each program required the most additional lines.

*Experimental design.* In order to control for individual differences in performance, a within-subjects 3<sup>4</sup> factorial design was employed in each experiment.<sup>12</sup> In Experiment 1 three types of control flow were defined for each of nine programs, and each of these 27 versions was presented in three levels of variable mnemonicity, for a total of 81 programs. In Experiment 2 three levels of control flow were defined for each of the three programs. Each of these nine versions was presented with one of three levels of documentation. Modifications at three levels of difficulty were developed for each program, generating a total of 81 experimental conditions. The first 27 participants in each experiment exhausted the total of 81 programs. The additional nine participants repeated 27 of the previous experimental tasks. Programmers at each location were randomly assigned to experimental conditions in order that they would experience each level of each independent variable. That is, within their three tasks they worked with a program from each class, with each type of control flow, and at each level of documentation (variable mnemonicity or type of commenting). Each of the first 27 participants experienced unique combinations of these levels across their three experimental tasks. The order of presentation of the three programs was assigned randomly to each participant.

*Covariates.* In order to obtain a measure of programming ability related to the experimental tasks, scores on the preliminary tasks in both experiments were used as a covariate. Participants reported their type of programming experience and the number of years they had been programming professionally. Order of presentation was a situational covariate.

#### *Complexity measures*

*Halstead's E.* Halstead's effort metric (*E*) was computed precisely from a program (based on Reference 22) whose input was the source code listings of the 27 distinct programs in each experiment. Programs differing only in variable mne-

monicity or type of commenting were not considered distinct programs in this analysis. The computation formula was:

$$E = \frac{\eta_1 N_2 (N_1 + N_2) \log_2 (\eta_1 + \eta_2)}{2 \eta_2}$$

where

- $\eta_1$  = number of unique operators
- $\eta_2$  = number of unique operands
- $N_1$  = total frequency of operators
- $N_2$  = total frequency of operands

*McCabe's  $\nu(G)$ .* McCabe's metric is the classical graph-theory cyclomatic number defined as:

$$\nu(G) = \# \text{ edges} - \# \text{ nodes} + 2 (\# \text{ connected components}).$$

McCabe presents two simpler methods of calculating  $\nu(G)$ . His metric equals the number of predicate nodes plus 1. Values of  $\nu(G)$  can also be computed from a planar graph of the control flow by counting the number of regions.

*Length.* The length of the program was computed as the total number of FORTRAN statements excluding comments.

#### Dependent variables

*Experiment 1.* The criterion for scoring the programs in Experiment 1 was the functional correctness of each separately reconstructed statement. Variable names and statement numbers which differed from those in the original program were counted as correct when used consistently. Control structures could be different from the original program so long as the statements performed the same function. The score on each experimental task was the percent of statements correctly recalled. Three judges scored each program independently. Interjudge correlations of .96, .96, and .94 were obtained across the three sets of scores. The average of the three scores (percents of statements correctly reconstructed) for each program was the dependent variable in the data analysis for Experiment 1.

*Experiment 2.* The dependent variables for Experiment 2 were the correctness of the modification and the time taken by the participant to perform the task. The individual steps necessary for correct implementation of the requested modifications had been delineated in advance and assigned equal weights. That is, prototypes of each program with each modification correctly implemented were established as the criteria against which participants' work would be compared. A percentage score reflecting the correctness of each modification was computed by comparing participants' changes with the criteria. The time to write a modification was measured to the nearest minute by an electronic timer.

#### Analysis

Results were analyzed in two phases. The first phase investigated the effects of experimentally manipulated variables,

while the second phase evaluated the performance predictions of the software complexity metrics. The experimental effects of programming practices were analyzed in hierarchical regression analyses. In these analyses domains of variables were entered sequentially into a multiple regression equation to determine if each successive domain added significant prediction to that afforded by domains already entered. Effects related to pre-existing differences among participants and programs were entered into analyses prior to evaluating the effects of programming practices. The variables representing the different conditions of experimentally manipulated variables were effect coded.<sup>19</sup>

Analyses investigating relationships among Halstead's  $E$ , McCabe's  $\nu(G)$ , number of statements, and performance were conducted with Pearson product-moment correlation coefficients.

## RESULTS

### Experimental manipulations

*Experiment 1.* Table I presents the results of the hierarchical regression analyses for Experiment 1. Figures presented in this and succeeding tables indicate the unique percent of variance contributed to the prediction of performance by a variable domain when added into the analysis with preceding domains. Significance levels identified by asterisks indicate the likelihood (expressed as a proportion) that a prediction of this significance could have occurred by chance.

An average of 50 percent of the statements were correctly recalled across all programs and experimental conditions. Pretest scores accounted for 17 percent of the variance among scores on the percent of statements correctly recalled. No relationships were observed for type and length of programming experience or job location.

Differences among the program classes accounted for 8 percent of the variance in performance scores in addition to that accounted for by individual differences among participants. Engineering programs were the most difficult (41 percent of the statements correctly recalled), followed by statistical (52 percent), and non-numeric (57 percent) programs. When the specific program was taken into account, an additional 20 percent of the variance in performance was explained. However, this result was not strictly a function of differences among programs, because variance related to

TABLE I.—Hierarchical Regression for Percent of Statements Correctly Recalled

Variable domain	$\Delta R^2$
Pretest	.17**
Class of program	.08**
Specific program	.20**
Control flow complexity	.07**

Total $R^2$	.53***

Note:  $n=108$ . \*\* $p \leq .01$ . \*\*\* $p \leq .001$ .

specific programs was confounded with variance related to participants. That is, each participant saw only three of the nine programs. Overall, 45 percent of the variance in performance was accounted for by differences among participants and programs.

The complexity of the control flow affected performance, accounting for 7% of the variance in addition to that accounted for by differences among programs and participants. As expected, unstructured programs were the most difficult to reconstruct. A post hoc analysis<sup>23</sup> showed the means for naturally structured and unstructured programs (56 percent versus 42 percent, respectively) to be significantly different ( $p \leq .05$ ). Performance on structured programs fell between these two. No differences occurred among levels of variable mnemonicity.

*Experiment 2.* Across all experimental conditions, an average of 62 percent of the steps for each modification were accurately implemented. The 108 accuracy scores ranged from five scores of 0 percent to 24 scores of 100 percent and were negatively skewed. The average time to complete the modifications was 17.9 minutes, ranging from 2 to 59 minutes with a positive skew. Accuracy and time were uncorrelated.

Table II presents hierarchical regression results for the accuracy of the participants' modifications. Only 19 percent of the variance in accuracy scores could be predicted by the variable domains studied. However, there were substantial differences in the degree to which performance on each of the three programs could be predicted. On two of the programs, 35 percent of the variance in accuracy scores was accounted for, while results for the third program were insignificant.

Order of presentation accounted for 5 percent of the variance in accuracy scores. Participants made more complete modifications in less time with each succeeding experimental task. However, the two programs on which performance proved most predictable were more frequently presented second or third in order. Thus, random assignment of presentation orders failed to counter-balance the number of times each condition appeared in each position order.

The difficulty of the modification accounted for 9 percent of the variance in accuracy scores on the two most predictable programs. Performance was poorer on modifications which required more lines of code to be inserted. The complexity of the control flow accounted for 7 percent of the variance in accuracy scores on the two programs for which

TABLE II.—Hierarchical Regression for Accuracy of Modifications

Variable domain	$\Delta R^2$	$\Delta R^2$
	(3 programs)	(2 programs)

Total $R^2$	.19	.35***

Note:  $n=108$  for 3 programs and  $n=72$  for 2 programs. \* $p < .05$ . \*\* $p \leq .01$ . \*\*\* $p \leq .001$ .

TABLE III.—Hierarchical Regression for Time to Completion

Variable domain	$\Delta R^2$
Pretest time	.03
Presentation order	.06**
Program	.01
Modification difficulty	.15**
Control flow complexity	.02
Type of commenting	.01
Total $R^2$	.28***

Note:  $n=108$ . \*\* $p \leq .01$ . \*\*\* $p \leq .001$ .

accuracy was most predictable. Modifications made to structured programs were more accurate than those made to unstructured programs. Accuracy scores did not differ among programs, nor among the type of comments included in the program.

Table III presents hierarchical regressions for time to completion. Across all three programs, 28 percent of the variance in the time required to complete the modifications could be accounted for by variables studied here. Time to complete the modifications was more easily predicted than accuracy scores across all three programs.

Results of the hierarchical regression for time were generally similar to the results observed for accuracy. The specific program and type of comments were unrelated to the criterion. Significant variance was accounted for by both the difficulty of the modification and the order of presentation. Again, however, the interpretation of the effect for this latter variable is confounded. Neither the pretest scores nor control flow complexity were significantly related to time, although they had been modestly related to accuracy.

Further inspection verified that the number of additional statements required in the code to accurately complete a modification was related to the time required to insert them. Fitting a curvilinear function to these data using least squares procedures resulted in a curvilinear correlation (second order polynomial) of .80 ( $p \leq .05$ ) and a standard error or estimate of 2.53 minutes. No such relationship was found for accuracy.

#### Software complexity measures

Since different levels of variable mnemonicity and type of commenting neither affected performance, nor caused any change in the value of the complexity metrics for a particular program, the data reported in this section were aggregated over the three levels of mnemonicity in Experiment 1 and type of commenting in Experiment 2. This procedure resulted in 27 data points for each experiment. Each datum represented the average of at least three performance scores. Table IV presents the correlations among the three complexity measures in both experiments. Correlations in the lower triangle are from Experiment 1; those in the upper triangle are from Experiment 2. Generally these correlations were quite large in both experiments.

Table V presents correlations between the complexity

TABLE IV.—Intercorrelations among Complexity Measures

Complexity Measure	<i>E</i>	$v(G)$	Length
Halstead's <i>E</i>		.88***	.92***
McCabe's $v(G)$	.84***		.89***
Length	.47**	.64***	

Note:  $n=27$ . \*\* $p \leq .01$ . \*\*\* $p \leq .001$ .

measures and performance criteria in both Experiments 1 and 2. In Experiment 1 the correlations between performance and each of the complexity measures were all negative, indicating that fewer lines were recalled as the level of complexity represented by these three metrics increased. Performance was moderately related to length and McCabe's  $v(G)$ , but not to Halstead's *E*.

Most of the significant correlations with performance in Experiment 2 were observed for measures computed on correctly modified rather than unmodified programs. Correlations reported in Table V were for measures computed on modified programs. All three measures were moderately correlated with time to complete the modification, while only length and McCabe's  $v(G)$  were significantly related to accuracy.

The complexity of the control flow moderated the relationships between performance and the complexity metrics in both experiments. That is, while insignificant correlations were observed when the control flow was structured or naturally structured, this was not the case for unstructured code. Correlations with percent recalled correctly in Experiment 1 of  $-.55$  ( $p \leq .001$ ) and  $-.45$  ( $p \leq .01$ ) for  $v(G)$  and *E* were observed on unstructured programs. In Experiment 2 correlations relating time with Halstead's *E* went from .08 in the structured code, to .28 ( $p \leq .05$ ) in naturally structured code, to .38 ( $p \leq .05$ ) in unstructured code. No such moderating effects were observed for McCabe's  $v(G)$ , nor for either metric with accuracy scores.

Correlations between the complexity metrics and performance criteria in Experiment 2 were also moderated by the type of commenting. When no comments were included in the program, significant correlations on modified programs for both Halstead's *E* and McCabe's  $v(G)$  were observed for both accuracy ( $r = -.34$  and  $-.35$ ,  $p \leq .05$ ) and time ( $r = .47$  and  $.44$ ,  $p \leq .01$ ). Insignificant correlations were usually observed when either global or in-line comments appeared in the code.

The amount of professional programming experience profoundly moderated the relationships observed between the complexity measures and percent of statements correctly

recalled in Experiment 1 and time to completion in Experiment 2. For programmers with three or less years of professional experience in Experiment 1, correlations of  $-.47$  ( $p \leq .001$ ) for McCabe's  $v(G)$  and  $-.35$  ( $p \leq .05$ ) for Halstead's *E* were observed. Insignificant correlations were observed for programmers with more than three years experience. For time to completion in Experiment 2, correlations of .55 ( $p \leq .001$ ) for Halstead's *E* and .52 ( $p \leq .001$ ) for McCabe's  $v(G)$  were observed for programmers with three or less years of professional experience, while no correlations above .20 were observed for programmers with more than three years experience.

## DISCUSSION

### Experimental manipulations

Several factors were consistently related to programmer performance. Individual differences among participants and the complexity of the control flow were found to influence programmer performance in both experiments. In Experiment 2 the difficulty of the requested modification and the order of presentation influenced both the accuracy and speed of implementing modifications. Each of these factors contributed independently to predicting program comprehension. Contrary to expectations, however, mnemonic variable names and types of commenting did not influence performance.

Control flow complexity was significantly related to both the percent of statements correctly recalled in Experiment 1 and the accuracy of the modifications on two of the programs studied in Experiment 2, but not to the time spent implementing modifications. In Experiment 1 naturally structured code was more easily comprehended than unstructured code. In Experiment 2 more accurate modifications were made to structured rather than unstructured code. It is not clear from the results of these two experiments whether rigidly structured code or code structured with a more natural control flow for FORTRAN can be maintained more efficiently. However, both of these control flows proved superior to unstructured code in at least one of the experiments.

Differences among programs played an important, but difficult-to-explain, role in these experiments. Effects on performance attributed to these differences may have resulted from some familiarity factor specific to the samples of programs and programmers studied. Further, effects due to differences among specific programs were confounded in Experiment 1 with effects related to individual differences among participants.

It is not surprising that the difficulty of a modification in Experiment 2 was related to the time required to implement it. The significant factor in the time spent implementing a modification was the number of new lines to be added rather than the number of in-line changes, such as deletions or substitutions. The difficulty of a modification also affected the accuracy with which it was implemented. Greater cog-

TABLE V.—Correlations between Complexity and Performance Measures

Complexity metric	Percent Recalled (Exp. 1)	Accuracy (Exp. 2)	Time (Exp. 2)
Halstead's <i>E</i>	-.13	-.29	.44**
McCabe's $v(G)$	-.35*	-.36*	.38*
Length	-.53**	-.34*	.46**

Note:  $n=27$ . \* $p \leq .05$ . \*\* $p \leq .01$ .

nitive difficulty appeared to be involved in creating new code than in merely deleting or altering it.

The inclusion of mnemonic variable names and either global or in-line comments were expected to improve programmer performance. The surprising lack of effects for documentation aids in both experiments may have occurred for several reasons. First, in Experiment 1 variable mnemonicity was manipulated and global comments were provided with all programs. In Experiment 2 type of commenting was manipulated and mnemonic variable names were provided in all programs. Thus, the existence of one type of documentation may have reduced the additional information available from the documentation aid being experimentally manipulated, reducing its impact on performance.

A second possibility is that documentation aids do not contribute significantly to performance for programs of the modular size (35-55 lines) employed here. In large systems with many modules and thousands of lines of code, documentation may have more impact on performance because of the increased amount of information programmers must remember. Thus, program size may moderate the relationship between documentation and performance.

Finally, although mnemonic variable names did not affect performance in Experiment 1, many participants seemed to prefer them. That is, they used their own, more meaningful names when reconstructing the least mnemonic versions of the programs. For the medium and most mnemonic versions, they tended to use the original names supplied. Thus, the contribution of mnemonic variable names is supported by anecdotal rather than statistical evidence.

Results for the modern programming practices studied here were probably conservative due to the small size of programs studied. The cognitive load placed on programmers attempting to understand or modify approximately 50-line programs did not require the amount of assistance provided cumulatively by structured coding, mnemonic variable names, and comments. While the information provided by these practices was not necessarily redundant, the task could be mastered with less information than presented. In a larger system composed of many modules, however, the cognitive burden of implementing modifications may be so great that each of these programming practices may contribute significantly to efficiency. Thus, future research needs to assess the independent benefits of these practices in substantially larger programs.

#### *Software complexity metrics*

The two experiments comprising this study produced empirical evidence that software complexity metrics were related to the difficulty programmers experienced in understanding and modifying programs. Deeper analysis indicated, however, that the Halstead and McCabe metrics predicted programmer performance only on certain programs. Programs on which significant prediction was observed were characterized by the absence of programming practices such as structured coding or commenting which provided assistance in understanding the code. These com-

plexity metrics were more predictive of the performance of less experienced programmers. A more complete presentation and discussion of these results is presented by Curtis, Sheppard, Milliman, Borst, and Love.<sup>3</sup>

Assessment of the psychological complexity of software appears to require more than a simple count of operators and operands or basic control paths. Many programs have characteristics unassessed by these metrics which may heavily influence psychological complexity. For instance, the use of structured coding techniques or comments may reduce the cognitive load on a programmer in ways unassessed by the complexity metrics. Further, complexity metrics may not be capturing the most important factors for predicting the performance of experienced programmers who may either be conceptualizing programs at a level other than that of operators, operands, and basic control paths, or who can fit the program into a schema similar to one with which they have had previous experience.

Even though moderating effects were observed in these data, stronger relationships with performance may have been masked by the effects of differences between individuals and programs which were enhanced by limitations in the economical multifactor designs employed. Uniformity in the sizes of programs studied may also have limited these results. The range of values assumed by complexity metrics computed on these programs may have been insufficient for correlational tests<sup>5</sup> to detect the strong relationships reported in other verifications of these theories. Studies reporting higher correlations for Halstead's *E* usually involved a broader range of program sizes.<sup>8,18</sup>

Further work in the area of software complexity should identify a set of cognitive principles relevant to programming tasks. Metrics could then be developed which would assess the qualities of software which are most closely related to these principles. Such an exercise might not only lead to improved metrics for assessing software complexity, but might also identify programming practices which could lead to more easily maintained software.

#### ACKNOWLEDGMENTS

The authors gratefully acknowledge the assistance of Ann Fitzsimmons in implementing this research, of Dr. Gerald Hahn in developing the experimental design, and of Beverly Day in manuscript preparation. Careful reviews of this report by Dr. John O'Hare, Dr. Maurice Halstead, and Thomas McCabe have resulted in substantial improvements. The support and encouragement of Gerald Dwyer has also been greatly appreciated.

This study was supported by the Office of Naval Research, Engineering Psychology Programs (Contract #N00014-77-C-0158). The views expressed in this paper, however, are not necessarily those of the Office of Naval Research or the Department of Defense.

Expanded reports of each experiment can be obtained by writing the senior author at: General Electric, Suite 200; 1755 Jefferson Davis Hwy.; Arlington, VA. 22202. Portions of this paper were drawn from articles to be published by

the Human Factors Society and the Institute of Electrical and Electronics Engineers.

# The use and abuse of a software engineering system

by D. J. PEARSON

*Bell-Northern Research*  
Ottawa, Ontario, Canada

In 1969, International Computers Limited of England set about the design of its 2900 Series which was to unify the primary thrust of the company and was to provide a hardware and software architecture which was, at least, state-of-the-art.<sup>1</sup> The systems also had to sell. Therefore, they had to satisfy the then market requirement for rich facilities and generally neat features. If ICL was seriously to compete with IBM (in Europe at least) the operating system, subsequently called System VME/B, would have to be comparable with the IBM products. ICL could not afford the staggering investments made in the 360 software systems. On the other hand, its recent track record had been less than outstanding for such software development. Faced with this dilemma, a project was set up to develop a system capable of minimizing the problems of software development by harnessing many of the current software engineering philosophies in order to aid management, reduce error rate and increase productivity. This system was subsequently called CADES (Computer Aided Development and Evaluation Systems). This paper describes briefly the major facets of this system and then goes on to discuss six years of product development experience with a software engineering system which was, by the standards of the day, state-of-the-art.

## THE SOFTWARE ENGINEERING SYSTEM

The original CADES system was based on System 4 and was implemented between 1970 and 1972. All the original VME/B software was itself implemented on the System 4 and written in a high-level language based on Algol 68 called S3. It was not until 1973/74 that a real transition to 2900 architecture took place as far as the product development activities was concerned. CADES itself was redesigned and reimplemented on 2900 during the period 1974–76. CADES consists of the following elements:

1. Formal Design Methodology
2. Design Definition Language
3. Product Data Base
4. Formal Data Capture and Control
5. Product Data Base Applications

## *Formal design methodology*

A methodology called Structural Modeling was defined and adopted. It was based on a formalized top-down, levels of abstraction approach with great emphasis being placed on the data-driven emergence of design, and attempting to quantify the iterative nature of design. Instead of the "design until you understand the problem, code until you realize you don't, then iterate" approach to design, the entire process was quantified and documented, with all the possible iteration paths identified and priorities assigned to them.

Using Structural Modeling, the designer was constrained first of all to analyse the problem in terms of *information flow* and to structure this information analysis into a tree-form, each level on the tree defining an *abstract machine*. One of the lower levels of abstract machine would map onto the S3 compiler data structures. This was the *implementation level*. After this information analysis, a function tree was constructed, compatible with the information tree, each level on this function tree representing the functional definition of that abstract machine. This was called the *holon tree* (holon, from Koestler, Reference 3; in this context a holon is defined as a unit of further design).

A lower level of the holon tree would map onto the concept of an S3 module. This was the *implementation level*. When both trees were compatible, that is, complementary from an abstract machine, levels-of-design point of view, the top-down design process was commenced, expressing the functional design of each holon, level-by-level, in terms of the information items at the corresponding level in the data tree and its interactions in terms of its peer-holons. These designs were defined in terms of the design definition language. Techniques were built into the modelling process to preserve the data and functional modularity, and to minimize the functional and data connectivity across the system.

## *Design definition language*

The emerging design was expressed in a formal System Descriptive Language, SDL. The structure of SDL was based on that of the implementation language S3. However,

it was provided with facilities to express design concepts such as an 'event' and a 'virtual machine,' and it contained no facilities for implementation concepts such as data structures and procedure declarations. An SDL definition dealt exclusively with the items defining the abstract machine under definition, and the conditions and assertions governing its function in terms of the recognized design concepts. When the designer, during his top-down design activities, reached the implementation level and started to define that in SDL, an automatic code generator was initiated and S3 code automatically generated from an SDL definition.

The advantages of using SDL were fourfold:

1. It ensured a formal, complete definition of the entire design.
2. Design definitions were machineable and could be captured in a data base.
3. Automatic code generation increased productivity.
4. Automatic code generation dramatically reduced finger-trouble error.

*Product data base*

One of the primary intentions of the CADES system was the construction of a product data base which would contain the entire set of information defining the VME/B product, from earliest design statement, S3 code and loadable versions, product releases, bug reports and fixes. One major reason for this was in order to be able to relate problems discovered in the field to the appropriate earlier design decision and hence define accurately the scope of such problems, rather than adopting the fire-fighting, piecemeal approach to product maintenance. The greater the contents of

the product data base, the more valuable it was in terms of information inversions. It reached maximum value at product release, and subsequently proved to be invaluable throughout all product maintenance activities. The data base itself is able to contain all *types* of VME/B product definition, as shown in Figure 1.

Updates were made to the data base using the formal data capture mechanism and expressed in SDL. Similarly, retrieval requests were expressed in SDL. The code generator, compiler, construction, loading and maintenance tools interacted directly with the data base. This interaction enabled the mapping between 'types' of operating system representation to be carried out consistently. Note that the mapping between high- and low-level design representations is carried out by the designer. When a change was made to the data base, entries were recorded in queues for action by the appropriate tools. The tools themselves return information such as sizes and indications of success to the data base. This return information itself might then cause further entries to be made on the queues for appropriate processing. In this way a degree of automation was achieved, human interventions, and hence error rate, decreased.

*Formal data capture and control*

As will be explained in the next section, the size of the project team was large. Data base information integrity in such an environment is very important, and yet very difficult, to achieve. In order to achieve the necessary level of integrity we were forced to implement a semi-batch interface for data capture, with a rigorous control scheme to validate every piece of information to be inserted into the data base. This level of control was achieved by associating an au-

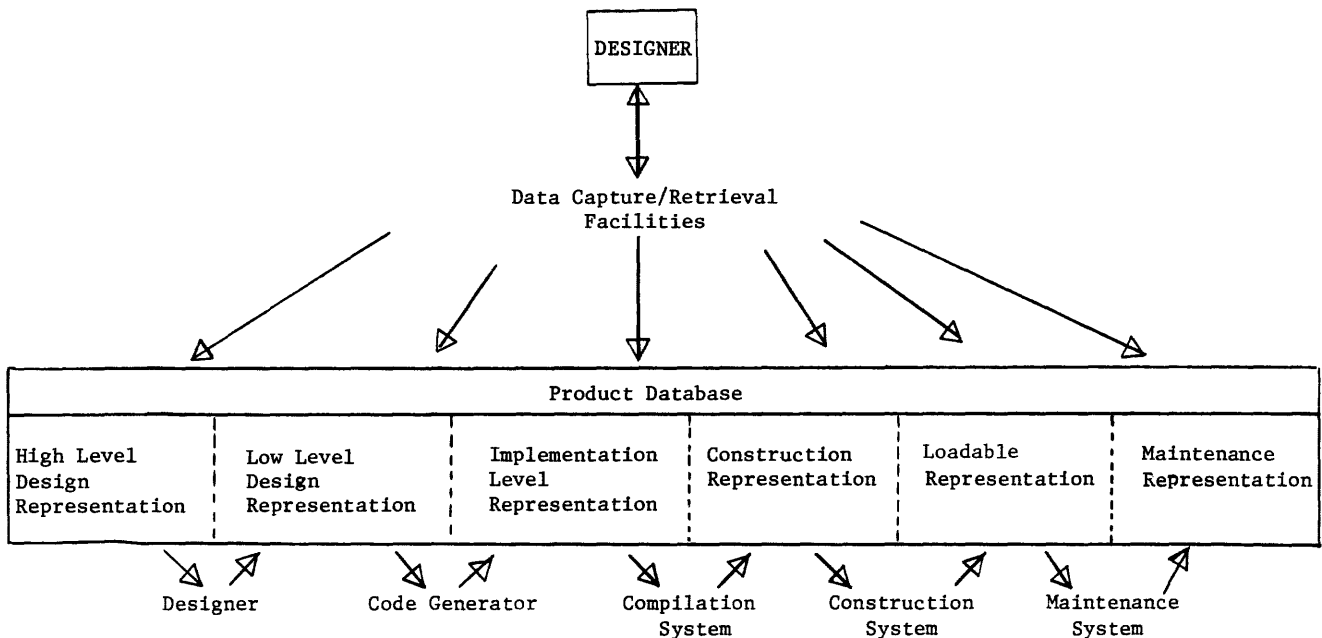

Figure 1

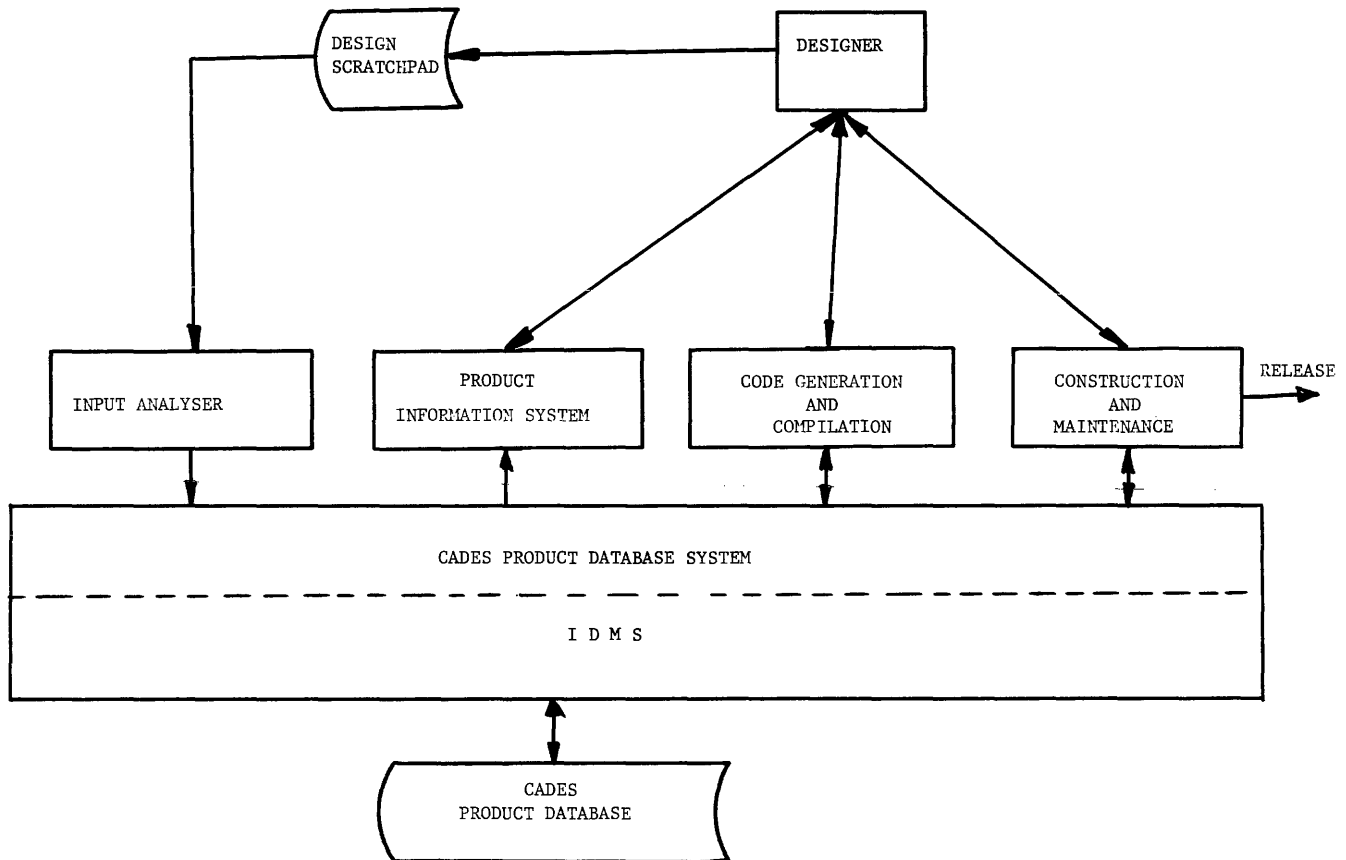

Figure 2

thorization form with every type of input to the data base system. The designer coded the proposed insertion (tree, SDL, management information, etc.), completed the appropriate authorization form and then collected the approval signatures of his team leader, chief designer and project manager before he was able to pass the update to a CADES service project for processing and return of an update acknowledgment. Although this system sounds horribly inflexible and bureaucratic it did achieve two things—the level of data integrity in the product data base after five years' use was very high, and it augmented and reinforced the project management mechanisms to a considerable degree. In fact, these controls placed on the development group for the sake of data integrity more than justify themselves purely in terms of rigorous software management techniques.

#### *Product data base applications*

Figure 2 gives an idea of the CADES system as a whole. The four applications shown, Input Analysis, Product Information System, Code Generation and Compilation, and Construction and Maintenance were the most significant in terms of impact, and certainly in terms of success. Less successful applications such as simulation and test program

generation were attempted and then subsequently fell into disuse due to lack of support.

The Input Analyzer was responsible for the syntax and semantic analysis of the design. It ensured that standards had been adhered to, that correct versions had been used, that the connectivity of the proposed design update was acceptable, etc. Less than full use was made of this checking stage. It would have been possible to code very rigorous and comprehensive checks in the Analyser, and for the project manager to choose what levels of validation he was prepared to accept in a trade-off against expediency. This would have been possible and would have led to some interesting results. However, time always seemed to preclude this level of 'luxury.'

The Product Information System presented an easy to use retrieval interface to the designers, in either interactive or bulk-data mode. The service project was the main users of this interface to regularly supply managers and designers with current product details and statistics. The interface also provided answers to 'what if. . .,' 'who uses. . .' and 'how did this happen' type of questions.

The Code Generation and Compilation application had a great impact throughout the product development. The application started from design specification in SDL at the implementation level, formed an S3 source code module

from macros and primitives in the product data base, compiled it, and stored the subsequent S3 object code in the data base for subsequent collection. Because the designer did not deal with any sort of declaration and because he was constrained to make maximum use of the primitive macros stored in the data base, code production rates were increased very considerably and error rates dramatically reduced. Other advantages were that the code generator automatically inserted error checking and tracking code, and it, of course, imposed its own standards on the entire product coding.

The Construction and Maintenance application was driven by the master product version/release plan built into the data base. From this the system was able to construct from the object code modules, architectural details, etc., a set of load modules for export to a specific user site. The system kept track of user configurations, trouble reports, etc., and automatically correlated the most recent updates and fixes with the version currently in use on site.

## THE ENVIRONMENT

Before discussing the results of using this CADES system on the VME/B product development, it will be useful to look at the target product and project involved.

VME/B is a facility-rich operating system with great emphasis placed on data management and job control language facilities. It supports a virtual machine architecture and is protected by 15 levels of hardware-implemented protection. A current typical release of VME/B represents, in total, between two and three million lines of S3 source code. Detailed design of the product was started in 1971 and the first version was running on 2900 architecture in 1973. The first customer release was made in 1975. The software was initially developed on System 4 machines, and then converted to run on a 2900 hardware simulator (i.e. 2900 architecture, old technology), before finally appearing on a true 2900 machine in 1974.

Until 1974 the project, about 200 people, was split over two sites which were two hundred miles apart. As the size of the project peaked the software engineering disciplines proved insufficient to handle this geographic split and the two teams were moved into one site. At any one time the CADES development and service group, including compiler development, represented about 15 percent of the total project team.

In the view of the above environment, and in view of the late 60s experiences by ICL in terms of operating systems development, the software engineering system was initially developed and controlled in order to promote the following VME/B attributes:

1. Highly structured, that is high modularity and low connectivity. This requirement initially dominated the performance requires.
2. Ease of maintenance and enhancement.
3. High predictability and reliability.

4. Strong management and technical control over a large project team.
5. Subsequent performance improvements.

The next section describes how these attributes were achieved in practice.

## THE PRAGMATICS

(*Pragmatic*—'practical as opposed to idealistic' (Webster's New Collegiate Dictionary).)

When we set out to formulate and create the CADES philosophy and system we attempted from the start to be as practical as possible. We certainly adopted a rather basic engineering, rather than scientific, approach. This approach is described in detail in Reference 5. For instance, the form of the design language was based more on the facilities we wanted to remove from the programming languages as far as the designer was concerned than on more esoteric considerations concerning concise, formal definitions of the evolving design. It had to be usable, capable of quick, error-free production and easy to learn. Hence it ended up as being rather inelegant. But we could express emerging design in it, and we could generate S3 from it.

This approach to life pervaded the entire CADES system—methodology, language, data base, applications and service. The goal was to save the company as much product development money and lead times as possible. We set out early in 1970 not knowing a great deal about how we were going to do this and learned a great deal during the next seven years—both in a controlled learning way and also by bitter and expensive mistakes and experience. Some of the lessons are discussed below.

### *Economics and productivity*

Over the seven-year period, the CADES system produced significant increases in programming productivity. At the end of the seven year period we were much better at producing code than at the beginning. Fred Brooks<sup>1</sup> quotes 'typical' IBM code production rates classified by the complexity of the product being generated. These are:

- Very few interactions—10,000 instructions per man-year.
- Some interactions—5,000 instructions per man-year.
- Many interactions—1,500 instructions per man-year.

He also quotes Corbato's (MIT's project MAC) overall production rate on MULTICS of 1200 lines of debugged PL/I per man-year. During the last three years of VME/B production when CADES represented a fully familiar, established and stable product, the production rate for the entire development team was around one module per man-month (four weeks). After generation, the average S3 source module was around 350 lines of code, derived from, perhaps, 100 lines of SDL. This represents a debugged programming rate of around 4500 S3 lines per man-year. This compares

favourably with the MULTICS rate and with the IBM rate for complex software. Hence, in terms of individual productivity CADES would appear to be at least a qualified success.

However, there is a more fundamental point here. In view of the ultimate size of the product and of the project, the experiences of the other manufacturers on products of similar size, and the problems we ourselves had during those seven years, it is *very* unlikely that the VME/B product could have existed at all without the CADES system, or an approach very akin to it. The power of CADES was that it forced software development activities, and in particular quantified design activities, into close proximity with rigorous management mechanisms. They presented sociological problems which will be discussed later. It did, however, provide us with an extremely well controlled and regulated large-scale software development.

#### *Connectivity controls*

One of the initial intentions in the CADES philosophy was to minimize and then subsequently control the evolution of the connectivity of the system. Connectivity is a major factor influencing the structure of a software product, the other being its modularity. Lehman<sup>4</sup> has compared software structure to negative entropy in his Program Growth Dynamics studies. The Law of Increasing Entropy states: "The entropy of a system (which is the cross-product of connectivity and the reciprocal of modularity) increases with time unless specific work is executed to maintain or reduce it." This is another statement of the well known Structural Decay phenomenon in which the difficulty of system modification increases with system release number. I believe that the secret of maintenance and enhancement, and hence economic product longevity, lies in mechanisms to monitor and control connectivity evolution. CADES had such mechanisms built into its methodology and database applications.

A measure of how successful we were can be gained by looking at a system attribute called *Ripple Factor* (RF) and calculating this for VME/B release sequences. The term Ripple Effect was defined by F.M. Haney<sup>2</sup> and occurs most noticeably in systems with a large number of components. An enhancement or fix in one component causes, as a side effect, further necessary changes in other components, and possibly itself. The RF is the factor by which the work increases relative to that planned. Haney, via various sample systems, quoted RF of around 10 as being representative for a maturing software system of medium-to-high complexity. When a similar study was made of VME/B releases in 1975 the derived RF was found to be 1.4. It represents a remarkable improvement if Haney's figures are taken as representative. Subsequent experience in VME/B maintenance and enhancement would tend to confirm the fact that it is indeed relatively economic to enhance and develop now that it has reached a steady-state maturity. It remains to be seen whether the management controls will remain sufficiently rigorous to present the Law of Increasing Entropy finally

dominating. The current signs are, however, that connectivity is still under control.

#### *Law of management futility*

Lehman<sup>4</sup> states a law which he calls the Law of Statistically Smooth Growth. I prefer to call it the Law of Management Futility, and to state it thus:

Growth trend measures of global system attributes may appear stochastic locally in time and space, but statistically are cyclically self-regulating with well-defined longer-term trends.

I believe that this law is a very fundamental one and explains why so many large-scale software developments go astray because of too much misdirected, rather than too little, management attention. Lehman's law, and my experience, state that management fire-fighting at any stage in the software development process is likely not to work. The fighting and extinguishing of a local bush fire will only raise the temperature of, and the pressure on, another area, probably more critical and expensive, downstream in the development process.

CADES recognized this phenomenon and prevented its abuse in two ways. Firstly, the product data-base was based on a comprehensive, complex schema which defined the *entire* development process, from statement of market requirements through to steady-state product maintenance, and defined in great detail the entire set of interrelationships existing throughout the life-cycle. As a result, little management action could be taken in isolation without its downstream impacts being automatically defined in a suitable degree of detail. I believe this schema, and its evolution in future systems, is fundamentally important and says very significant things about the very nature of the software development process.

Secondly, the CADES system itself, and its control over VME/B production, had a noticeable inertia to violent changes in direction by management dictate. The greater was the proposed change, the more noticeable was the inertia of the system. This may not seem to be a positive attribute of the system. However, Lehman's law says otherwise. Management actions should be smooth, controlled and fully cogniscent of the downstream implications of current action. The CADES system ensured this was true to a marked degree.

#### *Sociological implications*

It was obvious early in our formulation of the CADES principles that a large team would ultimately be employed on the VME/B development program. This one fact had a strong influence on the entire CADES system—its methodology, language and software. A decision was made that all aspects of the system would impose a rigid discipline and control over the project team, even at the expense of flexi-

bility and ergonomics. Indeed, one of the constraints on CADES development was that the entire system should "mechanize" as much as possible of the software development process, either with machinery (i.e. software tools) or by formal disciplines and procedures which attempted to take as much arbitrariness out of the process as possible. As a result, initially, some designers felt that their creativity was being stifled and their intellectual freedom curtailed. In some ways they were correct and, as a result, in the first two years of operation, a few designers left the project specifically because of the technology. Perhaps five percent of the workforce left over this two year period, ostensibly for this reason. However, at the end of the two years, the management team was able to agree that, if we had had to shed five percent because of redundancy or whatever, there would have been a close correlation between the two sets of five-percents. As the system proved itself during 73-75, designers and managers joined the project ostensibly for the same reasons.

#### *Multiple versions*

In the first version of CADES we were so intent on solving difficult, important problems that we completely underestimated the magnitude of the multiple versions problem for large systems development. As a result, in the new CADES version on 2900 we had to include comprehensive and powerful mechanisms for multiple version handling down to the local procedure and data item level. This consumed a significant amount of effort in the second CADES development. I believe such a mechanism is fundamental to the real usability of any production software engineering system. Not only should multiple, limitless versions of almost everything be allowed, but also automatic "inheritance" mechanisms have to be implemented between these multiple versions in order to accurately reflect the way software systems are developed in practice.

#### *On bridging data bases*

The final observation does not refer directly to software engineering or operating systems development at all, but rather to database administration. James Martin once told me that he had no knowledge of a *successful* migration of the entire contents of a large database from one database system to another. At the time I failed to understand the subtlety of the point. I now fully appreciate its meaning. In 1976 we were faced with the conversion of the CADES data base contents from the initial data base system, an in-house transposed file system, to the Cullinane IDMS system. The initial data base size was modest, about 60 MByte. The strategy was very simple; extract the information from Data Base 1, process these files into user input language for Data Base 2, and then input it to Data Base 2. The activity was at least four times as expensive as planned.

The reason was very simple. Data Base 1 had been in daily production use for four years. Although tight controls

had always been placed on the integrity of data submitted, it was inevitable that "semi-corruptions" would creep in from time to time. As the Data Base 1 evolved and was supported by the service group, it "learned" to handle these semi-corruptions (such as missing information) and still give adequate service. However, Data Base 2 and the bridging software knew nothing of this acquired knowledge and as a consequence fared badly when faced with less than 100 percent perfect information. Fortunately, the corruptions were minor and Data Base 2 made a good, but expensive, recovery.

#### CONCLUSIONS FOR THE FUTURE

I think that I have to conclude that CADES was at least a qualified success in its control of and contribution to the development of VME/B. The very existence today of VME/B would support this. Its use on this project did, I contend, save the company money running into millions of dollars. However, I doubt that the CADES system as it stands today will ever be even approximately repeated.

Mainframe manufacturers have now recognized that adding more and more people to a project does not reduce its risk of failure. Indeed, it can have quite the reverse effect. Although software is still getting more complex, teams are getting smaller. The software engineering systems of the future will reflect this. Such systems will become increasingly important and central to the well-being of even modest projects. However, they will reflect a greater emphasis on ergonomics and less on rigorous management and administrative control. This is the approach being taken at Bell Northern Research Laboratories in Ottawa in our development of a new-generation system called ISES, Integrated Software Engineering System. This system, the prototype of which has just entered trial use, combines many of the lessons learned from the CADES exercise with current, state-of-the-art thinking in software engineering. Some of the features embodied in the ISES system are:

#### *Requirements engineering*

In a commercial, industrial or government environment concerned with the development of high-quality, complex software destined for a highly-competitive marketplace, the rigorous definition and acceptance of product requirements is the Achilles' heel of the product development group. In this environment it is not enough to develop high-quality designs and efficient, timely implementations—they also have to be *appropriate*. Without a formal approach to product requirements definition and its total integration into the product-development and life-cycle process there is no quantified manner in which to assess this appropriateness until the customer receives, or refuses, his product. ISES includes an approach to definition of product requirements which is as quantified and integrated into the development process as are other, more accepted, aspects such as unit and integration testing.

### *Graphical design language*

I identified one of the "weaknesses" of CADES as being its gross approach to the control of Chinese-Army-type operations. The industry has moved on. Large teams become less and less the norm. So must software engineering evolve. Textual design languages are weak for describing the back-of-envelopes design activity. They demand completeness of expression. During the early stages of conceptual design completeness tends to be very low on the list of priorities, rightfully so. In this context, we need to be able to support the expressionism associated with the highly-dynamic, creative thought processes and decision making of our most experienced, creative designers. To do this, ISES provides the designer with a powerful abstract symbolic interface supported by an intelligent color raster graphics system. With this interface the designer can sketch out his design and architectural ideas in close to a random fashion whilst the system interprets these into more orthodox design representation, placing this into the global context of the current ISES data base.

### *Software metrics*

The more one formalizes and captures the total software life-cycle process with systems such as ISES and CADES, the more able one is to develop the physics of large software systems, or Software Metrics.<sup>7</sup> A large proportion of the software engineering community is striving to understand the nature of large-scale, complex software systems. We need to be able to define the parameters of these systems, the relationships governing these parameters, and how best to optimise them. The power of a system such as ISES in this context is that it controls and contains the total flow of information associated with a product's life-cycle. Hence, there is a level of activity-monitoring architecture within ISES—the system monitors its own usage and is able to evaluate and refine in-built metric models as a result of this day-to-day usage. It is a powerful step towards combining the worlds of theoretical and practical software engineering.

### *Hardware CAD compatibility*

In many product development situations the position of interfaces between the levels of hardware and software implementation is arbitrary to a large extent. The factors which dictate the divisions are tactical ones and include flexibility, maintainability and timing criteria. In hardware engineering

this arbitrary nature is well illustrated in the division of a design between custom and silicon chips and printed circuit boards. Indeed, several manufacturers now adopt the technique, with the aid of advanced computer-aided design systems, of prototyping their products in PCB technology and then, once proven, reducing these PCB's each to a single custom chip. This flexibility should also extend to the outer software-implemented levels of a product. In order to aid efficiency in critical areas a manufacturer may want to re-implement a software function, or series of functions, in a chosen hardware technology. Today, this is a highly complex, risk-laden task. The transfer into hardware usually stops at the firmware level. ISES, on the other hand, is being implemented as part of a total-technology CAD system. Eventually this system will be driven exclusively by technology-independent requirement and problem statement languages. The ultimate system will provide complete flexibility to the designer in terms of how his design is implemented, and freedom to move between technologies for a single piece of design. Thus this CAD system, which contains ISES, will support the fundamental concept of the Implementation Technology Independence of the holon design unit.

### ACKNOWLEDGMENTS

I should like to express my gratitude to the entire CADES team, both past and present members, for making the last seven years such enjoyable and entertaining ones. I should also like to express my admiration of ICL management for having the courage to follow through with the CADES program during times when the benefits were less obvious than they are today.

Permission to publish extracts from a paper delivered to the Second International Symposium on Operating Systems in Paris in October, 1978, is acknowledged by the author.

## INTRODUCTION

In the constantly expanding spectrum of microprocessor applications, there is a large class of systems which used to be implemented with large or minicomputers, in which new software engineering problems have emerged. Typically, these systems involve quite a few hierarchical microprocessors—they perform fairly sophisticated control functions, and must comply with stringent reliability and availability demands. Though the distribution of functions significantly reduces the complexity of some of the technical problems usually encountered in such systems, the volume of software to be developed remains large, and system tests are still a problem.

Furthermore, the development systems offered on the market by microprocessor manufacturers or independent vendors are very well adapted to the development of small applications which involve a unique microprocessor and a limited volume of code, but they are insufficient for the development of large systems. The system builder engaged in distributed system development will, therefore, have problems to solve, until the ideal support software and hardware are made available on the market.

## SOFTWARE DEVELOPMENT REQUIREMENTS

### *General requirements*

What a programmer expects from a development system is now well understood for large and mini-computer software development, and since it has to do mainly with the way the user sees the system, or with the way he gains access to it, and not with the way it is built, there is no reason, no matter how different the target processor may be, that the same rules should not apply to microprocessor software development.

The qualities assumed of a development system have to do with ease of use and access, the overriding consideration being, therefore, that the system should be terminal-oriented. This should give the user unrestricted access to all system facilities from his desk. In addition, it should limit the need to handle media; cards should be completely aban-

doned, listings should not be used as the support of run results, but as reference only, when a program has reached a satisfactory level of completion, and magnetic media should be handled for archives, deliveries, etc. . . , by the system itself, and not at all by the programmer. Even cassettes or diskettes, though handy, can create a great amount of confusion.

From his terminal, the user should have access to a certain number of programming aid facilities:

- Program handling aids such as text editors, library managers.
- Documentation support facilities, including document entry, document updating, document editing and printing, either directly on listings, or through phototype-setting for quality printing.
- Programming aids—Compilers, link editors, loaders, debugging facilities, etc.

Another extremely important feature of the development system is the command language it offers. It should be rich (i.e. it should offer many functions), and easy to use, which in fact means that it should be easy to invoke from a terminal, both directly through system commands and indirectly, through catalogued procedures built by the user to help him perform frequently repeated complex operations by means of simple commands.

### *Specific microprocessor requirements*

Programming problems are not significantly different in distributed systems, even large ones, from those encountered in others. Programming proper is not a problem—high-level languages, when available, are perfectly suited for distributed system programming, and the fact that some specific microprocessor features are not accessible through them will never justify going back to assembly languages, except, maybe, in a few sections where performance is critical. This is true, in fact, of any system and of any high-level programming language. On the other hand, in some areas, programming will be even simpler. The kernels which operate the microprocessors are generally message-oriented,

and support only fairly static processes and connections between processes, which makes them easy to understand and develop. Even reconfiguration mechanisms, generally quite sophisticated in other systems, tend to be rather simple in a distributed environment, at least from the programming point of view.

The problems associated with unit testing are of the same order of magnitude as those traditionally found in systems—depending on the detailed internal architecture, it will be more or less practical and economical to create an environment which lends itself to unit tests.

System testing is, however, a completely different problem in distributed systems—simulation works mainly for unit testing. The complexity of interactions, and the number and variety of components at work, generally make simulators uneconomical in such environments. The only economical means is to test software on prototypes, equipped with the appropriate hardware and software probes connected on the microprocessor, the memory and maybe some other critical points. Besides, these tests should be run in interactive mode under a system offering the right kind of debugging facilities, such as traces, breakpoints, snapshots, at the symbolic level.

#### CURRENT SOFTWARE DEVELOPMENT SYSTEMS

In a system development house, the approach first selected for the development of software for microprocessor systems is to use the existing computer facility. Typically, such a facility is a medium-to-large computer system operated in time-sharing (see Figure 1a). For the benefit of microprocessor software development, existing tools for system and program design, program management and documentation management may be used without problems. However, two questions do have to be answered: What "programming system" should be used? How should testing be done?

In this environment, as far as program translation is concerned, the only possibility is to develop a compiler or adapt an existing one to generate the target code, and to develop a linkage editor and other loader utilities as required by the microprocessor hardware. Further, a microprocessor test simulator has to be developed for unit tests.

When it comes to system testing, programs in load format have to be output on an external medium, which can be used as an input to the prototype system; but, for efficiency, debugging facilities have been implemented on the prototype system to fulfill the requirements stated previously. Though such a development system can work, it has many disadvantages:

1. Development of a cross compiler and of the other programming facilities may be a costly proposition for, after its development, it will have to be maintained and enhanced as required, adapted when new microprocessors have to be used, etc. Even if such a line of translators can be found on the market, adaptation to new microprocessors will generally introduce delays.

2. Simulators have to be developed.
3. Transfer of programs on an external medium is generally not satisfactory because:
  - There is not always a compatible medium on the development system and test system.
  - When an error is found, binary patches will be used on the prototype instead of source corrections, because of the time otherwise involved in updating, compiling, linking and transferring a program. Such a practice is potentially harmful and costly.
4. A debugging facility on the prototype system has to be developed. This may be expensive, if it is to perform symbolic debugging in an interactive mode.
5. When going to other microprocessor compilers, linkage editors, simulators and debugging aids will have to be extensively adapted.

The main advantages are the use of:

1. Existing systems.
2. Existing language-independent software tools, such as design aids, program librarians and documentation aids.
3. If a standard implementation language exists in the user organization, it can still be used on microprocessors at a certain cost, even though it might not give enough visibility to some of the processor functions.

Some of the problems just mentioned, especially in 3, can be alleviated by connecting all consoles to both the development and the test systems. This might be done as shown in Figure 1b, using a concentrator to which both the development system and one or more test systems would be connected via transmission lines. The transfer of programs can then be done automatically, and the user may have access from his console to all resources, whether development or test.

In a development facility equipped with a programmer's workbench,<sup>3</sup> the situation is not significantly better. A cross compiler, a linkage editor and a simulator would have to be developed for a "Programming Machine" (see Figure 1c), leaving the program and documentation-handling facilities on the programmer's workbench, which is essentially a file machine, and does not look like the right system in which to place compilers and simulators unless its configuration is expanded. But then it becomes a conventional system, like those described earlier. The programmer's workbench does not help to solve the system test problems any better either, since the required debugging facilities again have to be developed on the prototype system.

Another variant of this type of software development system is the Interactive Session Monitor,<sup>2</sup> in which microprocessors are connected directly to the existing development system (Figure 1d). Programming tools are run under time-sharing on the development system, and tests can be done either in simulation mode, or by executing the program on the microprocessor. This system again does not solve the problems discussed, since cross-compilers and simulators

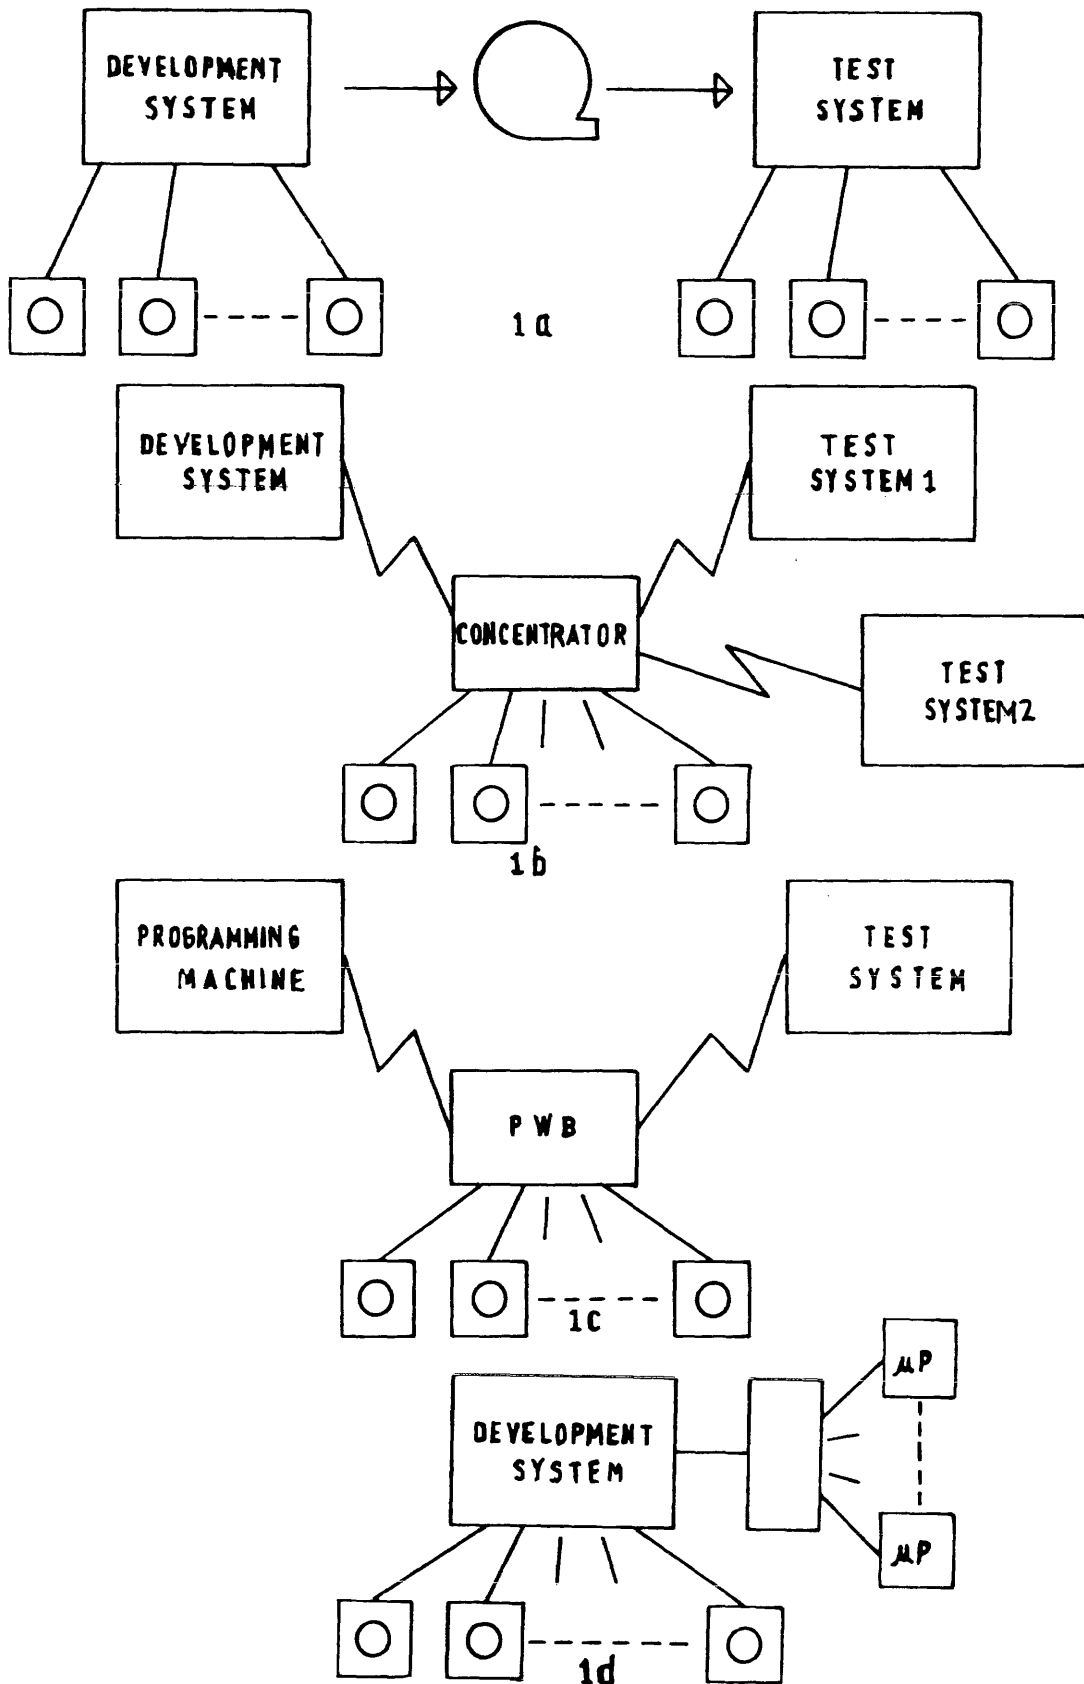

Figure 1—Conventional development systems.

have to be developed, and execution on the microprocessor offers only limited possibilities.

### MICROPROCESSOR DEVELOPMENT SYSTEMS

Software development systems offered by microprocessor or independent vendors can be used instead of an existing facility. For example, the software development facilities for the 8080 line of microprocessors found on the INTEL-LEC system are:

- A "Programming system", including
  - A text editor, to enter, update and inspect text.
  - Compilers, for high-level languages.
  - An assembler.
  - Link/loader facilities.
- A simple file system, to store programs in various formats.
- A debugging system, for unit tests on the system.
- An in-circuit emulator, for testing of a microprocessor program within the prototype environment.

The peripheral configuration consists of a single keyboard console, dual floppy disk drives, and optional printers and other peripherals.

The vendors' systems support their microprocessors only, but some independent suppliers offer systems which support several microprocessors. Indeed, microprocessor software development systems offer a very adequate range of functions for program development. However, the tools or utilities found on large or minicomputers are entirely missing; there are generally no program library managers (the file systems offered are insufficient in this respect), no documentation aids, no design aids, no project control utilities. Performances are limited—compilations are slow, printing is slow and secondary storage on floppy disks is limited in throughput and capacity.

The advantages, however, are:

1. The programmer has easy access to the system (a ratio of one system to two programmers is generally used).
2. These systems are relatively cheap (in the vicinity of \$20,000).
3. In-circuit emulation, which allows one or more programmers to debug on the prototype system, is generally very good.

In large projects involving more than a few programmers, where the volume of code to be produced exceeds 50,000 to 100,000 lines, the investment in development systems is no longer negligible, diskettes on which programs are stored proliferate and large compilations for system integration hit the limits of the development system, in terms of speed and secondary storage capacity.<sup>4</sup>

### INTEGRATED CONTROL, DISTRIBUTED POWER

The relatively low cost of microprocessor development systems, the programming facilities they offer, the easy ac-

cess to the system resources they provide and their in-circuit emulation functions make them hard not to use. Their shortcomings can be overcome by using a two-level system (Figure 2):

1. A centralized level, or "Central System," performing all functions of concern to the project as a whole, and offering services to the programmer where the microprocessor development system is insufficient.
2. A decentralized level, consisting of microprocessor development systems connected to the central system by transmission lines.

#### *Microprocessor development systems*

The following functions are performed at this level:

1. Program preparation—Program entry, update and inspection, and program translations, compilation/assembly, link editing.
2. Unit testing on the development system.
3. System testing on the prototype, using the in-circuit emulation facility.

Large volumes of input, such as the initial entry of large programs in source format, are performed on the central system, as is program library management. Typically, the user has his private work library on as limited a number of diskettes as possible, and access in read-only mode to the central library. To prepare his work he may request, from his console, transfer over the transmission line of any number of programs/files, as needed for his own work.

Individual programmer's programs are included in the central reference library, according to rules depending on the project, the system integration philosophy, and other considerations, but at times that guarantee enough visibility of the state of the work of each individual, throughout the project. A decision to include a new program in the reference library is, however, always an explicit project management decision.

#### *Central system*

Each microprocessor development system is seen by the central system as a time-sharing terminal, thus giving the user access to all central system resources.

The central system can be regarded as a *file machine* and *spooling machine*.

As a file machine, it manages program and documentation libraries; as a spooling machine, it performs all volume input/output—card input, listing and documentation editing. In fact, no card reader or printer of any sort need be connected on any microprocessor development system—all input/output can go through the central system. In addition, simple keyboard terminals can be connected for functions such as program or documentation entry/update/inspection, which can be done at the central level or elsewhere. Any other

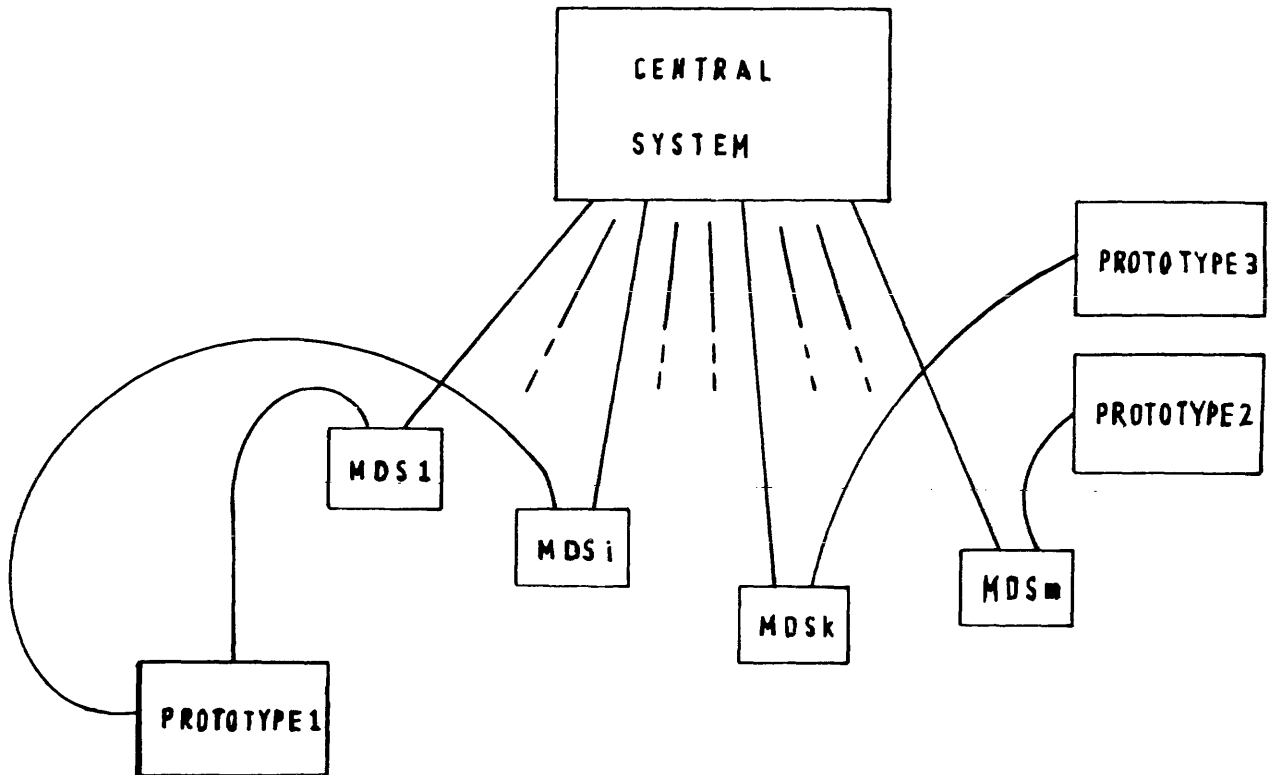

Figure 2—Centralized control distributed power.

utilities needed, e.g. a source code formatter, a macrogenerator, a test data generator, can be implemented singly on the central system, rather than on the several development systems.

The central system plays very much the same part as the programmer's workbench, except that the latter is a "front-end" processor, whereas here it is the microprocessor development systems that are front-end processors.

#### *Advantages and disadvantages*

What we have described is not ideal, but it does combine the advantages of centralized systems with those of microprocessor software development systems.

Its residual shortcomings are:

1. The file transfer rate over transmission lines is limited. Most time-sharing terminal throughput is limited to 9600 bauds, which means that the practical maximum transfer rate is around 1000 characters/s. This limitation is quite acceptable for a small program, but if a program of 10,000 lines of source code has to be transmitted over a 4800-baud line, transfer will take between 20 and 30 minutes. In practice, this is not really a problem, because:
  - a. Modules are stored in source and object format.
  - b. Modules are kept fairly small.
  - c. Source is transferred only when it is to be modified.

2. The programming languages and debugging systems are those offered by the vendor with the microprocessor development systems. This precludes the standardization of a single implementation language on all microprocessors within an organization—at least at the present time—and makes the client organization entirely dependent on any decision the vendor might make to enhance, abandon or maintain the corresponding products. Though this is not a satisfactory situation, it is not unusual either.

In compensation, however, it may be noted that the system described offers the advantage of being able to use tools, methods and techniques normally used in software development on computers other than microprocessors, thus yielding the kind of technical proficiency and managerial control that the state of the art in computer software engineering permits. Compared to other types of development systems, the flexibility and costs of this system are attractive features.

#### *Flexibility*

It is generally easy to connect a development system to a system running under time-sharing, so that, if various microprocessors are being used, it will be possible to connect the various corresponding development systems offered by the vendors, or some independent vendor. Further, for operations of general interest not requiring compilation, like

program or documentation entry, such as gathering information concerning library status, simple time-sharing terminals may be used. With a single central system it will therefore be possible to develop, manage and test programs for microprocessors of various origins.

This set-up, in fact, offers other interesting possibilities. For instance, concerning programming, although the system is clearly geared to perform compilations on development systems, it does not preclude using cross compilers. As reported in Reference 1, software for microprocessor *A* might be developed using a programming language available on the development system *M (B)*, designed to program microprocessor *B*. Program entry, compilation and unit testing are carried out on *M (B)*; then a cross compiler on the central system is used to generate code for microprocessor *A*. The development system *M (A)*, or an independent system, will be used to perform system tests using *A* on a prototype. Though this process seems fairly involved, it can be made fairly easy in practice, since *M (B)* and *M (A)* can both be connected to the central system.

### Costs

The load generated at the central system in such an application is fairly low, in terms of CPU usage, since most operations are file or terminal operations. A medium-to-large minicomputer should therefore be perfectly suitable. Moreover, actual connect time should be fairly low, since it is essentially determined by the frequency and durations of transfers or other operations requested from the central system.

It is assumed here that a minicomputer in the \$300,000 range (hardware only) could provide simultaneous support to 25 to 30 users,<sup>3</sup> and therefore that up to 50 microprocessor software development systems could be supported. The actual cost (purchase price) of the total system, per development station, would therefore be about \$6,000, plus the price of the development system itself, which is about \$20,000. If it is assumed that one development system can fulfill the needs of two programmers, that the central system has a lifetime of five years, that a development system will be obsolete after three years and that the cost of operating the central system is the same as the cost of hardware, the cost per programmer, per year should be in the vicinity of \$5,000.

The service thus provided should be of very good quality, combining those of a minicomputer-based time-sharing system with those of microcomputer development systems. The cost of computer time as assessed above should be compared to figures used for many system developments. Typically, on a system such as a 370/158 where an average of two hours of CPU time per programmer, per month is consumed, the cost per year and per programmer is around \$10,000. An overall cost reduction of around 50 percent can therefore be expected with respect to conventional systems.

With respect to stand-alone microcomputer development systems, the concept presented increases the hardware cost by around \$6,000 per development system, plus operating costs. But it is pointed out that:

1. Printers on the development systems are no longer necessary, since printing is done at the central site (typical cost of a printer is \$2,000-4,000).
2. Extra diskettes are no longer necessary, since a large disk capacity is accessible on the central system (an add-on, double density dual diskette costs around \$5,000).
3. Extra services such as library maintenance, documentation aids, etc., and fast I/O devices are accessible on the central system.

### CONCLUSION

This approach is being progressively implemented at CIT-Alcatel for the development of distributed microprocessor-based switching systems. Initially, INTELLEC systems were connected to CII-IRIS 80 as Remote Batch stations giving access to all development tools available for other developments, then, to improve access conditions and response times, they were connected to a CS 40 (a computer developed by CIT-Alcatel for switching systems), as time-sharing consoles. Replacement of the CS 40 by a minicomputer, to further reduce the costs of the system, is now being considered.

The system described offers distinct advantages with respect to developments on large systems, or on stand-alone microcomputer development systems, although in its present form the overall services offered are limited by the performance of the individual development stations, and by the transfer rates.

Nonetheless, the services offered and the flexibility gained make the system the real solution to the software development problem for the builders of large systems who want to use commercially available development products.

# On the fate of software enhancements

by NORMAN K. SONDHEIMER\*

*Bell Laboratories*

and

*The Ohio State University*  
Columbus, Ohio

## INTRODUCTION

One of the most serious problems for vendors of software is pressure from users to enhance and extend their products.<sup>1</sup> One important type of enhancement is the change in language form aimed at improving user productivity by making the system easier to learn and use. Ideas for this sort of enhancement appear regularly in such publications as *Sigplan Notices*. As evidenced by the correspondence in that publication, there are many opinions on the quality of these proposals. However, little is known about the actual fate of enhancements that have been added to existing software systems and released to users. When a new feature is released with the best of intentions and the usual fanfare of documentation and instruction, its acceptance by programmers may have little to do with the sincerity of the request or the quality of the feature.

This paper reports on one experimental study of the fate of enhancements to existing software systems. Features whose desirability was established by a survey of the user community were added to an established and heavily used text and program editor. The enhanced editor was then released to replace the old editor for a part of that community, and the reaction was monitored. The remainder of this paper details the experimental method, gives the results, and draws conclusions on the fate of software enhancements.

## EXPERIMENTAL METHOD

The experiment used to test the fate of user-requested enhancements to software systems proceeded through several distinct phases. In this section, I explain what was involved, beginning with the choice of software system and user community.

The system used in the experiment was the text editor of the UNIX\*\* time-sharing system.<sup>2,3</sup> The editor is the main tool for program and document developments on the system. It falls within the QED family of editors tracing back to Deutsch and Lampson's editor.<sup>4</sup> It is line-oriented and

biased towards the execution of single commands in isolation and identification by a pattern of strings to be modified.

The programming organization involved in the experiment was the Switching Operations Systems Laboratory of Bell Laboratories in Columbus, Ohio. The laboratory produces minicomputer-based real-time systems for the telephone network. The laboratory employs more than 150 people. Over 100 have some involvement with programming. Within the laboratory, large amounts of program and document development are regularly done with the text editor.

The experiment began with a set of proposed enhancements consisting of Features 1 through 5 listed in Table I. Included in the laboratory is a group specifically responsible for operating system support including dealing with user problems with the editor. The majority of ideas for enhancements were drawn from their experience. Each feature was aimed at making the system easier or safer to use by supplying facilities either significantly more complex to access or not available in the existing editor. Feature 1 allows the reduction of a sequence of two or more commands to a single step. Features 2, 3, and 4 allow savings in the size of commands. With Feature 2, surrounding characters need not be included in order to identify a string meant for substitution. With Feature 3, a repeated string of characters can be identified by a shorter string. With Feature 4, repeated replacement strings can be identified by even simpler means. Feature 5 is meant to protect against loss of information by premature exit from the editor. Hence, each feature made a positive contribution to the use of the editor. Features 3, 4, and 5 were suggested by the members of the support group, and Features 1 and 2 were developed with their assistance. All the additions were upward-compatible from the current editor, with the exception that the special character used in Feature 4 would take on a different meaning in a single context.

The entire laboratory then evaluated the proposals through a formal survey which detailed the enhancements. Respondents were asked to identify their usage of the text editor, to rate the proposed features in terms of helpfulness in their own work, to estimate their likely rates of usage, and to rank the features in terms of desire in seeing them implemented.

Based on the survey, Features 2, 3, and 4 were chosen

TABLE I.—List and Description of Enhancements Used in Study

No.	Description
1	A command to interchange two groups of lines.
2	The ability to identify for substitution specific instances of matches of patterns within a line. Previously, either the first or all matches had to be substituted for. Now, individual matches or sets of matches could be specified.
3	The ability to define simple macros within an editor session.
4	The ability to use a special character to stand for the second and subsequent references to a string when inserted by consecutive substitute commands.
5	A special warning when exiting from the editor without writing out the work space to a permanent file.
6	The ability to append the work space to the end of an existing file.

for implementation. The special character in Feature 4 was changed to a less-used symbol. In addition, another feature suggested by a member of the support group, No. 6 in Table I, was chosen for implementation. This feature allowed a sequence of editor and UNIX control language commands to be replaced by one editor command. The four features were implemented without noticeably changing the editor's performance characteristics.

The testing phase saw the extended editor replace the original on two selected computers within the laboratory. Two common methods of release were used. The editor was first released on the computer used for systems development by a group of nearly 50 people, herein called Group 1. Each person received extensive documentation on the new features, including examples of the features' usefulness. Group 1 was also alerted to the change in the editor by a message that appeared on its terminals whenever the UNIX system was entered. At a later date, Group 1 received replacement pages for the programming manuals describing the extended editor. Consulting was made available on the features during the first week after release. Announcement of the existence of the features also appeared several weeks later in an internal UNIX users' newsletter.

The extended editor was also installed on the development computer for another project involving a dozen people, herein called Group 2. The small size of this group allowed special attention to be given to the programmers, including a half-hour introductory lecture given to the entire group upon release, and individual follow-up sessions two weeks later. The same introductory memo and message used with Group 1 was used on the day of release to Group 2. The new manual pages were also distributed on that day. At that time, the newsletter had already been issued.

The evaluation of the features involved both automatic monitoring of editor usage and further surveys. All uses of the existing editor were monitored for a time prior to release of the extended editor to obtain a basis for comparison. After release, usage of the new features was monitored for an extended period of time. The monitoring dates are given in Table II. Group 1 had an initial monitoring period lasting over three months. Between 317 and 1151 editor sessions were recorded, with an average of 651 sessions per time

period. Total commands monitored numbered over 375,000. With Group 2, monitoring was done over the three weeks following release. Between 132 and 481 sessions were recorded for each full day; the average was 277 sessions. Total commands numbered over 53,000. All information was obtained while both groups were carrying out normal duties.

Approximately eight months after release of the revised text editor, a follow-up survey was distributed to the users to obtain their impressions of the helpfulness of the new features, especially with respect to other features in the editor. The users were also asked to estimate their familiarity with different features in the editor. A final monitoring period covering 1200 sessions and over 110,000 commands was employed for Group 1 (see Table II). At that time, Feature 3 had been removed from the editor (due to the preliminary interpretation of the results given in the following section).

To summarize the method employed, the user community was first consulted on the choice of enhancements. The usage of the editor was then monitored both before and after the release of the new features. Further polling was done after the user community had the opportunity to use the features. Some further monitoring completed the survey. The results of the experiment are given in the following section.

## RESULTS

The pre-implementation survey served as a check on the users' desire for the proposed enhancements. The monitoring and the follow-up survey established the fate of the enhancements. This section presents the quantitative results of these efforts.

The choice of enhancements was clear after the pre-implementation survey. Fifty-six users returned completed surveys; 27 were from Group 1 and 8 from Group 2. Ninety percent of the respondents indicated regular use of the editor. A high level of interest in the survey was reflected in the more than two dozen extra comments and suggestions

TABLE II.—Dates and Working-Days with Associated Time Period Labels on which Editor Usage was Monitored for Each Experimental Group

Time Period	Group 1		Group 2	
	Dates	Working Days	Dates	Working Days
Base	8/31-9/6/77	4	10/17-10/25/77	6.5
1	9/7-9/8/77	2	10/25/77	0.5
2	9/9-9/12/77	2	10/26/77	1
3	9/13-9/14/77	2	10/27/77	1
4	9/15-9/18/77	2	10/28-10/30/77	1
5	9/19-9/20/77	2	10/31/77	1
6	9/21-9/22/77	2	11/1/77	1
7	9/23-9/26/77	2	11/2/77	1
8	10/12, 10/18/77	2	11/7/77	1
9	11/3-11/4/77	2	11/9/77	1
10	11/16/77	1	11/10/77	1

Final	6/2-6/10/78	6		

TABLE III.—Average Estimates of Helpfulness of Each Proposed Feature Obtained from Preimplementation Survey, Indexed by Groups

Group	Features				
	1	2	3	4	5
Entire Lab	3.04	2.64	2.59	2.45	3.15
Group 1	3.00	2.89	2.65	2.44	3.30
Group 2	2.62	2.75	2.62	2.43	3.75

NOTE—Scale for point values show: 1=Very Helpful; 2=Helpful; 3=Somewhat Helpful; 4=No Help; 5=An Impairment.

concerning the text editor that were returned with the survey. Table III shows a near-uniform evaluation of Features 2, 3 and 4 as the most helpful. Table IV shows the three features as being the most preferred for implementation.

Respondents predicted a high usage of these features. They had the choice of predicting use as follows:

1. Every Session
2. Every Few Sessions
3. Occasional Sessions
4. Rare Sessions
5. Never

In Group 1, for example, 54 percent of the 26 respondents predicted use in the highest 3 categories for Feature 2. Seventy-six percent of 25 respondents chose these same categories for Feature 3. Eighty-one percent of 27 respondents did the same for Feature 4. We can conclude that the users see these features as desirable. With the monitoring results, it is easy to determine the accuracy of these predictions.

The surveys were completed by the end of July 1977. On September 7, the expanded text editor and documentation were released to Group 1. The actual usage of the features versus time periods is shown in Figure 1. The scale of the horizontal axis is proportionate for the first three work-weeks. The last four monitoring periods do not maintain the scale. However, results for these periods are approximately the same. The editor was released to Group 2 on October 25, 1977 at the same time the introductory lectures were given. The use of the features by Group 2 is shown in Figure 2. The horizontal axis in this figure is linear. The follow-up visit to Group 2 was on Day 11.

The two figures are very similar. Initially high usage rates decreased quickly. Figure 1 differs by showing a large "spike" for Feature 6. Figure 2 shows apparent recovery

TABLE IV.—Average Rank of Each Proposed Feature on a Preference-For-Implementation Ordering Obtained from Pre-implementation Survey, Indexed by Group

Group	Features				
	i	2	3	4	5
Entire Lab	3.30	2.75	2.50	2.15	3.45
Group 1	3.35	2.92	2.36	2.30	3.80
Group 2	3.14	2.29	1.33	3.00	4.29

NOTE—A rank of 1 indicates highest preference; 5 indicates lowest.

TABLE V.—Comparison of Uses Per Session and Usage Rate Categories of New Features and Eight Selected Old Features, *a-h*, with Values Established by Base and Test Period Monitoring, Indexed by Group

Features	Group 1		Group 2		
	Uses Per Session	Usage Rate Category	Features	Uses Per Session	Usage Rate Category
a	2.807	1	a	1.036	1
g	.841	1-2	g	.458	2
d	.178	2-3	d	.343	2
e	.115	3	e	.111	3
h	.082	3	h	.060	3-4
c	.075	3	b	.017	4
2	.030	4	2	.009	4-5
4	.026	4	c	.006	5
6	.025	4	6	.004	5
b	.019	4	4	.001	5
f	.008	5	f	.000	5
3	.005	5	3	.000	5

NOTE—Values for older features established during base period, except for feature *h* in Group 1 which was from test period. Values for new features established by use in Time Periods 6 to 11 for Group 1, and Time Periods 6 to 10 for Group 2. Features *a-h* represent a typical assortment of commands, e.g., the substitute and change commands, and features of commands, e.g., end-of-line marker and changing all matched strings.

from low values for Features 2 and 6 late in the period monitored, but a decrease on the last day. Also, Figure 1 has generally higher usage rates throughout than Figure 2. The data, therefore, indicates that the special attention given to Group 2 did not improve acceptance.

To get a better insight into the acceptance of the enhancements, their usage rates can be compared to that of older features obtained during the base period. This is done in Table V through a comparison with eight commands and features whose usage are representative of the distribution of rates for all features. In order to obtain fair values for the new features, usage rates are taken from the last half of the time periods monitored—Time Periods 6 through 11 for Group 1, and Time Periods 5 through 10 for Group 2. To aid in comparison with the categories on the pre-implementation survey, a "usage rate category" obtained from a scale shown in Table VI is used to characterize the information. Two numbers show rates between categories. In either evaluation, the usage of the new features is towards the low end of the usage rates.

Individualized rates were also low. Counting individual logon identifiers as distinguishing individual users, there were 45 users in Group 1 throughout the experiment. During Time Periods 6 to 11, 16 percent used Features 2 and 4 more frequently than at the "Rare" level. Eighteen percent used

TABLE VI.—A Numerical Interpretation of Usage Rate Categories Used on Preimplementation Survey

No.	Usage Rate Categories	Sessions Per Use	Uses Per Session
1.	Every Session	1 or less	1 or more
2.	Every Few Sessions	2-4	.5-.25
3.	Occasional	8-16	.125-.062
4.	Rare	32-64	.031-.016
5.	Never	128 or more	.008 or less

Figure 1—Usage of new features with respect to time by Group 1.

Feature 6 at that level. No one used Feature 3 at that level. This places the usage of Features 2, 3, and 4 well below those predicted on the pre-implementation survey.

Table VII gives another view of individual usage rates through the number of users accounting for percentage of use. It shows how many users in Group 1 accounted for 50 percent, 75 percent, 90 percent and 100 percent of all uses of the four new features during Time Periods 6 to 11. Since the total number of users on the system at the time was 45, no feature was used by a majority of users. Feature 3 is obviously lightly used (it was deleted shortly after this data was obtained). Feature 6 has the fewest users accounting for the most usage. Over the entire test period, two users accounted for 88 percent of its use. The spike seen in Figure 1 is a side effect of this since the heavy users concentrated their use of the feature on several isolated days. All three of the features that were used show a sharp decline in numbers of users as lower percentages of use are considered. Hence, a few users account for most of the usage.

For comparison, individual contribution to the use of four established features and the sum of all commands during the Base Period were analyzed for Group 1. This produced the same type of distribution seen in Table VII. Among other facts, this indicates that there are a few very heavy users of the text editor. Interestingly, these users do not substantially

contribute to use of the enhancements. One is among the 75 percent usage group of Feature 2, and another is among the 75 percent usage group of Feature 6. None fit in any 50 percent group.

Analysis of the individuals who used the new features showed that there is little overlap among users of the new features. Only two users account for usage in more than one feature at the 50 percent or 75 percent levels. In terms of usage per session, there are 12 different users in Group 1 at the Occasional level or higher for at least one feature. The same type of variation is seen among users of the four older features analyzed. Hence, both the style of use of the editor and the changes in style resulting from the enhancements differ widely.

TABLE VII.—Number of Users Accounting for Percentage of Use of New Features During Time Periods 6 to 11 for Group 1

Percentage	Features			
	2	3	4	6
100	13	1	10	11
90	6	1	6	6
75	4	1	4	2
50	2	1	3	1

Figure 2—Usage of new features with respect to time by Group 2.

The follow-up survey was distributed a few months after obtaining these values. At that time, I was inclined to think that the features were rejected. However, the response given in Table VIII indicated a different conclusion. Users who were in the two experimental groups at the time of the first survey clearly rated Features 2 and 4 more helpful than they did on the pre-implementation survey. Ignoring the votes of those who stated they were unfamiliar with the features, the popularity of these two enhancements is even higher. Further, users found Features 2 and 4 as helpful as the majority of the older features considered. Users therefore had accepted at least two of the four features.

In order to see if the acceptance of the features translates into new levels of usage, the results of the Final Period of monitoring of Group 1 can be analyzed. In some ways, rates are changed. Usage rates of Features 2 and 4 are .057 uses per session and .089 uses per session, respectively. This is nearly double and more than triple the earlier rates. Feature 2 is now near the top of the Occasional-To-Rare category,

while Feature 4 is well into the Occasional category. At the same time, Feature 6 is now in the Never category with a usage rate of .005 uses per session. As opposed to increases in usage rates, the number of users of the features has not substantially increased. There were 52 on the text editor during the period. Features 2, 4, and 6 were used by 14, 11, and 8 users, respectively. Table IX shows that the identity of the users of Features 2 and 4 during the earlier and later periods is often the same. The level of use is also similar. In particular, few users drop to the Never category. This shows that users have some loyalty to tools they have begun to use, but it also shows that the increases in overall usage rates of Features 2 and 4 are not matched by other increases.

#### DISCUSSION AND CONCLUSION

To summarize the preceding section, it can be seen that the study produced several distinct results. Users responded positively to a set of features presented to them through a

TABLE VIII.—Average Evaluation of Helpfulness of New Features and Selected Old Features, with Number Responding as Not-At-All Familiar with Each Feature, and Average Evaluation of Only Those Familiar, Indexed by Groups and Obtained from Follow-Up Survey

Group 1 (22 respondents)			
Feature	Average Helpfulness	Number of Respondents Not-At-All Familiar	Average Helpfulness of Those Familiar
a	1.00	0	1.00
e	1.24	0	1.24
h	1.33	0	1.33
d	1.55	0	1.55

4	2.00	0	2.00
e	2.82	0	2.82
6	2.86	1	2.66
3	3.20	3	2.67
b	3.33	4	2.50

NOTE—All respondents were members of laboratory at the time of the Pre-implementation Survey. Scale for point values show: 1=Very Helpful; 2=Helpful; 3=Somewhat Helpful; 4=No Help; 5=An Impairment.

survey. A high usage rate immediately after release quickly decreases to well below predicted levels and below the levels of use of most other features. The group receiving special instruction shows no higher usage rates. The effect of the enhancements on individual usage styles varies considerably and the style of the heaviest users of the system are less affected. A degree of loyalty to tools is evidenced by users. In addition, users' subjective evaluation shows greater acceptance of the features. These features were clearly desired by users. Assuming that these results are an example of the general reaction to software enhancements, it is important to understand their underlying causes and to consider the consequences the pattern has on computing.

Peter Naur<sup>5</sup> and many others have commented on the difficulty of new programming languages gaining acceptance. A guess at one reason for this is that people and organizations, through their personal commitment of resources, have developed strong usage habits. I believe that similar habits, those dictating the way in which people use

a particular language, are what produces the pattern that this experiment has uncovered.

There are a number of points that lead me to favor this explanation. Probably the most striking evidence is the peculiar distribution of users over both old and new features, and their loyalty to the features they have adopted. This points to the existence of well developed styles on a level that would interfere with acceptance of new features. The lack of agreement between reality and subjective observation can be explained by the tendency for habitual activities to be performed without conscious recognition. This lack of agreement is found in the users' evaluation of features versus their actual use. It also was evident in discussions with Group 2 where several users indicated they were using new tools more heavily than what concurrent monitoring showed. Finally, habit can be seen in the rejection of the enhancements by the heaviest users. These users are likely to depend most on habit to achieve their high usage rates.

Whether or not habits are the reason for the results arrived at, the consequences of the results must be considered. These consequences must differ with the perspective brought to the problem. As a vendor, the goal is to satisfy user demands. Since subjective evaluation can be high without correspondingly high usage rates, enhancements can be successful. As a user, or better yet, as the party who bears

TABLE IX.—Number of Users in Group 1 of Features 2 and 4 Compared by Usage Rate Categories: Time Periods 6-11 vs. Final Time Period

the expense of the enhancements, these same arguments can be presented. However, it is more likely that people will want to see some resulting usage. The experiment has shown that scattered usage is possible. This may be enough to justify the enhancements. There are, however, cases where as general an adoption as possible is desired; for example, when the enhancement is a software tool that will improve productivity. In conclusion, let's consider what to do in these situations.

The problem is to get as many users as possible to use a new feature. New arrivals to a system do not, of course, have established programming habits. Securing their acceptance of the desired feature should be easier. An environment that approaches that of a new arrival to a system appears achievable by revolutionary change in a programming environment. For example, a group at the Columbus laboratory reported success at changing their programming style when they changed from one programming language to another, from FORTRAN to "C."<sup>6</sup> At the same time, people already using the target language had a more difficult time adjusting.

In addition, there may be ways to reach users in evolutionary situations. The experiment shows that the habits of established users cannot generally be changed by simply presenting information. Even the more elaborate process employed with Group 2 failed. However, from my discussions with that group, one possible tactic emerged. Several people liked the features but did not remember them when they used the editor. Similarly, many people who had been in the two groups at the time of release noted on their surveys that they were Not-At-All familiar with some of them. Several commented that they would use one feature or another now that they knew it was available. For these users, the problem is not learning but remembering; typical aids to memory such as opcode cards, lists of features at work sites, and suggestions for use generated by systems are promising tools.

One final possibility is change via software project management. People respond to guidance. Weinberg and Schulman<sup>7</sup> have experimental evidence that programmers will dramatically alter the style and structure of the programs they

produce in response to guidance. Hence, in achieving general adoption of a software enhancement, there is the possibility of managing its adoption.

In summary, this paper has reported on a case where desired software enhancements were not generally adopted when introduced into an existing programming environment. I maintain that this indicates the presence of well established habits and suggest the need for more vigorous acceptance methods to ensure that new software tools produce changes in programming style. I conclude that it must be the task of software engineers not only to discover enhancements to software systems but also to discover better methods of ensuring their use.

#### ACKNOWLEDGMENTS

I wish to thank all my colleagues at Bell Laboratories in Columbus, Ohio. Special thanks are due to Art Kamlet who suggested the experiment; Tom Davison, off whom many of the ideas involved were "bounced;" and, Dale DeJager who helped with the UNIX system.

# Experiences in building and using compiler validation systems

by PAUL OLIVER

*E.D.S. Federal Corporation*  
Washington, D.C.

## INTRODUCTION

### *Software Validation*

For purposes of this discussion, the term "software validation" refers to the process of testing a completed software product in its operational environment. The scope of this paper is further limited in the following ways: the experiences described are not applicable to applications software; the validation systems discussed must be capable of functioning on a variety of dissimilar hardware and operating systems; the staff performing the validation is not involved in the development or the maintenance of the products being tested; and the result of a validation could impact the eligibility of the product for procurement. This environment imposes unusual and stringent requirements on the portability of the validation systems and the auditability of the validation.

The methodologies available for software validation are few. Design simulation<sup>1</sup> can and is being used, concurrently with software system design, to evaluate the effects of various system requirements or design alternatives once the system has been defined and modeled. Problem statement languages<sup>1</sup> provide a formal syntax and semantics with which to communicate needs of users to analysts, and are applicable during the system definition and design phases of a software development effort. Neither design simulation nor problem statement languages are applicable to the testing of a completed product. The experiences of the Federal COBOL Compiler Testing Service (FCCTS) suggest that functional testing<sup>2-4</sup> is the most thorough technique presently available for testing a completed software product.

### *Functional Testing*

Functional testing is the process of executing a series of generally independent tests designed to exercise the various functional features of a software product. The examples discussed in this paper will address the testing of compilers, but the findings and conclusions are applicable to system software in general. The exclusion of application software is not meant to suggest that such software is not amenable to functional testing, but is, rather, a reflection of the general

inadequacy of specifications for applications software. It is difficult to test for the valid implementation of functions when the functions themselves are ill-defined. This is of course a subjective observation, and it is also true that the specifications of a compiler's architecture (generally, the standard) often leave much to be desired.

Functional testing can be used to test characteristics of software such as performance and integrity, but is most commonly used for specifications testing. Thorough functional testing requires a complete test plan, systematic control of the testing effort, and objective measurements of test coverage. Functional testing is applicable during implementation (verification), during evaluation (validation), and during the maintenance phase of a software product's life-cycle.

This applicability to all phases of test activities is a principal advantage of functional testing. Furthermore, the thoroughness of testing is measurable in terms of number of functions tested, and the revision and evaluation of test specifications is relatively simple. Also, functional testing offers a high degree of visibility to a customer, and is apt to be well understood by that customer.

With these advantages come some disadvantages. The one most frequently cited is that it is generally not possible to assure that all possible features or decision points of a software product are in fact tested. With regard to compilers it is certainly true that it is not practical to test all possible combinations of language components and data types. We have not, however, found this to be a serious shortcoming, since it is certainly possible to test all reasonable combinations. What is "reasonable" is admittedly a subjective judgment, but such subjectivity regarding test limits is hardly unique to software testing. A more serious problem, from the FCCTS experience, is that functional testing can only be as good as the specifications being tested. Thus, it is an unfortunate fact that many important features of a compiler cannot be tested because the pertinent language specifications are ambiguous.

## THE FCCTS EXPERIENCE

The Federal COBOL Compiler Testing Service has, during the years 1973-1978, performed official validations of over four dozen COBOL and FORTRAN compilers,<sup>5</sup> in

support of Federal Government procurement regulations. What follows are descriptions of some of the results of these activities, a summary of the resources expended in performing such validations, a description of the technical problems encountered, and suggestions as to what future work remains to be done in this area. It is the intent of this paper to present data on specific experiences which can hopefully lead to useful generalizations regarding functional testing.

#### *Validation of FORTRAN and COBOL Compilers*

The importance and utility of higher-level languages is, in this writer's opinion, no longer at issue in data processing. The steady decline in hardware costs, a growing awareness of the importance of programmer productivity and software reliability and maintainability, and improvements in the quality of code produced by compilers have nearly terminated arguments regarding the relative effectiveness of lower- and higher-level languages.

This trend has made the compiler the most visible component of system software. To many programmers, the compiler *is* the system, since it is the tool which is most frequently used in building a piece of software. It is therefore important that the compiler conform to its specification. For some compilers, most notably COBOL, FORTRAN, and PL/I, these specifications (at the functional or architectural level) are embodied in a standard.

The software development manager is faced with a multitude of problems. The productivity of his average programmer ranges from three to nine lines of code per hour, and has been increasing at a rate of only about 3 percent per year.<sup>6</sup> Furthermore, the quality of his product is not too good, and he may require as much as 75 percent of his resources just to maintain the product once it is developed.<sup>7</sup> These are not very encouraging figures. Thus, it is paramount that the manager, and his programmers, at least be able to have some faith in the tools of their trade. In particular, it is not unreasonable to expect that a compiler conform to existing standards in its translation of programs written in standardized languages. There are of course limits to how much a standard can do. A language standard is not like most engineering standards. The state of the art in software technology (or the level of maturity of the data processing industry) is not yet at the point where such precision is possible. Furthermore, rightly or wrongly, most standards still allow quite a bit of latitude to the implementor with regard to the meaning of certain language constructs. Nevertheless, a language standard can and should provide a framework for a workable, well-disciplined approach to software development. This is in fact the fundamental contribution of a language standard. It is important to recognize this because one commonly hears dubious claims made on behalf of standards—the most frequent of which is that the presence of a language standard makes program conversion (within the language, e.g., COBOL-COBOL) costs disappear. This is simply not true. Programming practices, imprecise standards, and environmental factors (e.g., operating system differences) all contribute to keeping the cost of conversion

fairly high. An analysis performed by the FCCTS of some 32 COBOL-COBOL conversions reveals, for example, that the conversion cost of one line of COBOL code can range from \$.50 to \$6.00, and this suggests that conversion costs are still high, even for programs written in "standard" COBOL.

To repeat—the principal purpose of a language standard is to provide a disciplined, predictable, efficient framework for software development. To fulfill this goal, a compiler must perform according to the standard. Testing is required in order to determine conformity.

#### *The FORTRAN and COBOL Compiler Validation Systems*

The FCCTS has performed functional testing of FORTRAN and COBOL compilers since its inception in 1973. This testing has been done using the COBOL Compiler Validation System (CCVS)<sup>8</sup> and the FORTRAN Compiler Validation System (FCVS).<sup>9</sup> A detailed description of these systems can be found in the references; only a brief summary is presented here. The CCVS74 (COBOL 74) consists of nearly 219,000 lines of COBOL code which collectively exhaust the meaningful constructs in the COBOL language. The FCVS 78 (FORTRAN 77) consists of over 62,000 lines of FORTRAN code, and represents a subset of the full standard. The FCCTS has also produced a HYPO-COBOL Validation System and an FCVS for FORTRAN 66, but the size of these projects was so small (12,000 and 38,000 lines of code, respectively) that data derived from them would be misleading. The interested reader is referred to References 9 and 10.

The Validation Systems consist of syntactically correct programs and an executive routine. The executive routine is used to perform certain text editing (e.g., specification of implementor names), for program and test selection (hardware dependent language elements may not be testable), and for the generation of job control language statements appropriate to the host operating system. Furthermore, an audit log of these actions is produced. These functions are necessitated by the environment in which the FCCTS operates—portability of the validation systems and auditability of the test procedures may not be required for in-house testing (although they are not bad features to have).

#### *The Validation Process*

The Compiler Validation Systems used by the FCCTS are necessarily generalized products, almost in the sense that an operating system is generalized when it is first delivered to a customer. A system generation process must take place to produce a product which is tailored to the installation in which it is implemented. In the case of the Compiler Validation Systems, this generation process consists of inserting, through the executive routines, implementor names in the source code, generating operating system control statements, and deleting (actually, not generating) tests which the compiler is unable to process at all, e.g., language fea-

tures which the compiler does not implement. This generation process is performed by the organization whose compiler is being validated, with some assistance from the FCCTS.

Validation is performed by the FCCTS staff, and consists of executing the audit routines on site, reviewing the resulting raw data, and producing a Validation Summary Report.<sup>5</sup>

### Results

Experiences with COBOL compiler validations were reported by Baird and Cook.<sup>10</sup> It is encouraging to note that many of the anomalies reported in 1974 have disappeared from compilers today. Errors reflecting sloppiness or poor judgement, such as performing syntax correctness checks on comments, no longer occur. Errors in simple constructs such as ADD, SUBTRACT, and COPY statements in COBOL are no longer prevalent. There is little if any justification for such errors, and their disappearance suggests that the availability of an independently-administered validation service has had an impact on compiler developers.

Table I illustrates the downward trend in both the average and the maximum number of errors discovered during a validation. It should be noted that the failure to implement a particular language feature is regarded as an error by the FCCTS. While this type of error is irritating to a programmer who wishes to use the feature it is not as serious as the presence of a feature which is incorrectly implemented, since this latter type of error is deceiving. We are finding no strong patterns in the errors found—i.e., our data does not reveal any meaningful distribution of errors according to language elements. The distribution according to modules is what one might expect—65 percent of all errors were found in the Nucleus, while 29 percent were found in the I/O modules. It is perhaps surprising that only 1 percent of all errors occurred in the remaining modules. We do note that a large number of "errors" are in fact caused by purposeful implementation decisions on the part of compiler developers, particularly in input-output functions, data represen-

tation, and other language areas which are closely related to operating efficiency of the total data processing system. This seems to suggest that implementors, when faced with the decision of implementing a feature correctly or efficiently, will chose efficiency. Given a community of users which traditionally has favored "efficiency" over correctness this is not surprising; but it is not desirable. The misconception that a rigorous standard inhibits efficient implementation is still a prevalent one.

Finally, it should be noted that the reduction in errors found in COBOL compilers took place during a period of transition from COBOL 68 to COBOL 74. This makes the error trend even more significant since it took place in a development rather than a maintenance context, and occurred in the face of an expanded, more complex version of COBOL.

A less encouraging trend has been the number of language features which the FCCTS has been unable to include in its Validation Systems. The FCCTS COBOL Validation Summary Reports list 24 language elements which are fully or partially implementor-defined. Some, such as "computer-name" in the COBOL SOURCE-COMPUTER paragraph are innocuous and acceptable. Others, such as the representation of a valid sign in certain forms of numeric tests and the number of positions carried for intermediate results of arithmetic statements are, in this writer's opinion, indicative of a poorly-defined standard.

A typical result is that one recent COBOL Validation Summary Report listed 15 results "for information only," i.e., applying to tests whose results are not well-defined by the standard. Six of these referred to input-output functions, and four to computation or comparisons. Thus, a COBOL programmer cannot use such common and useful statements as COMPUTE with any degree of certainty as to what the results are to be from one compiler to the other. This is perhaps to be expected in a language which is defined by a committee, whose national standard is set by a second committee, and whose Federal standard is set by a third committee.

The results of FORTRAN compiler testing are not so dramatic. This is due partly to the fact that testing to date has been with respect to the 1966 FORTRAN standard. The features contained in this standard are but a subset of most FORTRAN dialects, and have remained stable over the past 12 years. Furthermore, FORTRAN is a simpler language than COBOL. It is therefore not surprising that the error rate found in FORTRAN compilers has been much lower than that found in COBOL compilers.

Two generalizations come to mind. One is that methodically and independently applied functional testing of compilers has produced meaningful and beneficial results. The other is that functional testing is limited by the quality of specifications.

### Resources Required

Table II summarizes workload and resources expenditures data compiled by the FCCTS during the 1974-1978 period.

TABLE I.—Validation Errors Summary

(1) Average number of errors found for COBOL 68 compilers (1973)	18
(2) Maximum number of errors found for COBOL 68 compilers (1973)	50
(3) Minimum number of errors found for COBOL 68 compilers (1973)	0
(4) Average number of errors found for COBOL 74 compilers (1977)	9
(5) Maximum number of errors found for COBOL 74 compilers (1977)	30
(6) Minimum number of errors found for COBOL 74 compilers (1977)	1
(7) Average number of errors found for FORTRAN 66 compilers (1977)	1
(8) Maximum number of errors found for FORTRAN 66 compilers (1977)	2
(9) Minimum number of errors found for FORTRAN 66 compilers (1977)	0

TABLE II.—Validation Projects Data

	CCVS 74	HCVS	FCVS 66	FCVS 78
(1) Lines of delivered source code	218,560	12,000	37,839	63,188
(2) Calendar months expended	49	13	11	20
(3) Man-hours expended	11,200	781	1,959	4,600
(4) Lines produced per man-hour	19.5	15.4	19.3	13.7
(5) Time distribution (percent) Design/Code/Test	35/42/23	36/48/16	40/37/26	50/30/20

The CCVS74 elapsed time data is somewhat misleading. The 49 months given for the development of CCVS74 were really devoted to development of three distinct versions of the product, each of which was really a distinct, usable product in itself. Thus, periods of relative inactivity are included in this timespan. The reason for this approach is that development of the CCVS had to be coordinated with development of COBOL compilers, and these were developed and released incrementally. The first releases of COBOL 74 compiler implemented subsets of the language, and therefore the audit routines tested only these subsets. It is a peculiarity of compiler testing that development of the test tool must rely on the compiler; it fact many vendors used portions of the CCVS74 in testing their compilers during development. The 49 months cited were therefore caused by a continuing mutual "piggy-backing" of compiler-audit routines development.

Productivity was quite high on all the validation systems development projects. This is due to a variety of reasons—the product specifications were to some extent already in existence (the standard represents specifications for audit routines as much as for compilers), the FCCTS staff was recruited for the specific purpose of software testing from the inception of the FCCTS in 1973, and the experience factor of the staff is quite high. Also, although a validation system may be quite large, as with the CCVS74, it really consists of a large number of relatively small, relatively independent modules. Productivity in developing this type of system will naturally tend to be well above average due to the lowered incidence of interpersonal communication required.

The project time distributions show a greater percentage of the development effort is devoted to coding than one would generally expect. Again, this is attributable to the nature of the product being developed. The major phases of

TABLE III.—Validation Time Requirements

Personnel Type/Phase	Average Hours Required
Professional/Preparation	4.0
Professional/Site Visit	20.0
Professional/Report Production	18.0
Clerical/Report Production	7.5

design, coding, and testing are not as distinct in this type of product as they are generally. The modularity and module independence of the audit routines make it convenient to combine much of the documentation and unit testing activities with the code production phase in a way which makes it impossible to separate the time associated with each.

Table III summarizes the FCCTS resources expended for validations. We believe that a good portion of the professional time presently spent in the report production could be shifted toward clerical time, and are taking steps to do this.

A few observations regarding the makeup of the staff might be of interest. The FCCTS was formed in 1973<sup>5</sup> and performs some of its functions in support of Federal procurement regulations. Previous experience with compiler validation existed,<sup>8</sup> but much remained to be learned. Recruitment and staffing therefore leaned toward experienced, highly competent personnel, and the positions established were fairly senior. This was wise at the time, but it is not the optimal staffing pattern once some experience has been gained, nor is it optimal outside the Federal procurement support environment. Development of validation systems requires a high level of skill, ingenuity and maturity during the design stages of the product, and for the development of certain support functions such as the executive routines and code generators; but the coding and testing processes bear such a resemblance to a production line that high-caliber personnel is simply neither required, nor desirable. Rather, such a project should be staffed along the lines of a Chief Programmer Team, with some obvious modification (it perhaps should be called a "chief designer team"). The project manager should also act as the chief designer, with the primary responsibility for developing the test specifications. A software specialist should be responsible for developing support software such as the executive system. The coding task can be relegated to junior programmers. Ideally, a single individual should be responsible for computer-based testing. It has been found very useful to have programmers visually review each other's code—the simple structure of audit routines makes this practice very cost effective. Documentation can be voluminous; the validation system itself should be self-documenting, but such documents as user guides should be produced by a literate technical writer. Finally, a "librarian" is both feasible and useful.

### Technical Problems

It was indicated earlier that lack of completeness can be a problem in functional testing. It has not been a problem in compiler validation. The reason is that the potentially combinatorial number of logic paths which should be tested in application software (whose inputs are unpredictable) is not a factor when testing a compiler. Ensuring that all meaningful language constructs are tested may tax the patience of the developer, but not his intellect. The problem is further alleviated by limiting the tests to correct language constructs, i.e., we do not insert erroneous code in the audit

routines. This decision is motivated by the environment in which the FCCTS functions. If we were developing tests for an in-house product we would very likely want to introduce erroneous code in the tests. We would then be faced with the traditional question of what errors to introduce, at what frequency distribution, and by whom should they be introduced.

A problem we *have* encountered is that of properly identifying the building blocks of the audit routines. This is a problem unique to validation of compilers. Since the audit routines must be compiled by the compiler which is being tested it is necessary to identify certain language constructs for which correct compilation is taken as a set of axioms, in the sense that if these features are not correctly implemented there is no point in continuing the validation. An example of this building block approach can be seen from the FORTRAN Compiler Validation System (FORTRAN 77). Some of the assumptions we have made regarding the Subset FORTRAN are:

1. Six (6) character symbolic names and five (5) digit statement labels are permitted.
2. Comment lines do not affect a program in any way.
3. Execution of the unconditional GO TO statement  

$$\text{GO TO } s$$
causes the statement identified by the statement label  $s$  to be the next statement executed.
4. Branching to a CONTINUE statement causes the statement following the CONTINUE statement to be the next statement executed.
5. The arithmetic assignment statements  

$$\text{variable} = \text{constant}$$

$$\text{variable} = \text{variable}$$
function correctly.
6. The arithmetic IF statement functions correctly:  

$$\text{IF } (e) \text{ } s_1, s_2, s_3$$
where  $e$  is any arithmetic expression of the form  

$$\text{variable} + \text{constant}$$

$$\text{variable} - \text{constant}$$
and  $s_1, s_2$  and  $s_3$  are statement labels.
7. The character assignment statements  

$$\text{character variable} = \text{character constant}$$

$$\text{character variable} = \text{character variable}$$
function correctly.
8. The logical expression  

$$\text{IF } (\text{character relational expression}) \text{ executable statement}$$
where the form of the character relational expression is  

$$\text{character variable} \text{ .EQ. } \text{character constant}$$
functions correctly.
9. The following form of the WRITE statement functions correctly:  

$$\text{WRITE } (u, f) \text{ iolist}$$
where  $u$  is a unit specifier,  $f$  is a FORMAT identifier, and  $iolist$  is an input/output list containing arithmetic or character variables. The format statement contains  $nH$  edit descriptors,  $X$  edit descriptors, numeric editing descriptors and/or  $A$  edit descriptors.

10. In order for the output report to have the correct format, the use of the first character of a formatted record for vertical spacing on a printing device must function correctly.

The two characters which are used in printing the report are:

Character	Vertical Spacing Before Printing
I	To first line of next page
blank	One line

11. The system output device has at least 56 characters per line.
12. An integer datum consists of at least 16 bits of which one bit is a sign bit.
13. A real datum contains at least 16 bits in the mantissa and eight bits in the exponent.
14. A character datum of length 14 is permitted.

These assumptions are necessarily subjective—a different designer might have made different choices. The point is that choices must be made, and that the validity of the choices must be determined prior to full testing.

Because the type of validation systems we are discussing consist of a large number of small independent modules, and because the high-level specifications are a "given" (i.e., the language standard) there is a tendency to bypass the design phase (after having determined the "axioms") and to plunge immediately into the coding phase. The danger with this approach is not that the resulting product will be a faulty one, but rather that it will be an unnecessarily voluminous one. We have found it useful to develop general specifications which define in a broad way a set of tests for a given language module or construct (e.g., arithmetic expressions), and to follow these with a set of detailed specifications which define each test. The general specs allow us to refine the estimates of time and resources required for the project, and to ensure completeness "in-the-large," while the detailed specs provide thorough documentation and enable the actual coding to be done by relatively junior personnel.<sup>12</sup>

Audit routines should be self-checking. The volume of output is far too large to be eyeballed. We have also found it useful to be able to suppress printed outputs during the testing phase of a validation system development.

We have encountered two problems which are unique to an outside testing group which is testing a product on different systems. One is portability of the validation system; the other is auditability of the test process itself. We must be able to execute the audit routines on any compiler-operating system-hardware combination, and we must be able to assure the consistency of our testing procedures. The executive systems allow us to fulfill both the goals. In-house testing would require no more than a good text-editor and a library management function. Additional details of the validation process using the executive routines are to follow.

Although our productivity has been high we believe that it is necessary to improve it. We would like to be able to develop a validation system for a new language, e.g., PL/I, in six months or less, while limiting the project staff to, say,

five people. This is not yet possible. We have taken some steps to increase our productivity. One has been to adopt very stringent and precise development procedures, so that tasks are completely interchangeable among project staff members. These are described in greater detail below. We have also found it useful to use the COBOL Compiler Validation System executive routine in developing the audit routines. This not only ensures consistency but also provides us with a useful and complete log of all significant development tasks. Our major effort at improving productivity has been the development of a pre-processor, or generator, as part of our FORTRAN validation system project.

The generator is used to speed up production of "boiler plate" material and repetitive code which changes only with regard to statement labels. Specifically, the generator is used to:

1. Produce standard comments which appear, unchanged, before each grouping of tests or before each individual test.
2. Produce code to be executed when a test is passed, failed, or deleted.
3. Produce "standard" variables declarations.
4. Generate statement labels which render the common code segments unique.

While the generator has been useful, it should be noted that it is *not* used to generate the test code itself. We have given this possibility serious thought for over three years, and have concluded that while test code generation is feasible, it is not productive. Such an attempt would be useful if either of these conditions were true:

1. We needed to produce multiple but differing versions of a validation system for a given product.
2. The generator could be used to produce validation system for different languages or products.

The former condition does not exist, while the latter is not feasible except for the most simple-minded languages. We are therefore faced with the uneasy feeling that we are reaching a practical limit on productivity with regard to validation systems development.

We do expect to achieve some improvements through a refinement of our programming practices. Our standard development rules presently specify the following:

- Symbolic name conventions
- Assumption or axioms
- Statement label conventions, particularly in distinguishing among test, pass, fail, delete, verify, and I/O code
- Convention for external unit identifiers
- File naming and contents rules
- Composition and organization of routines and tests
- Phases in the development cycle
- Use of the generator

We hope to find additional ways of expanding and using the

generator, but are skeptical as to the chances of making quantum improvements in our productivity.

### *The Executive Routines*

The executive routine is used to control the generation of a specific Validation System, to control the generation of job control language statements, and to perform updates. System generation consists of program selection, identification of options to be used and the validation environment, and the control of report outputs.

Job control statements are generated for a given operating system through a "higher-level language" which is used to indicate the need for accounting statements (e.g., JOB or RUN), for the invocation of processors such as compilers and collectors, and for the initiation of execution.

Finally, a simple set of text-editing statements is available for replacing, adding, or deleting source statements. As was indicated earlier, the need for an executive system is predicated on the degree to which the validation system itself must be portable.

### FUTURE WORK AND UNRESOLVED PROBLEMS

Much of our thinking during the past few years has been directed at determining the feasibility of automating the test generation process. Our motivation has been to increase the rate at which we can produce compiler validation systems. Others have been motivated by the perception of additional problems:<sup>13</sup>

1. Lack of a formal construction method
2. No reference to measures of test effectiveness
3. Manual preparation resulting in uneven product quality.
4. High costs

We believe, based on our experiences, that rigorous procedures, augmented by some support tools, adequately address the first three problems. We furthermore do *not* believe that cost is an inhibiting factor. The cost of CCVS74 has been approximately \$400,000 (including maintenance), or somewhat under \$2/line of code. This is an almost insignificant cost compared to development costs in general. Naturally, the fact that we act as a central service facility whose testing product is applied to many compilers reduces the relative cost—\$400,000 spent to test 40 compilers is a less disturbing figure than \$400,000 spent to test one compiler.

Our experience to date suggests to us that attempts at using a formal notation for the specification of programming languages as the means by which a language's syntax and semantics may be described, and by which tests may be generated, are ill-conceived. This approach is certainly feasible. But, as anyone familiar with syntax-directed compilation knows, this approach will not significantly reduce the time required to produce compiler validation systems. The

reason is simple enough—it is no easier to specify a test using a formal notation than it is to specify it in the programming language directly. Furthermore, the differences among languages are great enough to preclude using a single test specification to generate multiple tests, each in a different language. We have not closed the door on this approach, but we have become very skeptical of its merits.

A more serious problem, in our opinion, is that of the poor quality of language specifications. It is in fact somewhat fruitless to concern oneself with the completeness of a test vehicle when so many significant language features are ill-defined. This is a solvable problem, but its solution will require a "consumer movement," whereby users become more critical of what is handed to them by standards committees. As of now, inadequate language specification represent the most significant limitation on function validation. The PL/I Standard is a major step forward in addressing this problem, despite the criticism it has received.

A related problem has to do with the stability of the product being tested. The FCCTS receives numerous complaints that we often insist on revalidating a compiler because of new releases of the compiler or of its operating system. Our rejoinder is that we will drop our requirement for revalidation when offerors of compilers stop putting out a new release every six months. The industry as a whole has standards of software quality control that would embarrass most other professions.

Finally, more attention needs to be given to the development of specifications languages, so that the process of testing the specifications, producing a product from these specifications, and producing a testing system with which to test the product could be a largely automated, coordinated

effort. We are aware of the work that is under way in this regard, but results have been very meager.

# Automatic program synthesis via synthesis of loop-free segments\*

by JOE W. DURAN

The University of Texas at Dallas  
Richardson, Texas

## INTRODUCTION

Work on theorem-proving-based automatic program synthesis (see Lee, *et al.*,<sup>7</sup> for example) has been neglected lately. In their 1971 paper, Manna and Waldinger<sup>8</sup> covered one of the main reasons why—the difficulty of synthesizing program loops within the current state of the art of automatic theorem-proving. However, there is a great deal of continuing work in theorem-proving, and it is important that motivating work in related areas such as program synthesis not be neglected.

Most theorem-proving-based synthesis systems attempt to constructively prove theorems of the form, “for all input values satisfying the desired input predicate  $I$ , there exists a corresponding set of values of output variables which satisfy the desired result predicate,  $R$ .” The resulting program (if any) is correct with respect to the input and output predicates. In general, inductive proofs are needed to synthesize the loops within a program. This causes difficulty, and in fact previous work has not been notably successful with loops. To quote Manna and Waldinger, “. . . these systems have been fairly limited; for example, either they have been completely unable to produce programs with loops or they have introduced loops by underhanded methods.” Since most interesting programs contain loops in some form, this is a crucial problem for successful synthesis. We will limit our discussion to iterative loops.

Manna and Waldinger outlined an approach to automatic synthesis which attacked the problem of iterative loops, and discussed the use of various forms of induction for reducing synthesis to the proving of loop-free (i.e., induction-free) lemmas. However, they were dissatisfied with the large number of equivalent induction principles required by their approach. In fact, only a single rule is needed. Loop invariants can be used to provide a single, general rule for expressing the synthesis of loops in terms of loop-free lemmas.

We consider only input and output predicate pairs,  $I$  and  $R$ , which make sense in the context of program synthesis; i.e., they must be decidable and “define” a nontrivial recursive function, in the sense that  $\exists F\{I(v)\rightarrow R(v,F(v))\}$  is true. If a recursive function is “defined” by an  $I,R$  pair,

then there exists a program for computing the function. We show that such a program can be synthesized via synthesis of only *loop-free* program segments. The necessary formulations are constructed by using loop invariants associated with **while—do** loop forms to state these loop-free lemmas, which can take the standard forms expected by many synthesis systems.

## DECOMPOSITION INTO LOOP-FREE SEGMENTS

If a program  $P$ , correct with respect to an input predicate  $I$  and a result predicate  $R$ , can be found, then it computes a function  $F_P$ , such that

$$I(v_{in})\rightarrow R(v_{in},F_P(v_{in})) \quad (1)$$

where  $v_{in}$  is the vector of values of the program’s input variables. For a large class of recursive functions, there exist natural decompositions of the form  $F_n(F_{n-1}(\dots F_1(v)\dots))\equiv F(v)$ ,  $n>1$ , where  $F$  is the original function and  $v$  is its argument. This form of the decomposition still holds for any function for the trivial cases where one of the  $F_i$  is  $F$  and the rest are identity functions. Let us consider some decomposition of our function  $F_P$ , such that

$$F_n(F_{n-1}(\dots (v_{in})\dots))\equiv F_P(v_{in}) \quad (2)$$

Let  $P_j$  be a program for computing  $F_j$ . A program computing  $F_P$  may be constructed by concatenating the programs  $P_1, \dots, P_n$ . Though the decomposition (2) may be trivial, for most programs there will exist non-trivial ones.\*\* Now consider the set of all  $P_j$  satisfying the decidable input and result predicated defined as follows:

$$I_1\equiv I,$$

$$I_j(v)\stackrel{def}{=} \{\exists v_{in}[I(v_{in})\wedge v=F_{j-1}(\dots F_1(v_{in})\dots)],$$

$$\text{for } 2\leq j\leq n,$$

$$\text{and } R_j(v,v')\stackrel{def}{=} \{v'=F_j(v)\}.$$

Any concatenation  $P_1P_2\dots P_n$  of  $P_j$ s satisfying these

\* This work was partially supported by NSF Grant No. GJ-36424.

\*\* It will be recognized that this decomposition is included in the very well known concept of stepwise refinement in program construction (see Mills<sup>9</sup>).

predicates will produce a program which computes  $F_p$ , provided that each  $P_j$  is constructed to terminate. The program so produced will thus be correct with respect to  $I$  and  $R$ .

We proceed to show that, under this scheme, there will always be a satisfactory set  $\{P_1, P_2, \dots, P_n\}$  such that each  $P_j$  contains at most one loop. Since any computable function can be computed by a program with a single loop, each  $F_j$  can be computed with at most a single loop. Each such single-loop program has an associated loop invariant which is sufficient for a Floyd-type correctness proof. This follows from the loop invariant existence proofs in References 2 and 4. Therefore there will always be a satisfactory set of  $P_j$ s such that each one contains at most one loop, which can always be of the form "*initialization* while  $B$  do *loop body*."  $F_p$  can thus be computed by a concatenation of single loop program segments which have associated loop invariants. We will use this fact to complete the analysis leading to our characterization of general program synthesis in terms of loop-free lemmas.

Manna and Waldinger<sup>8</sup> considered synthesis in terms of the proof of first-order theorems of the form

$$\forall v_{in}[I(v_{in}) \rightarrow (\exists v_{out})R(v_{in}, v_{out})], \quad (3)$$

where  $v_{in}$  is the vector of input variable values, and  $v_{out}$  the vector of output variable values. Let us now consider any arbitrary single loop program with while—do loop form, correct with respect to input and result predicates  $I$  and  $R$ . Such a program has two segments—the initialization code and the loop body code—and has a loop control predicate,  $B$ , and a loop invariant,  $Q$ , such that  $Q \wedge \sim B \rightarrow R$ . We can synthesize the two segments separately and then use the two segments to assemble the program into its while—do structure.

Initialization code must produce output satisfying the loop invariant whenever the input predicate is true. Thus the loop invariant acts as the result predicate of (3) and initialization can be stated in terms of the induction free lemma

$$\forall v_{in}\{I(v_{in}) \rightarrow \exists v_0[Q(v_0, v_0)]\}, \quad (4)$$

where  $v$  is the vector of all program variables, with  $v_0$  representing its initial value.

The input conditions for loop body code entry are that the loop control predicate,  $B$ , is true and that the loop invariant,  $Q$ , is true. The desired output of the loop body code must satisfy the loop invariant. Further, since we wish to synthesize programs which terminate, we require that the input to the loop body code, which satisfies  $B$ , must be transformed into output which is closer to not satisfying  $B$ . The predicate ensuring this, denoted by  $P(v, v')$ , is essentially Dijkstra's variant function.<sup>3</sup> (Here  $v$  is the program variable vector before loop execution and  $v'$  is the updated value after execution.) The complete result predicate is thus  $(Q \wedge P)$  and the loop body code lemma is stated as

$$\forall v_0 \forall v \{B(v) \wedge Q(v_0, v) \rightarrow \exists v' [Q(v_0, v') \wedge P(v, v')]\}. \quad (5)$$

## SYNTHESIS

Existing first order synthesis systems can be applied to the above lemmas after they are generated for a given problem. For instance, Lee, *et al.*,<sup>7</sup> have presented a resolution based algorithm for producing loop-free programs which is proved to generate correct programs. Their system constructively proves theorems of the form

$$\forall v_{in} \forall v_{out} \{R(v_{in}, v_{out}) \rightarrow ANS(v_{out})\}. \quad (6)$$

The predicate  $ANS(v_{out})$  is used to record the unification substitutions which take place for  $v_{out}$  during a resolution proof. To use their methods, lemmas 4 and 5 are converted to the form of (6). Our desired result predicate for initialization is  $Q$ , and for loop body code is  $Q \wedge P$ . Although Lee, *et al.*, make no explicit mention of input conditions, clearly these can be included in their form. Thus (6) can be used for initialization by letting  $R = \{B \wedge Q(v_0, v) \wedge Q(v_0, v') \wedge P\}$ , giving us

$$\forall v_{in} \forall v_0 \{I(v_{in}) \wedge Q(v_0, v_0) \rightarrow ANS(v_0)\} \quad (7)$$

and

$$\forall v_0 \forall v \forall v' \{B(v) \wedge Q(v_0, v) \wedge Q(v_0, v') \wedge P(v, v') \rightarrow ANS(v')\}. \quad (8)$$

If the assumptions (or axioms) that  $I(v_{in})$ ,  $B(v)$ , and  $Q(v_0, v)$  are true are added, (7) and (8) can be shown to be logically equivalent to (4) and (5). Thus we have logical equivalence where  $I$ ,  $B$ , and  $Q$  are true, which is the only real case of interest.

The following example illustrates our approach in conjunction with resolution based loop-free synthesis as in Reference 7.

### Example 1: Factorial Function

$$I = \{N \geq 0\} \quad R = \{z = f(N)\}$$

$f$  is the factorial function, defined by  $f(0) = 1$  and  $f(x+1) = (x+1) * f(x)$ . We choose  $Q(z, k) = \{z = f(k)\}$ ,  $\sim B(k, N) = \{k = N\}$ , and  $P(k, k') = \{k < k'\}$ , so that  $Q \wedge \sim B \rightarrow R$ . (The non-active elements in  $v_0$  and  $v$  are suppressed in the above argument lists.)

- *Initialization code*—From (7), the theorem to be proved is  $\forall N \forall z \forall k \{I(N) \wedge Q(z, k) \rightarrow ANS(z, k)\}$ , or  $\forall N \forall z \forall k \{N \geq 0 \wedge z = f(k) \rightarrow ANS(z, k)\}$ .

From  $f(0) = 1$ , we have  $Q(1, 0)$ . Expressing the theorem in clause form appropriate for performing resolution, we have

$$(a) \sim I(N) \vee \sim Q(z, k) \vee ANS(z, k).$$

The axioms specifying  $I$  and  $Q$ , as required for resolution,

are

- (b)  $I(N)$  (since we are interested only in cases where  $I$  is true) and
- (c)  $Q(1,0)$  (by definition of factorial).

Resolving clauses (a) and (b) yields

- (d)  $\sim Q(z,k) \vee ANS(z,k)$ .

Resolving clauses (c) and (d) yields

- (e)  $ANS(1,0)$ .

The unification substitutions, carried in  $ANS$ , are  $1 \rightarrow z$  and  $0 \rightarrow k$ . From this, initialization code is  $z := 1; k := 0$ .

- *Loop body code*—From (8) the loop code generation theorem may be stated as the clause

- (a)  $\sim B(k,N) \vee \sim Q(z,k) \vee \sim Q(z',k') \vee \sim P(k,k') \vee ANS(z',k')$ .

From the definition of factorial, we have the axiom

- (b)  $\sim Q(z,k) \vee Q(z*(k+1),k+1)$ .

From the hypothesis that control is still in the loop, since that is our condition of interest, we have

- (c)  $B(k,N)$ , which is the condition, “ $B$  is true”, and
- (d)  $Q(z,k)$ , which means, “the loop invariant holds.”

The axioms needed to specify the progress requirement predicate,  $P \equiv \{k < k'\}$ , are expressed by the clauses

- (e)  $\sim P(0,L) \vee P(M,M+L)$  and
- (f)  $P(0,1)$ .

A string of resolutions leading to isolation of  $ANS(z',k')$  is as follows:

- (g)  $Q(z*(k+1),k+1)$ , from (b) and (d)
- (h)  $\sim B(k,N) \vee \sim Q(z,k) \vee \sim P(k,k+1) \vee ANS(z*(k+1),k+1)$ , from (a) and (g)
- (i)  $\sim Q(z,k) \vee \sim P(k,k+1) \vee ANS(z*(k+1),k+1)$ , from (c) and (h)
- (j)  $\sim P(k,k+1) \vee ANS(z*(k+1),k+1)$ , from (d) and (i)
- (k)  $\sim P(0,1) \vee ANS(z*(k+1),k+1)$ , from (e) and (j)
- (l)  $ANS(z*(k+1),k+1)$  from (f) and (k)

Thus the loop body code, derived from the substitutions for  $ANS$  arguments leading to (l), is  $z := z*(k+1); k := k+1$ .

Example 1 illustrates a difficulty with resolution-based methods—the fact that rather oblique axiomatization is necessary to define  $Q$  and  $P$ .

It is desirable to have an automatic (or semiautomatic) synthesis system which parallels good programming methodology. Thus we might wish to carry out the necessary theorem proving by the use of “natural deduction” rather than resolution. An interactive approach, allowing human intervention, is the best immediate hope for a practical synthesis system. Natural deduction systems, by definition, retain theorems and intermediate steps in a form near to that which humans usually use. The deductions are kept reasonably close to the rules of inference usually used by synthesis. Additionally, such systems have much of the necessary axiomatization built into their deductions, definitions, and rewrite rules. This greatly simplifies setting up a synthesis problem, compared to resolution. Of course, natural deduction systems are usually incomplete, but this is not expected to be a practical handicap. Bledsoe and Bruell<sup>1</sup> have presented a system, called PROVER, which combines natural-deduction-like theorem proving with a capability for man-machine interaction. PROVER has been modified for use in a practical correctness proving system (Good, London and Bledsoe<sup>6</sup>). Much of this adaptation should be useful also for synthesis proofs.

The lemma schemata (4) and (5) are already in natural form. Example 2 shows the form applied to the integer multiplication problem and illustrates a natural deduction style proof, after the methods of PROVER.

#### Example 2: Integer Multiplication

$$I \equiv \{y \geq 0 \wedge z \geq 0\} \quad R \equiv \{x = y * z\}$$

$$Q \equiv \{x + c * d = y * z\} \quad \sim B \equiv \{c = 0\}$$

- The initialization theorem is

$$(i) \forall y \forall z \{y \geq 0 \wedge z \geq 0 \rightarrow \exists x \exists c \exists d [x + c * d = y * z]\}$$

The quantifiers are removed by treating universally quantified variables as constants, identified by the subscript  $o$ , as in  $y_o$ . Existentially quantified variables are left as is. Thus we have

$$(ii) y_o \geq 0 \wedge z_o \geq 0 \rightarrow x + c * d = y_o * z_o.$$

The  $o$  subscript indicates that no value substitutions can be made. Since  $y_o$  and  $z_o$  are general constants, any substitution for  $x, c, d$  which satisfies (ii) will satisfy (i). Thus, for our purposes, (i) and (ii) are logically equivalent. In the PROVER system, an hypothesis of the form in (ii) is removed and added to the axiom list, leaving the basic theorem to be proved as

$$(iii) x + c * d = y_o * z_o.$$

A key problem for synthesis proofs is existential inference, as necessary to satisfy (iii). A natural deduction system will certainly require heuristic methods for guessing these inferences, which can then be checked for validity within its deductive framework. For instance, (iii) can be solved by term matching to get  $x=0, c=y_o$ , and  $d=z_o$  as

the desired substitutions, which is easily shown to be valid by current formula manipulation and simplification systems.

- The loop body code theorem is

$$\forall y \forall z \forall c \forall d \{c \neq 0 \wedge x + c * d = y * z \rightarrow \exists x' \exists c' \exists d' [x' + c' * d' = y * z \wedge c' < c]\}.$$

Eliminating quantifiers yields

$$(i) [c_o \neq 0 \wedge x_o + c_o * d_o = y_o * z_o] \rightarrow [x' + c' * d' = y_o * z_o \wedge c' < c_o].$$

The splitting heuristics of PROVER yield the subgoals

- (ii)  $[c_o \neq 0 \wedge x_o + c_o * d_o = y_o * z_o] \rightarrow x' + c' * d' = y_o * z_o$  and
- (iii)  $[c_o \neq 0 \wedge x_o + c_o * d_o = y_o * z_o] \rightarrow c' < c_o$ ,

which must be proved under the restriction that (ii) and (iii) must be satisfied by the same set of substitutions.

The simplest solution to subgoal (iii) is  $c' = c_o - 1$ . Trying this in (ii) yields  $c_o \neq 0 \wedge x_o + c_o * d_o = y_o * z_o \rightarrow x' + c_o * d' - d' = y_o * z_o$ . Matching expressions across " $\rightarrow$ " gives  $x_o + c_o * d_o = x' + c_o * d' - d'$  as a necessary and sufficient condition for validity of (ii). A solution to this is  $x' = x + d_o$  and  $d' = d_o$ .

Example 2 indicates that heuristics similar to those presented for second-order synthesis in Reference 5 will be helpful to a PROVER-like system. We are currently constructing a PROVER-based synthesis system to use such heuristics.

## CONCLUSION

A program  $P$  can be synthesized as a set of programs  $\{P_1, \dots, P_n\}$  so that the concatenation  $P_1, \dots, P_n$  computes  $F_P$ . We have demonstrated that a satisfactory set  $\{P_1, \dots, P_n\}$  exists such that each member has at most a single loop of the **while—do** form. Therefore, the synthesis of each  $P_j$  requiring a loop can be stated in terms of proving lemmas of the form of (4) and (5) (or (7) and (8)) for each  $P_j$ . Any loop-free  $P_j$ s can be directly synthesized from the form of (3) without the need for inductive proofs. If nested loops are desired, the synthesis can be performed hierarchically

to expand operations considered primitive during higher-level synthesis.

We have not addressed the problem of mechanically (or otherwise) arriving at a good decomposition and finding loop invariants and variant functions. It has, however, become part of the general lore of programming methodology that it is desirable for a programmer to perform such decompositions before writing programs, and Dijkstra and others have recommended that the loop invariant and variant function be discovered by a programmer before he actually writes a program loop. Thus a successful synthesis system which operates from a specification of the decomposition and associated loop invariants and variant functions is a very desirable goal.

## ACKNOWLEDGMENT

The author would like to thank T. W. Pratt and R. T. Yeh for their support and criticism during the early part of this research.

# Semantic similarity analysis—A computer-based study of meaning in noun phrases

by LYNN L. PETERSON

*The University of Texas Health Science Center at Dallas  
Dallas, Texas*

## INTRODUCTION

The purpose of this paper is to present a method by which a computerized data base which contains phrases of natural language information can be created and interrogated in the semantic domain for multiple uses and users. The method takes into account both the individual user's needs and concepts of similarity in meaning of textual material represented by the stored data. The method is applicable to arbitrary bodies of natural language text which occur in the syntactic format of the noun phrase. The method was developed and tested, however, using noun phrases of medical text since its capabilities are directly applicable to needs in that area.

### *Data base containing medical text*

Ways of dealing with a data base which contains natural language information from medical text warrant examination because of the nature of medical records. There are several objectives the medical recording process should fulfill.<sup>1</sup> The first and most important in the present usage is to serve as a self-reminder for the responsible physician. However, in the modern hospital, the medical record has an equally important task—it is the primary channel of communication between many individuals working together as a team. In either case, computer-based files of patient data are generated and maintained first and foremost to improve health care delivery for the benefit of the patient. The same files should also be available for retrieval of that part of the patient information useful and accessible for research and educational purposes.

Integral parts of these files of medical records are non-numeric and best expressed as natural language, e.g. admitting diagnosis, operative procedures, etc. In fact, components of a problem-oriented medical record are normally expressed as noun phrases using large vocabularies.<sup>2</sup> The non-numerical component of the medical record serves the function of interpretation of the numeric data, as well as the recording of observations and the communication among medical staff.<sup>3</sup> As such, this natural language component of the stored data needs to be handled appropriately.

The simple noun phrase is the construct of which the vast

majority of entries in a problem-oriented medical record are composed.<sup>4</sup> It is therefore appropriate that the simple noun phrase serve as the focus of attention in the consideration of a procedure which would be applicable to a data base containing medical text.

A data base of medical information will characteristically be created and interrogated for multiple uses and users. This requires a procedure for semantic analysis which can deal accurately with the meaning of words and the relationship between words, and can recognize and use the distinction between synonyms and near-synonyms. According to Pratt, in medicine, the distinction between synonyms and near-synonyms is important for the proper interpretation of the medical record, and remains one of the major problems which will have to be resolved to produce effective systems.<sup>5</sup>

Presently we can make things that mean the same thing fall together; we wish to be able to recognize when things mean nearly the same thing, to quantify this semantic nearness in a meaningful and useful way, and to use this knowledge to aid in the retrieval from the data base of semantically-related information.

### *Individual concept of similarity*

A basic premise of this approach is that similarity in meaning between two pieces of medical text is not an absolute notion. On the contrary, this approach recognizes that (a) one user's concept of similarity may differ from that of another user, i.e., things may not mean the same thing to two different people, and (b) an individual user's interests may differ from one retrieval request to another. At one time a user of the data base may wish to retrieve all those records which contain the same operative procedure ignoring all differences in other areas, i.e., similarity sufficient to retrieve requires an exact match on operative procedure and ignores differences in, say, topography. At another time, however, the user may care very much what anatomical area is involved, i.e., similarity of records will require the involvement of an anatomical area close to the one specified. Thus, by applying different weightings, sets of records can be grouped into different "semantic subspaces," stressing or ignoring features based on their perceived importance to the user.

SEMANTIC SIMILARITY ANALYZER

To address the objective of permitting a data base containing noun phrases of text to be created and interrogated for multiple uses and users, a Semantic Similarity Analyzer, SSA, was constructed. Significant features of the system are highlighted.

MEANINGEX-based system

The system called MEANINGEX, developed by Mishel-ovich in 1970,<sup>4</sup> takes the simple noun phrase and performs on it a "semantic analysis." This semantic analysis is composed of (a) a lexical phase in which each input word or term is recognized and then mapped to a standard term and a part of speech, (b) a syntactical phase in which the head term or main noun is identified, the remaining terms are treated as adjectives, and (c) a semantic parse, or "sparse," phase in which a tree is constructed with the head term as root and the structure of the remainder of the tree determined from entries in a "tree directory" for the head term and its modifiers. The sparse phase is generative of semantic information in that entries in the tree directory supply related and relevant terms which are not physically part of the normalized text.

As an example, let us consider the simple noun phrase

MODERATELY SEVERE PNEUMOCOCCAL ARTHRITIS OF THE LEFT KNEE.

The normalized text produced by the lexical and syntactical phases

SEVERE.ACUTE.PNEUMOCOCCUS.LEFT.KNEE ARTHRITIS.

is produced by using a lexicon whose relevant section is shown in Figure 1. The section of a tree directory which shows the relationships among the head term in this phrase and its modifiers is shown in Figure 2, where two types of terms on next node are indicated:

- (a) An inclusive node in which all the terms are used.
- (b) A selector node, indicated by the \*, in which only one of the choices is selected.

The tree generated by MEANINGEX from the phrase of normalized text is then shown in Figure 3, where levels of

TERM	STANDARD TERM	PART OF SPEECH
MODERATELY SEVERE	SEVERE	ADJ
SEVERE	SEVERE	ADJ
PNEUMOCOCCUS	PNEUMOCOCCUS	ADJ
PNEUMOCOCCAL	PNEUMOCOCCUS	ADJ
ARTHRITIS	ARTHRITIS	NOUN
ARTH.	ARTHRITIS	NOUN
ACUTE	ACUTE	ADJ

Figure 1—The section of the lexicon dealing with "arthritis" in the Original MEANINGEX.

TREE DIRECTORY TERM	TERMS ON NEXT NODE

ETIOLOGY	*INFECTIOUS *OSTEO *RHEUMATOID
INFECTIOUS	*BACTERIAL *VIRAL
INFLAMMATION	DEGREE DURATION ETIOLOGY LOCATION
JOINT	JOINTNAME SIDE
JOINTNAME	*SHOULDER *FINGER *HIP *KNEE *TOE
LOCATION	*POLY *JOINT *CAVITY *ORGAN
SIDE	*LEFT *RIGHT *BOTH

Figure 2—The section of the tree directory dealing with "arthritis" in the Original MEANINGEX. Two types of nodes, depending on the terms on the next node, are indicated: an inclusive node in which all terms are used and a selector node (indicated by \*) in which only one of the choices is selected.

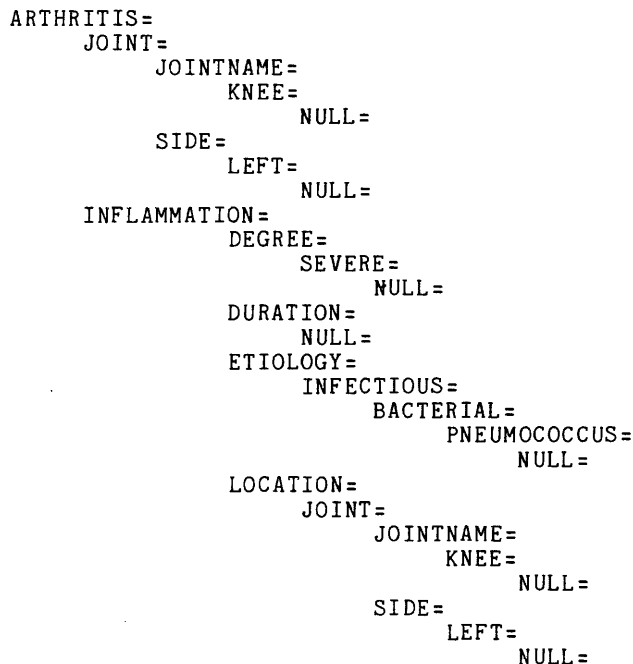

Figure 3—The sparse tree in the Original MEANINGEX for the phrase MODERATELY SEVERE PNEUMOCOCCAL ARTIHRITIS OF THE LEFT KNEE.

indentation indicate levels of hierarchy. The tree constitutes the primary output from the MEANINGEX semantic analyzer. From the tree, a linear string of the nodes of the tree can be constructed by reading the tree bottom up. The string of nodes, which can then function as descriptors or keys for information retrieval, is as follows from the current example:

```
/NULL/LEFT/SIDE/NULL/KNEE/JOINTNAME/
JOINT/LOCATION/NULL/PNEUMOCOCCUS/
BACTERIAL/INFECTIOUS/ETIOLOGY/NULL/
DURATION/NULL/SEVERE/DEGREE/
INFLAMMATION/NULL/LEFT/SIDE/NULL/
KNEE/JOINTNAME/JOINT/ARTHRITIS/
```

Obviously, then, the information which determines the resultant semantic parse of a piece of medical text via MEANINGEX is found primarily in the tree directory. Additionally, however, a synonyms list is made available to MEANINGEX showing terms to be considered to have a meaning equivalent to that of a term already recognized, and an implications list is included to indicate how the presence of one or more recognized terms, Boolean fashion, implies the presence of another term. The generative properties of the semantic parse come about as a result of the semantic information imbedded in the tree directory and the synonyms and implications lists.

The original MEANINGEX system was implemented in 1970 in assembly language for the CDC 3300 computer at The Johns Hopkins University. Published material<sup>6-9</sup> indicates that the system was applied to semantic analysis of medical records and to bibliographic indexing, but the approach to semantic analysis was sufficiently general to admit other applications. Retrieval aspects were not addressed by the original MEANINGEX *per se*, but the linear string of descriptors generated by MEANINGEX was in the proper format for processing by the generalized data management system in use at Johns Hopkins.

In 1976 a new MEANINGEX system was implemented on the DECsystem-10 computer by Steve Bush at The University of Texas Health Science Center at Dallas (UTHSCD). The concept and functional description are the same as those of the original MEANINGEX but the new computer system is interactive and has added several features which increase its usefulness in the study of generated meaning. It was implemented primarily in the FORTRAN language, using in addition some well-documented macro-string manipulation routines, adding a measure of transportability to the MEANINGEX system.

The new MEANINGEX, called UTHSCD MEANINGEX, preserves the basic concepts of the original MEANINGEX system. The domain of semantic interest, i.e., the set of terms used in the natural language phrases to be considered together with the relationships among the terms, is specified by the input lexicon, implications list, and synonyms list. However, in the new system, this information can be entered from the keyboard or from a file. Furthermore, additions can be made to the implications and synonyms list from the keyboard, adding a dynamic aspect to the management of this information. Figure 4 shows the list

of statements used to convey to UTHSCD MEANINGEX the same specifications shown in Figure 2 for the "arthritis" example of the original MEANINGEX.

The SSA utilizes the semantic analysis procedures of UTHSCD MEANINGEX and thus also makes use of the input scheme shown in Figure 4. A tree directory can be output by the SSA in a graphic form shown in Figure 5 which is then available for study, elaboration and correction. The tree of knowledge represents a composite view of the terms and hierarchical relationships active in the domain under consideration. The display itself opens for study the details of construction of such a hierarchical directory for a specific domain.

#### *Context weightings/user profiles*

Fundamental to the understanding of semantic similarity is the notion that the meaning of a phrase may differ from individual to individual or even within an individual as times or purposes differ. In order to permit differing values of importance or interest to be attached to terms in the vocabulary in a domain of semantic interest, the facility of context weightings is used.

The SSA allows a user of the system to associate with each term in the tree directory a numerical value representing its weight. In some situations, weights are actually assigned by the user to all or only some of the terms in the domain with weightings for the remaining terms derived by inheritance from parent nodes to which weights were assigned. All weights are determined by the user input and the placement of terms relative to others in the tree representing the domain, i.e., the context, so the weights are called "context weights." The entire set of weights then, in a sense,

Figure 5—The section of the tree directory dealing with "arthritis" utilizing display techniques of the SSA.

represents the user's notions of importance of or interest in the terms. For this reason, the set of weights together with a short narrative description of the set is called a "user profile."

Numerous methods of specifying weights have been considered during the development of the SSA and two general methods are in use now. The methods fall into the general categories of explicit weighting, or direct generation of the weighting set, and implicit weighting, or generation of the set of weights from general information presented to the system by the user.

*Explicit weighting*

The most straight-forward method of generating a weightings set is to have the user explicitly provide the numerical weights to be used. In this method of generating a set of context weightings, the user will actually traverse the tree directory for the entire domain of semantic interest by means of an interactive display. Each node is displayed in turn, showing its already established context weight and the names of each of its subnodes. The user is then asked to enter a weight for each of the subnodes. Thereafter the context weight for each node is the product of the context weight of its parent node and the user-entered weight. By this means, context weights are generated for all nodes in the tree directory. As an example, consider a situation in which a user is interested in those childhood illnesses usually accompanied by a rash. Within this context, then, we will wish to carry out the retrieval of those strings similar in meaning to a reference string. To create this context via a weightings set, a dialog such as that shown in Figure 6 would ensue. The result of this dialog is the establishment of a set of context weights and a narrative description of the set, represented thereafter by the user profile "RASH."

However, some drawbacks to explicit weighting do exist. The method does require the user to interact with the SSA via a terminal for a significant period of time before even the simplest retrieval can be tried, if he wishes to use his own user profile. However, it is true that the unit weight option can always be selected, that is, all weights can be

assigned the value 1. Also, certain user profiles are provided in the SSA system for illustration. Secondly, this method requires the user to "pick numbers out of the air" to assign as weights, to actually enter numeric values, a task which may be unpleasant to some users. So the explicit weighting method has not been felt to be entirely successful in providing a way for a user to generate a user profile.

#### *Implicit weighting via profile-capturing*

The difficulties encountered in explicit weighting have led to a second method which involves an implicit determination of the numerical weights and the terms to which the non-unit weights should be assigned. Methods of implicit determination of weights have been utilized in a variety of theoretical and practical settings, and have been referred to by the general title "policy capturing." An admittedly sexist yet easily understood illustration of "policy-capturing" can be seen in the fable of the king who, once upon a time, decided to select a harem larger than King Solomon's. . . .

So the word went out, and soon thousands of young girls were arriving from the various provinces to seek the king's approval.

Early one morning the king began his selection process. As each girl filed by, he looked her over carefully and then expressed his judgment.

"Excellent!" he would say. "This one is very pleasing to my eye." Or perhaps he would hum and haw with indecision. Many times he would show his disapproval in no uncertain terms. "Never!" he would say. "Pass on! Pass on!"

In each instance, the Court Recorder attempted to quantify the king's degree of approval by checking the appropriate level on a nine-point scale which had been devised especially for the occasion by the Chief of the Royal Psychometricians.

By suppertime the king had considered some 300 girls. His eyes and his imagination were beginning to tire.

"Most High First Counselor," he said, "you've been watching me all day, and by now you should know my likes and my dislikes. I've decided to leave the selection of my harem in your hands. But take care! If your choices do not please me, it will be your head!"

After the king retired, the Most High First Counselor summoned the Chief of the Royal Psychometricians. "I'm passing the job on to you," he said. "If you fail to please the king, your head will roll along with mine."

The Chief of the Royal Psychometricians called his staff together and explained the situation.

"We must not fail," he said, "or it will be all of our heads."

"How shall we proceed?" asked one of the young staff members who was fresh out of the Royal Academy.

"Well," responded the Chief, "we know how the king rated the first 300 girls. Right?"

"Right!"

"And we can see everything the king saw when he looked at the girls. Right?"

"Right!"

"Then all we have to do is to uncover the characteristics considered by the king and determine how he weighted them in his judgment. . . ." <sup>10</sup>

The point was to use the knowledge or approximation to the knowledge of how the process was carried out to continue to carry out the process. Since the goal of utilizing a policy-capturing technique in the SSA is the determination of a "user profile," the general technique of determining a profile in this implicit way is called "profile-capturing."

Several profile-capturing methods were tried for use in the SSA. The method currently used makes use of the capabilities of MEANINGEX to process a natural language phrase. Phrases are elicited from a user in response to one or more questions about what the user is or is not interested in. In each of these phrases, the MEANINGEX analysis determines the terms which should be weighted, with the actual weights being assigned by the SSA relative to a user-selected maximum weight. A sample profile-capturing dialog is shown in Figure 7.

It appears that in practice the profile-capturing method of weight determination may not provide enough ability to discriminate between sets of records which are intended to fall in different "semantic subspaces." It may be in practice that some combination of profile-capturing as a first cut and explicit weighting for finer discrimination will become the weighting method of choice.

#### *Similarity measures*

The determination of the semantic similarity of a pair of natural language strings in the SSA basically involves the application of a type of function called a "similarity measure" to a pair of vectors representing the semantic characteristics associated with each of the natural language strings. The semantic characteristics relevant in any application of a similarity measure to a pair of strings are the terms or nodes of the smallest tree generated by the MEANINGEX semantic analyzer which still includes the meanings contained in both phrases. Since MEANINGEX is generative of semantic information, the full context surrounding the meaning of both phrases is included in the set of semantic

Figure 7—Sample profile-capturing dialog which results in a weightings set in which the term "respiratory" and all terms below it in the tree (all its subnodes and sub-subnodes) are assigned a maximum weight—in this case, 5. Secondly the terms "necrosis" and "inflammation" and all terms below them in the tree are assigned a weight of approximately one-half the maximum value—in this case, 2. Finally, the term "parasitic" and all terms below it are assigned a weight of 0, to decrease in importance any phrase which contains a component of meaning in this area. Weighting of all terms in the tree directory not affected by these phrases remains at 1.

characteristics used to construct the vectors. The elements of the vectors forming a pair are then 0 or 1 depending on the presence or absence of each semantic characteristic as part of the generated tree for the phrase it represents. Certain terms are considered to be "structural" nodes while most are "content" nodes, carrying meaning; an element of the vector will always be 0 if the corresponding term is a structural node. It is on vectors constructed in this way that the similarity measures operate.

The class of similarity measures in use can be characterized as correlation measures, as indicators of the interdependence of the semantic characteristics of the two strings.<sup>11</sup> We do not claim or require that these functions measure the similarity of the two strings in an absolute sense but serve as indicators of the association in meaning between the two strings.

The specific similarity measures currently in use in the SSA are derived from some of those most extensively used in bibliographic retrieval according to Salton.<sup>12,13</sup> In some cases, a weighting scheme has been imposed on a familiar similarity measure to yield a measure more appropriate to the needs of an individual user or a specific type of retrieval request. The form of several of the similarity measures is shown in Figure 8.

For each retrieval request, a determination is made of

similarity between an input string and the set of stored strings using a similarity measure chosen from the set of built-in similarity measures. A stored string is then retrieved if the calculated similarity index is sufficiently high, that is, exceeds a threshold value which is specified by the user based on the selected function and the degree of interdependence required.

Some of these functions have proven more useful than others in similarity determination based on subjective notions of similarity. As utilization of these functions proceeds, it is anticipated that additions and changes will be made to the set of similarity measures built into the SSA, working toward enhancing their utility. However, it is not anticipated that a selection of the "best" function would ever be made. The use of any one function in retrieval or comparison studies obviously depends on what the user wishes to consider as the criteria for similarity determination. Hence it is the philosophy of the SSA to present the features of functions which accomplish similarity determinations based on a variety of criteria and let the user select the one or ones which best meet the current needs.

#### Structure of the semantic similarity analyzer

The structure of the SSA containing the features just described is shown in the diagram in Figure 9. The SSA System code and Reference Manual are available on request.

Function #1

$$\sum wt(i) * v1(i) * v2(i)$$

Function #2

$$\left( \sum v1(i)*v2(i) + \sum \bar{v1}(i)*\bar{v2}(i) \right) / N$$

where  $\bar{v1}(j) = 1 - v1(j)$  is the complement of  $v1(j)$  and  $N$  is the number of elements in the vector.

Function #3

$$\frac{\sum wt(i)*v1(i)*v2(i)}{\sum wt(i)*v1(i) + \sum wt(i)*v2(i) - \sum wt(i)*v1(i)*v2(i)}$$

Figure 8—Several similarity measures used in the SSA. In each case, V1 and V2 are binary vectors representing the semantic characteristics associated with each of the natural language strings, WT is the vector of weights, and the summation is over all elements of the vector. Function #1 is a weighted vector product representing the sum of the weights of the characteristics occurring in both natural language strings. Function #2 is the unweighted function which counts the number of matching properties divided by the total number of such characteristics. Function #3 is a weighted normalized measure.

which to build a data base. Sample retrievals from this data base demonstrate the differing retrievals resulting from differing specifications of conditions such as user profiles. Given the reference string

#### ACUTE INFLAMMATION OF THE LUNG

the SSA was asked to find and type out all strings in its data base similar to the reference string, in the sense defined by the conditions set at the time retrieval was initiated. The results showed that the SSA runs efficiently on the DEC-system-10, processing the storage of strings in this domain in from 0.8 to 1.0 CPU seconds and handling a retrieval request from this data base yielding three to seven strings in 2.0 to 2.5 CPU seconds. For this reference string, the set of strings retrieved differed as the choice of retrieval function changed, as was to be expected. In particular, for a function which focused on the occurrence of matching concepts in the pair of phrases, the pattern of retrieval was

*all equally good matches*

LUNG; FOCAL GRANULOMATOUS  
PNEUMONIA  
LUNG; MODERATE SUPPURATIVE  
PNEUMONIA  
LUNG; MILD BRONCHOPNEUMONIA  
LUNG; INTERSTITIAL PNEUMONIA,  
MODERATE

For functions which penalize the similarity index values for mismatches, the pattern changes to show:

*best match*

LUNG; INTERSTITIAL PNEUMONIA,  
MODERATE

*next best matches*

LUNG; FOCAL GRANULOMATOUS  
PNEUMONIA  
LUNG; MILD BRONCHOPNEUMONIA

*also good matches*

LUNG; MODERATE SUPPURATIVE  
BRONCHITIS  
LUNG; PULMONARY EDEMA

Secondly, a consideration of a single function as user profiles change shows the way in which the weighting system operates in carrying out weighted retrieval. Utilizing a weighted vector product measure, Function #1 in Figure 8, and a weighting system in which all weights are one results in the retrieval of the strings

*best match*

LUNG; ACUTE EDEMA AND  
HEMORRHAGE WITH BACTERIAL INVASION

*next best matches*

LUNG; FOCAL GRANULOMATOUS  
PNEUMONIA  
LUNG; MODERATE SUPPURATIVE  
PNEUMONIA  
LUNG; MILD BRONCHOPNEUMONIA  
LUNG; INTERSTITIAL PNEUMONIA,  
MODERATE

However, using a weighting profile which assigns a weight of five to "bacterial etiologic agent," a weight of two to "inflammation," a weight of zero to "non-bacterial etiologic agent" results in the retrieval of the strings just shown with the addition of the following strings as additional good matches:

TRACHEA; MILD SUPPURATIVE TRACHEITIS  
TRACHEA; NONSUPPURATIVE  
TRACHEITIS, MODERATE

representing inflammations of another part of the respiratory system.

What is retrieved in a request to find all strings similar to a given string is dependent on what is important to a user of the system and how the user wishes the retrieval function to operate. A user-responsive, functionally directed retrieval technique as part of a system which admits natural language input can therefore be applicable to a real situation.

Hence, in the Semantic Similarity Analyzer, it appears we have a system which meets the overall objective of permitting a data base containing phrases of natural language information to be created and interrogated in the semantic domain for multiple uses and users. The system is being applied to the Veterinary Pathology Record Retrieval System currently under development at UTHSCD, and the usefulness of the technique in practice will continue to be evaluated in this setting.

# Heuristic control of design-directed program transformations

by CHRISTINA L. JETTE

University of Washington  
Seattle, Washington

## INTRODUCTION

This paper describes a class of semantic source-to-source program transformations called design-directed program transformations (DDPT) for use in a transformational implementation (TI) approach to programming. A methodology is developed for applying such transformations based on symbolic evaluation and experimental computation of programs. A DDPT is a cognitive model of source-to-source transformations; it knows *what* it is trying to accomplish and contains a strategy of *how* to accomplish it. A DDPT is more than a syntactic pattern replacement rule; it is a semantic program transformation which is intuitively closer to one that a good programmer would invoke in transforming his program.

DDPTs are a natural extension to TI systems.<sup>1,6,7,8,10,12,13</sup> The importance of a TI approach to programming has been made earlier, most notably by Balzer *et. al.*<sup>1</sup> In a TI environment, the user interactively constructs and modifies a program by applying "correctness-preserving" transformations. Viewed as a programming methodology, this approach strives to relieve the user from worrying about the details of the actual implementation, thereby transforming his role to one of "designer" and "optimizer," delegating the role of "implementer" to the TI system.

To date, TI systems provide only syntactic transformations. A syntactic transformation can usually be represented by a production-like pattern replacement rule of the form "LHS-pattern $\Rightarrow$ RHS-replacement-pattern." (LHS is left-hand side, RHS is right-hand side.) The user *selects* a particular rule. The TI system tries to *match* the LHS-pattern with a portion of the program to be transformed (called the *target program*). If successful, the RHS-replacement-pattern is *substituted* for the matched portion of the program.

A DDPT is not so easily described as a syntactic replacement rule because the LHS and RHS patterns are not "one-to-one" with the statements in a programming language. i.e., they contain user-supplied descriptions of what the program fragment is doing such as "update," "put," etc. Further, the RHS-replacement-pattern cannot always be specified *a priori*. It is instead dynamically generated based on the interaction of the specific target program and the specific DDPT. Consequently, a DDPT is defined by 1) an

*input pattern* whose language is semantically rich and 2) a *procedure* which derives instances of the RHS-replacement-pattern. This pattern instance encodes the underlying strategy of the transformation. In the next section, we give a detailed example of a DDPT definition called BYPASS-LOOP.

What distinguishes the DDPT method from the more syntactic approach is 1) the goal-directedness of a specific DDPT (e.g., "bypass" a looping computation if possible), 2) the nature of the input pattern (e.g., pattern elements contain descriptive annotations such as "update," "put," etc.) and 3) the synthesis of replacement program fragments which when substituted into the program, achieve the overall goal of the transformation (e.g., bypass a loop for special cases).

Considering only syntactic transformations leads to several operational difficulties.<sup>1</sup> They include 1) Size—An enormous number of transformations exist. How can their numbers be reduced? 2) Selection—How are transformations selected/accessed? 3) Control—How are transformations applied, i.e., in what order should they be tried and how are they invoked? In this paper we show how these problems can be alleviated in some instances using DDPTs.

## Summary

In the next section, we present several examples of design-directed program transformations, and compare the design-directed paradigm to a more traditional syntax based paradigm. In the third section we relate this work to others and in the fourth section we give our conclusions.

## DDPT EXAMPLES AND COMPARISONS

In this section, we define the steps of the transformation process. Based on these steps, and using detailed examples for illustration, we compare the syntax based pattern-replacement rule paradigm with the design-directed paradigm.

The process of manipulating a program can be factored into four steps. They are *selection*, *matching*, *substitution* and *replacement*. A transformation "rule" is selected (either

automatically or by the user), and matched to a program fragment. If the match is successful, the variable portions of the matched part are substituted for the variable portions of the replacement pattern. Finally, the replacement pattern replaces the matched target program fragment. In the next two examples, we show how the DDPT approach extends each of these steps by making them more "computational" in nature.

### BYPASSLOOP DDPT

This example illustrates how the DDPT method extends the matching and substitution processes. We first look at the syntactic approach.

Consider the sequence of syntactic transformation rules necessary to transform the program fragment

(a) **while**  $i \leq n$  **do** ( $b[i] := b[i] + p * (i-1)$ ;  $i := i+1$ )

into the program fragment

(b) **if**  $p=0$  **then**  $i := n+1$   
**else while**  $i \leq n$  **do** ( $b[i] := b[i] + p * (i-1)$ ;  $i := i+1$ ).

This transformation takes advantage of the special case for which the loop does no "significant" processing, i.e., for " $p=0$ ." Figure 1 defines six transformation rules, T1 through T6, to transform (a) into (b).

In this approach, T1 is applied to the target program (a) by matching the LHS-pattern of T1 to (a). The result of this match is a list of (argument,value) bindings. e.g.,

$\langle A: (b[i] := b[i] + p * (i-1)) \rangle$

Next, the value for  $A$  is substituted in the RHS-replacement-pattern. Note that the predicate " $p=0$ " which is bound to  $R$  in the RHS-replacement-pattern must somehow be specified by the user. The RHS-replacement-pattern replaces the matched portion, producing a new program fragment to which T2 will be applied, etc. The program fragment (b) above is the result of applying T1 through T6 to (a).

The problems inherent with this method are:

1. The overall goal to "bypass the loop for the special case that the no computation path is taken," is completely obscured by the details of invoking the correct sequence of applicable transformations.
2. Six transformation rules are invoked in this case, but these six are not necessarily the only sequence of syntactic rules which would transform (a) into (b). How do we select the applicable ones, and how do we know which ones are available for selection?
3. The user is completely responsible for the selection of a correct sequence—the system merely carries out each selection by matching the appropriate code segment and accomplishing a straightforward replacement.

4. The user is also responsible for discovering properties of the program which might be derivable automatically by a more intelligent system, such as the predicate " $p=0$ ," and the action " $i:=n+1$ " in the example above.

In comparison, the design-directed approach has a single DDPT called BYPASSLOOP, whose strategy is to bypass a looping computation for the special cases in which the loop does no "significant" processing.<sup>5</sup> We call this strategy the *abstract design* of the DDPT. It is abstract in that it does not specify the "details" of the target program to which it applies. It does, however, specify the necessary constraints of the transformation. The abstract design specifies that the target loop has a "no computation" path, but it does not specify the specific action sequences of that loop. This strategy is encoded as the procedure which generates the replacement program fragment for a DDPT.

A DDPT is defined by giving: 1) An *input pattern*, and 2) A *replacement fragment constructor procedure* which constructs an incompletely specified replacement program fragment based on the given target program and the underlying strategy or goal of the transformation. It contains both *concrete*, or known actions and predicates and *abstract* or unspecified actions and predicates. The concrete parts are derived from the matched input pattern; the abstract parts are exactly those portions of the yet-to-be-transformed program which must be synthesized to achieve the overall goal of the transformation.

For BYPASSLOOP, the input pattern is:

**do;** (transient-updates | non-transient-updates); **od**

where "do; . . . ; od" is a pattern which denotes a looping computation, "(transient-updates | non-transient-updates)" is an alternation pattern which denotes one of two specializations of "update." (A transient variable is one with a non-repetitive value structure, e.g., a non-array. Hence a transient-update is an assignment to a transient variable, e.g.,  $i:=i+1$ .) Note that the input pattern for BPL is considerably more abstract than the patterns T1-T6 in Figure 1.

The BPL replacement fragment constructor procedure may informally be stated as:

1. Let  $M$  be the matched portion of the target program and the input pattern. Let  $TU$  be the transient variables, and  $NTU$  be the non-transient variables. Create a conditional statement such that:
  - (a) The else branch is  $M$
  - (b) The true branch is  $TU := F(TU)$ ,
  - (c) The predicate condition is  $r$   
 $\Rightarrow$  "if  $r$  then  $TU := F(TU)$  else  $M$ "
2. Define  $r$  to be exactly that abstract predicate which is true for the bypass path to be taken. That is,  $P\{M\}Q \Rightarrow \text{Pand } r\{TU := F(TU)\}Q$ .
3. Define  $TU := F(TU)$  to be those update actions which may be expressed as non-looping computations. For all  $x$  in  $TU$ ,  $F(x)$  is the value  $x$  would have had on exit from the loop if the loop had executed.

RULES:

T1:  $P\{A\}Q \Rightarrow P\{\text{if } R \text{ then } A \text{ else } A\}Q$

T2:  $P\{\text{if } R \text{ then } A \text{ else } B; C\}Q \Rightarrow P\{\text{if } R \text{ then } A;C \text{ else } B;C\}Q$

T3: Partial evaluation, i.e., symbolic evaluation of the result of substituting known values for variables, actual parameters for formal parameters in procedures, etc.

T4:  $P\{x:=x\}Q \Rightarrow P\{\text{noop}\}Q$

T5:  $P\{\text{while } R \text{ do if } S \text{ then } A \text{ else } B\}Q \Rightarrow$   
 $P\{\text{if } S \text{ then } (\text{while } R \text{ do } A) \text{ else } (\text{while } R \text{ do } B)\}Q$   
 when  $S\{A\}S$  and  $S\{B\}S$ .

T6: Computing linear relationships and values of variables.

TRANSFORMATIONS:

let target program fragment = while  $i \leq n$  do  $(b[i]:=b[i]+p*(i-1);i:=i+1)$ ;

$\Rightarrow_{T1}$  while  $i \leq n$  do (if  $p=0$  then  $b[i]:=b[i] + p*(i-1)$   
 else  $b[i]:=b[i] + p*(i-1)$ ;  
 $i:=i+1$ )

$\Rightarrow_{T2}$  while  $i \leq n$  do (if  $p=0$  then  $(b[i]:=b[i] + p*(i-1);i:=i+1)$   
 else  $(b[i]:=b[i] + p*(i-1);i:=i+1)$ )

$\Rightarrow_{T3}$  while  $i \leq n$  do (if  $p=0$  then  $(b[i]:=b[i]+0;i:=i+1)$   
 else  $(b[i]:=b[i]+p*(i-1);i:=i+1)$ )

$\Rightarrow_{T4}$  while  $i \leq n$  do (if  $p=0$  then  $i:=i+1$   
 else  $b[i]:=b[i] + p*(i-1);i:=i+1$ )

$\Rightarrow_{T5}$  if  $p=0$  then while  $i \leq n$  do  $i:=i+1$   
 else while  $i \leq n$  do  $(b[i]:=b[i] + p*(i-1);i:=i+1)$

$\Rightarrow_{T6}$  if  $p=0$  then  $i:=n+1$   
 else while  $i \leq n$  do  $(b[i]:=b[i] + p*(i-1);i:=i+1)$

Figure 1—The transformation process using syntactic pattern-replacement rules.

Figure 2 shows the DDPT method applied to BYPASSLOOP. The first step matches the input pattern to the target program fragment, "while  $i \leq n$  do. . ." The second step invokes the BPL replacement fragment constructor procedure above. This results in an incompletely-specified program fragment whose abstract elements  $r$  and  $TU:=F(TU)$  are constrained by the BPL strategy. Finally in Step 3, these abstract portions are synthesized with  $p=0$  for  $r$  and  $i=n+1$  for  $TU:=F(TU)$ . (The details of the synthesis procedure are beyond the scope of this paper.)

The advantages of this approach are:

1. The overall goal (to bypass the loop) directs the transformation process.
2. Once BYPASSLOOP is selected, any "low-level" analysis is carried out automatically (e.g., partition variable assignments into types).
3. The system derives properties such as the predicate  $p=0$ , instead of requiring the user to specify them.
4. The input pattern and replacement fragment construc-

input pattern : "do; (transient-updates | non-transient-updates); od"

target program : while i<= n do (b[i]:=b[i]+p\*(i-1);i:=i+1)

1. MATCH BPL input pattern to target program. Analyze statements in loop. Partition variable assignments into transient and non-transient updates. (See section 2.1.)

```
=> <do;...;od : while i<=n do ...>
    <transient-updates : i:=i+1>
    <non-transient-updates : b[j]:=b[j]+p*(j-1), 1<=j<=n>
```

2. INVOKE BPL replacement fragment constructor procedure.

- (a) Bind M to value of <do;...;od>
- (b) Bind TU to {i}
- (c) Bind NTU to {b}
- (d) CREATE-CONDITIONAL(pred = "r", truepart = "TU:=F(TU)", elsepart = M)

```
=> "if r then TU:=F(TU) else M"
```

3. SYNTHESIZE abstract parts "r", and "TU:=F(TU)".
  - (a) Compute F(TU), the final values of x in TU.

```
=> i:=n+1
```

(b) Compute predicate "r". Let  $x_i$  denote the  $i$ th value of  $x$ . For each non-transient variable  $x$ , for each iteration  $i$ , construct a predicate  $r_i = AE(x_0 = x_n)$ . (AE is abstract evaluation [BIGG77a].) Let  $r = r_1$  and  $r_2$  and ... and  $r_n$ .

```
=>> AE(b_0[1]=b_n[1]) and ... and AE(b_0[n]=b_n[n])
```

```
=>> AE(b_0[1]=b_0[1]+0) and ... and AE(b_0[n]=b_0[n]+p*(n-1))
```

```
=>> T and p*1=0 and ... and p*(n-1)=0
```

```
=>> p=0
```

- (c) Return fully instantiated program fragment.

```
=> "if p=0 then i:=n+1 else while i<=n do ..."
```

Figure 2—DDPT method applied to BYPASSLOOP.

tor procedure of the transformation applies to a large class of target program fragments.

#### Cancel DDPT

A general selection procedure is yet another important aspect of our system which is illustrated in this example. We are experimenting with automating this step of the transformation process by using the program annotations sup-

plied by the programmer for clarity. A database of related annotations is maintained. For example, "loop," a syntactic program control structure element, and "update," a descriptive action verb element, are related by a relation R-BPL. The selection procedure essentially constructs a list of those related elements contained in a target program which are related in the database. Each relation (e.g., R-BPL) is suggestive of one or more DDPTs (e.g., BPL). Hence the selection procedure returns a list of potential transformations to be tried.

The program in Figure 3 processes characters given in an array `text[0:n]`. In and out are two integer pointers such that during execution of the main loop,

- (a) `text[1:out]` is the text processed "so far," and
- (b) `text[1:in]` is the output or "saved" text.

The text processing 1) replaces linefeeds by blanks, 2) removes redundant blanks and 3) removes non-alphabetic characters. (This is an example discussed in Reference 1.)

Abstractly, the main loop of the program is:

```
while moretext do
  (get next character from input;
  put character in output;
  case on character type:
  linefeed: (replace character by blank;
             if redundant blanks then remove character
             from output);
  blank:    if redundant blanks then remove character
             from output;
  alpha:    noop;
  else:     remove character from output);
```

In Figure 3 we "fill in the details" of this abstract program; the abstract operations above are left as annotations.

An applicable DDPT is the CANCEL transformation.<sup>2</sup> Intuitively the strategy of this transformation is to rearrange the action sequences so as not to have to "undo" or "can-

```
procedure processtext(var text:array[0:n] of char);
var ch:char; in,out:integer;
begin
  in:=out:=0; text[0]:= ' '; /** initialize **/
  while out<n do
  begin
    /** get next character from input **/
    out:=out+1;
    ch:=text[out];
    /** put character in output **/
    in:=in+1;
    text[in]:=ch;
    /** case on character types **/
    case ch in
    linefeed: begin
      /** replace character by blank **/
      ch:=text[in]:=' ';
      /** test for redundant blanks **/
      if text[in-1] = ' '
      then /** remove character from output **/
        in:=in-1;
      end;
    space:   begin
      /** test for redundant blanks **/
      if text[in-1] = ' '
      then /** remove character from output **/
        in:=in-1;
      end;
    alpha:   begin /** noop **/ end;
    else:    /** remove character from output **/
      in:=in-1;
    end; /** case **/
  end; /** while out<n **/
end; /** procedure processtext **/
```

Figure 3—Program to process characters.

cel" any previous action. In this case, CANCEL will eliminate action sequences such as `["put"; . . . ; "remove"]` by replacing the "puts" and "removes" with "noops", i.e., `["put"; . . . ; "remove"] ⇒ ["noop"; . . . ; "noop"]`. Applying CANCEL to the abstract program above yields the transformed abstract program:

```
while moretext do
  (get next character from input;
  noop;
  case on character type:
  linefeed: if not redundant blanks then put blank in out-
            put;
  blank:    if not redundant blanks then put character in
            output;
  alpha:    put character in output;
  else:     noop);
```

Those portions in italics are program parts affected by the transformation. The complete program is shown in Figure 4. In this version, note that the "put" is done only when needed; the "replace" and "remove" actions have been eliminated.

How can one use the program's annotations in Figure 3

```
procedure processtext(var text:array[0:n] of char);
var ch:char; in,out:integer;
begin
  in:=out:=0; text[0]:= ' '; /** initialize **/
  while out<n do
  begin
    /** get next character from input **/
    out:=out+1;
    ch:=text[out];
    /** case on character types **/
    case ch in
    linefeed: begin
      /** replace character by blank **/
      ch:= ' ';
      /** test for redundant blanks **/
      if text[in] ~= ' '
      then begin
        /** put character in output **/
        in:=in+1;
        text[in]:=ch;
      end;
    space:   begin
      /** test for redundant blanks **/
      if text[in] ~= ' '
      then begin
        /** put character in output **/
        in:=in+1;
        text[in]:=ch;
      end;
    alpha:   begin
      /** put character in output **/
      in:=in+1;
      text[in]:=ch;
    end;
    else:    begin /** noop ** / end;
    end; /** case **/
  end; /** while out<n **/
end; /** procedure processtext **/
```

Figure 4—Processtext modified by DDPT CANCEL.

to *select* the CANCEL DDPT? If the program contains a "put" followed by a "remove," then there is a chance that the CANCEL transformation is applicable. A database of relationships is maintained for potentially related annotations. The system searches the program, constructing a list of these related elements. For this example, there are several instances of a relationship named R-CANCEL. In the first abstract program above, there are three paths containing the sequence [put; . . . ; remove]. The pair (put, remove) is contained in the database under the relation R-CANCEL. The system collects three instances:

```
R-CANCEL:
{(PUT001,REMOVE001),(PUT001,REMOVE002),
 (PUT001,REMOVE003)}
```

The presence of these related annotations in the program causes the corresponding DDPT, CANCEL, to be selected. Later, these annotations are used to locate the specific instances of these actions in the match input pattern step of the transformation process. The CANCEL replacement fragment constructor procedure analyzes the target program, reorders and eliminates the offending action sequences, and produces an incompletely specified replacement program fragment (as with BPL). The synthesizer fills in those remaining abstract portions producing the program shown in Figure 4.

In addition to automating more of the transformation process, the advantages to having the transformation system aid in the selection part include

1. Elimination of the problem of "pointing" to the places within the program text where the transformation is to be applied—these places are pointed to by the annotations and remembered by the system.
2. The program is manipulated at the semantic level, e.g., manipulate the verbs "put" and "remove," rather than at the syntactic level, e.g., manipulate "text[in]=ch" and "in:=in-1."

#### Other DDPTs

Many program manipulations fall naturally into the design-directed paradigm, because of the ability to analyze the "matched" portion of the program in order to synthesize replacement program fragments—the replacement fragment constructor procedure built into each DDPT can be quite general.

In this section, we list a number of DDPTs of interest. The reader is referred to Reference 9 for more details.

FLAG-MONITOR—Replaces an arbitrary boolean test with an equivalent boolean flag variable which "monitors" the original condition.

DO-EITHER—Generates (synthesizes) "special case" program fragments from a specification of the "general case."

GENERALIZE—Synthesizes "general case" program fragments from a sequence of "special cases."

EXTEND—Data structure extension.<sup>13</sup> (A form of GENERALIZATION.)

## RELATION TO OTHER RESEARCH

As noted earlier, most other transformation systems are syntax-based and two "rule-types" have emerged. One is the production-like syntactic pattern replacement rules shown earlier;<sup>1,8,10,12,13</sup> the other is a system of rules which manipulate recursive programs.<sup>6,7,11,14</sup> The restrictions imposed by these methods have been pointed out in the second section. Mostly the problems center on control and the degree of complexity allowed in transformations.

The major differences between our rules and their syntax-based counterparts rests in the degree of flexibility in specifying the "patterns" associated with the transformation process. Our matching mechanism allows for more general pattern matching; the substitution and replacement mechanism is more computational in nature, and we provide a mechanism for automatic selection based on the program's annotations. The syntactic rules are both useful and necessary in a TI system; we simply extend the type of rules available to the user.

Design-directed transformations extend the work of Biggerstaff and Johnson,<sup>3,4</sup> in which automatic program synthesis is viewed as a process directed by known abstract program designs.

## CONCLUSIONS

The design-directed approach to program transformations is a natural extension to other, more syntactic-oriented approaches. DDPTs are shown to have more general selection, matching and replacement procedures than their syntax-based counterparts. The advantages of this generality are

- Higher degree of automation.
- Each single transformation has a larger scope (it affects a larger target program fragment).
- Transformations are intuitively closer to ones a good programmer would select in transforming his program.
- Reduction in the number of transformation rules at the user level.
- Makes use of system's ability to analyze and reason about programs (e.g., using symbolic evaluation and program synthesis).
- Each transformation applies to a large class of target programs.

We are currently implementing these transformations and several others in LISP on a DEC 2020, at the University of Washington.

## ACKNOWLEDGMENT

The author would like to thank Dr. Ted J. Biggerstaff for his influence, guidance and support in this research. Notable contributions to portions of this work are attributed to his continuing interest. The author is also indebted to Professor David L. Johnson for his continued support and suggestions.

Finally, thanks is due to the referees whose comments greatly improved the content of this paper.

# A data flow evaluation system based on the concept of recursive locality\*

by A. L. DAVIS

University of Utah  
Salt Lake City, Utah

## INTRODUCTION

In an attempt to increase the performance of computing machines, there appears to be two main approaches—(1) to use faster components in existing architectures and (2) to design new architectures which are capable of exploiting some form of concurrency. The first approach is inherently limited in that the effects of reduced integrated circuit geometry, new process technology, and new logic families can be expected to increase overall system performance by only a couple of orders of magnitude. While this is initially impressive, it does not allow the desired machine performance projected to be necessary to solve large physics problems, or needed for accurate weather prediction.<sup>16</sup> The second approach, while being a considerably more difficult organizational problem, is inherently unlimited in nature. There are numerous levels at which concurrency can be exploited in digital computers, i.e. multiple data paths, more concurrent realization of low-level circuit functions, overlap and pipeline processing within a single processing element, multiple processors, etc. In developing any new "fast as possible" machine, it is important to attempt to implement all of the above suggestions. However the work reported here will mainly be concerned with solving the problem of how to utilize and organize systems containing large numbers of independent processors.

In attempting to escape the fundamental performance bounds imposed by von Neumann architectures, it is insufficient to modify only a few aspects of the von Neumann style system ideas. Alternative proposals to the "clock-driven" von Neumann architectures are numerous. There are at least two areas which have some promise. One is the "demand-driven" approach espoused by Friedman and Wise,<sup>10</sup> Backus<sup>3</sup> and Berkling.<sup>5</sup> Another is the "data-driven"

approach taken by Dennis,<sup>8</sup> Bahrs,<sup>4</sup> Davis<sup>6</sup> and Arvind, Gostelow and Plouffe.<sup>2</sup> The work described here is of the data-driven variety due to the feeling that the demand-driven approach does not support intra-process pipelining very well. In addition, the propagation of demands takes time, and while demand-driven programs do allow for increased expressive power, the emphasis here is on performance. The data-driven approach naturally describes both pipelined (vertical) concurrency and independent operation (horizontal) concurrency.

The intent of this paper is to present an overview of the "Utah approach" to data-driven computation. The major emphasis will be on the architectural aspects of an existing machine, DDM1 (Data-Driven Machine #1). Details of the method by which data-flow programs are evaluated on DDM1 will also be discussed. The major differences (and motivations for these differences) between the Utah approach and other published data flow groups will be considered. Part of the material presented here has been published elsewhere in a less general and more detailed form.<sup>6,7</sup> The new topics presented here are principally concerned with automatic resource allocation, and the flow balance during pipelined processing.

It is evident that any machine architecture intended to have a general commercial appeal must be feasible with respect to the changing constraints of integrated circuit technology. For architectures which fit nicely into the VLSI realm, the advantages are numerous. Among these are lower cost, increased reliability, increased speed and decreased power consumption.

The actual machine language of DDM1 is a linearized encoding of a directed graph schema called data-driven nets<sup>6</sup> or DDNs. DDNs are very similar to the data flow nets of Dennis<sup>8</sup> and Rodriguez.<sup>15</sup> The asynchronous nature of DDNs makes it easy to decompose a given net into a set of concurrent subnets, which can then be allocated to independent physical resources. The main distinction between the Dennis nets and DDNs is that in DDNs no distinction is made between the net tokens which are used for control purposes, and other net tokens. All DDN tokens are considered to be data items, and no explicit distinction is made to distinguish between classes of tokens. Another difference is that the primitive DDN cell types are slightly more high-level than

\* The work reported in this paper was supported by Burroughs Corporation. DDM1 is an operational hard-wired data-driven machine, and was completed in July 1976 at the Burroughs Interactive Research Center in La Jolla, California. Many of the early systems ideas were developed in conjunction with Robert S. Barton. Gary Hodgman, Lawrence Rogers, and Karl Boekelheide were instrumental in the conceptualization and implementation of the actual machine. An improved version of DDM1 now resides at the University of Utah, where the project continues under the support of the Burroughs Corporation.

the Dennis nets. Finally, some primitive activities which are explicitly specified in the Dennis schema are implicit in DDNs. An example is the Dennis "link" which serves as both a transmission and copy site. The functions of such links are implicitly incorporated into the output mechanism of DDN operators. The result is that both the DDN and Dennis schemas share the same properties with respect to ease of program verification, ease of program conceptualization and ease of machine evaluation. Due to slightly higher-level primitives and a less explicit schema, a DDN program graph will typically have less vertices (cells) and arcs (data paths) than a functionally equivalent net in the Dennis schema. This difference is mostly one of style and is not particularly significant, although the differences are reflected in the respective architectures.

The only sequencing constraint in DDNs is that of data dependence, and since no weaker sequencing constraint exists without doing non-productive computation,<sup>14</sup> DDNs are naturally a maximally concurrent representation of a given algorithm. While such concurrency may add to the "naturalness" of the programming experience, it is operationally useless as a speed-up mechanism unless it can be mapped onto a set of physical resources capable of exploiting this concurrency. If this mapping is done at run-time, then the time to map must not overshadow the speed-up attained as a result of the concurrent execution. The attitude about how and when this mapping gets done marks a major difference in the Utah approach and that of other data-driven computation projects.

Lastly, a number of additional goals for the machine structures presented here are felt to be desirable. Namely, it is intended that these machines be general purpose, extensible, reliable, easily programmable, support very high levels of concurrency and also be economical with respect to their performance and existing technology. In particular, this effort is not concerned with one of a kind or special purpose machines. Special purpose machines are perhaps ideal for a given environment, but suffer from inherent limits in their applicability to other problems.

## THE IMPACT OF VLSI

The advantages of high density integrated circuit technology are so overwhelming that the constraints of VLSI must be considered as a primary force on future architectures, the global influences of which are summarized here. Due to the tremendous commercial emphasis on MOS VLSI, the following discussion will mainly be concerned with the properties of MOS device integration.

The most highly publicized VLSI benefits are those involving cost. A single custom VLSI chip (64-pin package) currently costs about \$80,000 to \$300,000 to produce. Even then, production typically must be guaranteed for about a quarter of a million parts at an additional cost of \$7 to \$10 per part. This clearly indicates that VLSI cost advantages can be obtained only if any given chip can be used in very large volumes. If a part does not have universal appeal, then

the use of such a part in a new architecture brings about some high-pressure constraints. Either the part must be used a large number of times in a single system, or a single system must have a very high sales volume, or some combination of the two. The number of part types in a given system is also a major concern in that it becomes a multiplicative factor in the system development cost.

Another factor heavily influenced by a VLSI implementation is speed. The dominant speed factor is due to the capacitive effects on a given transmission path. Typical off chip loads are on the order of 100 picofarads, while on chip loads are approximately one picofarad. Since delay times are proportional to the capacitive load (for constant drive current), this implies that signals which can remain on the chip will be driven about two orders of magnitude faster than those which must be driven to destinations off the chip. Additional speed-up can be obtained from the decreased geometries of switching elements and conductor path lengths. This is a very strong argument for architectures which attempt to maximize locality of processing. For architectures in which processing and local storage cannot be done at the same locality, massive delays must be incurred as a result. The only way around the slow off chip drive problem is to drive more current off the chip. This requires a series of relatively large output drivers, which are extremely costly in terms of chip real estate and power consumption. In addition, locality of processing will reduce the amount of contention for a given system transmission path. This contention is important in a highly parallel system in that the resultant sequencing will yield reduced system efficiency.

The number of pins is an important VLSI metric. If chip types are used in sufficient quantities to amortize the initial layout cost, then the physical cost to manufacture a machine becomes approximately linear with pin count. In addition, increasing the number of pins on a particular chip causes decreased yield due to bonding problems. Increased pin count also implies that even more silicon area must be allocated to connection pads and pin drivers.

VLSI implementation also yields the more commonly discussed advantages such as (1) increased system reliability due to reduced part count, (2) decreased system power consumption since voltages on a given chip scale with physical feature size and (3) decreased system maintenance cost as chip replacement policies become more effective in highly integrated systems.

The extent to which these VLSI advantages can be realized is proportional to the logic/pin ratio of the proposed system modules. If the logic/pin ratio is relatively small then the situation is very much that of an SSI machine. If the logic/pin ratio is very high then true VLSI advantages can be obtained. This is a challenge to architects to devise systems which can be modularized into high complexity modules which communicate with their environment infrequently, using relatively few signal paths. Furthermore, as integration technology advances causing feature sizes to shrink even more, these new architectures must remain viable.

## ARCHITECTURAL PRINCIPLES

The VLSI constraints indicate that future architectures to support very high levels of concurrency should consist of a set of processing sites capable of performing localized storage and computation of a reasonable complexity. These sites should be essentially the same physical module, which ideally can be constructed as a single part type. An additional goal of the architecture presented here is that of extensibility. More specifically, the architecture should be extensible without bound in the following way:

1. Machine power should be enhanced by the addition of more modules (i.e. allow greater concurrency due to the increased number of processing sites).
2. The addition of new modules should not require any change to the existing operating system in order to manage the resulting larger system.
3. Additional resources should be added simply by "plugging in new modules" without any special tuning of the existing hardware to create consistent system timing and communication for the expanding system.
4. The extension should be available in small quanta.

The first and last points indicate that a user should be able to purchase only the power needed and not much more or much less. The other points indicate that the manufacturer should need to support only a single module, rather than a large number of system configurations.

Systems such as these cannot be implemented in a synchronous, centrally controlled manner. Central control of arbitrarily extensible systems implies that the control must be able to function on an arbitrarily large amount of state information, which either slows the control drastically or requires controller modification to access the new state information. In an arbitrarily extensible synchronous system the problem of unbounded clock skew (maximum difference in the perceived clock time between any two processing sites in the system) will cause failure. The systems described here will therefore be asynchronous, fully distributed systems. Fully distributed systems are defined here to have the following characteristics: (1) no module of a fully distributed system can determine the total system state, and (2) no module of a fully distributed system can enforce simultaneity in other modules. Holt<sup>13</sup> has shown that the notion of total system state in complex asynchronous systems is counterproductive. Furthermore, the enforcement of simultaneity in physically separate, asynchronous devices is impossible.

There are many ways to organize an extensible set of modules in a distributed control system. The advantages of hierarchical organizations are (1) reduction in the amount of complexity to be dealt with at a given level, (2) verification by inductive methods can be done for uniform hierarchic systems and (3) the superior-inferior relationship can be utilized to resolve problems such as contention and deadlock in multi-resource systems. It will be seen that hierarchy also facilitates a nice resource allocation policy. Recursive hier-

archies are of particular interest in that they imply that the same module can be used at each level.

Recursive systems are nicely extensible. A recursively structured machine is one which has exactly the same structure at every level. Clearly physical recursion must terminate at some point. This point will be seen to be the deepest set of resources in the physical hierarchy. Additional advantages of recursively structured systems have been discussed by Glushkov.<sup>11</sup> It will be shown that the width of a level in these recursive hierarchic structures can be used to execute independent operations, while the depth of the hierarchy will be used to facilitate pipelined operations.

## THE ARCHITECTURE OF DDM1

The architecture consists of a set of asynchronous modules which communicate by passing messages. The basic computational unit of the architecture is a processor-store element (PSE). A PSE consists of a processor module (P) and its associated local storage module (S). Any PSE can execute any machine language program, providing that it has a sufficient amount of local storage. No module that is not a PSE can perform this function. The architecture is a recursively organized set of these PSEs. The recursive definition of the structure is

$$\begin{aligned} \langle PSE_n \rangle &::= \langle P_n \rangle \langle S_n \rangle \\ \langle S_n \rangle &::= \langle ASU_n \rangle \\ \langle P_n \rangle &::= \langle AP_n \rangle \langle AP_n \rangle \langle PSE.GROUP_{n+1} \rangle \\ \langle PSE.GROUP_{n+1} \rangle &::= \langle PSE_{n+1} \rangle \langle PSE_{n+1} \rangle \langle PSE.GROUP_{n+1} \rangle \end{aligned}$$

Subscripts denote the recursive level at which the module physically resides.  $\langle AP \rangle$  is an atomic processor module, which has no further sub-structure (contains no PSEs). Similarly an atomic storage unit  $\langle ASU \rangle$  has no PSE substructure. The width of a  $\langle PSE.GROUP \rangle$  has a physical bound. For DDM1 this bound is eight. The structure is depicted in Figure 1.

This structure allows for a hierarchical distributed storage organization. Any S or ASU may consist of an arbitrary amount of storage of any desired medium. Higher levels of PSEs are considered logically superior to lower-level PSEs. It is advantageous if higher-level stores (ASUs) are slower and larger than the stores of lower levels. The interface and functional ability of any ASU (regardless of size, speed and level) is the same. The structure also allows for an arbitrary number of processors that can be used concurrently. It is important to note that all APs are identical regardless of level. However, the processors at higher levels will be more powerful, in that they contain more PSE substructure than the processors at lower levels. More substructure implies more internal concurrent processing capability.

When viewed non-recursively this structure is simply a tree structure with a single root and a possibility for up to eight sons at any node. Each node of the tree is a PSE and is capable of executing any machine language program. The leaf nodes have no substructure and therefore consist of an

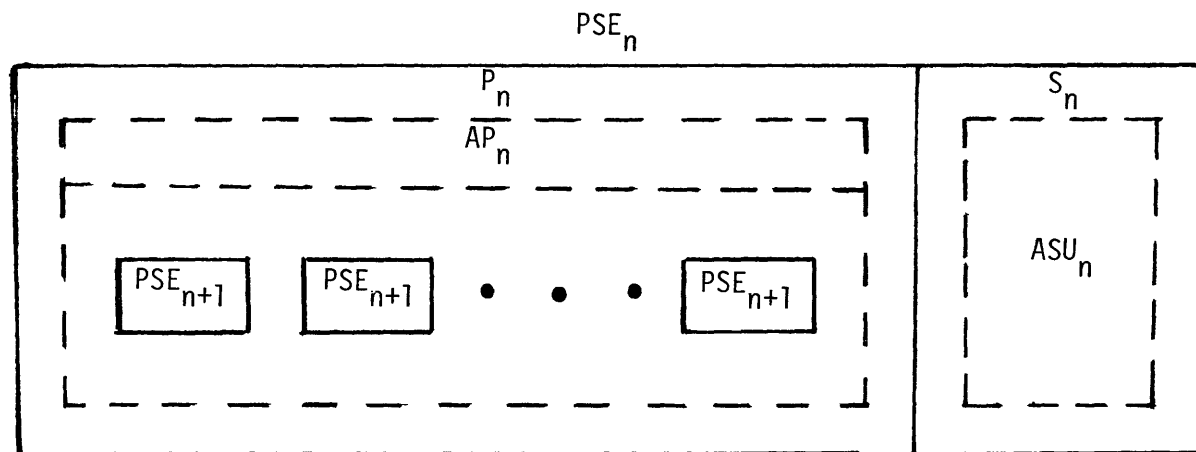

Figure 1—Recursive definition of PSE at level  $n$ .

AP and an ASU. At each node the fan-out is fixed but the depth of the tree is arbitrary. In this manner the architecture allows any desired number of PSEs to be configured for a given machine. The desired goal is for machine performance to improve with the addition of more PSEs.

There are a number of ways to enforce this logical tree structure onto a collection of PSEs. All involve some form of a connection network to implement the desired communication paths. A number of general interconnect networks have been considered—busses, crossbars, Banyan nets<sup>12</sup> and permutation networks.<sup>17</sup> For tree-like machines, full connectivity is not required. The expense of crossbar switches vary as the square of the connected elements. Bus conflict could drastically reduce actual parallelism in the machine. Permutation networks present a tremendous problem in that they may need to be totally reconfigured when a single new connection is necessary. This is difficult to do reliably in a multi-path distributed control environment. Banyan networks have some merit, but do not easily allow for the desired hierarchic pipelined communication. Therefore, in DDM1 a simple one-to-eight-switch was chosen as the interface unit between successive levels of PSEs. The result is that the physical and logical recursive structures are the same. The structure is fixed and cannot be dynamically changed.

Information is passed between PSEs as messages which are variable length character strings. Upward traveling messages are passed on by the switch in an arbiter-like manner. Downward going messages contain header fields which indicate their destination. This header is deleted by the switch as the message is passed. Downward and upward messages are dealt with by independent hardware, and therefore are controlled concurrently. This character serial nature of the machine has the following advantages:

1. Hardware modules are made simpler and more applicable for VLSI implementation due to the reduced pin count.
2. Hardware communication paths are more general in that variable length information units can be transmit-

ted as varying numbers of fixed-width base characters. This facilitates a hardware substitution strategy for modules. Each module can interpret the variable length message and perform the indicated function.

These advantages aid in greatly reducing the cost of the hardware modules. Some low-level performance is lost by doing everything serially. The philosophy is to regain that lost performance many times over by providing a systems organization that allows for highly concurrent levels of activity.

Physical queues are placed between levels of PSEs in order to facilitate pipelining and increase physical module independence. Without queues, the sender of a message would need to wait on receiver availability. If a queue becomes full, only then must the sender wait until the receiver has freed up some queue space. If queue sizes are adjusted so that a sender is rarely required to wait for space, then the system would be well tuned for efficient processing. Optimal queue size depends on the average message length. It is therefore impossible to guarantee that no waiting will occur. Strict hierarchical control and a restricted process structure insures that the system does not deadlock. A block diagram of the PSE structure is shown in Figure 2. All DDM1 paths, except for the path between the ASU and the AP, consist of six wires (a two-wire request-acknowledge control link and a character-width data bus; in the DDM1 prototype four-bit characters are used).

The variable length, character serial message structure and DDN representation indicate that the ASU should be a highly flexible storage structure. Further requirements are that the ASU deal with pipelining of data items and their continual destruction upon cell firings. In order to increase efficiency of the PSE, all storage management functions are performed internally by the ASU. The ASU appears as a variable field length file system, which directly executes commands, such as initialize, skip, insert, read, write, delete and index. The free space is managed automatically by the ASU.

This PSE structure allows for a high degree of processing

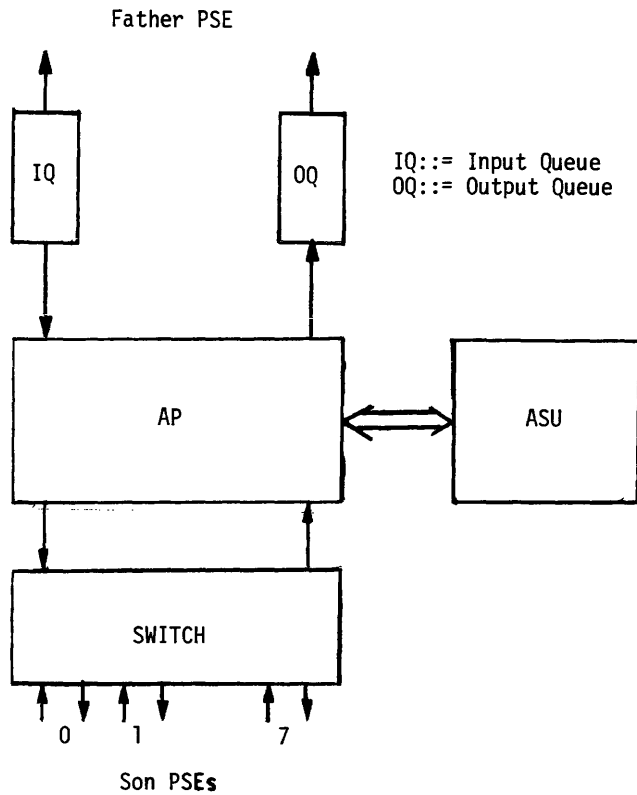

Figure 2—PSE structure.

locality in that any PSE can execute any DDN program (assuming that there is sufficient storage in its local ASU). In addition, the PSE admits nicely to VLSI implementation. The one-to-eight-switch can be implemented using a set of one to two switches of similar function. Using 1:2 switches, DDM1 module complexities (pin and gate count) are shown in Figure 3. The pin counts include pins for power, ground, initialization and extension. The indicated module pin counts are rounded up to coincide with standard package sizes.

These complexities are all within reason for current VLSI designs, and are attractive with respect to the logic/pin ratio. Approximately 30% of the AP and ASU gates are used in statistics and maintenance circuits.

**AUTOMATIC RESOURCE ALLOCATION AND EVALUATION**

When a message corresponding to a DDN program enters a PSE at any level, the PSE may take one of two actions:

1. *Decomposition and allocation*—If the PSE has substructure and if there exists some set of concurrent subnets in the DDN process, then the PSE may split the DDN and send concurrent subnets to PSEs at the next lower level.
2. *Execution*—If the PSE has no subresources, or if there is no exploitable concurrency in the DDN, then the PSE executes the DDN at that level.

To aid the decomposition process, a structural descriptor may precede the incoming DDN in the message structure. This additional storage can greatly reduce time required for decomposition decisions in the PSE. In addition, each PSE must contain information about the number of available PSEs and the sizes of their respective stores. Problems would result if a DDN were sent to a PSE that was too large to fit in its local store. Only the local store sizes of immediate subresources are known. This ensures the recursive nature of the decomposition process.

The decomposition process takes some time. It is important that the speed-up gained by the extra concurrency resulting from decomposition is not overshadowed by the time to decompose. Experiments have indicated that a "first fit" decomposition is almost always better than a "best fit" decomposition strategy. It also appears not to be generally worthwhile to decompose the DDN structure completely on this architecture. At fine granularities, the slowdown resulting from loss of locality is not regained by the concurrent execution of very small subtasks. The exception to this rule is in the case of pipelining, where subtasks remain allocated for relatively long periods of time and sustain high activity at each site.

If decomposition and resource allocation occur at run-time, it is important that they be simplified as much as possible. It is possible to perform these tasks completely at compile-time. This however is inadvisable since it depends on knowing the run-time availability of PSEs in the system. In a system containing large numbers of PSEs, the probability is high that some PSEs will fail or be busy doing other things. In addition, large portions of a process may only be evaluated conditionally. A compile-time allocation would have to allocate tasks which may never be executed. The strategy is taken here to split the decomposition task into two phases—(1) at compile time do all of the resource and condition independent work and (2) at run-time, dynamically make the actual allocation of executable tasks to available physical resources.

DDNs are quite randomly structured graphs and DDM1 is a very regularly structured set of resources. Direct run-time allocation would be too slow, due to the structural disparity between program and machine. At compile-time, the two-terminal DDN process structure is transformed into a well structured and functionally equivalent series parallel graph (SP-graph). Two-terminal means that the graph contains a single "first" cell and a single "last" cell. This

Module	Gate Count	Pin Count
IQ, OQ (1K Characters)	3,000	16
Ap	20,000	64
ASU (4K Characters)	47,000	64
1:2 Switch	2,000	40
Ap + ASU	67,000	64
Ap + ASU + IQ + OQ	73,000	64
Ap + ASU + Switch	69,000	64
PSE	75,000	64

Figure 3—PSE module complexities.

facilitates the determination of net termination and initiation. SP-graphs are acyclic, two-terminal, directed graph structures which can be formed by successively combining cells and/or SP-graphs in series or in parallel. The SP-graph structures are then allocated as necessary at run-time. Data flow graphs in general admit nicely to arbitrary restructuring due to their asynchronous and local control characteristics.

A detailed description of the compiler algorithms to convert a DDN to a functionally equivalent SP-graph is too lengthy to be presented here. An English description of the process is given, describing the nature of the algorithms. The first steps are:

1. Encapsulate all cycles at the outermost level into single cells. The result is a two-terminal acyclic graph at the outermost level. This can be done since DDNs are required to have well nested cycles.
2. Remove all transitive paths. That is if there exists a path from  $A$  to  $B$ ,  $B$  to  $C$ , and  $A$  to  $C$ , remove the  $A$  to  $C$  path and cause it to pass from  $A$  through  $B$  to  $C$ . This requires the semantics of cell  $B$  to be modified slightly. The original inputs are treated the same, while the new inputs are merely passed on unmodified when the cell fires. These new inputs are known as the pass set and may be attached to any cell as a result of this phase of compilation. At this point the graph is a lattice.

For a lattice to be transformed into a functionally equivalent SP-graph, some degree of freedom must be given. There are two meaningful freedoms investigated so far—work and time. If time is free to be changed, then work remains fixed and the resulting graph is called the least-work SP-graph. Conversely, if work is the degree of freedom, then the result is a least-time SP-graph. "Least" is not used in any formal sense but only to indicate that the resultant work or time is equivalent to the original lattice net. Work is defined to be the number of cells which must fire to cause the net to terminate. It will be seen that some additional synchronization cells will need to be executed to enforce the SP topology in the least-work nets. Time is defined to be the critical path length from the first to the last cell at the outermost level (inner levels being those which were encapsulated in Step 1).

For the least-work transformation:

1. Number of paths from the first to the last cell.
2. Make a cut across all paths of equal number.
3. Place a synch cell across all cuts which are not already SP. Non-SP cuts are those which have (1) a set of sender nodes  $S=\{s, \dots, sn\}$  and a set of receiver nodes  $R=\{r, \dots, rm\}$  such that  $n>1$  and  $m>1$  and (2) there exists a pair of sender cells  $si, sj$  and a pair of receiver nodes  $ra, rb$  such that there are at least three connection paths between  $\{si, sj\}$  and  $\{ra, rb\}$ . The result at this point is a least-work SP-graph.

For the least time net, an SP-graph is built from sender-

receiver relationships in the lattice graph as follows:

1. Clear the TODO and SENDER lists.
2. Place the last cell in the TODO list and in the LTSPGRAPH list.
3. Place all cells (which send messages to cells in the TODO list) into the SENDER and LTSPGRAPH lists.
4. For every cell in the SENDER list which is the only sender to the set of cells  $\{ril, \dots, rik\}=Ri$  in the TODO list, and where  $si$  sends to no cell outside of  $Ri$ , build links in the LTSPGRAPH list from  $si$  to  $ril, \dots, rik$ .
5. Delete  $\{ril, \dots, rik\}$  from TODO list and  $si$  from SENDER list.
6. For all remaining cells  $sj$  in the SENDER list, add  $n-1$  copies of  $sj$  to the LTSPGRAPH list, where  $n$  is the number of output paths of cell  $sj$ . Build links in LTSPGRAPH from senders  $sj$  to the receivers  $sj$  such that each copy of  $sj$  has only one outpath. (This step performs the typical node splitting operation which is done in finite state machine reduction. The idea is to duplicate work in order to regularize the structure in a least-time fashion.)
7. Clear the SENDER and TODO lists. Place the  $T$  list cells into the TODO list. Clear the  $T$  list.
8. Repeat the process starting at Step 2 until all cells in the original lattice graph have been processed. The resulting LTSPGRAPH list is the desired least-time net.

Examples of the lattice to least-time and least-work SP-graphs are shown in Figure 4.

It is interesting to note that the algebraic SP expressions in Figure 4 can be (1) shown to be functionally equivalent and (2) transformed from one form to the other, using techniques similar to algebraic factorization and distribution (of the series and parallel relations). In DDM1 the decision to produce the least-time or least-work SP-graph is made at compile-time by the user. It would be nice to make this decision at run-time based on resource cost and availability. This, however, would increase the run-time overhead to a level which is currently felt to be excessive. The previous procedures are applied recursively to the levels defined by loop encapsulation, and are performed down to the desired granularity.

The allocation of SP-graphs onto tree-structured physical resources is an easy task. If the SP-graph of Figure 5 is folded back onto itself about the middle, the result is a tree-structured SP-graph. The SP-graph, its folding, and the allocation onto a tree of physical resources are all shown in Figure 5.

In this way full upward and downward communication can be carried on concurrently to achieve pipelining. Horizontal parallelism can be achieved by spreading independent subtasks across a given level of the architecture. Resource allocation is performed automatically by the hardware in DDM1 to achieve very high degrees of parallelism. The amount of obtainable concurrency is a function of available hardware resources and the program structure.

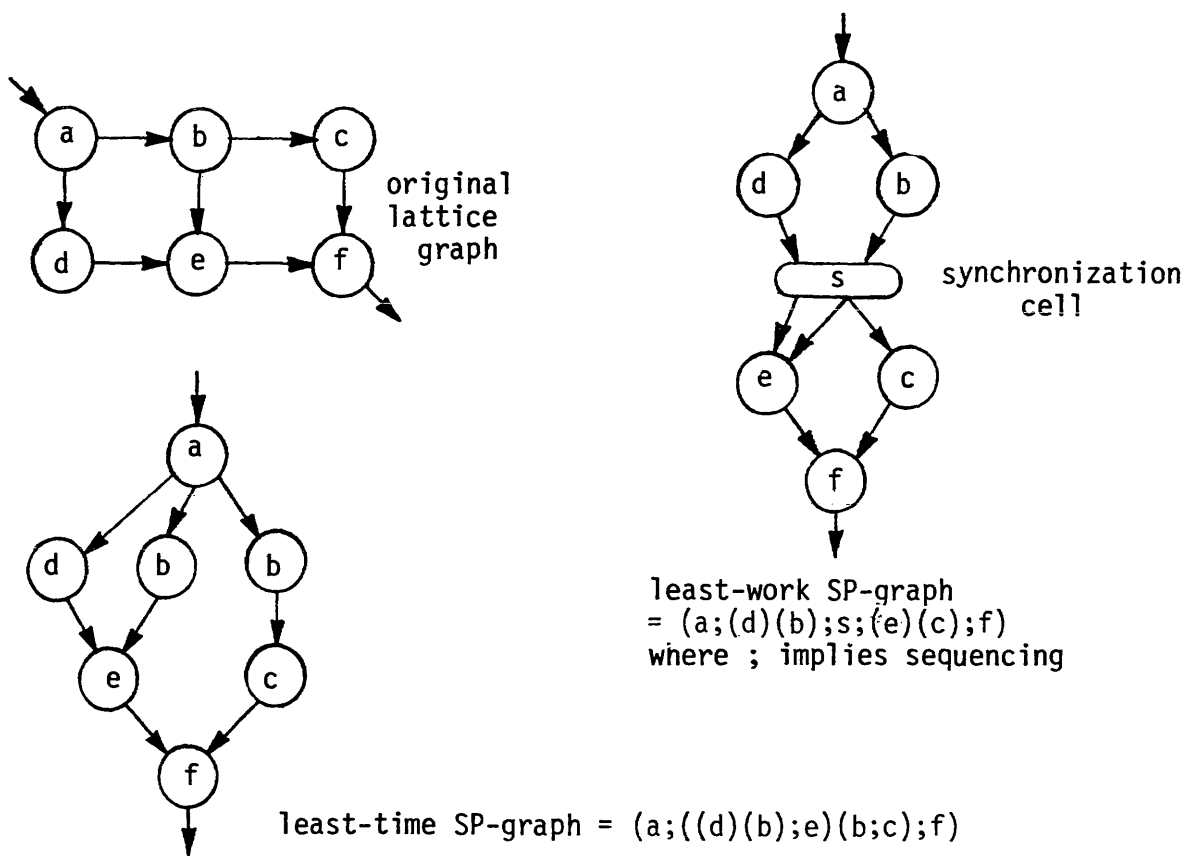

Figure 4—Lattice to least-time and least-work SP-graphs.

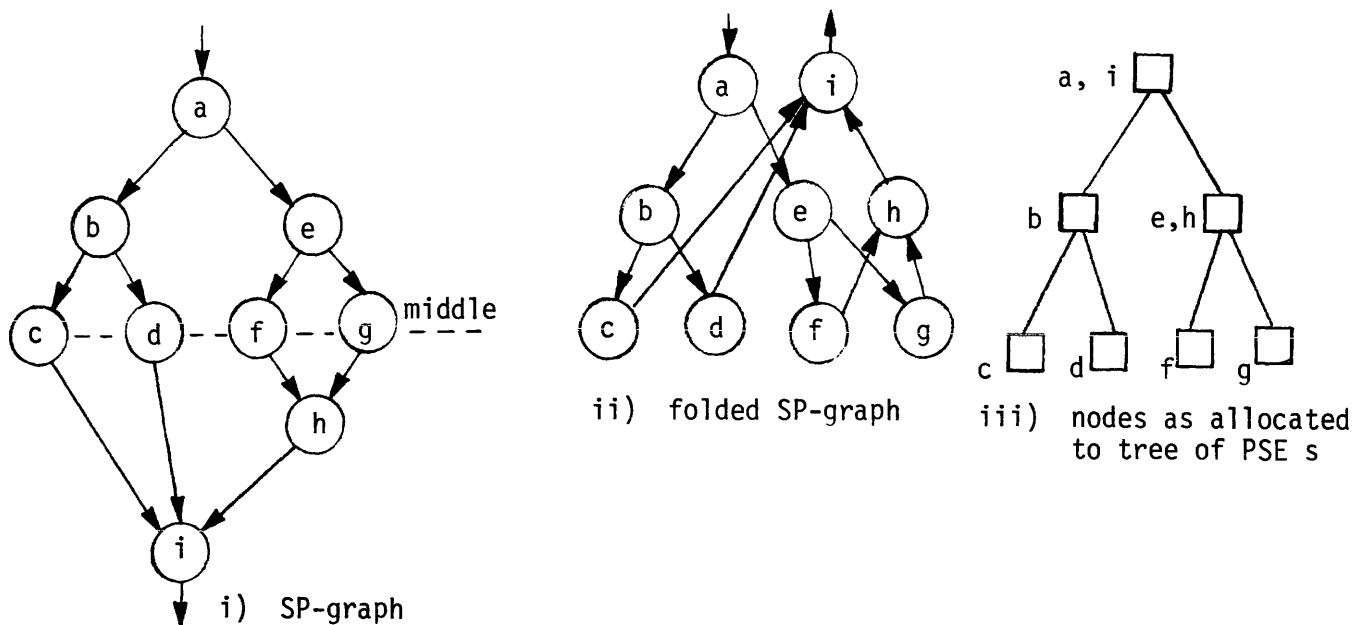

Figure 5—The allocation of SP-graph programs onto a PSE tree.

## CONCLUSIONS

An architecture and evaluation scheme for data-flow programs has been presented. The architecture exploits recursive hierarchy to reduce complexity and allows for the arbitrary expansion of system resources. Physical resources are organized such that they can be used to exploit both pipelined and independent tasks. The system exploits the notion of locality that is important for both increased speed and decreased cost aspects of a VLSI implementation. This notion of locality also indicates that this system is not intended to exploit concurrency at the lowest possible level. It is felt that the additional overhead involved to do this would actually reduce overall performance levels.

Current status of the project is that DDM1 is operational and executes DDN programs. DDM1 communicates with a DEC-20/40, which is used to support conventional software tools such as compilers, simulators, and measurement programs. The current programming language is a statement description of a DDN. An interactive graphical programming language is in the works (in both a high-level and a low-level form). A simulator is being written on the DEC-20 which will manage any specified tree of resources (virtual) and use the DDM1 for actual evaluation. A number of large application programs are being written for DDM1. Detailed statistics will be taken during the execution of these programs to aid in formal evaluation of the DDM1 hardware.

The main points of departure of the "Utah" approach and that of Dennis<sup>9</sup> is the use of a recursive hierarchy of physical resources, the exploitation of physical locality to decrease message frequency and increase the speed of VLSI implementations, dynamic hierarchical resource allocation, the lack of specialized functional modules to reduce the chip type count and a slight difference in the structure of the low-level schema. The architecture of DDM1 differs from that of Arvind and Gostelow<sup>1</sup> in that it does not try to achieve concurrency at all possible levels (because of the locality issue), the interconnection scheme is much simpler and no bus contention is possible, no special address space management needs to be done, allocated tasks may consist of many cells rather than just a single operation, and tasks are allocated only when all of their necessary input operands are present.

The disadvantages of the system described here are:

1. The current ASU design is not nicely extensible to allow more storage capacity to just be "plugged in."
2. The fixed, hard-wire tree structure is not flexible and results in certain PSEs in one subtree remaining idle when another heavily loaded subtree badly needs more resources.

3. There is currently not enough empirical data from test runs on very large programs to accurately quantify the overhead involved in decomposition.
4. Failure of a PSE will cause the entire subtree below the failure to become unusable. In general, the issues of fault tolerance have not been properly attended to.
5. Certain "perverse" SP-graph topologies can not be allocated such that full pipelining can be supported.

# Data flow languages

by WILLIAM B. ACKERMAN

Massachusetts Institute of Technology  
Cambridge, Massachusetts

## INTRODUCTION

There are several computer system architectures which have the goal of exploiting parallelism—multiprocessors, vector machines and array processors. For each of these architectures there have been attempts to design compilers to optimize programs written in conventional languages (e.g. “vectorizing” compilers for the FORTRAN language). There have also been new language designs to facilitate using these systems, such as Concurrent PASCAL for multiprocessors,<sup>6</sup> and languages that utilize the features of such systems directly, such as GLYPNIR for the Illiac IV array processor<sup>19</sup> and various “vectorizing” dialects of FORTRAN. These languages almost always make the multiprocessor, vector, or array properties of the computer visible to the programmer—that is, they are actually vehicles whereby the programmer helps the compiler uncover parallelism. Many of these languages or dialects are “unnatural” in that they closely reflect the behavior of the system for which they were designed, rather than reflecting the way programmers think about problem solutions.

Data flow computers also have the goal of taking advantage of parallelism. As will be seen below, the parallelism in a data flow computer is both microscopic (much more so than in a multiprocessor) and all-encompassing (much more so than in a vector processor). Like the other forms of parallel computer, data flow computers are best programmed in special languages. In fact, their need for such languages is stronger—most data flow designs would be extremely inefficient if programmed in conventional languages such as FORTRAN or PL/I. However, languages suitable for data flow computers can be very elegant. The language properties that a data flow computer requires are beneficial in their own right, and are very similar to some of the properties that are known to facilitate understandable and maintainable software, such as the absence of undisciplined control structures and module interactions. In fact, languages having many of these properties have been in existence since long before data flow computers were conceived. The principal property of a language suitable for data flow is *freedom from side effects*, which will be described below. The (pure) LISP language<sup>20</sup> is the best known example of a language without side effects. The connection between freedom from side effects and efficient parallel computation has been known for over ten years.<sup>25</sup>

To see why data flow computers require languages free of side effects, we must examine the nature of data flow computation and the nature of side-effects. A detailed description of the mechanism of data flow computers is beyond the scope of this paper. The interested reader is referred to References 2, 12, 15, 21, 22, 23.

There are three “data flow” languages that will be discussed in this paper. VAL<sup>1</sup> and ID<sup>3</sup> were developed by the data flow projects at the Massachusetts Institute of Technology and the University of California at Irvine, respectively. LUCID<sup>4</sup> was developed for program verification, not for programming data flow computers. It nevertheless is a suitable language for data flow computation.

Let us begin by examining a simple sequence of assignment statements written in a conventional programming language such as FORTRAN:

```
1 P=X+Y
2 Q=P/Y
3 R=X*P
4 S=R-Q
5 T=R*P
6 RESULT=S/T
```

A straightforward analysis of this program will show that many of these instructions can be executed concurrently, as long as certain constraints are met. These constraints can be represented by a graph (see Figure 1) in which nodes represent instructions and an arrow from one instruction to another means that the second may not be executed until the first has completed. So the permissible computation sequences include, among others:

```
(1,3,5,2,4,6)
(1,2,3,5,4,6)
(1, [2 and 3 simultaneously], [4 and 5 simultaneously], 6)
```

This type of analysis (commonly called data flow analysis, a term which long predates data flow computers) is frequently performed in two situations—at run-time in the arithmetic processing units of high performance conventional computers such as the IBM 360/91, and at compile time in optimizing compilers. In optimizing compilers, data

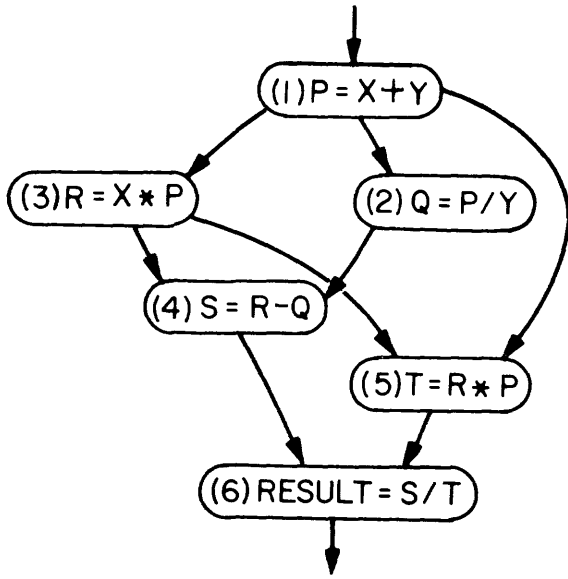

Figure 1

flow analysis yields improved utilization of temporary memory locations. For example, on a computer with high-speed general purpose or floating point registers, this program can be compiled to use the registers instead of core memory for P, Q, R, S and T, if it can be determined that they will not be used again. (This determination is very difficult, principally because of GO TOs, which is one of the reasons why it is very difficult to write optimizing compilers for languages such as FORTRAN.)

In the graph representation, an instruction can be executed as soon as all the instructions with arrows pointing into it have completed. On a multiprocessor system, we could allocate a processor for each instruction, with appropriate instructions (such as semaphore operations<sup>13</sup>) to enforce the sequencing constraints, but execution would be hopelessly inefficient because the parallelism of this example is far too "fine grained" for a multiprocessor. The overhead in the process scheduling and in the *wait* and *signal* instructions would be many times greater than the execution time of the arithmetic operations. A data flow computer, on the other hand, is designed to execute algorithms with such a fine grain of parallelism efficiently. In these machines, parallelism is exploited at the level of individual instructions, as in the previous example, and at all coarser levels as well; in most programs there are typically many parts, often far removed from each other, at which computation may proceed simultaneously.

To exploit parallelism at all levels, the instruction sequencing constraints must be deducible from the program itself. Let us refer again to the previous program to see how this may be done.

The sequencing constraints in Figure 1 are given by arrows. It is not difficult to see that these arrows coincide with data transmission from one instruction to its successor through variables. In fact, the graph could be redrawn with the arrows labeled by the variables that they represent, as in Figure 2.

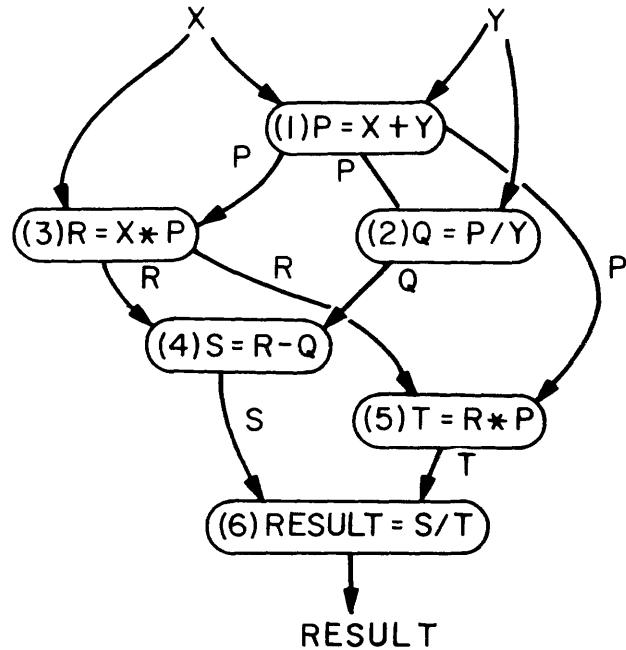

Figure 2

In a data flow computer, the machine level program is represented essentially in this form—a graph with pointers between nodes, the pointers representing both the flow of data and the sequencing constraints. Each instruction is kept in a hardware device (an extremely simple "processor") that is capable of "firing" or executing an instruction when all of the necessary data values have arrived, and sending the result to the processors that hold destination instructions.\*

The programming language for a data flow computer must therefore satisfy two criteria:

1. It must be possible to deduce the data dependencies of the program operations.
2. The sequencing constraints must always be exactly the same as the data dependencies, so that the instruction firing rule can be based simply on the availability of data.\*\*

There are two general properties of a language which make it possible to meet these criteria: locality of effect and freedom from side effects.

\* Although the language concepts presented in this paper assume that the computer exploits parallelism at a microscopic level, not all "data flow" or "data driven" computers do so. Designs of data flow computers that exploit parallelism only at the subroutine level may be found in References 10 and 24.

\*\* Not all designs for data flow computers accept the second of these criteria or its consequences. The LAU language<sup>9</sup> is intended for execution on a data flow computer, but it was designed to support data base updating and retrieval, so it has side effects on certain operations. The sequencing of these operations must therefore be constrained by means other than data dependencies, and so it does not satisfy the second criterion. The extra constraints in LAU are specified by path expressions<sup>7</sup> written into the source program.

## LOCALITY OF EFFECT

Locality of effect means that instructions do not have unnecessary far-reaching data dependencies. For example, the FORTRAN program fragment given previously appears to use variables P, Q, R, S and T only as temporaries. A similar program fragment appearing elsewhere in the program might use the same temporaries for some unrelated computation. The logic of the program might be such that the two fragments could be executed concurrently were it not for this overuse of names. (Unfortunately, many conventional languages encourage this style of programming.) Any attempt to execute the program fragments concurrently would be impossible because of the apparent data dependencies arising from overuse of these temporaries, unless the compiler can deduce that the conflict is not real and remove it by using different sets of temporaries.

In languages such as FORTRAN and PL/I, this is not so easy to determine. A reference to a variable in one part of the program does not necessarily imply dependence on the value computed in another part—the variable might be overwritten before it is next read. Careful analysis is required to determine whether a variable is actually transmitting data or is “dead.” This analysis is made much more difficult if unrestricted GO TOs or other undisciplined control structures are allowed.

The problem can be simplified by making every variable have a definite “scope,” or region of the program in which it is active, and carefully restricting the entry to and exit from the blocks that constitute scopes. It is also helpful to deny procedures access to any data items that are not transmitted as arguments, though this is not really necessary if global variables are avoided and procedure definitions are carefully “block structured” as in PASCAL.

## SIDE EFFECTS

Freedom from side effects is a necessary property to ensure that the data dependencies are the same as the sequencing constraints. It is much more difficult to achieve than locality of effect. This is because locality only requires superficial restrictions on the language, whereas freedom from side effects requires fundamental changes in the way the language’s “virtual machine” processes data.

Side effects come in many forms—the most well known examples are procedures that modify variables in the calling program, as in the following PASCAL example:

```
procedure GETRS(X, Y:real); (* RS is declared in
begin RS:=X*X+Y*Y          an outer block *)
end;
```

Absence of global or “common” variables and careful control of the scopes of variables make it possible for a compiler to prohibit this sort of thing, but a data flow computer imposes much stricter prohibitions against side effects—a procedure may not even modify its own arguments. In fact, in a sense nothing may ever be modified at all.

To determine what kind of prohibitions against side effects are needed to achieve concurrent computation, we must examine programs that manipulate structured data such as arrays or records, since the problem does not arise when only simple data values are used.

Consider the following procedure which modifies its arguments by a conventional “call by reference” mechanism. SORT2 is a procedure to sort two elements, J and J+1, of array A into ascending order by exchanging them if necessary.

```
procedure SORT2(var A:array[1..10] of real;
J:integer);
var T:real;
begin if A[J]>A[J+1] then begin
T:=A[J];
A[J]:=A[J+1];
A[J+1]:=T;
end
```

end;

- (1) SORT2(AA, J);
- (2) SORT2(AA, K);
- (3) P:=AA[L];

Statements 1 and 2 might interfere with each other and with Statement 3. Since the values of J, K, and L are not known to the compiler, it must assume that the statements will conflict, and execute them in the exact order specified. Any attempt at parallel execution might result in the incorrect results, depending on J, K, L, and unpredictable fluctuations in timing.

A phenomenon known as “aliasing” makes the problem even more difficult. This occurs when different formal parameters to a procedure refer to the same actual parameter, that is, they are “aliases” of each other:

```
procedure SORTREAD(var A, B:array[1..10] of real;
I, J:integer);
begin SORT2(A, I); (* SORT2 is defined above *)
RESULT:=B[J];
end;
```

In this program it would appear that, since A and B are different arrays, the invocation of SORT2 and the reference to B[J] could proceed concurrently. However, if this were part of a larger program and SORTREAD were invoked in the statement

```
SORTREAD(Q,Q,M,N);
```

the arrays A and B would actually be the same. Languages such as FORTRAN and PL/I, in which external procedures are not available to the compiler when the calling program is being compiled, make the problem harder still. Facilities for manipulating data structures by pointers, such as the “pointer” data type in PL/I and the record manipulating operations of PASCAL make it possible for all of these problems to arise without using procedures.

Even if procedures and pointers are not used, the sequencing constraints may be far from clear, as in

- (1) A[J]:=3;
- (2) X:=A[K];

If the convention is made that any statement modifying any element of an array constitutes a "writing" of the array, then Statement 1 clearly passes array A to Statement 2. But then a statement such as the assignment in

```
for J:=1 to 10 do
  A[J+1]:=A[J]+1;
```

depends on itself!

The inescapable conclusion is that, if arrays and records exist as global objects in a memory and are manipulated by statements and passed as procedure parameters, it is virtually impossible to tell, when an array element is modified, what effects that modification may have elsewhere in the program.

One way to solve some of these problems is to use "call by value" instead of the more common "call by reference." This solves the aliasing problem and the problem of procedures modifying their arguments. In a "call by value" scheme, a procedure copies its arguments (even if they are arrays). This way it can never modify the actual argument in the calling program. Call by reference has traditionally been used instead of call by value because it is a more natural way of thinking about computation (and is more efficient) on von Neumann computers.

APPLICATIVE LANGUAGES

For data flow languages, a scheme is used which goes far beyond call by value: all arrays are *values* rather than *objects*, and are treated as such at all times, not just when being passed as procedure arguments. Arrays are not modified by subscripted assignment statements such as

```
A[J]:=S;
```

Instead, they are processed by *operators* which create new array values. The simplest operator to perform the nearest equivalent of modifying an array takes three arguments—an array, an index, and a new data value. The result of the operation is a new array, containing the given data value at

```
function SORT2(A, J)
  if A[J]<A[J+1] then A
    else (A[J:A[J+1]])[J+1:A[J]]
  end
end
% No temporary needed during this
% exchange because A is not modified.
```

Note that the array construction operator may be composed with itself and with other operators in the same way as arithmetic operators.

Figure 3

the given index, and the same data as the original array at all other indices.

In the VAL language,<sup>1</sup> the syntax for this elementary operator is

```
A[J: S]
```

In the ID language,<sup>3</sup> it is

```
A+[J]S
```

This operation *does not modify* its argument. Hence, in this VAL program:

- (1) B:=A[J:S];
- (2) C:=A[K:T];
- (3) P:=A[L];
- (4) Q:=B[M];
- (5) R:=C[N];

Statements 1 and 2 do not interfere with each other or with array A. Statement 3 may be executed immediately, whether 1 and/or 2 have completed or not, since they would have no effect on Statement 3 anyway. Statement 4 can be executed as soon as Statement 1 completes, whether Statement 2 has completed or not. The sequencing constraints are shown in Figure 3.

Note that this situation is similar to the one in the simple FORTRAN example of the first section. The sequencing constraints are exactly the same as the data dependencies, which is the property we seek for data flow.

An operator-based handling of arrays and records automatically accomplishes call by value. As in a call by value scheme, a routine such as SORT2 would not accomplish its purpose. SORT2 must return the new array as its value. It could be written in VAL (omitting type declarations) as:

In conventional languages, procedures do most, if not all, of their work through side effects—a procedure might be designed to alter dozens of variables in the calling program.

Functions, on the other hand, are typically limited to returning a single value, which typically may not be an array or record. To make functions as powerful and flexible as procedures in conventional languages, applicative languages often allow functions to return several values, or entire records or arrays, or both. If a function returns several values, its call can be used in a "multiple assignment" such as

```
X,Y,Z:=FUNC(P,Q,R) % FUNC returns 3 values
```

Treating arrays and records as values instead of objects is perhaps the most profound difference in the way people must think when writing programs in data flow languages instead of conventional languages. The customary view is of arrays as objects residing in static locations of memory, and being manipulated by statements that are executed in some sequence. As we have seen, this view is incompatible with detection of parallelism among the statements. The correct view for data flow is of arrays and records as values manipulated by operations just as simple values (integers, reals) are. Then the parallelism among the operators can be deduced from the data dependencies just as for simple values.

The value-oriented approach to arrays is confusing to some at first, but it need not be. An integer array should be thought of as a string of integers, just as an integer can be thought of as a string of digits. If J has the value 31416, the statement

```
K:=J-400;
```

leaves K equal to 31016; no programmer would expect the value of J to be affected. If A is an array with elements [3,1,4,1,6], the statement

```
B:=A[3:0];
```

is completely analogous; it leaves B with elements [3,1,0,1,6] and of course does not change A.

Languages which do all processing by means of operators applied to values are called *applicative* languages, and are thus the natural languages for data flow computation. The earliest well known applicative language implemented on a computer is LISP.<sup>20</sup> (It is applicative only if RPLACA, RPLACD, and all other functions with side effects are avoided; this subset of the language is often called "pure" LISP.) The connection between applicative languages and the detection of parallelism has been reported by Tesler and Enea<sup>25</sup> and by Friedman and Wise.<sup>14</sup> The development of LISP and other applicative languages, and the Tesler/Enea paper, all predate the data flow computer concept by several years. The concept of computation by applicative evaluation of expressions goes back to the invention of the lambda calculus in 1941.<sup>8</sup>

## EFFICIENCY CONSIDERATIONS IN APPLICATIVE LANGUAGES

Applicative languages have recently given rise to controversy concerning their time efficiency in practical situations.

It is claimed that many algorithms cannot be executed as efficiently in applicative languages as in conventional statement-oriented languages. The issue is only one of exploiting parallelism, not any fundamental limitation in the computing power of applicative systems. This is because any program written for a conventional von Neumann computer can be rewritten in an applicative language by treating the entire memory space as one array. Statements that manipulate the memory then become operations on that array. The array must be passed from each operation to the next, so execution in such an applicative system must be strictly sequential—no parallelism can be exploited. However, in the original program written in a conventional language, a knowledgeable programmer might be able to explicitly specify parallelism, making the program run more efficiently than in the applicative system.

Consider the conventional program

- (1) A[J]:=S
- (2) A[K]:=T;
- (3) P:=A[M];
- (4) Q:=A[N];

If the programmer knows that the set of indices for the array A can be divided into two disjoint sets, with J and M in one set and K and N in the other, then Statements 1 and 2 could be executed simultaneously, 3 would only need to follow 1, and 4 would only need to follow 2. If the programmer has the ability to control parallelism explicitly (say, by semaphores, monitors, or path expressions), he could specify exactly those constraints. This is not possible in a data flow language without some additional mechanism. However, the problem can often be avoided by dividing the array into separate parts, manipulating them separately, and combining them only when necessary. For example, suppose array A1 contains only those elements that J and M are known to index, and A2 contains those that K and N index. Then

```
B1:=A1[J:S];
B2:=A2[K:T];
P:=B1[M];
Q:=B2[N];
```

exploits the parallelism exactly. There are other ways of overcoming the tendency for arrays to limit parallelism, which will be discussed later. The question of how to exploit parallelism in applicative languages for a wide variety of programming problems is an active area of research.

## DEFINITIONAL LANGUAGES AND THE SINGLE ASSIGNMENT RULE

Having accepted an applicative programming style and a value-oriented rather than object-oriented execution model, we next examine the implications of this style upon the meaning of assignment statements.

Except in iterations, (which will be discussed later), an assignment statement has no effect except to provide a value

and bind that value to the name appearing on its left hand side. The result of the assignment is accessible only in subsequent expressions in which that name appears. If the language uses blocks in which all variables are local to the block for which they are declared, the places where a variable is used can be determined by inspection. If the expression on the right hand side of an assignment is substituted for the variable on the left hand side in all places where that variable appears within its scope, the resultant program will be completely equivalent.

$$\begin{array}{ll} S:=X+Y; & \\ D:=3*S; & \text{is equivalent to } D:=3*(X+Y); \\ E:=S/2+F(S); & E:=(X+Y)/2+F(X+Y); \end{array}$$

(The program on the left is clearly more efficient, requiring only two additions instead of four. We are not proposing that the substitution be made in practice.)

Now this situation is the same as a system of mathematical equations. If a system of equations contains " $S=X+Y$ ", it is clear that " $3*S$ " and " $3*(X+Y)$ " are equivalent. Hence the statement

$$S:=X+Y;$$

means the same thing in the program that the equation " $S=X+Y$ " means in a system of equations, namely that, in the scope of these variables,  $S$  is the sum of  $X$  and  $Y$ . The correspondence can be thought of as holding for all time; it is not necessary to think of the statements as being executed at particular instants. (In fact, perhaps the word "variable" is an inappropriate term.) Of course, the addition of  $X$  and  $Y$  to form  $S$  must take place before any of the operations that use  $S$  can be performed, but the programmer doesn't need to be directly concerned with this.

Hence the statement  $S:=X+Y$  should be thought of as a *definition*, not an assignment. Languages which use this interpretation of assignments are called *definitional languages* as opposed to conventional *imperative languages*. Such languages are well suited to program verification because the assertions one makes in proving correctness are exactly the same as the definitions appearing in the program itself. In conventional languages one must follow the flow of control to determine *where* in the program text assertions such as " $S=X+Y$ " are true, because the variables  $S$ ,  $X$ , and  $Y$  can be changed many times. Assertions must therefore be associated with points in the program.

In a definitional language the situation is extremely simple: If a program block contains the statement

$$S:=X+Y;$$

then the assertion  $S=X+Y$  is true. Of course, care must be taken to prevent circular definitions such as

$$\begin{array}{l} X:=Y; \\ Y:=X+3; \end{array}$$

We can either have the compiler allow definitions to ap-

pear in any order as long as there is some consistent order, or we can require them to appear in a consistent order. A consistent order is one in which no name is referred to (on the right hand side of a definition) before it is defined. This condition is easily checked by a compiler. So the actual proof rule is: If a program block contains the statement

$$S:=X+Y;$$

and the program compiles correctly, then  $S=X+Y$  is true. Strictly speaking, it is only true in the statements after the one defining  $S$ , but, since  $S$  does not appear in any earlier statements, the assertion can be treated as being true throughout the block.

The power of definitional languages for program verification is well known outside of the data flow field. LUCID<sup>4</sup> is an example of an applicative definitional language designed expressly for ease of program verification.

There is a problem that could ruin the elegance of definitional languages—multiple definition of the same name. Definitional languages almost invariably obey the *single assignment rule*: A name may appear on the left hand side of an assignment (definition) only once within its scope. The single assignment rule prevents program constructs which imply mathematical abominations, such as

$$J:=J+1;$$

Since the appearance of  $J$  on the right hand side precedes the definition of  $J$ , it implies an inconsistent statement sequencing that the compiler would diagnose. The prevention of such abominations is of course necessary if the definitions in the program are to be carried directly into assertions used in proving correctness, because the assertion " $J=J+1$ " is absurd.

It is not actually necessary that a data flow language conform to the single assignment rule. A data flow language with multiple assignments could be designed in which the scope of a variable extends only from its definition to the next definition of the same variable. The next definition in effect introduces a new variable that simply happens to have the same name. A program written in such a way can be easily transformed into one obeying the single assignment rule: simply choose a new name for any redefined variable, and change all subsequent references to the new name. However, the advantages of single assignment languages, namely, clarity and ease of verification, generally outweigh the "convenience" of re-using the same name.

## ITERATIONS

There remains one area in which statements such as

$$I:=I-1;$$

or

$$A:=A[J:X+Y];$$

seem to be necessary, explicitly or implicitly, in conven-

tional languages, and that is in iterations. The technique of renaming variables to make a program conform to the single assignment rule only works for straight-line programs: If a statement appears in a loop, renaming its variables will not preserve the programmer's intentions. For example:

```
for I:=1 to 10 do      cannot be      for I:=1 to 10 do
  J:=J+1;              transformed to  J1:=J+1;
```

If the language allows general GO TOs, with the resulting possibility of complex and unstructured loops, the problem is indeed difficult. However, data flow languages generally have no GO TO statement, and require loops to be created only by specific program structures such as the "while. . .do. . ." and similar statements found in PL/I and PASCAL. This makes the problem easy to solve, and makes it possible to give iterations a very simple and straightforward meaning.

To develop the data flow equivalent of a "while. . .do. . ." type of iteration, we must consider what the "do" part of such a structure contains. Since there are no side effects, the only state information in an iteration is the bindings of the loop variables, and the only activity that can take place is the redefinition of those variables through functional operators. An iteration therefore consists of

1. Definitions of the initial values of the loop variables.
2. A predicate to determine whether, for any given values of the loop variables, the loop is to terminate or to cycle again.
3. If it is to terminate, some expression giving the value(s) to be returned. These values typically depend on the current values of the loop variables.
4. If it is to cycle again, some expressions giving the new values to be assigned to the loop variables. These also typically depend on the current values of the loop variables.

An iteration to compute the factorial of N could be written (omitting type declarations) in VAL as follows:

```
for I, J:=N, 1;          % Give loop variables I and
                        % J initial
                        % values N and 1
                        % respectively. I will
                        % count downward. J will
                        % keep
                        % accumulated product.
do if I=0                % Decide whether to
                        % terminate.
  then J                 % Yes, final result is current
                        % J.
  else iter I, J:=I-1, J*I;
                        % No, compute new values
                        % of I and J,
end                       % and cycle again.
```

It could be written in ID as follows:

```
initial I←N; J←1
while I≠0 do
  new I←I-1;
  new J←J*I;
return J
```

Its representation in LUCID is similar to that in ID.

Although the values of the loop variables do change, they change only between one iteration cycle and the next. The single assignment rule, with its prohibition against things like "I=I-1" is still in force within any one cycle. All redefinitions take place precisely at the boundary between iteration cycles (though they need not actually occur simultaneously). This is enforced in VAL by allowing redefinitions only after the word *iter*, which is the command to begin a new iteration cycle. In ID and LUCID, the "new" values become the "current" values at the boundary between cycles.

Since the single assignment rule is obeyed, and names have single values, within any one iteration cycle the mathematical simplicity of assertions about values still exists. The assertions typically take the form

"In any cycle,  $S=X+Y$ "

Assertions used in proving correctness of an iteration are usually proved inductively. Because assertions take such a simple form, such proofs are usually simpler than in conventional languages. For example, the assertion

$I \geq 0$  and  $J*(I!) = N!$

is used to prove correctness of the previous program. The basis of the induction is that it is true for the initial values  $I=N$  and  $J=1$ . (We assume  $N \geq 0$ .) The induction step is that, if another cycle is started with the values  $I-1$  and  $J*I$ , they will obey the assertion, that is,

$I-1 \geq 0$  and  $(J*I)*((I-1)!) = N!$

which is clearly true if we observe that a new cycle will only be started if  $I > 0$  and hence  $I-1 \geq 0$ .

## ERRORS AND EXCEPTIONAL CONDITIONS

Locality of effect requires that errors such as arithmetic overflow be handled by *error values* rather than by program interruptions or manipulation of global status flags. If an error occurs in an operation, that fact must be transmitted to the destinations of that operation and nowhere else. This can be easily accomplished by enlarging the set of values to include error values such as overflow, underflow, or zero-divide.

If the intention is to abort the computation when an error occurs, this can be achieved by making the error values *propagate*—if an argument to an arithmetic operation is an

error, the result is an error. When an error propagates to the end of an iteration body, that iteration always terminates rather than cycling again. In this way the entire computation will come to a stop quickly, yielding an error value as the result. If the computer keeps a record of every error generation and propagation, that record will provide a detailed trace of when and where the error occurred, and what iterations and procedures were active.

If the intention is to correct an error when it occurs (perhaps keeping a list of such errors in some array), that can be accomplished through operations that test for errors. For example, a program to set Z to the quotient of X and Y, or to zero if an error occurs, could be written in VAL as follows:

```
ZZ:=X/Y;
Z:=if is__error(ZZ) then 0 else ZZ end;
```

#### METHODS OF OBTAINING MAXIMUM PARALLELISM

To achieve the greatest parallelism, it is necessary that computations not be performed sequentially unless necessary. The iteration constructs described previously imply a sequential execution of the various cycles. If the values of the iteration variables in one cycle depend on those of the previous cycles (as they do in the factorial example given previously), nothing can be done about it, although a data flow computer can often execute *part* of a cycle before the previous one has completed. If the values in one cycle do *not* depend on those of the previous cycles, the cycles can be performed in parallel. In VAL this is accomplished with a *forall* program construct which does not allow one cycle to depend on the others, and directs the computer to perform all cycles simultaneously. In ID the same effect is achieved automatically by tagging the values of the iteration variables with their cycle number, and allowing them to be processed out of sequence, or simultaneously, whenever they do not depend on each other.

Another potential "bottleneck" in data flow computation is the requirement that all elements of an array be computed before any element of that array may be accessed. If function "F" creates an array value by filling the array one element at a time, and then passes the array to "G," which reads the elements one at a time, G cannot begin until F completes. In many instances this delay is unnecessary, and various techniques have been proposed for eliminating it without departing from the principle that the sequencing constraints are exactly the data dependencies. One method, mentioned in the fifth section, is to explicitly divide the array into pieces, or use separate data items instead of an array. This method is quite general, but it requires specific calculation by the programmer of which parts of the array are needed at which time.

#### Streams

A method of overcoming the array bottleneck is the use of "streams."<sup>2-11,26</sup> A stream may be thought of as an array

that is fragmented in time and is processed one element at a time.

In the previous example of F creating an array one element at a time and passing it to G, a stream would be the natural way to do this. G would receive each element as soon as F created it, so G would be processing the N<sup>th</sup> element while F computes the N+1<sup>st</sup>, resulting in parallel "pipelined" computation of F and G.

The constraint that stream elements be created and consumed in strict sequence may be enforced by placing some restrictions on the source program to prevent "random access." A program to manipulate streams may be written in a recursive style,<sup>11,26</sup> in which a stream is treated like a list in LISP, or in an iterative style<sup>3</sup> in which the rebinding of an iteration variable denoting a stream causes that stream to advance to the next element. Either method enforces the sequencing constraint if certain rules are followed regarding the permissible recursions or iterations.

When streams are viewed not as temporally separated arrays but as sequences of data items, functions that process streams have a few interesting and useful properties that pure mathematical functions do not have: they can emit more (or fewer) outputs than their inputs, and they can exhibit "memory" from one element to another. This makes stream functions suitable for "on-line" applications such as updating a data base. Stream functions are also useful for operations normally performed by coroutines, such as a function to remove all (newline) characters from its input, or insert a (newline) after every 80 characters. A stream function is equivalent to a coroutine that communicates by transmission and reception of data values. A data flow program using streams is a network of parallel communicating coroutines, a computational model that has been of some theoretical interest in the last few years.<sup>16-18</sup>

#### Streams and input/output operations

Streams form a natural mechanism for handling input and output. By treating the sequence of characters read in from an external medium as a stream, it is possible for a program to operate on the data as it is read in. The program can generate an output stream, which is printed as it is produced.

#### CONCLUSION

There have recently been calls for the abandonment of the traditional "von Neumann" computer architecture as a good way of realizing the enormous potential of VLSI technology.<sup>5</sup> There has also been widespread recognition that proper language design is essential if the high cost of software is to be brought under control, and that most existing languages are seriously deficient in this area.

Fortunately, the implications of these trends for language design are similar—languages must avoid an execution model (the "von Neumann" model) that involves a global memory whose state is manipulated by sequential execution of commands. Such a global memory makes realization of

the potential of VLSI technology difficult because it creates a "bottleneck" between the computer's control unit and the memory. Languages that use a global memory in their execution model also exacerbate the software problem by allowing program modules to interact with each other in ways that are difficult to understand, rather than through simple transmission of argument and result values. Future language designs based on concepts of applicative programming should be able to help control the high cost of software and to meet the needs of future computer designs.

U.S. Census Bureau  
Washington, DC

George Field  
Honeywell Information Systems, Inc.  
Waltham, MA

Tom Pritchard  
IBM Corporation  
White Plains, NY

Thomas C. White  
AFIPS  
Montvale, NJ

FISCAL COMMITTEE

*Chairman*

James F. Welch  
F. W. Woolworth Co.  
New York, NY

Rita M. Lane  
Chemical Bank  
New York, NY

OPERATIONS COMMITTEE

*Chairwoman*

Lori Capodanno  
Bell Laboratories  
Holmdel, NJ

*Vice Chairman*

Doug Rochester  
Manufacturers Hanover Trust Co.  
New York, NY

Thomas A. D'Auria  
City of New York  
New York, NY

---

George Brucia  
New York Telephone  
New York, NY

Ed DuCasse  
Pace University  
New York, NY

Harriet Shair  
The Computer Corner  
White Plains, NY

Claire Chase  
City of New York  
New York, NY

Mike Goldberg  
Pace University  
New York, NY

Robert Soudant  
New York Telephone  
New York, NY

#### PERSONAL COMPUTING COMMITTEE

*Chairman*

Richard A. Kuzmack  
Mathematica, Inc. (MATHTECH)  
Arlington, VA

Charles Floto  
Phillips Publishing, Inc.  
Washington, DC

Joe Kasser  
Comsat Laboratories  
Silver Spring, MD

*Vice Chairwoman*

Burchenal Green  
*Creative Computing Magazine*  
Morristown, NJ

Edward J. Fox  
Department of Defense  
Fort George G. Meade, MD

Jay P. Lucas  
U.S. Patent and Trademark Office  
Washington, DC

Russell Adams  
U.S. Patent and Trademark Office  
Washington, DC

Portia Isaacson  
Electronic Data Systems Corp.  
Dallas, TX

Harriet Shair  
The Computer Corner  
White Plains, NY

#### PROFESSIONAL DEVELOPMENT SEMINARS COMMITTEE

*Chairman*

William A. Baker  
Aetna Life & Casualty  
Hartford, CT

Richard K. Edwards  
Aetna Life & Casualty  
Hartford, CT

G. Robert Grover  
Lever Brothers Company  
New York, NY

Ed Marks  
Software Design Assoc.  
New York, NY

#### SPECIAL ACTIVITIES

*Philately*

Ira W. Cotton  
National Bureau of Standards  
Washington, DC

*Science Film Theater*

Adrian J. Basili  
AT&T  
Piscataway, NJ

*Pioneer Day*

Henry P. Stevenson  
AT&T  
Basking Ridge, NJ

*Special Functions*

J. William Woythaler  
Summit, NJ

*Amazing Micro Mouse Finals*

Susan L. Rosenbaum  
Honeywell Information Systems  
Westfield, NJ

---

“TODAY AT THE NCC” COMMITTEE

*Chairman*

Roger M. Firestone  
Sperry Univac  
Blue Bell, PA

George Field  
Honeywell Information Systems  
Waltham, MA

Stanley Winkler  
IBM Corporation  
Armonk, NY

---

**AMERICAN FEDERATION OF INFORMATION PROCESSING  
SOCIETIES, INC. (AFIPS)**

OFFICERS AND BOARD OF DIRECTORS

*President*

Albert S. Hoagland  
IBM Corporation  
San Jose, CA

*Vice President*

J. Ralph Leatherman  
Hughes Tool Co.  
Houston, TX

*Secretary*

Sylvia Charp  
The School District of Philadelphia  
Philadelphia, PA

*Treasurer*

Walter Johnson  
Consolidated Paper Co.  
Wisconsin Rapids, WI

*Executive Director*

Robert W. Rector  
AFIPS  
Montvale, NJ

*Association for Educational Data Systems*

E. Ronald Carruth  
Minneapolis School District  
St. Paul, MN

*American Society for Information Science*

Harold Borko  
University of California  
Los Angeles, CA

*American Institute of Aeronautics and Astronautics*

H. Lewis Parker  
Comsat Labs.  
Clarksburg, MD

*American Statistical Association*

George Minich  
World Bank  
Washington, DC

Aaron Finerman  
University of Michigan  
Ann Arbor, MI

Steven S. Yau  
Northwestern University  
Evanston, IL

Daniel McCracken  
Ossining, NY

*Institute of Internal Auditors*

William E. Perry  
IIA  
Altamonte Springs, FL

Stuart Lynn  
University of California  
Berkeley, CA

*Instrument Society of America*

Arthur C. Lumb  
Proctor & Gamble Co.  
Cincinnati, OH

*Data Processing Management Association*

Delbert Atwood  
Utah State Board of Education  
Salt Lake City, UT

*Society for Industrial and Applied Mathematics*

Donald L. Thomsen, Jr.  
SIAM Institute for Mathematics  
New Canaan, CT

Barry D. Lynch  
Mercantile National Bank  
Dallas, TX

*Society for Information Display*

Carlo Crocetti  
Rome Air Development Center  
Griffiss Air Force Base, NY

Robert Marrigan  
Mail Communications, Inc.  
Everett, MA

*Society for Computer Simulation*

Per Holst  
Foxboro Co.  
Foxboro, MA

*IEEE-Computer Society*

Tse-Yun Feng  
W. Bloomfield, MI

*AFIPS Immediate Past President*

Theodore J. Williams  
Purdue University  
West Lafayette, IN

AFIPS EXECUTIVE COMMITTEE

Albert S. Hoagland  
IBM Corp.  
San Jose, CA

Walter A. Johnson  
Consolidated Papers, Inc.  
Wisconsin Rapids, WI

J. Ralph Leatherman  
Hughes Tool Co.  
Houston, TX

Sylvia Charp  
School District of Philadelphia  
Philadelphia, PA

Yorktown Heights, NY

Per Holst  
Foxboro Co.  
Foxboro, MA

#### NATIONAL COMPUTER CONFERENCE BOARD

*Chairman and AFIPS Representative*  
J. Ralph Leatherman  
Hughes Tool Company  
Houston, TX

*Treasurer and AFIPS Representative*  
Walter A. Johnson  
Consolidated Papers, Inc.  
Wisconsin Rapids, WI

*Secretary and DPMA Representative*  
Robert Marrigan  
Mail Communications, Inc.  
Everett, MA

*AFIPS Representative*  
Albert S. Hoagland  
IBM Corporation  
San Jose, CA

*AFIPS Representative*  
Harold Borko  
University of California  
Los Angeles, CA

*ACM Representative*  
W. Smith Dorsey  
North American Rockwell  
Orange, CA

*SCS Representative*  
Carl Malstrom  
Clemson University  
Clemson, SC

*IEEE-CS Representative*  
Dick Simmons  
Texas A & M  
College Station, TX

#### NATIONAL COMPUTER CONFERENCE COMMITTEE

*Chairman*  
Jerry Koory  
On-Line Business Systems  
San Francisco, CA

Morton M. Astrahan  
IBM Research Laboratory  
San Jose, CA

*Secretary*  
Irwin J. Sitkin  
Aetna Life and Casualty  
Hartford, CT

Harvey L. Garner  
University of Pennsylvania  
Philadelphia, PA

---

Jeffery D. Stein  
On-Line Business Systems, Inc.  
San Francisco, CA

Portia Isaacson  
Electronic Data Systems Corp.  
Dallas, TX

Al Hawkes  
Sargent & Lundy Engineers  
Chicago, IL

Merlin G. Smith  
IBM T. J. Watson Research Center  
Yorktown Heights, NY

Russell K. Brown  
Moore Paper Companies  
Houston, TX

Herbert Safford  
GTE Data Services, Inc.  
Marina del Rey, CA

#### INDUSTRY ADVISORY PANEL

*Chairman*  
Frederick M. Hoar  
Fairchild Camera and Instrument Co.  
Mountain View, CA

S. A. (Sandy) Lanzarotta  
Xerox Corporation  
El Segundo, CA

Russell Berg  
Hewlett-Packard  
Palo Alto, CA

William Lonergan  
Xerox Development Corp.  
Beverly Hills, CA

Gordon Daggy  
Fairchild Systems  
Santa Fe, CA

Richard Mau  
Sperry Rand Corp.  
New York, NY

Arnold Lerner  
IBM Corp.  
Armonk, NY

#### AFIPS HEADQUARTERS AND CONFERENCE SUPPORT STAFF

Robert W. Rector  
*Executive Director*

Deborah Reinfreid  
*Receptionist*

Diane Lancaster  
*Secretary*

Ann Lonergan  
*Actg. Manager Finance*

Jane Smith  
*Actg. Manager Administration & Volunteer Support  
Services*

Sue Welch  
*Bookkeeper*

---

Olive M. Shilland  
*Secretary*

Marie Stewart  
*Manager, Exhibit Sales*

Thomas C. White  
*Director of Communications*

Rita Henderson  
*Coordinator, Office Automation Conference*

Marjorie Greimel  
*Coordinator of Communications*

Deborah Colombo  
*Secretary*

Lorraine J. Stanley  
*Administrative Assistant*

Katherine D. Morrison  
*Secretary*

Rustine Tilton  
*Secretary*

Sandra Rider  
*Secretary*

Gerard F. Chiffrieller  
*Director of Conference Operations & Conference  
Coordinator*

Alexander D. Roth  
*Director, AFIPS Washington Office*

Pender M. McCarter  
*Research Associate*

Carol Sturgeon  
*Manager, Conference Operations*

Linda Martin  
*Administrative Assistant*

## NCC '79 REFEREES

On behalf of the NCC '79 Program Committee, I wish to thank the following referees for their efforts, without which this Proceedings could not maintain its high quality. Although an attempt was made to list as referees all individuals who participated in this procedure, there will undoubtedly be omissions.

RICHARD E. MERWIN
