What can GE offer small farmers? Photo: Bert Lof

Using the poverty of the south to justify GM food to the north

Many concerned people, both in the South and the North, are appalled at how the poverty of the rural people of the South is made use of to justify genetically modified food to Northern consumers. The following reasons were cited in a letter of protest:

1. Poverty in the South is structurally rooted in the prevalent North-South relationships. The present systems of international resource control, commodity pricing, education, training, research, finance, banking, insurance, transportation etc. are all components of the system that controls wealth and poverty, and which started being put in place during the slavery and colonial periods and have matured in this post-colonial period. Southern poverty, especially rural poverty, is a consequence of this.

2. As such, the solution to rural poverty lies in a multidimensional corrective measure that would enable sufficient local control of the appropriation of the benefits that arise from the use of and trade in resources, as well as the application of labour.

3. The assumption that the complex rural poverty that afflicts the South can be solved through single technological inputs is grossly incorrect and totally objectionable since it would misdirect efforts.

4. Though technological inputs have a role to play in rural development, and genetic engineering could be a technology to consider, it would remain but one technology among many. For example even if potential yields of food crops were to be dramatically improved, if storage, transportation, marketing, distribution, and the ability to buy the food were not simultaneously improved, the effort would still remain ineffective. In fact, as we keep pointing out, it is not shortage of food that is the problem, but its distribution. More GE food is not the point: it is improving access and local food security. But corporations do not profit from such solutions.

5. There are high yielding varieties in rural areas, but their impacts remain limited by the bottlenecks imposed by many of the other variables. The agricultural research stations that are found in Southern countries have also produced many such varieties and the potentials of these varieties remain unrealised because of the other negative factors. But research must continue so that there will always be higher yielding varieties to be used as and when conditions allow it. It is a gross oversimplification to state that such seed would solve rural food problems. The picture is the same with seed of improved nutritional quality such as vitamin A rice.

6. At the heart of the inequity that maintains the present poverty of the South is the inherited positive advantage that the Northern transnational corporations enjoy. We consider the use of the South's rural poverty to justify the monopoly control and global use of genetically modified food production by the North's transnational corporations, not only an obstructive lie, but a way of derailing the solutions to our Southern rural poverty. It is the height of cynical abuse of the corporations' position of advantage.

■

(from a letter to the Channel Four News and The Times newspaper, UK, in response to a documentary (Equinox) and article (Gm foods and the luxury of choice) signed by a large group of concerned people from all continents)

Visit our website: www.ileia.org

Say no to GMOS: Grassroots education, activities and resources in Texas for consumer choice and a genetically viable future

www.saynotogmos.org

This activist website provides a lot of information about the disadvantages of growing GM crops. Scientific information in a readable style, but also a lot of information on court cases throughout USA and Canada. Real grassroots information.

People and Plants online

www.rbgkew.org.uk/peopleplants/

People and Plants promotes the sustainable use of plant resources, and the reconciliation of conservation and development, by focusing on the interface between people and the world of plants. This website is a gateway to information on practical ways of working with communities in applied ethnobotany. Its main focus is on Africa, Asia and the Pacific. Besides newsletters and interesting links, the *People and Plants Handbook* series, which is a source of information on applying ethnobotany to conservation and community development is available from this website. It is designed for people who work in the field, including park managers, foresters, students, researchers, cultural promoters, and members of non-governmental, governmental and indigenous organisations. These handbooks are also available in Spanish. (downloadable and printed)

Transgenic plants and world agriculture

Report, 46 p, 2000, downloadable pdf file.

www.nap.edu/html/transgenic

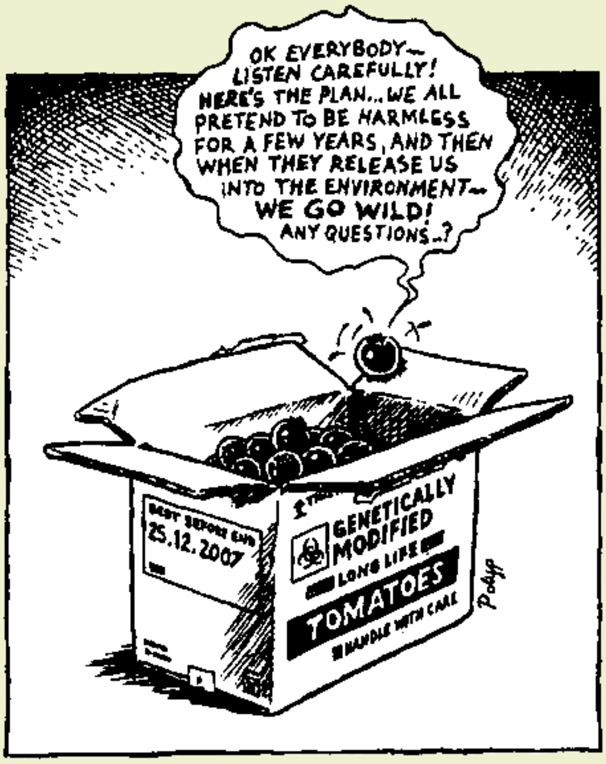
A working group consisting of a number of Academies of Sciences from all over the world, including the Third World Academy of Sciences, has prepared this report. These scientists have come together to provide recommendations to the developers and overseers of GM technology and to offer scientific perspectives on the ongoing public debate on the potential role of GM technology in world agriculture.

The report concludes that developers of GM technology should make sure that their efforts address the needs of small farmers in developing countries. It recommends a number of security measures. It also states that the system of patents and licenses should be broken down to facilitate sharing of GM technology with scientists in developing countries.

FoEE Biotechnology Programme

www.foeeurope.org/biotechnology/about.htm

Friends of the Earth Europe's Biotechnology Mailout is an overview of the ecological, ethical, political and legal developments of biotechnology in the European Union. The principle aim of the mailout is to provide regular, reliable information on the ecological, social, political and legal aspects of genetic engineering and thereby generate public awareness and debate, and provide a factual basis for campaigning by interest groups. The FoEE Biotech Mailout is published every six weeks as a paper and an E-mail version. It is available from this website, also in Spanish.



AG Biotech Infonet: Genetic Engineering, impacts and implications

www.biotech-info.net/

This website covers all aspects of the application of biotechnology and genetic engineering in agricultural production and food processing and marketing. It is a resource for anyone trying to better understand the implications of agricultural biotechnology. The goal is to facilitate access to critical, original documents and information, and recognised experts.

Christian Aid: Biotechnology and Genetically Modified Organisms

www.christian-aid.org.uk/indepth/0001biot/biotech.htm

This is the position paper of Christian Aid about biotechnology and Genetically Modified Organisms. Christian Aid's concern is with the implications and effects of biotechnology on developing countries, and on small farmers and the poor in those countries in particular. Its view is that, taken together, the possible environmental effects and the concentration of commercial control add up to a major threat to developing countries' food security and to the sustainability of poor farmers' livelihoods.

GeneWatch

www.genewatch.org/

GeneWatch UK is an independent organisation concerned with the ethics and risks of genetic engineering. It questions how, why and whether the use of genetic technologies should proceed and believes that the debate over genetic engineering is long overdue. Though the home country of GeneWatch is United Kingdom, the site is oriented to a worldwide audience and provides a lot of information.

GENET Archive

www.gene.ch/archives.html

This site has been established to support discussions about genetic engineering and to provide information intelligible to non-scientists. At present decisions are being taken which are influencing society and the environment worldwide: New crops are being planted and products derived from them are being sold fraudulently (without labels and risk information) on the world market.
Huge areas are being invaded by newly designed organisms: organisms whose long-term effects to eco systems are unknown and which can never be brought back if there are adverse effects. This archive provides plenty of background information.

International Food Policy and Research Institute: Biotechnology and Genetic Resource Policy

www.ifpri.cgiar.org/index.htm

This site of IFPRI provides downloadable policy papers about biotechnology and genetic resource management for developing countries, eg. booklet of CGIAR Centre Policy Instruments, Guidelines and Statements on Genetic Resources, Biotechnology and Intellectual Property Rights.

Friends of the Earth's European campaign to halt GMO pollution

www.foeeurope.org/halt-gmo-pollution/home.htm

Thorough information on the European anti GMO movements and the state of the art concerning GMOs in the different European countries.

Biotechnology and food: Voices from a Southern Perspective

www.southernvoices.nl/announce1.html

An online debate about biotech has taken place on this website. More information is to be found in the lastest issue of Biotechnology and Development Monitor. Here ordinary people could join the discussions on biotech, as still is possible on the ILEIA website.

CIMMYT: Biotech in the developing world

www.cimmyt.cgiar.org/ABC/map/developing_world/index.htm

CIMMYT, the international maize and wheat improvement center, provides information about biotech and corn crops in the developing world. A number of informative papers is available on this site for free, many also in Spanish.

Can agricultural biotechnology make a difference in Africa?

Woodward B, Brink J and Berger D, 1999, AgBioForum vol. 2(3/4) pages 175-181

www.agbioforum.org

There has been much recent dicussion on the potential impact of biotechnology on the development in Africa. Would a strategy combining conventional breeding with good crop management, farmer participatory research, and the provision of disease-free planting material be sufficient to increase yields in Africa? This paper states that the introduction of transgenic crops combined with the conventional approach mentioned above could contribute to improving the yields obtained by African farmers.

Grains of delusion: Golden rice seen from the ground

Report, 12 p, 2001, downloadable pdf file.

www.grain.org/publications/delusion-en.cfm

This document available from the website of GRAIN was researched, written and published as a joint undertaking between BIOTHAI (Thailand), CEDAC (Cambodja), DRCSC (India), GRAIN, MASIPAG (Philippines), PAN-Indonesia and UBINIG (Bangladesh). The report concludes that, while many doubt the ability of golden rice to eliminate vitamin A deficiency, the machinery is being set in motion to promote a GE strategy at the expense of more relevant approaches. The best chance of success in fighting vitamin A deficiency and malnutrition is to better use the inexpensive and nutritious foods already available, and in diversifying food production systems in the fields and at household level.

Cropchoice

www.cropchoice.com/index.asp

Cropchoice is an information source for American farmers about genetically modified crops, alternatives, management options, and profitability. Cropchoice has news that big companies may not want farmers to hear. An informative and well ordered source.

Themes for next issues

Issue 18.2, May 2002.

Rural communication and information management for sustainable family farming.

Rural communication and information management play an important role in spreading information on successful farmer innovations and in getting access to new knowledge. Participatory development programmes increasingly use rural radio, TV and other mass communication media as tools for farmer-to-farmer exchange. In some places, farmers even use mobile phones to get information on market prices. The use of internet and CD-ROMs by development workers, researchers and even farmers for networking and information exchange is gradually increasing as communication facilities improve. Yet, in many rural communities, traditional methods of communication continue to have a significant impact on the spread of information. What practical experiences have been gained with new as well as with more conventional approaches to rural communication and information management to enhance the expansion of farmer movements towards sustainable agriculture? How can access to electronic information and communication technologies be enhanced? How can these technologies be made into participatory tools? What experiences have been gained with local centres for information and farmer exchange? These are some of the practical questions that we wish to raise in this issue. First deadline for contributions: 1st of February 2002.

Issue 18.3, August 2002

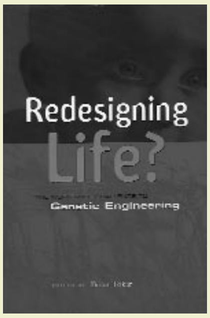
Ecological soil management, key to sustainable agriculture

Many problems in agriculture are related to soil and soil fertility management, i.e. soil erosion, low efficiency of fertilisers, nutrient imbalances, soil borne diseases, pests and weeds, soil compaction, farmer induced drought, water pollution, etc. Successes in raising productivity and ecological sustainability in agriculture often come from improvements in soil management. More insights are being gained into ecological soil and soil fertility management in the tropics. What do we know of ecological soil management? How do (traditional) farmers look at soil management and what can we learn from approaches such as organic agriculture, agroecology, natural farming, integrated soil fertility management, zero tillage and integrated pest management? Can traditional and organic technologies be combined with chemical fertilisers? As organic soil management technologies can be very labour demanding, appropriate mechanisation can be important. What experiences have been gained in this regard? Ecological soil management is site and crop rotation specific. What experiences have been gained with fine-tuning ecological soil management for specific conditions and rotations? Your practical experiences are very welcome. First deadline for contributions: 1st of May 2002.

You are invited to contribute to these issues with articles (about 800, 1600 or 2400 words + 2-3 illustrations and references), suggest possible authors, and send us information about publications, training courses, meetings and websites.

Redesigning life? : the worldwide challenge to genetic engineering by Tokar B (ed). 2001. 432 p. ISBN 1 85649 835 2 (pbk) : USD 19.95. ZED Books, 7 Cynthia Street, London N1 9JF, UK / zedbooks@zedbooks.demon.co.uk

Everyone who wants to know about the hazards of new genetic technologies should certainly read this book. It is a comprehensive examination of the critical threats of genetic engineering, and provides the knowledge required to counter and transcend it. Twenty-six internationally respected critics from all over the world provide their analysis of the issues, the inherent social and ethical implications, and the stories that made the headlines and brought genetic engineering to the forefront of public controversy.



The editor, Brian Tokar, has written a very useful and informative introduction called challenging biotechnology. Part I of the book consists of eight articles about health, food and the environment. Part II discusses medical genetics, science and human rights. In part III patents, corporate power and the theft of knowledge and resources are dealt with and part IV is about the worldwide resistance to genetic engineering. The list of "resources for information and action" at the end of the book provides useful links to many organisations and sources.

The book draws on the expertise of many experienced writers, is very readable and highly recommended. (WR)

Biotechnology : building on farmers' knowledge by Bunders J, Haverkort B, Hiemstra W (eds). 1996. 240 p. ISBN 0 333 67082 5 : GBP 8.95. ETC Netherlands, PO Box 64, 3830 AB Leusden, The Netherlands. Macmillan Education, Houndmills, Basingstoke RG21 6XS, UK.

This book aims at demonstrating the wealth of alternative biotechnological knowledge among farmers. They manage micro-organisms in the areas of animal health, biopesticides, food processing and crop genetic resources. Farmers' knowledge should be the starting point to make biotechnological research less supply-driven and more demand-driven. Part 1 examines existing biotechnological practices of farmers in animal health, biopesticides, food processing and crop genetic resources.

It begins with the experiences of one farmer from Kenya. Part 2 focuses on science-based bio-technology research and assesses the potential for small-scale farmers in the tropics. As views on the potential contribution of formal biotechnology research to food security differ widely, a chapter on the socio-political context has been included.

Part 3 presents a participatory and interactive methodology that builds on farmers' knowledge and makes use of the latest scientific insights. It ends with a model for integrating the formal and informal research and development systems.(WH)

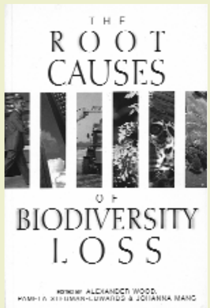
Biotechnology of food crops in developing countries : plant gene research, basic knowledge and application by Hohn T, Leisinger KM (eds). 1999. 222 p. ISBN 3 211 83240 8, GBP 34.00. (Plant Gene Research). Springer-Verlag, Wien, New York.

This book advocates biotechnological innovations as an important tool for agriculture in developing countries. The recent advances in gene technology, plant transformation, and the growing knowledge of DNA sequences of plants as well as of their most important parasites and symbionts offer many interesting prospects for the breeding of new crop varieties.The book contains results of agricultural research on crop improvement, obtained worldwide. The researchers who have written this essay take into consideration some ethical and socio-political aspects of crop improvement. But the larger part of the book focuses on technical information for the improvement of the major grains and other staples important for the various climatic zones of the third world. The successes and routes to obtain crops resistant to fungi, viruses, insects, and other pests, adapted to harsh climatic and soil conditions, and of high yield and nutritive value are described. Useful information for agricultural researchers.(WR)

Intellectual property rights, the WTO and developing countries: the TRIPS agreement and policy options by Correa CM. 2000. 96 p. ISBN 1 85649 737 2 (Pbk) : GBP 16.95. ZED Books, 7 Cynthia Street, London N1 9JF, UK / zedbooks@zedbooks.demon.co.uk ; Third World Network, Malaysia.

The whole architecture of international trade is being fundamentally recast by the various agreements which the new agency, the World Trade Organization, is responsible for policing. This book cuts through the daunting technicalities of one of the most important of these agreements, that dealing with Intellectual Property Rights and their treatment as internationally tradeble commodities. Professor Correa helps us understand what the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS Agreement) is about and explains its main provisions. This book is an essential introduction to TRIPS and provides elements to develop policies and laws on intellectual property from a developing-country perspective.

The root causes of biodiversity loss by Wood A, Stedman-Edwards P, Mang J (eds). 2000. 398 p. ISBN 1 85383 699 0 GBP 17.95. WWF. Earthscan Publications, 120 Pentonville Road, London N1 9JN, UK / www.earthscan.co.uk : earthinfo@earthscan.co.uk

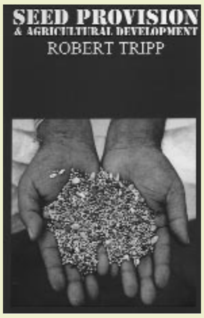


This book is a result of the "Root Causes Project", a joint project of The World Wide Fund for Nature (WWF), Macroeconomics for Sustainable Development Program Office (MPO) and the Global Environment Facility (GEF). These organisations are convinced that the conservation of biological diversity needs to be based on an understanding of the factors and the dynamics that drive its loss. The project conducted case studies in ten separate countries: Brazil, Cameroon, China, Bulgaria and the Slovak Republic, India, Mexico, Pakistan, Philippines, Tanzania, and Vietnam. Analysis of the findings has been used to provide a framework for understanding the interrelationship between socio-economic root causes and biodiversity loss. This framework gives a clear picture on how the various parts of the puzzle, from local population growth to national politics to international markets, together drive loss of biodiversity at a given site. This book is an invaluable contribution to understanding these processes, and provides a basis for effective conservation of diverse resources. Strongly recommended for economists and policy makers besides ecologists and conservationists. (WR)

Anti-GenetiX : the emergence of the anti-GM movement by Purdue DA. 2000. 161 p. ISBN 0 7546 1216 3 USD 37.50. Ashgate publisher, 130 Milton Park, Abingdon, OX14 4SB, UK / orders@bookpoint.co.uk ; www.ashgate.com.

The development of genetically modified foods has given rise to much widespread and heated debate on the possible consequences-both positive and negative- of this new technology. Based on his PhD thesis, Derrick Purdue has written a book that explores the emergence of a social movement in response to the patenting of life forms via biotechnology and the global crisis of natural and agricultural biodiversity. This book outlines the connections between gene patenting and biotechnology, their impact on international relations, and examines the social movement emerging against GM food. It gives a lot of information on issues such as intellectual property rights, application of patenting to genes and the consolidation of expert systems. The book is recomended for people who want to take part in the global GM food discussions.(WR)

Seed provision and agricultural development : the institutions of rural change by Tripp_R. 2001. 192 p. ISBN 0_85255_420_6 GBP 14.95. Overseas Development Institute (ODI), London UK / publications@odi.org.uk. James Currey Publishers, 73 Botley Road, Oxford OX2 0BS, UK.



Seed is at the forefront of many debates about development. It features in concerns about globalisation and intellectual property rights. Controversies over the future of biotechnology focus on the impact on seed systems. Robert Tripp has based this book about seed provision on six years of research in various aspects of seed system development. The examples in the book are drawn from original research in Asia, Africa and Latin America, as well as from an extensive review of the literature.

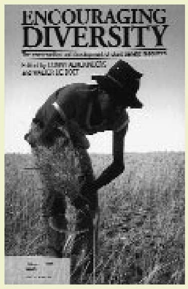
The book provides a detailed look at the strengths and weaknesses of seed management in traditional farming systems, reviews the history of formal plant breeding and the origins of seed trade, and examines the roles of the public and private sectors in the contemporary seed systems of industrialised and developing countries.

The book also describes the major types of aid interventions in developing country seed systems and explains why many of these have not been successful. With this book the author allows the reader to have a comprehensive picture of seed provision and the complexities involved within the context of agricultural development.(WR)

Organic cotton : from field to final product by Myers D, Stolton S (eds). 1999. 267 p. ISBN 1 85339 464 5 : GBP 16.50. The Pesticides Trust, Eurolink Centre, 49 Effra Road, London SW2 1BZ, UK. Intermediate Technology Publications (ITP), 103-105 Southampton Row, London WC1B 4HH, UK / orders@itpubs.org.uk ; www.itpubs.org.uk
This book is rich with details of successes, difficulties and challenges. It is primarily about organic cotton, though it goes on to tell a wider and vitally important story about how agriculture can become more sustainable while making significant improvements to people's lives. Cotton is a globally important fibre, providing returns to many small farmers in developing countries, as well as being worn at one time or another by most of the world's population. But most cotton is produced in a way that causes great damage to the environment.

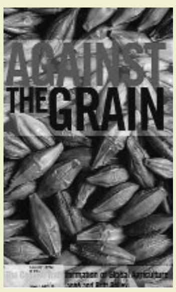
This book describes organic cotton production and processing, and is the first complete overview of its kind. There are signs that organic cotton is moving into a mass market. The book provides a very good and complete picture of the insights gained so far, and compiles case studies from all over the world. Besides cultivation (including the growing of genetically engineered cotton) and processing, attention is paid to economic and marketing aspects, the conversion process, certification and support requirements for projects.(WR and IHG)

Encouraging diversity : the conservation and development of plant genetic resources by Almekinders CJM, Boef W (de). 2000. 368 p. ISBN 1 85339 510 2. Intermediate Technology Publications, 103-105 Southampton Row, London WC1B 4HH, UK / orders@itpubs.org.uk ; www.itpubs.org.uk
Presents around 80 brief contributions with perspectives and experiences in plant genetic resources in the South and the North, from established institutions, researchers, pioneers and activists. These experiences illustrate the apparent conflict between crop conservation and crop development, and contribute to the understanding of opportunities that new approaches and activities in this field offer. Similarities between problems in the South and the North are apparent. Experiences and perspectives of genebanks, plant breeders, seed programmes and NGOs involved in crop development and conservation are analysed and placed in the context of new approaches in local and global Plant Genetic Resource (PGR) management by the formal and informal sector. The last part of the book talks about future developments in PGR management. It discusses the implications of integrated and adaptive management approaches in PGR management and the institutional organisation required to bring about changes that can help farmers and professionals in PGR management stand up against the pressures of a range of external global forces.



Agrafood: biotech 2001. 24 p. subscription for one year USD 698.-. Agra Europe (London) Ltd., 80 Calverley Road, Tunbridge Wells, Kent TN1 2UN, UK / www.agra-net.com ; marketing@agra-net.com. AgraFood Biotech no. 65 October 2001.
The Journal AgraFood Biotech, published every two weeks, reports on the application of biotechnology in agriculture and food. The debate over GM products has reached a global level. The US, China and Argentina are spearheading the growing of GM crop varieties and biotechnology companies are continuing to fund the development of GM food products. Consumer and environmental organisations in Europe and elsewhere are lobbying for a halt to trade and the freedom of choice for the consumer over the purchase of GM foods. By reading AgraFood Biotech you can stay in touch with the latest industry issues, discussions and regulations. The journal does offer objective and accurate reports on the subject , but at a very high price.(WR)

Against the grain : the genetic transformation of global agriculture by Lappé M, Bailey B. 1999. 163 p. ISBN 1 85383 576 5 : GBP 15.99. Earthscan Publications, 120 Pentonville Road, London N1 9JN, UK / orders@lbsltd.co.uk ; www.earthscan.co.uk
This book from 1999 still is a valuable, politically-oriented contribution to the debate about biotechnology, genetic engineering and transgenic crops and animals. The book examines new developments and their implications, looking in particular at developed countries. The achievements of transgene technology have penetrated into our lives at an enormous speed and scale, whether we like it or not. This publication helps to shape our viewpoint by a thorough analysis of the situation. Contains a glossary of terms, useful in this difficult field.

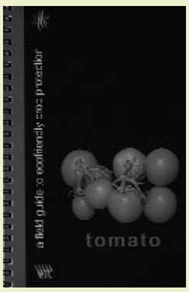


Farm planning 2000. 36 p. USD 4.-. World Neighbors (WN),4127 NW 122nd St. Oklahoma City, OK 73120-8869, USA / order@wn.org ; www.wn.org. (The practical guide to dryland farming series no 7).

This new manual on farm planning in the series practical guides to dryland farming is a useful booklet for extension workers and farmers. The booklet aims at helping farmers to fulfil farm families' needs and overcome problems caused by poor planning. Extension workers in the province Nusa Tenggara Timur in Indonesia have developed approaches for facilitating farm planning. In a process that involves the whole family, extension workers help farmers learn to analyse their needs as well as the problems they face. By better understanding these issues, farmers are better able to find more effective ways of managing available natural resources in order to improve their productivity. This approach is described here in a clearly-written and sufficiently-illustrated booklet. The booklet is also available in the Bahasa language and can be ordered from Studio Driya Media, Jl.Ancol Timur XIV, no.1 Bandung 40254 Indonesia / ybm-sdm@indo.net.id (WR)

National strategies for sustainable development: learning from experience: website CD-Rom for supporting dialogues / volume two. 2001. cdrom. GBP 30.- non OECD 15.-. International Institute for Environment and Development (IIED), 3 Endsleigh Street, London WC1H 0DD, UK / www.nssd.net
Natural Resources Institute (NRI).
With this CD-ROM, NRI and IIED made available their website with information and dialogues about strategic planning for sustainable development in developing countries for people that have not so easily access to internet. All the information on the website is to be found on the CD-ROM. It includes information and documentation in English, French and Spanish from participating countries, project documents and policy guidance, a bibliography on strategies for sustainable development, with many full text documents. Every three months an updated CD-ROM is available. This is a nice example of how to keep in contact with people who are not able to surf the internet daily. (WR)

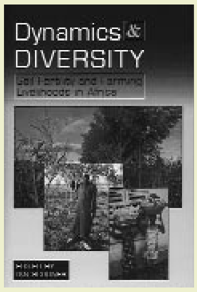
Tomato : a field guide to ecofriendly crop protection by Lanting H, Rao MS, Ravi K. 2001. 52 p. ISBN 81 87293 04 7. Agriculture Man Ecology (AME), 368, 4th Cross, JP Nagar 3rd Phase, Bangalore 560078, Karnakata, India / amebang@giasbg01.vsnl.net.in.
This first booklet in a series of field guides, AME has planned, is an illustrated handbook of insect pests and diseases most commonly found in the tomato-growing regions of India. It aims at promoting organic plant protection practices. This user-friendly and practical guide is primarily intended for tomato growers in India and their extension workers. The booklet provides clear information on organic protection measures for the economically important and prevalent pests of tomato and has plenty of pictures of the mentioned pests. Recommended.(WR)



Shifting cultivation: towards sustainability and resource conservation in Asia 2001. 421 p. ISBN 1 930261 01 2 USD 15.-. IFAD, IDRC, CIIFAD, ICRAF, International Institute of Rural Reconstruction (IIRR), Y.C.James yen Center, Biga, Silang, Cavite, Philippines / www.iirr.org ; Bookstore@iirr.org.
This resource book was produced through a participatory writeshop organised by IFAD, IDRC, CIIFAD, ICRAF and IIRR in August 2000 in the Philippines. The aim of the workshop was to produce a publication that would be of special relevance to development workers and trainers from local and national governments, agricultural colleges, NGO's and small farmer organisations. The focus therefore is on short, succinct overviews, which are generously illustrated and attractively presented. The resulting resource book is to be used and disseminated widely and readers are encouraged to utilise the materials in any form considered relevant: for training purposes, farm-radio broadcasts, in schools etc. Relevant materials can be adapted and translated freely.

The current shift of focus of many development agencies towards the very poor must draw attention to the marginalized groups of minorities dependent upon shifting cultivation for their livelihoods. This publication offers reasons for being optimistic about what can be achieved with these groups. The book deals extensively with traditional shifting cultivation systems and practices, with adaptive strategies and best practices, with research and development approaches and with future directions for shifting cultivation. A very important information source on agroforestry. (WR)

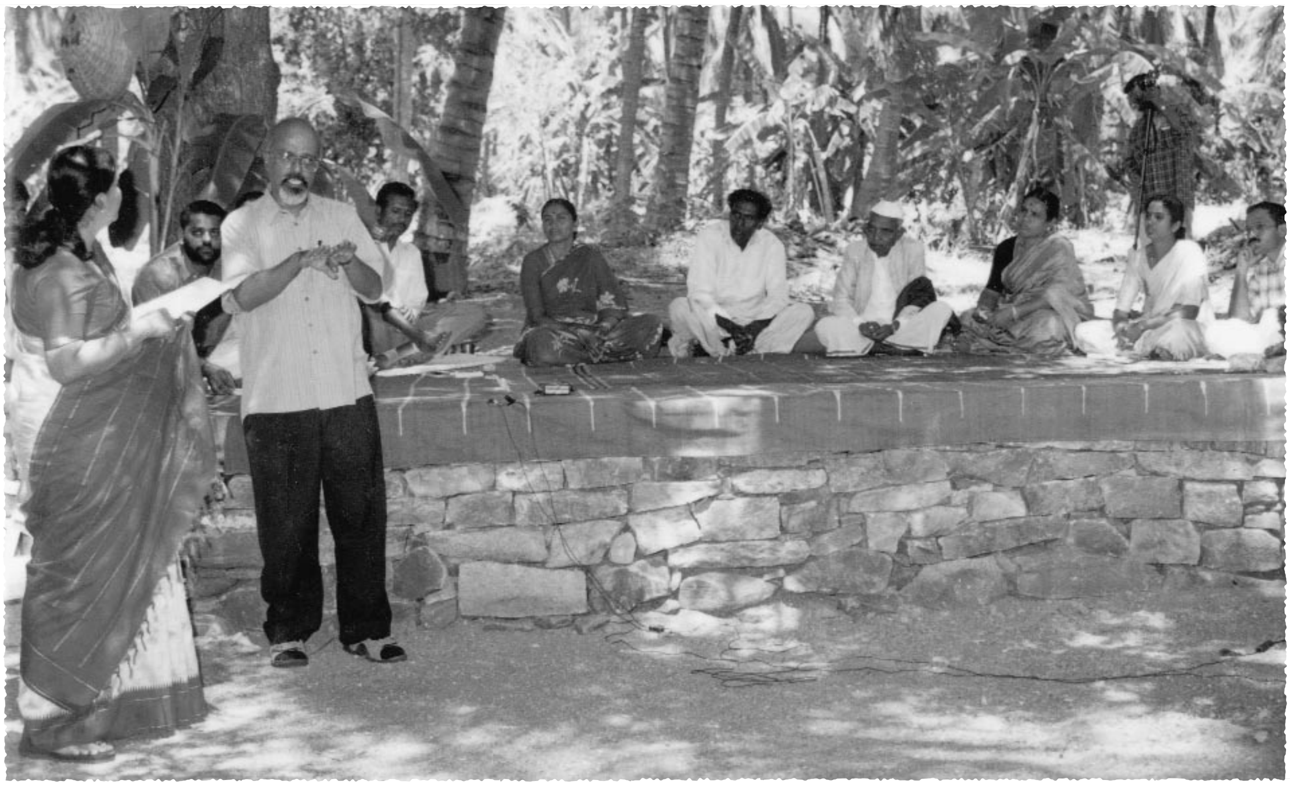
Dynamics and diversity: soil fertility and farming livelihoods in Africa: case studies from Ethiopia, Mali and Zimbabwe by Scoones I, (ed.). 2001. 256 p. ISBN 1 85383 820 9 GBP 16.95. Earthscan Publications Ltd, 120 Pentonville Road, London NI 9JN / earthinfo@earthscan.co.uk / www.earthscan.co.uk.



Ian Scoones is a well known expert in the field of soil fertility and small scale farming in Africa. With this new book on the subject he adds an important reference work to his list of publications. This book is based on research carried out by teams of researchers from Africa and Europe over three years in a range of contrasting locations. The research results add up to a new approach to looking at soil management issues in Africa, with significant implications for development policy and practice. The results suggest a more positive view of the prospects for sustainable agriculture in small-scale farming systems in Africa than the overridingly negative views of crisis and collapse that have dominated the policy debate. The research also points to the need for developing new technologies and management practices which are suited to the diversity of farmer needs and settings, when addressing the challenges of natural resource management. (WR)

Food for all: can hunger be halved? by Madeley J. 2001. 48 p. ISBN 18 7067 055 8 free or GBP 5.00. FAO. (Panos Report no 42). The Panos Institute, 9 White Lion Street, London N1 9PD, UK / www.panos.org.uk ; markc@panoslondon.org.uk.
This nice little booklet available free of charge from the Panos institute or downloadable, is a scream for action to the world's governments. Hungry people cannot wait another 15 years.

In 1996 the world's governments agreed to cut world hunger in half by the year 2015. But today there are still nearly 800 million people who go hungry every day. Over 140.000 people die from hunger related diseases each week. This report examines the reasons why we are not making more progress towards halving hunger. It outlines who the undernourished people of the world are, and where they live. It looks at the links between hunger and poverty, and examines the successes and failures of different kinds of agriculture in increasing food production to the levels needed. The effects of international agreements made in the World Trade Organisation and other fora on reducing hunger in the world today and how more progress can be made is also discussed.



Dr PK Ghosh of Dept Biotech, GoI, presents the results of government tests of GM crops. Photo: AgroIndia

Citizens' juries on GMOs and farming futures in India

Michel Pimbert, Tom Wakeford and PV Satheesh

Over the past quarter century a number of 'participatory' methods have been developed in an attempt to democratise policy-making. Some of these methods and processes include citizens' juries, neighbourhood forums, consensus conferences, scenario workshops, multi-criteria mapping, participatory rural appraisal, visioning exercises and deliberative polling. These methods have the potential to empower people to move beyond being passive recipients of development policies or users of externally-imposed technologies, to become active "makers and shapers" of the policies and technologies that affect their lives.

This article describes the use of some of these methods in enabling citizens to assess the pros and cons of using Genetically Modified Organisms (GMOs) in small scale farming, in India.

Citizens' Jury on GMOs, Karnataka

This citizens' jury was organised by ActionAid India and took place on a farm in a small village in the state of Karnataka, India. This dryland area of the Chitradurga district contains a high proportion of marginal farmers and landless peasants.

As it is the lives of small farmers that would be primarily affected by the introduction of GMOs, the jury was composed of fourteen small and marginal farmers, six men and eight women. They represented the variety of farming traditions, income levels and social groupings. The jury also included expert witnesses who presented evidence for and against GMOs and other participants and observers. Scientific Institutes, commercial biotechnology corporations (Monsanto), development NGOs, Farmers Unions and Government agencies were represented among them.

A multi-stakeholder panel ensured that the jury event was conducted in a trustworthy and fair manner. All deliberations were filmed and subsequently made publicly available ensure complete transparency.

The jury spent three to four days hearing information from 'witnesses' on the merits and limitations of GMOs. The subject under discussion was the possible future role of GMOs in the context of reducing rural poverty and promoting sustainable agriculture.

No to GMOs

Having heard four days of evidence, the jury gave its verdict on the question: Would you sow the new commercial (GMO) seeds proposed by the Indian Department of Biotechnology & Monsanto on your fields? The results were: 4 yes, 9 no, 1 invalid ballot paper (by secret ballot). The jury's rejection of the GMO seeds was not simply a negative response. It was supplemented by a list of actions that should be taken by the government and transnational corporations to get better acceptance for their new seeds.

- Microbes and beneficial insects should not be damaged. Also new seeds should not cause damage to animal populations and other environmental elements.
- They should be lawfully released only after extensive field trials for 5-10 years in which farmers shall be involved, not only in yield assessments, but in safety, environmental and other aspects.
- They should not damage the next crop that is grown on the same field or adjoining fields.
- The success of the new seeds should be judged not just under lab conditions, but also, on fields involving farmers.
- The technology must be easy to adapt.

Surmangala, a woman farmer, cross questions a witness about insect resistance to GM crops. Photo: AgroIndia

A proportion of the jury felt that there was no use of such technologies since they were inherently eco- unfriendly, and would destroy biodiversity. Others in the jury were ready to grow the new seeds so long as certificates from the concerned company were issued to protect them from any potential risk to their livelihood. Yet others felt that GM crops were OK, so long as it was kept to non-food crops.

The jury responded cautiously to the issue of increasing farmer confidence in multinational corporations (MNCs) and biotechnology:

- A proportion of the jury was afraid of any contact with MNCs, having heard about them in the context of WTO and patents. They felt that the powerful MNCs, which develop their seeds in laboratory conditions, could ultimately gain control over seeds and farmers' sovereignty.
- If the seeds fail for any reason, whether to do with the technology itself, or weather conditions, the MNCs should not only compensate for the loses, but also buy up the whole crop at double the price.

Citizens' Jury / Scenario Workshop on Food Futures for Andhra Pradesh

Prajateerpu, the citizens' jury on food and farming futures in Andhra Pradesh (A. P.), was another exercise in involving rural people in decisions that have a strong impact on their livelihoods. This participatory process was jointly organised and facilitated by the UK-based International Institute for Environment and Development (IIED) and the Institute of Development Studies (IDS) and the India-based Andhra Pradesh Coalition in Defence of Diversity, The University of Hyderabad, AP and the all-India National Biodiversity Strategy and Action Plan (NBSAP).

This citizens' jury was made up of small and marginal farmers, food processors and consumers. Reflecting the reality of rural Andhra Pradesh, the jury also included a large proportion of Dalit (untouchable caste) and indigenous (known in India as 'adivasi') people. Over two thirds of the jury members were women, reflecting the greater role women have in agricultural work. The jury members were presented with three different scenarios. Over a period of four days, they listened to and cross-questioned twelve witnesses including representatives of the Government of A.P., the Indian branch of the International Federation of Organic Agriculture Movements (IFOAM) and Syngenta, one of the world's largest biotechnology corporations. It was up to the jury to decide which of the three scenarios, or combination of elements from each, was most likely to provide them with the best opportunities to enhance their livelihoods, food security and environment twenty years from now.

Three visions for the future

Vision 1: Vision 2020.

This scenario was put forward by Andhra Pradesh's Chief Minister backed by a loan from the World Bank. It proposes to consolidate small farms and rapidly increase mechanisation and modernisation. Production enhancing technologies such as genetic modification will be introduced in farming and food processing, reducing the number of people on the land from 70% to 40% by 2020.

Vision 2:

An export-based cash crop model of organic production. This vision is based on proposals within IFOAM and the International Trade Centre (UNCTAD/WTO) for environmentally friendly farming linked to national and international markets. It is also increasingly driven by the demand of supermarkets in the North to have a cheap supply of organic produce and comply with new eco-labelling standards.

Vision 3:

Localised food systems. A future scenario based on increased self-reliance for rural communities, low external input agriculture, the re-localisation of food production, markets and local economies, -with long distance trade in goods that are surplus to production or not produced locally.

Here, too, the jury/scenario workshop process was overseen by a panel consisting of a variety of interest groups (donors, government, civil society organisations). It was presided over by a retired Chief Justice from the Supreme Court of India. The panel's role was to ensure that the entire process was carried out in a fair and unprejudiced way. As part of the methodology, media professionals were also involved in relaying information on the event to a larger audience.

Jury supports localised food systems

The key conclusions reached by the jury – their 'vision' – included a desire for:

- Food and farming for self reliance and community control over resources
- To maintain healthy soils, diverse crops, trees and livestock, and to build on our indigenous knowledge, practical skills and local institutions.

And opposition to:

- The proposed reduction of those making their livelihood from the land from 70%-40% in Andhra Pradesh
- Land consolidation and displacement of rural people
- GM Crops - including Vitamin A rice & Bt cotton
- Labour-displacing mechanisation
- Contract farming
- Loss of control over medicinal plants including their export

Some key lessons

a) The voices of small and marginal farmers can enter the policy process when appropriate methodologies are used as in the two cases mentioned. For example:

- putting the perceptions, priorities and judgement of ordinary farmers at centre stage,
- conducting the events in a rural setting : under a tamarind tree on a farm (Karnataka) and a the farm of a rural training centre (Andhra Pradesh),
- getting government bureaucrats, scientists and other expert witnesses to travel to farmers in order to present evidence on the pros and cons of new technologies,
- using television and video technology to ensure transparency and free circulation of information on the process and the outcomes

b) In both Karnataka and Andhra Pradesh, the jury process demonstrated the competence with which farmers, many of whom had not finished basic schooling, or were even illiterate, could discuss often highly technical issues to which they had no previous exposure, such as genetically engineered crops. They achieved this by carefully eliciting from each witness the information relevant to their livelihoods. Rather than attempting to build up a basic knowledge of genetics, they asked whether the 'new seeds', as they called them, could address their needs, such as returning organic matter to their soils, and reducing their susceptibility to rapidly changing market prices for their harvested produce.

c) As in the case of a controversial technology such as GMOs, a wider understanding of the inter-linkages between biotechnology, corporate control, and local power structures is more likely to be achieved by taking a scenario approach than by merely asking a jury to say yes or no to a particular technology. In Karnataka, the comparison was of two starkly different technological approaches to agriculture (or visions) – one based on GM seed and continued chemical use, the other on saved indigenous seeds, traditional technologies and organic methods. In the "Prajateerpu" example, the jury was able to compare and evaluate three contrasting whole scenarios, each being the logical product of a series of interdependent values, assumptions and predictions. GMOs were thus not taken and judged in isolation - they were perceived and evaluated as an integral part of a wider system or development model.

d) In a recent briefing paper on GM crops and the Third World, the UK Government's Overseas Development Institute condemned the "poorly informed arguments" that used "formulae, slogans and slick advertising". It called for greater research towards providing sound evidence on the risks and potential benefits of GM crops for the South. "The most pressing need", it concluded, "is for good information". Citizen juries, scenario workshops etc. clearly offer appropriate methodologies to address this information deficit. More fundamentally, these methods and approaches can help overcome the *current deficit in democracy in policy processes, science and technology.* At the very least this means moving beyond the rhetoric of "listening to the voices of

Brazilian small-scale farmers and poor consumers reject GMOs

The second citizen's jury on GMOs took place in Belem do Para, capital of the Amazonian State of Para, Brazil, in September 2001. 800 small-scale farmers, landless people and poor urban consumers attended the event, organised by ActionAid Brasil, FASE (national Brazilian NGO), Assema (associations of small farmers from Maranhão State), MST (land less movement), CUT (central of labour unions) and the municipality of Belem.

Before the event, the organisers chose 6 community-based associations (2 landless settlement associations, 2 rural workers' labour unions and 2 urban associations). These organisations provided the organisers with complete lists of membership. 4 members, 2 men and 2 women, were picked at random from these lists, in public and in the presence of the local press. Thus, 24 potential members for the jury were identified. The first activity of the jury was to select, at random, 7 members from this list for the jury (4 women and 3 men). After that, the judge, head of the Law faculty of the Federal University of Pará, read the case, which had been agreed upon by the prosecution and defence, prior to the hearing. This case presented a definition of GMOs, the scope of the jury – GM agricultural varieties tolerant to herbicides, insects, plant diseases and new nutritional qualities, and the questions that the members of the jury were suppose to answer: 1) Can GMOs address the problem of hunger? 2) Can GMOs improve the food security of small-scale farmers? 3) Is there enough evidence that GMOs do not threaten the environment? 4) Is there enough evidence that GMOs do not threaten food safety? 5) Is the process of liberalisation of tests and commercial use of GMOs democratic, transparent and careful enough?

After the presentation of the case, the prosecution and the defence lawyers made their first speeches, presenting the main arguments against and in favour of GMOs. The prosecutor was a lawyer from the municipality of Belem, and the defence lawyer was a researcher on biotechnology, from the Federal University of Pará. After the opening statements, the lawyers invited their witnesses, three each. Each witness gave a 20-minute long presentation, and was then cross-examined by the defending and prosecuting lawyers, the judge and the members of the jury. The witnesses of the prosecution were an economist - a specialist on patents and transnational corporations, a geneticist - professor at the University of São Paulo and a specialist on environmental matters, and an anthropologist - a specialist on rural sustainable development. The defence witnesses were two biotechnology researchers from EMBRAPA, the national agricultural research institute, and a professor from the Federal University of Paraíba - a specialist in biochemicals and a member of the national commission on biosafety.

After the presentations and cross-examination of the witnesses, the defence and prosecution made their closing arguments, after which the members of the jury went with the judge and an assistant to a closed room to proceed with the secret ballot on the 5 questions above. The members of the jury voted unanimously against GMOs with a clear NO to all five questions.

This event had various outcomes. The sentence itself has confirmed the position of the national campaign for a GMO-free Brazil, which states that GMOs threaten the environment, food safety and small-scale farming. But the main outcome is not the sentence itself, but the strong, new experience that these 800 poor people had, listening and learning about the very different opinions on GMOs for 2 days. These people, always excluded from the process of policy-making in issues that affect them very much, had the opportunity to access all the information and to decide about it via the members of the jury. Another outcome was the appropriation of the methodology. Several months after this event, some students from a very poor area of Maranhão State have organised a citizen's jury on GMOs in their schools!

Adriano Campolina, Actionaid, Corcovado 252, Jardin Botanio, Rio Janeiro, Brazil 22460050. Phone/Fax (+552) 1 254 05707 E-mail: actionaid@actionaid.org.br

the poor" to actually planning, funding and acting more on the basis of the poor's own definitions of life and well being. It means taking their policy futures and visions of food and farming as starting points. Donors, and the think tanks they rely on, need to experiment more with initiatives such as those described here and re-orient their theory and practice accordingly.

e) The results of the jury had a significant impact in global media and lobbying arenas. However, the process has so far not been conducted over a long enough time-scale so as to bring pressure on national and state governments, donors and corporations that are significant forces in the lives of India's rural poor. Once citizens' juries reach their conclusions it is essential that appropriate intermediary individuals and channels exist to act between the jury and those with the power to create change. NGOs, federations of farmers' organisations and consumer organisations have a role to play and can use the findings of the juries for their campaigns and lobbying activities.

To sum up, the Karnataka citizens' jury on GMOs and "Prajateerpu" were both innovative attempts to include the genuinely poor and socially excluded into policy-formulation processes. Bringing perspectives of the developing world's farmers to national and global debates about the pros and cons of GM crops is based on a belief that rural people in the South have a democratic right, and sufficient knowledge, to judge the issue for themselves. The jury outcomes will hopefully encourage more public deliberation and pluralism in the framing and implementation of policies on poverty, food and agriculture in India, thus contributing to better democratic governance.

Discussing genetic engineering with communal farmers in Zimbabwe

Zimbabwe is surrounded by countries (South Africa, Malawi, Zambia and Mozambique) where testing or commercial production of Bt cotton and/or Bt maize has already taken place. Zimbabwe-based seed companies - Monsanto, Pioneer and Pannar - are awaiting permission from the Zimbabwean Biosafety Board for Bt cotton and Bt maize field trails. For communal farmers, maize is the staple crop and the most common cash crop. As such, they should be able to make informed and reasoned choices about the introduction of GM crops, argue many NGOs. They emphasise that sharing information on what GE technology is, whether it is needed and the possible alternatives is important. The "impact assessment methodology of GE organisms on the livelihoods of resource-poor people", developed by ITDG (Intermediate Technology Development Group) is one such information-sharing initiative.

In Zimababwe, the assessment was carried out as a comparison between two technologies: IPM/IPPM (Integrated pest management and Integrated production and pest management) and genetically modified crops. The exercise consisted of six steps:

Step 1: Introduction of the programme, Group discussions on farming systems (community strengths and assessment of assets related to crop/animal production).
Step 2: First group information sharing on GM crops and Bt-maize. Second group: information sharing on IPM/IPPM.
Step 3: Farmers' response, questions and clarifications about the technologies
Step 4: Assessment of the technology (Bt-maize and IPM/IPPM) under the Sustainable Livelihoods Framework.
Step 5: Overall assessment by farmers.
Step 6: Feed back on the communication approach and process.

An interesting feature of this methodology was the use of drawings to explain genetic engineering to farmers who did not have an education in biology. This methodology helped farmers to get insight into the topic, and to ask questions like: "How does the Bt gene get expressed in the stalk and the leaves but not in the cob?", Are the Bt genes passed on to the progeny?", Which other insects die besides the stalk borer". Farmers also discussed aspects such as fertility requirements, weevil resistance, environmental impact etc. "What effect would it have on soil structure, and on the crops that are grown thereafter?" was another question asked. Farmers also raised their concerns about resistance build-up in pests. They were also keen to find out about the economics related to the price of Bt seed and the cost saving in pesticides.

Other important categories were health, religion and power-relations. Farmers wanted to know whether the toxin that kills maize stalk borers wouldn't also affect them in the long term, by eating the stalks and the cobs, by eating meat of animals fed on Bt-maize stalks. A strong feeling of powerlessness towards the seed sector/agribusiness was often mentioned. One farmer said: " if farmers see a variety that kills all insects, they will want it, because they don't understand the other factors". On which another remarked: "marketing companies don't give the full picture, for example Dieldrin, they just said how good it was, but said nothing about the human health effects or how to use it safely."

"We may be given seed, or sold it cheaply by companies for a while, but then the subsidy may be withdrawn and we've all lost the varieties we used to use".

Another farmer raised the issue of control mechanisms against contamination of their varieties: "we talked to our neighbours to try and reduce contamination by keeping the maize varieties separated from each other... but without by-laws we can't make decisions as a community on excluding varieties". Another remarked: "Even if there is a law against a variety, people may still want to grow that variety, Any law must be monitored for enforcement, otherwise it is pointless".

This exercise shows, once again, that farmers, given the chance, are perfectly capable of discussing technical issues related to GE and in making their choices.

Can we afford to loose this diversity of maize? Photo: Greenpeace

Mexico, centre of diversity for maize, has been contaminated

Doreen Stabinsky and Niccolo' Sarno

The Mexican government, by means of its Intersecretarial Commission for Biosecurity and Genetically Modified Organisms (CIBIOGEM), announced research showing that 15 of 22 communities where maize seeds were tested this year were found to have been contaminated by GE maize. 3 - 10% of the maize seed tested contain genes from GE maize. Two communities showed even higher rates of contamination. Clearly many traditional maize fields in the region have been contaminated but authorities do not yet know the extent of the contamination.

GE varieties are not grown in Mexico but they are imported from the United States for feed and industrial use. The contamination was found in the rural Southern Mexican states of Oaxaca and Puebla, centres of origin and diversity of maize strains grown around the planet.

The magnitude of the problem in Oaxaca is large and the potential for contamination of neighbouring fields is a serious reality. While most maize pollen will fall within 500 meters of the crop field, transport of pollen over longer distances is possible. Bees can disperse pollen up to several miles; under unusual weather conditions, wind may carry pollen up to hundreds of kilometres.

Why care about crop genetic contamination and genetic diversity?

Jack Harlan, the famous botanist, has noted that genetic diversity "stands between us and catastrophic starvation on a scale we cannot imagine." According to the UN Food and Agriculture Organization (FAO), 75% of our crop genetic diversity has been lost within the last one hundred years. Loss of genetic diversity is epidemic worldwide; it is termed genetic erosion.

Because of the continued need of modern breeding programmes for new characteristics and genes, crop genetic conservationists concern themselves with preserving wild relatives of crop plants, as well as those local varieties of crops that small-scale agriculturalists grow in the many diverse cropping system habitats found throughout the world. Often these wild relatives and landraces, as local varieties are often called, are found in small populations, making conservation difficult.

Crop diversity is essential to the future of our agricultural systems. But it is also an essential component of our cultures. Consider the many varieties of potatoes grown by peoples living in the Andes, or the wide variety of eggplants, squashes and gourds used throughout Asia. Preservation of crop diversity is also a means of preserving elements of cultural diversity.

Maize under threat

Lack of genetic diversity can be linked to many of the major crop epidemics in human history. For example, in 1970, the maize crop in the southern United States was attacked by a disease called Southern cornleaf blight. Because of genetic uniformity among the maize varieties grown across the US, the loss to this disease was great – in total the US lost 15% of its harvest – at the time worth around US$1 billion. Loss of genetic diversity due to loss of cultivated varieties – genetic erosion – is happening in maize as well as in all our other major and minor crop plants. According to Genetic Resources Action International "only 20% of local maize varieties reported in Mexico in 1930 are still known."

Currently maize resources are under threat in two primary ways: the displacement of local varieties and the contamination of teosinte (see Box next page) by hybrid maizes. These threats are likely to increase in magnitude with genetically engineered maize.

Consequences of transgene contamination for the teosintes

Because crop plants and their wild relatives are closely related evolutionarily, they are often able to interbreed. This means that there is the potential for genetically engineered crops to hybridise with wild relatives and for the offspring to be viable. Most scientists agree that teosintes and cultivated maize interbreed. The offspring of a maize-teosinte cross may be more or less successful than the wild parent; either result could have negative long-term consequences for diversity conservation.

One problematic result of a maize-teosinte cross would be if the crop-wild relative hybrids were more successful in some way. Certainly crops engineered to be tolerant to pests and their offspring would have an advantage over wild relatives that had no such novel gene. Scientists have raised the concern that such hybrids could become problem weeds, creating a nuisance for farmers and also out-competing the wild relatives in the non-agricultural environment.

A second concern raised by scientists is the potential for crop-to-wild gene flow to lead to the extinction of rare species. This extinction can happen in two ways – through processes known as swamping and outbreeding depression. In swamping, the population of wild plants is continually exposed to the crop, and hybrids are continually forming. If the hybrids are viable and continue to mate with the wild relative, eventually the genetic integrity of the wild relative is swamped by the continual influx of genes from the cultivated plant. Small populations and rare species can be lost. The second process is known as outbreeding depression, where there is detrimental gene flow, resulting in offspring that are less fit. Eventually the population disappears. According to Ellstrand et al. (1999), "both phenomena can lead to extinction rapidly."

Most of the small populations of wild teosintes are already under serious threat. Contamination from an escaped transgene could push them over the edge.

GE maize poses broader ecological threats as well

Most probably, the contaminating gene found in Mexican landraces is a form of the Bt gene, which produces a pesticide toxic to many species of lepidopteran insects. There has been a huge controversy in the United States and other countries over the use of Bt genes primarily because of the potential ecological impacts associated with plants producing the pesticide. These impacts include harm to non-target organisms, including species such as the monarch butterfly and the green lacewing, a beneficial predatory insect; and impacts on soil biota through discharge of Bt from maize roots.

The diverse ecological risks associated with Bt maize are troubling if one considers that the contamination of maize landraces could be long lasting. As noted above, the gene will almost certainly transfer to the landraces it contaminates; farmers and natural selection forces will help to maintain populations containing the gene. If the gene becomes widespread in landrace populations, as it appears to be currently, the ecological damage will be impossible to prevent or mitigate.

Greenpeace believes that the only way ahead is for the Mexican government to implement an emergency plan that should include the following steps:

- Undertake immediately a rapid assessment of the scope and magnitude of the contamination in Mexico and the GE varieties involved.
- Determine the source of the contamination.
- Declare an immediate halt to the importation of GE maize.
- Develop and implement immediately a de-contamination plan.
- Establish quickly national legislation and regulations to guarantee that this contamination will not occur again.
- Investigate the legal responsibilities of the governmental authorities that allowed the contamination to take place.
- File legal action on behalf of the affected communities against the companies responsible for production and dissemination of GE maize.

In Mexico, teosinte, the closest wild relative of cultivated maize, is found growing from Chihuahua to Oaxaca. In addition to teosinte, a large store of maize diversity exists in the multitude of landraces – local cultivated varieties – grown throughout Mexico and other maize growing countries in Central and South America. In Mexico, the thousands of landraces of maize are called criollo maize.

The many varieties have different growing characteristics suited for changing climate conditions. In Chihuahua, Mexico, the fast growing variety Apachito is planted when the rains are delayed. Coloured varieties correlate with varying maturation periods. Blue and red pigments in maize stalks help maize varieties warm up quickly on cool mornings. This makes them especially suitable to be planted earlier in the year. A fast maturing variety in Colombia was given the name matahambre, which translates as 'hunger killer'.

Many small farmers depend on maize for food and money.

Plants protecting other plants
An alternative to pest-resistant GM crops

Luis Gomero Osorio

One of the justifications for the development of GM crops is to build-in resistance to insects and diseases, which in turn is expected to reduce the negative impact of agrochemicals on health and the environment. Of the total area planted to GM crops worldwide in the year 2000, 19% represent insect-resistant crops and 7% occupy crops combining both herbicide and insect resistance. Herbicide-tolerant crops form the majority as they fit very well in the strategy of large agrochemical companies like Monsanto that sell the seeds with the chemical inputs such as glyphosate in one package.

Research on genetic modification that is taking place in the Andean countries is predominantly focusing on plant health: herbicide-tolerant cotton and soya, resistance to Lepidopteros in cotton, resistance to nematodes in potatoes, resistance to white leaf in rice etc. Significant financial and human resources are being invested in research that will eventually bring benefits only to large-scale industrialised agriculture. The majority of Andean farmers will not benefit from the introduction of these GM varieties.

Biodiversity as a source for plant protection

In agriculture, the fight against harmful organisms is essential, and it is therefore necessary to develop appropriate technologies to regulate and control pests. Environmentally-friendly, biological options that do not make use of Genetic Modification do exist. These options are based on natural crop protection approaches that make use of the diversity found in nature itself. Some institutions are already investigating and promoting these non-chemical and non-GM options, providing excellent and competitive alternatives for pest management.

Preparation of plant-based pesticides on the farm. Photo: Bert Lof

The challenge in natural crop protection is to have simple and low-cost technologies that are able to regulate pests and diseases and to reduce or completely avoid the problem of contamination by agrochemicals. One such natural crop protection approach is based on the use of plants with biological control properties. Plant types with insecticidal properties that can be used in curative form are equally important. At the moment successful experiences with this type of plant products exist and some of them are even available on the market.

Peru has a great potential of plants that have these properties, but research programmes to validate the technical and ecological benefits of these plants are required. Until now, the research efforts for seeking alternatives to chemical inputs have been very limited. A review of research indicated that over the past 40 years, 90% of research has been related to the management of chemical inputs rather than in finding alternative options.

Plants that protect other plants

Within the framework of ecological pest management, an important and promising set of technologies is being provided by making use of plants as biological control agents. An inventory made in Peru indicated the existance of more than 300 plant species - both native and imported - that are useful for the management of populations of harmful insects. 14 possible applications emerge from this inventory, of which the most important are insecticide, repellent, nematicide and fungicide, indicating that ecological pest management has a great potential for further development.

So far, most of the research work has been focused on the rescue and technical validation of a series of these plants. Many plants have demonstrated a certain level of efficiency in regulating pests and diseases, and have been proven on the basis of statistically-sound research. E.g. extracts from a wild forest plant named "cardo santo" (*Argemone sufusiformis*) was found to be an effective regulator of *Spodoptera frugiperda* populations (army worm) in their larvae stage; "cuncuno" (*Vallesia glabra*) and "laurel" (*Nerium oleander*) demonstrated to be efficient fungicides, especially to control *Fusarium solani* and *Rhizoctonia solani*; in some zones of Peru, plants like "cola de caballo" (*Equisetum sp.*) are being used to regulate the presence of "Rancha" (*Phytophthora infestans*) in potatoes. The high silicium content of the plant helps in neutralising the multiplication of the fungus.

Similarly, research is being done on the identification of plants with properties for controlling nematodes such as "crotolaria" (*Crotolaria sp.*) and – again – "cardo santo". Furthermore, the oil of various plants helps to fight pests that cause damage to grain in storage. Research demonstrates that with small investments, the damage of pests in the warehouses can be mitigated.

The use of extracts of the wild coastal plant "tonuz" (*Pluchea chingoyo*) has shown to be of great potential to control "polilla" (*Phthorimaea operculella*) in stored potatoes, a plague that inflicts great economic damage to Andean farmers. Also the use of eucalyptus (*Eucalipthus sp.*), muña (*Minthostachis spp.*) and lantana (*Lantana camara*) has been reported by the International Potato Centre (CIP) as being capable of controlling pest attacks on stored potatoes.

Many more experiences exist. Although the steps towards more ecological pest management are just being taken, alternative and competitive approaches on the basis of the diversity of plant species will be found in the future.

Plants with a market potential

Large-scale use of plant-based biological control is not yet taking place. The existing experiences are mainly related to the traditional use by farmers, cases that are unfortunately not very well documented. Nevertheless, the existence of four plants widely-known and studied for their biological control properties represent an alternative for pest control. Their characteristics and potential for commercial application are as follows:

a. Kumo (*Lonchocarpaus nicou L*)

Kumo is widely distributed in the forests of Peru where it grows spontaneously as a wild plant. In other zones of the Amazon forest it is also known as *barbasco*. This plant contains in its roots a well-known toxic substance, locally known as *rotenona.* Native farmers use it to for pest control and for fishing. Before the 1950s this plant was harvested and exported, but after the introduction of synthetic pesticides its use has gradually declined.

Plant extracts used in pest control. Photo: Bert Lof

Recently, a private company has again taken up the collection of this plant and has begun exporting it, mainly to the U.S.A. On the local market it is now being sold as a bio-pesticide with the commercial name "Agrosan". At the moment, a small plant for the processing of Kumo is being set-up in the Apurimac valley as part of a United Nations programme to promote alternatives to coca growing. Similarly, another company is offering rotenona in a liquid formula. Kumo controls a good number of pests and therefore has a great potential for agroecological agriculture.

b. Sabadilla *(Schoenocaulon officinale*)

This is a plant with insecticidal properties that is mainly known in Venezuela, Colombia and Mexico. In Peru, it is supposed to have been introduced before the 1950s in order to control skin infections as it kills fleas, lice and mites. After the introduction of DDT in the country, this plant was used less and less, and, today, its insecticidal qualities are hardly known to young farmers and agricultural workers. Farmers indicate that the plant is disappearing because of burning and is only to be found in very degraded and hilly zones.

Sabadilla is a perennial plant belonging to the family of the irises. It is the mature seeds that have the insecticidal properties. The main pests it controls are fleas, fall army worms, corn borers, lice, mites, thrips, leaf bugs and cockroaches (Gaby Stoll, 2000).

c. *Neem* (*Azadirachta indica*)

The neem tree, pertaining to the Meliaceae family, originates from Southeast Asia and is very well known world-wide because of its biological control properties. Though the tree was probably brought to Peru a long time ago, it is only recently that a number of institutions like the Network for Action on Alternatives to the use of Agro-chemicals (RAAA), have started distributing seeds on a larger scale. At the moment, around 3.000 seedlings have been planted in various areas.

Neem is cultivated in many regions of Africa, Australia and Latin America, because it adapts very well to the soils and semi-arid climates in tropical and sub-tropical countries. It shows a good tolerance to dry conditions and soil salinity. Its medicinal properties present a potential for treating animals and humans.

The specific use of neem in India for natural crop protection, has extended almost world-wide over the past number of years, including a great number of countries where it is being sold commercially. The production of insecticide from the neem seeds can be done in a relatively simple, artisanal way or else as an industrial process.

Studies indicate that the active substances of the neem seed (Azadirachtin, Salanin, Nimbin, Nimbidin, Meliantrol, etc.) have repellent effects. Upon ingestion, they have a very special effect on the metamorphosis of insects, preventing their growth and development. These substances are not toxic to human beings, mammals, birds, reptiles and fish. Applied in the indicated concentrations they do not affect the beneficial flora or fauna in the cultivated fields.

d. Paradise tree (*Melia azedarach*)

This is a tree that grows in wild form in Peru. It is a close relative of the neem. It contains contact toxins that can serve as an insecticide, repellent, and growth inhibitor. RAAA has made investigations to demonstrate their effectiveness in the control of fall army worms with satisfactory results. In Cuba there is already some experience in making use of the insecticidal properties of the Paradise tree. A commercial product on the basis of melia is available under the name Melitox. The seeds of this tree can also be processed in the same way as neem seeds.

Conclusion

Biological Control represents a concrete alternative to the use of GM crops, because it saves and strengthens the ecological balance that existed before the use of agrochemicals. This control method diminishes the dependency of local farmers on external inputs like pesticides, thus allowing for healthier living and working conditions.

Organic Cotton Production
an alternative to GM Cotton for small farmers?

GM cotton is unlikely to have much appeal to small-scale cotton farmers. Photo: Coen Reijntjes

Dorothy Myers

Global cotton production has tripled (to around 20 million tonnes) since the 1930s largely due to the intensive use of synthetic chemicals; irrigation and higher-yielding varieties have also played their part. Large quantities of the most toxic pesticides are used on the cotton crop - with associated health and environmental problems, especially in developing countries. Regulatory systems are weak or are not enforced; farmers are not adequately informed of the dangers and lack the necessary skills and equipment to protect themselves and their families. Recent NGO research in Benin has revealed many poisonings and deaths related to the use of the highly toxic pesticide, endosulfan.

GM cotton production

By 2000, some 5.3 million hectares of genetically modified (GM) cotton were grown, representing 16% of the total cotton area planted worldwide. It is grown commercially in Argentina, Australia, China, South Africa and the USA. There are three main types of GM cotton: herbicide tolerant (tolerant to glyphosate and bromoxynil – 2.1 million ha), insect resistant (with the *Bacillus thuringiensis -Bt-* toxin genes inserted – 1.5 million ha) and a third type which combines both attributes (1.7 million ha). Concerns about the increasingly widespread use of this technology abound. Predicted reductions in herbicide use appear not to have occurred and transfer of genes to related wild species seems inevitable. There are also concerns about the development of resistance to Bt. Strategies are in place to prevent this happening but questions have arisen about their effectiveness and enforcement. Moreover, GM cotton is unlikely to have much appeal to small-scale cotton farmers in the South – mainly for economic reasons. For example, GM cotton is sold as a package that includes the herbicide which the cotton is engineered to tolerate – usually glyphosate. Farmers are also required to buy new seed each season contrary to their customary seed saving practices. GM seed is more expensive than conventional seed since a 'technology fee' is included in the price.

Alternative cotton production

Concerns about costs and the detrimental effects on health and the environment of the high usage of synthetic pesticides on cotton have persuaded many small-scale farmers to seek alternatives where opportunities exist. Expanding interest on the part of Northern consumers and established verifiable regulatory systems for organic production such as the IFOAM Basic Standards (see p.12) have stimulated interest in the development of projects in many countries. Organic cotton production started in Turkey and the USA in the early 1990s. Other projects followed throughout the last decade in South Asia, Africa and Latin America.

Certified organic cotton fibre is currently produced in widely varying production systems in 12 countries. Global production of organic cotton was about 8000 tonnes in 1997 and indications are that it has stayed stable at that level since then.

In most of the organic cotton projects involving small-scale farmers there has been significant involvement of outsiders. Projects have been initiated and supported by a variety of actors including private companies (eg. Remei, Verner Frang, Bo Weevil), development cooperation agencies, and NGOs (PAN-UK, for example). Knowledge of marketing practices and potential markets is often in short supply, when projects are not directly linked to companies that buy the output.Financial support is also needed to meet the costs of organic certification. A good level of technical support has been a feature of many projects and is essential in the early stages of transition to organic when decreases in output may occur.

As is to be expected, a range of factors seems to determine the success, or otherwise, of organic cotton projects including project structures, management, agronomic back-up and expertise, market conditions and access. The key factor is the motivation of farmers which, especially for small farmers in Africa, for example, appears to be determined by economic reasons first and foremost. With the collapse in recent years of state extension services, the level of support available within projects to help convert to organic systems has also proved to be highly significant and is much appreciated by farmers.

Finding local solutions

At the technical level, organic cotton is a product of an organic farming system, which relies on crop rotation, organic fertilisation and on non-synthetic chemical pest control methods. More specific technical details of production systems are site-specific and are determined by local conditions. In Benin, for example, a palm oil tree residue is used as fertiliser, in Uganda a species of black ant is used for pest control, and in Senegal and elsewhere neem extract is used for pest control. In addition to cotton, such integrated systems produce other crops, which can also generate income and should be accounted for when assessing profitability.

In general, organic systems produce less than conventional systems, but this is compensated through savings on inputs, payment of premiums, and perceived improvements in health for people, their animals and their environment. In Zimbabwe, for example, even though yields were lower in organic than in conventional cotton production systems, profits were higher even for the poorest farmers. The approach was highly valued by AIDS widows as reported in an article of the LEISA Magazine (Vol. 17.1, p.28). Differences in results depend on whether significant amounts of synthetic chemicals have been used in the previous production system and on the role and position of cotton in the overall production system. The conversion period is obviously longer where large quantities of chemicals have been used previously.

In Senegal, the number of women participating in the project in Koussanar is increasing steadily. In the past they have been unable to grow cotton because of lack of access to credit for inputs. People who are normally excluded from cash crop production within input-based conventional systems are able to participate in organic systems because no cash investment is called for up-front.

Experiences from Benin and Senegal

Work on sustainable alternatives to pesticide-dependent agriculture at the Pesticides Action Network UK (PAN UK) has focused on promotion and support for organic cotton production with partners in Senegal and Benin. Benin is highly dependent on its cotton crop for export, and at the domestic level cotton is the main cash crop for many farmers. Crop protection in the conventional cotton sector relies entirely on chemical pesticides. The Beninese NGO, OBEPAB, started working on organic agriculture in 1995 when a group of farmers from Mangassa in the Djudja district of Benin approached OBEPAB for help. The farmers had become dissatisfied with the conventional production system. Their profits were being eroded through increased costs of inputs and they were concerned about the lack of openness in the state system – especially regarding payments for their cotton crop. Farmers had become aware of the serious problems related to the pesticides that they were called upon to use.

The number of farmers involved in organic cotton production has increased steadily over the years, from about 100 initially to over 200 now. Kitche Denis is one of the Mangassa farmers who converted to organic. He described the situation in the following way:

"We used chemicals on our cotton crop and had higher yields than now, but we were often sick and had to spend some of the money we earned on medicines. After harvesting groundnuts this season, I grew cotton without any chemical fertiliser or pesticides. We used palm oil cake, ash, and cattle manure as fertiliser and put the organic matter back into the soil through the cotton leaves, which fall early. We treated the pests with extracts of neem, crushed papaya leaves, cow urine and garlic. There are ten in my family and we all work in the fields, sometimes with extra help. The women do the sowing, weeding and harvesting. And with organic agriculture it is safe for them to be in the fields with the children because the natural sprays do not harm us.

We are now in our fourth season of organic cotton production and yields are increasing year by year. My message to other farmers is that we should rely on ourselves instead of depending on others. Our neighbours admire our village and want to become like us and the number of farmers in the project is increasing each year."

More farmers join

PAN UK is currently involved with partners in research covering all the African organic cotton projects. Results are expected in early 2002. Country reports indicate that farmers join and decide to stay in the organic system, not only because of the financial, health and environmental benefits. Their interest also has to do with being paid on time, not becoming indebted, and having a good level of support. Farmers have also expressed the view that their knowledge and experience is valued, which in turn generates greater confidence. It is vital that information and experiences generated by the projects is widely shared in order to expand the take-up of organic agriculture and to build a credible alternative to conventional production which may in future be increasingly dominated by GM crops.

However, the rapid spread of GM cotton could pose a threat for organic cotton producers as the Basic Standards for Organic Agriculture prohibit the use of GM varieties. Where organic and conventional cotton are grown side by side, contamination could be an issue. Organic cotton farmers are accustomed to planting with a 'safe' distance between their organic fields and the conventional fields of their neighbours to avoid spray contamination. The introduction of GM cotton reinforces this requirement and probably would require greater distances. To date, most small-scale organic cotton farmers are not faced with this problem – but that could change in the future.

Genetically modified soybeans
Blessing or curse for Brazilian agriculture?

Jean Marc von der Weid and José Maria Tardin

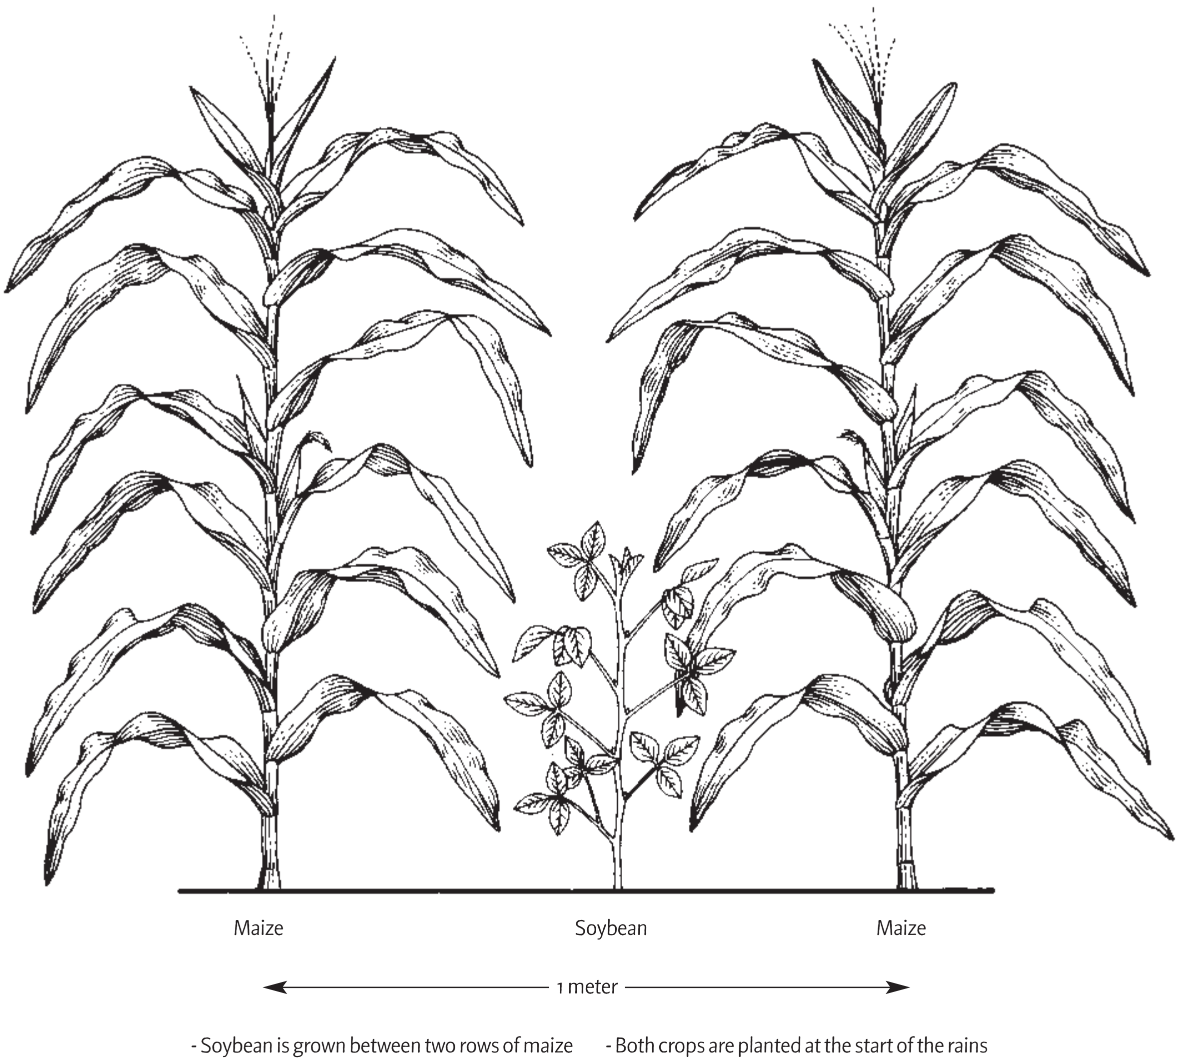
Brazil is the "last of the big dominoes" in the soybean market still resisting the GM onslaught. *"If Brazil legalizes biotech production"*, says Bob Callanan, a spokesman for the American Soybean Association, *"Europe and Asia would have almost nowhere to turn for adequate supplies of non-biotech soybeans"*. The United States, Brazil and Argentina account for about 90% of soybean exports with Brazil occupying 26.4% of grain, 24.8% of soybean meal and 16.2% of soybean oil exports worldwide. The demand for non-biotech soybean has grown to 25% of the EU market, 44% of which is supplied by Brazil (Pelaez and Schimidt, 2001). The Brazilian anti-GM position is therefore decisive for the future of GM agriculture as a whole, for as Callanan says, *"if that (Brazil) goes, it's all gone"*.

Having this picture in mind Brazilians have to decide where their strategic interests lie. According to the Brazilian government, the transnational corporations like Monsanto and Syngenta and the big soybean producers, the country will lose markets if it lags behind in biotechnological improvements in soybean production. Nevertheless, sober assessments of agricultural performances, costs and market opportunities dismiss this position as completely unreal. This article shows that Brazil is doing well without GM soybean, and what's more, that agroecological soybean production is a viable and competitive option for many small-scale farmers in Brazil

Conventional non-GM soybean production

Over the past 30 years soybean production has developed enormously in Brazil, with increases in both yields and area planted. The most spectacular growth has been in the state of Mato Grosso and the Cerrado area of central Brazil. Here soybean yields have more than doubled, whereas harvested areas have increased about tenfold. Given the relatively low cost of land clearing in Brazil, it is likely that soybean production will continue to increase in the years to come.

During this period, soybean production systems have been able to reach this level of high performance with reduced costs



Intercropping - one feature of the agroecological system of soya production (diagram from "A farmer's primer")

because of strong inputs from public research. Conventional genetic improvement has permitted farmers in various ecosystems to choose from around 170 varieties. In addition, the widespread adoption of nitrogen-fixing bacteria (NFB) eliminated the use of expensive nitrogen fertilizers. Moreover, the major pest threat to soybean production in Brazil, the *Anticarsia gemmatalis* worm, is controlled with a cheap biological agent, *Baculovirus anticarsia*.

Considerable reduction of Soybean production costs have also been due to the fact that at least 30% of the seeds used are produced by the farmers themselves. More recently conventional soybean farmers have very rapidly adopted less costly direct sowing, no till methods. In this system herbicides are intensively applied to suppress weed infestation resulting in heavy leaching of residual chemicals.

Comparing GM to non-GM soybean

The question to be answered is a simple one: does GM soybean have enough advantages to compensate for the risks of adverse impacts? If we compare yields of Brazilian non-GM soybean to USA yields (50% planted to GM soybean), the latter attained 2,560 kg/ha in 2000/01, and the former 2,710 kg/ha. In the 5-year period since the introduction of GM soybean in the USA the average yield was 2,520 kg/ha. compared to 2,400 kg/ha. in Brazil (Pelaez and Schimidt, 2001). Even though the USA has increased its acreage of GM soybean drastically in this 5-year period, the figures indicate that the yields of non-GM soybean in Brazil have increased faster than soybean yields in the USA with GM varieties.

Production costs are found to be higher for GM soybeans. In 1998/99 GM soybeans cost 611.70 US$/ha in Illinois, USA, whereas conventional soybeans cost 373.80 US$/ha in Mato Grosso, Brazil – a marked difference to GM soybeans!

Theoretical calculations on what GM soybeans would cost in Brazil also showed a disadvantage against the conventional product. Admitting industry claims of 30% herbicide reduction as true, GM soybeans would still cost 24.75 US$/ha more than conventional soybeans. Costs of GM seeds (76.50 US$/ha) clearly outweigh herbicide costs reduction.

This comparison can be taken further by looking at the export markets to see where Brazilian interests reside. With the increasing demand for non-GM soybeans from Europe, Brazilian exports have soared from 11 million tons in 1999 to 14 million tons in 2000, whilst US exports have stagnated. Moreover, non-GM soybeans have got a premium of 11 US$/ton, whereas prices for biotech products have dropped (Pelaez and Schimidt, 2001).

Apart from economic concerns, there are also environmental concerns. Scientists have warned against the intensive use of herbicides as these chemicals can have harmful effects on soil bacteria. As research in the USA indicates, decreased nitrogen fixation is a likely explanation for the 5-10% yield drag of RR GM soybeans when compared to otherwise similar conventional varieties (Benbrook, 2001). This negative impact will be far more pronounced in Brazil as varietal improvement has been geared to increase response to NFB (Nitrogen Fixing Bacteria). If GM soybean has negative impacts on NFB, then the losses incurred by Brazilian farmers could be substantial, as the gain in terms of reduced nitrogen fertilizers amount to 1.8 billion dollars annually (Franco and Baldani, 1999).

With all these clear advantages for non-GM soybeans why have Brazilian farmers in the southern state of Rio Grande do Sul taken the risk of smuggling GM soybean seeds from Argentina? According to some big soybean producers it is a supposed benefit to farmers of 14.00 US$/ha by using GM soybean seeds. But, in fact, this claim is clearly untrue considering that the Brazilian farmers are getting their smuggled seeds at 16.40 US$ per bag whereas the real cost of a bag is around 57,40 US$. And this is only possible because Monsanto has chosen not to enforce its prohibition on the re-sale of GM soybean seeds on farmers in Argentina, a tactical move to facilitate GM acceptance both in that country and in Brazil.

The agroecological alternative

In southern Brazil, Agroecological soybean production is being developed as part of its family-farmer programme by AS-PTA (a Brazilian NGO) and the Farmers' Forum for the Southern Paraná Regional Development (see LEISA 17.03, 23-25pp). It is based on direct sowing, no-till using green manure varieties as cover crops and weed control based on mechanical/ hand weeding. It is reported to have minimum soil losses, minimal losses from leaching, and no soil, food nor water contamination.

If we compare agroecological soybean production with conventional systems in Brazil the advantages are astounding. Studies made by AS-PTA on the property of the Bischoff family - a family from the southern state of Paraná experimenting with agroecological systems - indicate a yield of 2,677 kg/ha from the soybean plot for the agricultural year 2000/01, whilst production costs were 240.95 US$/ha. Prices for conventional and organic soybeans also differed significantly, 17.20 US$ compared to 24.60 US$ per 60kg bag of grain. The Bischoffs who were testing the new agroecological alternatives for soybean production on a 2.4 ha plot are increasing the acreage by 300% for the 2001/02 season. In the nearby southeastern Paraná region agroecological soybean production is already a major economic alternative for family farmers, with nearly 400 of them involved in this activity since 1995.

How can such extreme cost differences between GM (USA), conventional (Mato Grosso, Brazil) and agroecological (Bischoff) soybean productions be explained?

The Bischoffs noticed that weed infestations have dropped by 50% in 4 years with continuous agroecological practices in their bean and maize plots. They expect this to be the case also in their soybean plots, further reducing their production costs in comparison to chemical systems. The Bishoffs do not use any chemicals in their system, adopting crop rotations, green manuring and biofertilizers produced on the farm. No pesticides or fungicides are used and the Bischoffs attribute this to crop rotations and the conservation of natural vegetation on the borders of the plots, which harbour predators of pests. They also use low doses of lime to correct soil acidity.

Around 10,000 family farmers in this region are involved in intensive experimentation on various agroecologial practices, particularly in soil management, traditional seed improvement and agroforestry. The Bishoffs, like all participants in this programme, have small holdings with diversified cropping systems, including beans, maize, soybeans, potatoes, erva mate (a kind of Brazilian tea) etc.

In the light of the figures presented above, we can conclude, beyond any doubt, that agroecological soybean production is competitive with both conventional and GM cropping systems, without the harmful impacts of the former and the apparent risks of the latter. Wider application of these experiments depends more on enabling public policies, mostly related to credit, rural extension and participatory research.

The push pull system – a less risky, less expensive and sustainable option for pest control Photo: Bert Lof

The Push-Pull system
a viable alternative to Bt maize

Flemming Nielsen

In early 2000, a five-year test programme with genetically engineered Bt maize was initiated in Kenya. The aim of this programme is to reduce the considerable damage of stemborer larvae that attack the leaves and stems of maize plants resulting in yield losses of 15 - 40% in East Africa. The recommended practise today for stemborer control is the use of chemical pesticides. Not only can the farmers hardly afford these expensive chemicals, these chemicals also cause environmental and health problems. It is evident that alternative solutions to suppress these pests are badly needed.

Although Bt maize is being promoted rather aggressively at present, it is certainly not the only option. Promising organic alternatives have been developed. One of them is the push-pull system that relies on natural repellent and trapplants. The system has passed the trial phase successfully and is now being promoted by the national extension system in Kenya. Not only does the push-pull system address the stemborer problem – it also suppresses the noxious witchweed (*Striga hermonthica*) that causes further yield losses of 10-20%.

Background

Stemborers are larvae of moths such as *Noctuid Busseola fusca*. In Africa four indigenous species of stemborer are significant pests in grains. They feed on natural grasses and used to be kept in check by natural enemies like the wasp *Cotesia sesamiae*. However, this balanced eco-system was disturbed when maize was brought into Africa about 100 years ago. Maize had little resistance to the African stemborers. About 70 years ago an exotic stemborer found its way to Africa from India and Pakistan. This is the spotted stemborer *Chilo partellus* that in its area of origin is a harmless pest. However, in Africa it has no natural enemies and consequently it has developed into a major pest in maize.

Approaches to pest control

Four main approaches to fighting stemborers have been developed:

a. Pesticide application

Pesticide application has been the recommended practise for a long time but it is expensive, causes health and environmental problems and kills natural predators.

b. Genetically modified Maize

Bt maize that produces pesticide thus killing the stemborer larvae is currently being tested but not released yet. Bt maize is created by adding a pesticide-producing gene from the bacterium *Bacillus thuringiensis* (Bt) to the maize. It was originally developed to kill the European corn-borer, which is a close relative of the African stemborer, so it is likely to be efficient in controlling the pest, at least initially. Early last year the multinational company Novartis started a 5-year test programme in Kenya with Bt Maize at the cost of US$ 6.2 million. They are collaborating with the governmental Kenya Agriculture Research Institute (KARI), the Kenyan Ministry of Agriculture and the International Maize and Wheat Improvement Centre (CIMMYT).

Apart from the problems of genetic pollution (see pg. 25) and farmers' dependency on a few multinational companies (see editorial pg. 4) for their seeds, there is also evidence that pests quickly develop resistance to Bt maize.

To reduce the risk of genetic pollution, most countries require farmers to have a buffer zone of 100 m to related non-GE crops. Most countries are likely to increase the demanded buffer zone after recent studies have shown that pollen is easily spread 800m or even further (New Scientist 24 November 2001). To delay the development of insect resistance to Bt maize it is recommended that farmers create a "refugia" of non-GE crops for the pests to feed on. Most small-scale farmers will not be able to create the required buffer zone or allocate land for a "refugia".

c. Introduction of natural predator insects
In Asia, the wasp *Cotesia Flavipes Cameron* is a natural enemy of the *Chilo partellus* stemborer. In 1993, the Kenya-based International Centre of Insect Physiology and Ecology (ICIPE) introduced the wasp to Africa as a biological control agent. The wasp tracks down the stemborer larvae buried deep inside the maize stalks and lays its eggs into the pest. The eggs hatch and consume the borer from within.

After successful field trials the wasp is now being released on a larger scale. It shows great potential in fighting the introduced spotted stemborer and three of the indigenous species. Results so far indicate that the stemborer population has been cut by half in Kenya's Kwale and Kilifi districts, four years after the initial release. The wasp has steadily spread and is now found throughout the southern part of Kenya.

ICIPE is currently working with national programmes in Kenya, Uganda, Somalia, Ethiopia, Mozambique, Malawi, Zambia, Zimbabwe and Zanzibar to release the Cotesia wasp.

So far, no side effects have appeared or are anticipated because the wasp is very specialised. However, history tells us that the introduction of a foreign species can have totally unanticipated long-term consequences.

d. The push-pull system
The fourth approach is the push-pull system in which intercropped repellent plants "push" the insects out of the fields to trap crops outside the fields that "pull" the insects in. This system makes optimal use of existing biological interaction and relies on mechanisms that have proven to be stable in nature over extended periods. This system is now beyond the trial phase and is being actively disseminated in Kenya.

This article takes a closer look at the push-pull system because it is the most "mature" alternative to genetically modified crops. It is also the least risky, offers the best long-term stability, can be managed by small-scale farmers, and requires no expensive inputs.

The Push-Pull system
The Kenya-based ICIPE has headed the development of the push-pull system for maize in East Africa. Close collaborators include the governmental Kenya Agricultural Research Institute (KARI) and the Institute of Arable Crop Research (IARC), Rothamstead, UK.

Initially, the principal scientist Dr. Zeyaur Khan and his team identified more than 30 grasses with strong stemborer-attracting odours. Farmers were invited to select the grasses they preferred. They chose Napier grass (*Pennisetum* purpureum) and Sudan grass (*Sorghum vulgare Sudanese*) both of which are important fodder crops. The grasses produce a gummy substance that traps the pests and only 10% of the stemborer larvae survive to adulthood.

Of the repellent plants that were researched, the choice was for Molasses grass (*Melinis minutiflora*) and the leguminous Silverleaf (*Desmodium uncinatum*). Research shows that the molasses grass repel stemborer by releasing a complex mixture of volatile substances (terpinoles, nonatrienes etc). It also increases stemborer parasitism by harbouring a natural enemy, the wasp *Cotesia* sesamiae. In trials, Molasses grass reduced crop loss from 40% to 4.6%.

Silverleaf also turns out to have a number of positive attributes apart from repelling the stemoborer. It is nitrogen fixing, a good forage crop and surprisingly it also happens to be very efficient in suppressing the noxious Striga (witchweed, *Striga hermonthica*) weed that is spreading quickly across Africa. Striga is a parasite that feeds on the maize roots and can cause a total crop loss. Currently the average crop loss due to Striga in East Africa is estimated to be 10-20%. Trials have shown that maize intercropped with Silverleaf can suppress Striga by a factor of 40 compared to mono-cropped maize. The reason for this effect is not understood yet but is currently being researched by ICIPE.

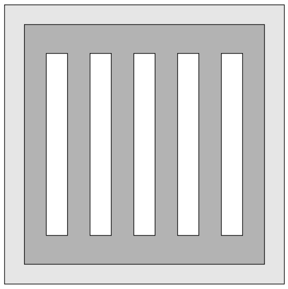

Figure: Push-pull system

In practise, the push-pull system consists of line planted maize with intercropped rows of Molasses grass and/or Silverleaf, surrounded by a belt of Napier and/or Sudan grass.

On-farm testing
The push-pull system was initially tested by more than 600 farmers in 6 districts of Kenya. In the fertile region of Trans Nzoia a yield increase of 15-20% was observed. In the semi-arid Suba district, where both stemborer and Striga damage is high, a substantial increase in maize yield has occurred over the last four years. Economic analysis of the on-farm trials shows that farmers who plant Napier grass and Silverleaf together get a return of US$ 23 for every US$ 10 invested, as compared to a return of US$ 14 from mono-cropped maize.

After the successful on-farm trials, the push-pull system has now been officially released in Kenya and is being disseminated through the extension system. The response by farmers is very positive.

The future
The biological principles of the push-pull system are not new. In fact they are used in many traditional intercropping systems. However, the application of science has made it possible to make very efficient use of these basic biological principles. Similar systems are likely to work elsewhere but may require different repellent and trap crops. Other research centres are already experimenting with push-pull systems. For instance the ARC-Grain Crops Institute in South Africa is conducting research on the use of Vetiver grass as a trap crop around maize fields.

The push-pull system is an ideal option as it builds on existing resources, does not create dependency, is manageable by small farmers and does not pose a threat to the eco-systems. It is estimated that full adoption of the push-pull system by small-scale farmers in East Africa will increase food production sufficiently to feed 6-8 million more people.

However, this system is of little interest to profit-oriented private companies, as it does not require any external inputs. And it is this very fact that may be the biggest obstacle to its dissemination.

The System of Rice Intensification
Agro-ecological opportunities for small farmers?

Norman Uphoff

Besides Madagascar, where it was developed in the 1980s, the system of rice intensification (SRI) is now showing, also in other countries, that it can be more productive than other methods for growing irrigated rice.

A full description of the SRI methodology can be found in the ILEIA Newsletter 15.3&4, pp48-49 with additional information in ILEIA Newsletter 15.4, p.12.

Encouraging results

A recent communication from Sri Lanka reported SRI yields between 9.3 t/ha for a traditional variety (*Rathhel*) and 17.8 t/ha for an improved variety (BG-358) (Gamini Batuwitage, Additional Secretary, Ministry of Lands). Communications from Cuba have reported yields of 9.1 and 9.6 t/ha for first-time users of SRI, working from written instructions (Rena Perez, Advisor, Ministry of Sugar).

SRI gives healthy plants and higher yields
Photo: Association Tefy Saine

Trials with SRI during 2000 at the national agricultural research station at Sapu, The Gambia, gave yields between 5.3 and 8.5 t/ha (Mustapha Ceesay, former director of Sapu station). Two analyses of SRI yields on farmers' fields in two different areas of Madagascar over a five-year period, involving over 1,000 farmers, showed an average of 8 to 9 t/ha (data from Association Tefy Saina around Ranomafana, 1994/95-1998/99; and from a French-assisted project on the rehabilitation of small-scale irrigation systems around Antsirabe and Ambositra during the same period).

Results with SRI practices naturally differ from place to place, between seasons, and across varieties. There is surely also a skill factor involved in how well farmers observe their fields and how carefully they manage the plants, soil, water and nutrients.

Agroecological management - the key

Agroecological management requires attuning practices to crops and conditions, rather than applying a fixed set of practices. The latter "technological" management assumes that the most determining factors are genetic, rather than the management of interactions between genetic potential and environmental conditions which guides an agroecological approach to crop production.

SRI has revealed for rice –and possibly also for other crops- that there exists a substantial genetic potential that can be effectively tapped by adjusting the agronomic management practices. Association Tefy Saina, which has pioneered the work on SRI in Madagascar, has shown that SRI practices will double production for practically all of the rice varieties, local or improved. Indeed, the highest yields with SRI methods have come from "improved" varieties: a World Bank 1996 report on rice in Madagascar, noted that four farmers in the Andapa region who used SRI methods with the high-yielding variety (HYV) IR-46, developed by the International Rice Research Institute, averaged 13.7 t/ha, with one farmer reaching 16.5 t/ha. Similar high yields were obtained in the Ranomafana area with x265, derived from IR-15, and 2067, descended from Tainung-16, a Chinese HYV. Note that the government research agency FoFiFa reported the average yield from 2067 as 5.6 t/ha, with a 'maximum observed yield' of 7.7 t/ha. In the 1998-99 season, a farmer near Soatanana, in his sixth season using SRI, had a yield of 21 t/ha with 2067, more than 10 times the national average (CIIFAD 1999, p.47). Based on these results one may well question whether, indeed, research in genetic engineering can be as effective in raising yield levels as research in agronomic management.

Is genetic modification necessary?

Thus the SRI experience leads one to two very different conclusions:

1. There appears to be ***a large genetic potential in existing rice varieties*** that can still be tapped through agroecologically sound practices. This would imply that genetic modification efforts are not necessary, at least for some time to come, if increasing food production and lowering costs of production are the main objectives. Farmers at Namal Oya in Sri Lanka found not only that SRI methods raised their yields from 2.9 t/ha with conventional

methods to 8.5 t/ha, but they also calculated that it reduced their costs of production, from 6 rupees/kg to 3 rupees/kg.

2. Agroecological methods of crop production appear to give ***better results with genetically-improved varieties***. Some varieties have a greater potential for tillering, root growth and grain filling than others in response to wide spacing, aerated soil, and other SRI practices. Quite likely, though we have not been able to evaluate this systematically, some varieties would also have better pest and disease resistance, or greater drought tolerance, when grown with SRI practices. This implies that there is still considerable potential for conventional breeding and selection to identify varieties that are specifically adapted and responsive to SRI practices.

The question of whether *transgenic* research is justified or needed is different from whether *genetic improvement* should be undertaken. There may be risks with the former that are as yet inadequately assessed, and one can reasonably object to companies with criteria of success based more on private than on public interests directing and driving the process of genetic modification. Such ‘broad-spectrum’ objections don’t apply to conventional genetic improvement towards SRI adapted varieties.

SRI Field. Photo: Association Tefy Saine

Soil health - essential for increasing yield

A different line of criticism of GMOs would be that a preoccupation with genetic changes deflects efforts from studying and improving what may be the most important factor in increasing yield: the management of natural resources. As we work with SRI and try to explain differences in plant response to the different management practices, our attention is increasingly directed to differences in soil quality, or more metaphorically, in soil *health* as understood in terms of soil biological activity.

There has been much concern about the conservation of biological diversity in recent decades. Almost all efforts have focused on above-ground flora and fauna. We think that soil biodiversity - the vast and complex communities of bacteria, fungi, mycorrhiza, actinomycetes, protozoa and nematodes as well as earthworms and other soil ‘megafauna’ - holds the key to high productivity with SRI methods.

Given such high yields from some of the poorest soils in the world, one would expect yields to decline over the years. This is certainly to be expected when only low-quality organic material is applied, rather than nutrient-rich chemical fertilizer. Yet, farmers find that their yields usually increase from year-to-year. This we think is due to increases in the variety and number of micro-organisms playing different roles in plant nutrition such as biological nitrogen fixation and phosphorus solubilisation.

SRI is not necessarily an ‘organic’ methodology; it can be used with agrochemicals. But the systematic evaluations we have done so far show that continuous use of compost gives higher yields than does NPK fertilizer. Also, pest and disease problems under SRI are usually not serious enough to warrant the use of biocides, and thus a ‘healthy’ soil can be maintained, which in turn further reduces the need for chemicals.

Optimal use of resources

Much research and evaluation remains to be done on SRI. It will not be appropriate or feasible in all rice-growing areas, e.g. there needs to be sufficient irrigation and drainage infrastructure to control water applications and maintain well-drained soils. Although the SRI practices may have the potential to double or triple the production of rice in the world, this is not a reasonable goal or use of the methodology. Rather it should give small farmers additional opportunities to raise the productivity of their land, labour and water resources, while trying to meet their staple food requirements.

Ultimately, productivity is what is most important to farmers: how to get the most from their limited land, labour, capital and (increasingly) water. Understanding *the sources and biological processes* that lead to increased productivity should be a researcher’s overall priority, while working closely with farmers. We think that SRI confirms the general value of an agroecological perspective, and that this should increasingly guide agricultural research, not only for rice but also for other crops (Stoop et al. 2002).

Further genetic research will be more beneficial if it is linked to agroecological theory and practice, not assuming that gains in productivity are due only or even primarily to genetic improvements.

Non-GE approach to salt tolerant rice

As the problem of salty soils grows, so does the search for salt tolerant rice. In parts of Northeastern Thailand rice harvests are seriously decreased due to salinity. Much of the research in the last years has relied on molecular biology to find salt-tolerant genes and move them to the desired plant species. However, Chalermpol Kirdmanee of the National Centre for Genetic Engineering in Thailand has a breakthrough that is not based on transgenic plants. By searching through the country’s rice “gene bank”, a collection of 7000 indigenous varieties, Chalermpol selected 4 that can withstand high levels of salt. He says, “We can’t grow genetically modified organisms in Thailand, so I wanted to find something that farmers could use.” He credits the country’s rich biodiversity with his progress.

The newly selected rice strains are part of a larger project to find salt-tolerant plants for Northeast Thailand. In a four-year field experiment conducted by Chalermpol’s lab, salt-tolerant grasses and trees reduced the level of salt in the soil from 10% to less than 0.5%.

Stimulating GMO-free breeding for organic agriculture: a view from Europe

Edith Lammerts van Bueren and Aart Osman

In the mid-90s the organic agricultural sector decided not to allow the use of GMOs in organic production. This was partly due to the risks of undesired and unknown environmental and health-related side effects of GMOs. But the main reason was a more ethical choice of respecting the integrity of plants and animals. The decision to remain GMO-free is incorporated in the Basic Standards of the International Federation of Organic Agriculture Movements (IFOAM) and hence applies worldwide. These standards define how organic products are produced, processed and handled. Most organic certification bodies use these standards for certification purposes.

A new vision for organic plant breeding

European organic agriculture is greatly dependent on the conventional seed industry. Organic farmers use modern productive varieties, bred for a high-input farming system with the use of chemicals. Although these varieties yield better than the old land races, they are not adapted to specific organic conditions. They lack traits like nutrient uptake efficiency, early soil coverage against weeds, broad field tolerance against pests and diseases etc. This was hardly an issue in the organic sector in The Netherlands until the threat of GMO varieties put it on the agenda. Space was thus created for a thorough discussion on the suitability of current plant breeding techniques for organic agriculture.

Louis Bolk Institute, a private research institute for organic agriculture, organised a discussion with all key players in the organic and conventional sectors (organic farmers, traders, commercial plant breeders and researchers of national agricultural research institutes) in the Netherlands. This resulted in a vision on organic plant breeding that was further discussed at workshops throughout Western Europe in order to formulate a common standpoint for those involved in organic seed production. The findings were finalised at a recent workshop by a group of European key players (organic sector, commercial seed enterprises). The resulting proposal was forwarded to IFOAM for incorporation in the Basic Standards for Organic Agriculture.

Cross pollination within natural barriers Photo: Louis Bolk Institute

Principles of organic farming as the basis

Judging the suitability of plant breeding methods is based on the principles of organic farming. Organic farming is not merely the avoidance of chemical fertilisers, pesticides and GMOs. It takes the living soil as a basis and uses methods which stimulate (agro-)ecological processes, without exhausting natural resources. Being founded on the integrity and intrinsic value of living entities like the soil, plants, animals and human beings, organic farming respects the environment, farm ecology and the complexity of nature. This attitude of respect prevents farmers from taking actions that affect a plant's reproductive potential and impede the sustainable use of cultivars.

Thus, the concept of organic plant breeding as formulated by the European key players reads as follows: "*The aim of organic plant breeding is to develop plants which enhance the potential of organic farming and bio-diversity. Organic plant breeding is a holistic approach that respects natural crossing barriers and is based on fertile plants that can establish a viable relationship with the living soil.*"

Biodiversity - an essential feature

As biodiversity is one of the main features of a sustainable organic farming system, the organic sector places great value on the free exchange of the genepool. The rights of breeders are respected but patents and techniques to make plants sterile endanger the free exchange, and consequently the genetic diversity. One of the techniques to prevent free exchange of genetic diversity is the utilisation of *cytoplasmic male sterility* without restorer genes to produce hybrids (see Box p.14). The absence of restorer genes prevents the production of seeds and hence this type of hybrids should be forbidden. All other types of hybrids produce viable seeds. They do not maintain purity after multiplication at the farm, but can still be used for developing new varieties.

Seed saving is not practised in the highly specialised horticultural sector in Europe. Dutch organic farmers prefer to buy their seeds, and most of them prefer hybrids. The uniformity of the plants allows for mechanical harvesting and reduces the requirement of seasonal labour that is scarce. Whether hybrids are the best option for the South depends very much on the socio-economic circumstances. Often there are valid arguments against hybrids. Low-income farmers who do not have sufficient funds to buy new seeds every year are better off with varieties that they can multiply inexpensively.

The cell level divide

The biotechnological techniques used in modern plant breeding (see Box p.14) can be divided into those that stay within the realm of life and those that go beyond. If the cell is considered the lowest organised structural entity of life, then all breeding techniques that intervene below cell level do not conform to the organic principles. This means that genetic modification (which interferes at DNA level) and protoplast fusion should be forbidden for the organic sector. All other cell biological techniques, including embryo rescue techniques and in vitro-pollination, are acceptable.

A few plant breeders are willing to go further: not only banning the techniques that go below cell level, but also avoiding those that intervene at cell level. The proposed certification system will label the latter as “organic varieties”. Varieties that respect the standards for organic breeding, but go beyond plant level, will be labelled as “organic seeds”. “Organic seeds” come from conventional breeding programmes, which respect the organic breeding standards and are multiplied under organic growing conditions for at least one generation.

Re-thinking plant breeding

For the breeders who want to work with as little biotechnology as possible, the challenge is to develop new concepts and breeding strategies that make it redundant. Most biotechnological techniques in plant breeding are used to introduce specific genetic resistance traits from wild relatives and other species into modern cultivars. This has led to a disproportionate reliance on resistant genes and negligence of other characteristics and techniques that prevent the build-up of diseases and pests. For example, the build-up of soil-borne fungal diseases is delayed in cereals, which are taller and have a more open plant structure (opposed to the compact short straw types). Growing varietal mixtures and intercropping also prevents disease epidemics. An organic breeding strategy would therefore aim at compensating for low genetic resistance with a better plant structure and varieties that perform well in mixtures. In this way it would not rely just on a single resistant gene, but on a larger, more sustainable set of measures. Breeding with as little biotechnology as possible requires a rethinking of what we want to achieve and how we can reach our goals. The principles of organic agriculture can help us with this task.

Setting standards for organic breeding

The development of new varieties requires considerable financial investments. As a relatively small sector, organic farming in Europe depends largely on conventional seed breeders for new varieties. Setting standards for organic plant breeding can influence technology development for the organic sector. These standards specify the techniques allowed for the development of new varieties. To make the implementation of these standards feasible, the private (conventional) seed sector has been involved in the discussions on organic breeding from the beginning.

‘Think twice before you act’: EU blocks new GM crops to be released

GM Crops such as Bt-maize, RR soybean and Bolgard cotton, are widely accepted in the United States, but public opinion in Europe continues to be increasingly sceptical to GMOs. Only 11 GM varieties were licensed for cultivation in the European Union before an informal moratorium was introduced in 1998 as compared to some 50 GM varieties that are commonly planted in the US, Canada and Argentina.

Last October, EU governments rejected the idea of lifting this three-year ban on importing and planting of new GM crops. Environment ministers spoke against plans to restart licensing GM seeds. Biotech companies like Monsanto and Novartis have been waiting for years to start selling their new varieties of modified maize, soy bean, etc. in the EU. A total of 13 GM varieties are awaiting approval. In 1998, a number of EU countries said they would not allow any new GMOs into the EU until tough rules on testing, labelling and tracing were put in place. Before such an operational system will be implemented it could take another two years, or even longer if the issue of environmental liability has to be turned into law as well.

In non-EU member Switzerland, the release of genetically altered plants into the environment is also forbidden. The government states that, on the basis of current knowledge, it is not possible to gauge the dangers to humans and the environment of the release of such organisms. This precautionary principle by (some of) the EU countries and neighbouring Switzerland is an important acknowledgement of the fact that GM crops are different from “naturally” improved varieties. ‘Think twice before you act’ seems to be the European answer to GM crops.

Sources: www.ictsd.org/weekly, and www.nzz.ch/english/swiss_week

The formulation of standards for organic plant breeding gives the seed companies clarity on what is expected from them. Some companies in the Netherlands, like Vitalis Biologische Zaden, are willing to adhere to these standards and breed organic seed without using the undesirable biotechnologies.

The standards for organic plant breeding do not indicate how the actual varieties should look like. Louis Bolk Institute helps farmers to formulate their specific wishes (i.e. adaptation to organic soil, tolerance to problematic diseases etc.) by way of crop ideotypes. Seed companies are requested to provide varieties, which comply with these ideotypes for trials on farmers' fields. The trials are evaluated in the field with farmers and breeders. Here a platform of discussion between breeders and farmers is created. The exchange of knowledge stimulates the development of varieties, which better meet the needs of the farmers and are more adapted to an organic farming system. ■

Biotechnological Techniques applied in Plant Breeding

At cell level

Embryo culture Ovary culture In-vitro pollination	Used for crossing of closely related species, such as cultivated tomatoes and wild relatives. Such crosses occur in nature but do not result in viable seeds as the embryos are aborted prematurely. When these organs are separated from the plant and grown in test tubes, they develop into mature plants.
In-vitro selection	Mostly used to select new varieties, which are tolerant to stress conditions, such as salinity. Plants are grown in test tubes containing a salt solution. Plants that survive are selected.
Anther culture Microspore culture	Pollen and anthers are grown in-vitro. These male sexual organs are not fertilised and hence contain only half a set of chromosomes. This set is doubled with chemicals to get plants that are genetically identical.
Meristem culture Micro propagation Somatic Embryogenesis	This is used for a rapid propagation of plants with an identical genetic make-up. Plant cells are multiplied in test tubes and these cells are regenerated into new plants.

Below cell level

Genetic modification Protoplast fusion	Genetic material of unrelated species that do not cross in nature are inserted into cells. Protoplast fusion implies the merging of complete cells. In genetic modification only small pieces of foreign DNA are inserted into the cell.
Cytoplasmatic Male Sterility (CMS) without restorer genes	Used to produce parent lines for hybrid production which are male sterile. A plant cell is merged with a cytoplast (a plant cell of which the chromosomes are removed). The cell plasma of the cytoplast contains factors, which cause male sterility. CMS does occur in nature, but is accompanied with factors that neutralise the male sterility. When CMS is transferred from an unrelated species into a crop, without the neutralising factors (restorer genes), the new male sterile plants can not be multiplied in nature.
DNA marker assisted selection	Certain sequences of DNA can be associated with certain plant traits. These sequences (markers) can be used to select plants for characteristics, which are not directly visible in the field, such as drought tolerance. This technique makes use of available DNA sequences in the plant cells, but does not change them, and is acceptable for organic agriculture. Sometimes radiation or genetically modified enzymes are used to detect these markers, which is not acceptable for organic farming. Detection can be done with substances that are permitted by organic agriculture such as fluorescence.

Small farmers need a basket of options to meet their site-specific requirements Photo: Bert Lof

Biotechnology
a basket of options

Bert Visser

From traditional to modern biotechnologies
The brewing of beer from barley or bananas, wine making, the fermentation of milk into various products such as yoghurt and cheese as well as of soybean into curd, the combination of cereals and pulses to improve nitrogen availability, the use of ethnoveterinary vaccines to protect cattle are all examples of traditional biotechnology. According to the Convention on Biological Diversity (1992) biotechnology is defined as 'any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use'. The keywords in this definition are living, technological, and products. Biotechnology that has been developed and utilised by humans over the ages falls within the parameters of this definition. However, it is not this traditional use of biotechnology that has brought it into the focus of current global debate.

Recent sharp increase in the knowledge of biological science (biochemistry, molecular biology, genetics) has complemented these traditional forms of biotechnology with modern applications. Not only are modern biotechnologies based on new scientific knowledge, they also depend largely on the availability of capital and skilled human resources. This makes biotechnology a specialised affair and takes it into the realms of private research funded by multinational corporations. And it is this trend in biotechnology and the perceived risks that has aroused the present debate.

Much of the debate is centred on two questions: (a) who determines which applications to develop and where to apply? (b) who benefits from those applications? To widen the public debate and to render the discussions productive, a basic knowledge of major modern biotechnologies amongst a larger public is indispensable. The aim of this article is to describe four major modern biotechnologies, their applications and the inputs they require, i.e. *in vitro* technologies, detection technologies, genomics and genetic modification. Although the last application is discussed in more detail, care should be taken not to equate biotechnology to genetic modification of living organisms.

In-vitro technologies
The meaning of the Latin words *'in vitro'* is 'in glass'. In-vitro technologies separate parts of living organisms in closed containers to manipulate and maintain this material. Several well-known and relatively older applications belong to this category.

Plant tissue culture became established in the 1970s. It involves the maintenance of plant material (complete plants, specific organs or cells) under sterile conditions and in the presence of nutrients. Plant tissue culture allows the rapid multiplication of crop plants at a small scale in comparison to *'in vivo'* (living) conditions. Starter material for crops can thus be supplied in large quantities, solving bottle-necks in supply to farmers. Particularly for crops that are propagated vegetatively (not through seed), plant tissue culture forms a useful instrument to multiply starter material. Plant tissue culture also allows for the cleaning of virus-infected starter material. A third use of plant tissue culture is to conserve useful crop genetic resources in a less vulnerable environment than in the field. Finally, plant tissue culture, done in-vitro, can be used to transfer useful traits from wild relatives into crop varieties by crossing sexual barriers that do not take place under normal (in vivo) conditions.

Nowadays, more than a thousand plant species are being propagated in tissue culture. The costs of plant tissue culture are modest. A new banana plant of a desired variety can be produced and made available at less than one US dollar. This option also offers the added benefit of providing healthy planting material. Oil palm, cassava, potato and ornamentals are also propagated in-vitro. The only facilities required are two rooms: one in which the material can be handled under sterile conditions, and the other a growth room with the necessary light, temperature and humidity. Basic training is adequate to teach the principles of sterile handling of material. Local communities who have been trained to do so and have access to the facilities can manage in vitro growth. In-vitro technologies are also used in animal husbandry. Artificial insemination of cattle is a rather old application, in which sperm is stored under sterile conditions at low temperatures for large-scale insemination. Modern extensions of this technology are: "in vitro fertilisation", in which a sperm and an egg cell are made to fuse, thus speeding up the generation of new breeds; "embryo transfer", which allows the use of carrier animals for the new offspring to develop; and "cryopreservation", the storage of valuable starter material at very low temperatures. Evidently, these applications are being used both in animal breeding, and for the conservation of animal diversity. Except for artificial insemination, which is a low-cost application, the costs here are much higher than for plant tissue culture and require more advanced facilities.

Detection technologies
Detection technology has been developed to detect the presence or absence of specific traits in individual organisms. A major part of this technology is the use of an array of DNA marker techniques. These marker techniques make use of patterns of specific DNA sequences (the building blocks of all genetic information) that reveal the genetic difference between two individual organisms. This technology has considerably increased the speed of plant and animal breeding. If DNA marker sequences are linked to specific traits, such sequences can be used to search for the presence these traits in the offspring of a cross breeding, long before the trait is actually expressed. A

major aspect of these techniques is that they do not alter the DNA (the genes, the traits). Instead they just allow a fast appraisal of what can be found in the offspring of a breeding programme. Various forms have been developed over the last fifteen years that differ in robustness, costs, facilities needed, and the type of information provided.

In comparison to in-vitro technologies, costs in this case are higher and the facilities required are more advanced. Until now, the extent to which this technology is applied in plant and animal breeding and its impact is much larger than that of genetic modification (see below), because it requires less time and financial investments. These techniques are being applied in small-scale agriculture as in a maize-breeding project aiming to increase the drought tolerance in local maize germplasm in Kenya and Zimbabwe. Markers have also been used to better understand farmers' selection of local rice varieties in the Philippines and Vietnam, and to more efficiently maintain the genetic diversity in enset, a staple crop of small-scale farmers in Ethiopia.

Monoclonal antibodies constitute another biotechnological detection technology. Cells derived from the immune system that produce specific antibodies are maintained and multiplied in-vitro for the production of large amounts of antibodies that can be used to search for specific material. Apart from main applications in health care, the technology is being used in agriculture to detect pathogens (agents causing pests and diseases) in plants and animals, thus allowing accurate pest and disease management. These technologies are used to provide the pest/disease free import guarantees on products as required by many countries, facilitating cross-border exchange of plants and animals. Whereas the costs for the development of monoclonal cells producing specific antibodies are high and specialist expertise is needed, the use of such monoclonal cells and their antibodies is relatively simple and requires only modest facilities.

Tissue culture can be useful for small farmers. Photo: AgroIndia

Genomics

Genomics is a field of biology that has developed very rapidly over the last decade. It involves the large-scale sequencing of DNA, including entire genomes (all the DNA of a single individual), and the comparative analysis of the resulting sequences across species barriers. Major highlights in this field are the sequencing of the total DNA of man, but also of a substantial number of micro-organisms (model organisms, pathogens and organisms used in traditional biotechnology), of plants (including rice) and of animals. Genomics produces enormous datasets and a complete new science, bio-informatics, has been developed to handle these databases and to allow retrieval and analysis of the information they contain. The costs of genomics research are high and only a few specialised institutions worldwide, located almost exclusively in developed countries, are able to contribute to this newly-evolving science. Although no immediate spin-off for agricultural applications should be expected in the next 5-10 years, a detailed knowledge of plant and animal genomes will, in the long run, speed up breeding, also in tropical agriculture.

Genetic modification

Genetic modification, also termed genetic manipulation, concerns the transfer of genetic information - in the form of DNA sequences - across sexual barriers between species, which under normal conditions would not exchange DNA. The resulting organisms are called genetically modified organisms (GMOs) or transgenics. Genetic modification is currently used only to introduce a single new trait, which might be based on the activity of a single gene, or a small number of genes. The number of genes with known functions that has been isolated is still too small to allow for more complicated traits or combinations of traits to be introduced using genetic modification. In agriculture, genetic modification has been applied in a number of major crops. The majority of these applications involve the introduction of resistant traits, particularly to herbicides and insects. A smaller number of applications involve the quality of the resulting product, e.g. the shelf life of tomatoes, or the production of alternative sweeteners in sugarbeet. Whereas farmers mainly deal with the former type of agronomic applications, the processing industry and consumers are confronted with the latter. Transgenic animals have been produced under laboratory conditions, but up to now have not been released for industrial application.

In all cases, the costs of developing GMOs are high, and the technology is dependent on very expensive facilities and highly skilled experts. The cost of the development and commercialisation of a GMO crop variety was recently estimated at US$30 million. In an increasing number of countries, legislation and regulations to contain GMOs and their products during the development and extensive testing phases before release are strict and costly. Although 70 transgenic crop varieties were registered for commercial cultivation in 1999, as of now international agricultural biotechnology companies have focussed their activities on a few crops, including the seed companies' cash earners such as cotton, rapeseed, maize, soybean, and wheat.

Impact on tropical agriculture

In developed countries agriculture has been industrialised over the course of the twentieth century. Breeding has developed from a farmer's activity into a specialist's affair. The conditions of the farmers' fields have been adjusted to the new breeds by extensive application of fertilisers and pesticides. Crops have become increasingly uniform to facilitate mechanised cultivation, harvesting and processing. Because of the more capital-intensive nature of agriculture, the size of an average economically sustainable farm has increased several times over the last century. Agricultural biotechnology will certainly enhance this trend by increasing the dependence of the entire production chain on a very limited number of crops and varieties with new traits. Modern agriculture will continue to be high-input dependent and become even more uniform. Genetic modification will allow the production of the same raw materials (e.g. plant oils) in different crops. The negative impact of modern agriculture on agrobiodiversity might be worsened by the wide-scale introduction of genetically modified crops and farm animals.

Tropical agriculture, however, is still dominated by small-scale systems. Often, farmers' access to external inputs is low. Therefore, international companies developing GM crops do not consider small-scale agriculture as an important market. Besides, GM crops would not cater to the diverse agro-ecological conditions encountered in farmers' fields and would be of little benefit to them.

The field release of GMOs is generally heavily regulated and major short-term effects on the crops and the agro-system environment are expected to show up in the test phase. Yet, small-scale systems may well have to face the environmental risks of GMOs. In the long term it is difficult to imagine how the appearance of GMO traits in non-GMO crops can be avoided as a result of uncontrolled crossing, particularly in cross-fertilising species. The question is whether we regard this an unacceptable tinkering of nature, a risky development in terms of food safety and environmental and genetic pollution, or simply as a new harmless step in the interference of humans on the plants and animals that provide our food. In any case, it will certainly pose problems to the organic agriculture sector that is devoted to the maintenance of a GMO-free chain.

Although GMOs may currently have little or no direct relevance to small-scale tropical agriculture, this reality does not follow from the biological nature of biotechnological applications but from the socio-economic context in which biotechnological applications are developed. This leads us to the question of whether and under what conditions other appropriate biotechnologies for small-scale farmers are feasible.

Appropriate biotechnologies: a reality or fantasy?

Biotechnology has the potential to serve all farmers, including small-scale farmers in tropical production systems. Appropriate biotechnologies may be developed on the basis of demand and in consultation with farmers and/or their representatives (community-based organisations, supportive NGOs, dedicated extension services). It can be expected that modern biotechnologies that require relatively few investments and that can be applied in-country or even in the community stand the best chance of being appropriate. In particular, this could apply to plant tissue culture technology to produce healthy, much valued varieties in large enough quantities. Also the use of monoclonals may in time allow farmers and extension services to monitor for specific pests and diseases. The use of artificial insemination could be extended also to well-adapted indigenous breeds. Cryopreservation and tissue culture of valuable plant and animal varieties and breeds might also serve the small-scale farming sector in providing a back-up for their genetic resources maintained in the field. All these applications form a potential reality.

However, it can be doubted whether genetic modification has anything to offer to small-scale farmers other than a growing dependence of farmers on the seed industry. It can be doubted whether and to which extent the lack of interest by the private sector will be compensated for by increased public breeding efforts that should prevent a widening technology gap between a rather small number of commercial crops and crops of regional or local importance. On the other hand, it should be realised that for any application in the public domain aimed at benefiting small-scale farmers, co-operation with the private sector will be absolutely indispensable since the private sector owns all the key patents needed to develop GMOs. The case of Golden Rice forms an interesting one as it represents an exceptional effort in the public domain to alleviate problems of low-income groups including many small-scale farmers in developing countries (vitamin A deficiency) through the application of genetic modification. However, many patent exemptions in the form of licences had to be obtained to allow Golden Rice to be developed for farmers in developing countries, and whether Golden Rice will fit social and cultural patterns will have to be awaited. Also, it is yet too early to predict how often such patent exemptions will be granted to allow the development of public sector initiatives to benefit the small-scale sector.

In my opinion, more than the risks of monster organisms, food safety problems and environmental pollution, the real threat of GMOs might be the socio-economic dependence it creates for its users from the companies selling such GMOs.

Genetically engineered crops
will they feed the hungry and reduce poverty?

Peter Rossett

Small and peasant farmers are the primary producers of staple foods, accounting for very high percentages of national production in most Third World countries. This sector, which is so important for food production, is itself characterised by poverty and hunger, and in some cases lagging agricultural productivity. If these problems are to be addressed by a proposed solution – genetic engineering in this case – we must begin with a clear understanding of their causes. If the causes lie in inadequate technology, then a technological solution is a possibility. Thus let me begin by examining the conditions faced by peasant producers of staple foods in most of the third world.

Historical background

The history of the third world since the beginning of colonialism has been a history of un-sustainable development. Colonial land grabs pushed rural food producing societies off the best lands most suitable for farming. These lands were converted to production for export in the new global economy dominated by the colonial powers. Instead of producing staple foods for local populations, they became extensive cattle ranches or plantations of indigo, cocoa, copra, rubber, sugar, cotton and other highly valued products.

Farming peoples–accustomed to the continuous production of annual crops on fertile, well-drained soils with good access to water– were driven into marginal areas. As a result forests were felled and many fragile habitats were subject to un-sustainable production practices, in this case by poor, newly destitute and displaced farmers. The favoured lands were, simultaneously, being degraded by continuous export cropping at the hands of Europeans.

National liberation from colonialism did little to alleviate the environmental and social problems generated by this dynamic. Post-colonial national elite came to power with strong linkages to the global export-oriented economy, often, indeed, connected to former colonial powers. The period of national liberation, corresponded with the rise of capitalist market and production relations on a global scale, and in particular, with their penetration of third world economies and rural areas. This was the era of modernisation with its dominant ideology that bigger is better. In rural areas it meant the consolidation of farmland into large holdings that could be mechanised, and the notion that the "backward and inefficient" peasantry should abandon farming and migrate to the cities where they would provide the labour force for industrialisation. This ushered in a new era of land concentration in the hands of the wealthy, and drove the growing problem of landlessness in rural areas. The landless rapidly became the poorest of the poor, subsisting as part-time seasonal agricultural or day labourers, share croppers or migrating to the agricultural frontier to fell forests for homesteads.

Thus rural areas in the Third World are today characterised by extreme inequalities in access to land, in security of land tenure and in the quality of the land farmed. By keeping wages and living standards low, the elite guarantees that healthy domestic markets will never emerge, reinforcing export orientation. The result is a downward spiral into deeper poverty and marginalisation, even as national exports become more "competitive" in the global economy. One irony of our world, then, is that food and other farm products flow *from* areas of hunger and need *to* areas were money is concentrated, in the North.

The same dynamic drives environmental degradation. On the one hand, rural populations have historically been relocated from areas suitable for farming to those less suitable, leading to deforestation, desertification and soil erosion in fragile habitats. This process continues today, as the newly landless continuously migrate to the agricultural frontier.

The situation is no better in the more favourable lands. Here the better soils of most nations have been concentrated into large holdings used for mechanised, pesticide and chemical fertiliser-intensive, monocultural production for export. Many of our planet's best soils are today being rapidly degraded, and in some cases abandoned completely, in the short-term pursuit of export profits and competitiveness. The productive capacity of these soils is dropping rapidly due to soil compaction, erosion, waterlogging, and fertility loss, together with growing resistance of pests to pesticides and the loss of in-soil and above-ground functional biodiversity. The growing problem of "yield decline" in these areas has recently been recognised as a looming threat to global food production by a number of international agencies.

Changes in macro economic policies

The past three decades of world history have seen a series of changes in national and global governance mechanisms. These changes have been made within a paradigm that sees international trade as the key resource for promoting economic growth in national economies, and growth as the solution to all ills. The balance of governance over national economies has shifted away from governments toward market mechanisms and global regulatory bodies like the WTO. Southern governments have progressively lost the majority of the management tools in their macro-economic policy toolboxes. The ability of Southern nations to ensure the social welfare of poor and vulnerable people, achieve social justice, guarantee human rights, and protect and sustainably manage their natural resources, have been critically weakened.

They have been forced to drastically cut government investment and to slash or eliminate subsidies of all kinds, including social services and price supports for small farmers. While such changes have in some cases created new opportunities for poor people to exploit new niche markets in the global economy (organic coffee, for example), they have for the most part undercut both government provided social safety nets and guarantees. The majority of the poor still live in rural areas, and these changes have driven many of them to new depths of crisis in sustaining their livelihoods. Increasingly they have been plunged into an environment dominated by global economic forces, where the terms of participation have been set to meet the interests of the most powerful. Small farmers find the prices of the staple foods they produce dropping below the cost of production in the face of cheap imports freed from tariffs and quotas.

Lagging productivity

Third world food producers demonstrate lagging productivity not because they lack 'miracle' seeds that contain their own insecticide or tolerate massive doses of herbicide, but because they have been displaced onto marginal, rain-fed lands, and face structures and macroeconomic policies that are increasingly unfavourable to food production by small farmers. These then, are the true causes of low productivity. In fact, in many parts of the third world, especially in Africa, *farmers today produce far less then they could with presently available know-how and technology,* because there is no incentive for them to do otherwise - there are only low prices and few buyers. No new seed, good or bad, can change that, and thus it is extremely unlikely that, in the absence of urgently needed structural changes in access to land and in agricultural and trade policies, genetic engineering could make any dent in food production by the world's poorer farmers.

When seen in this light, it should be clear that genetic engineering is only touching at best the conditions and needs of the farmers we are told it will help – it in no way addresses the principal constraints they face. But superficial is a far cry from 'bad.' Now I turn to the question of whether genetically engineered crops are simply irrelevant to the poor, or if they might actually pose a threat to them. First we must ask about the actual circumstances of peasant farming.

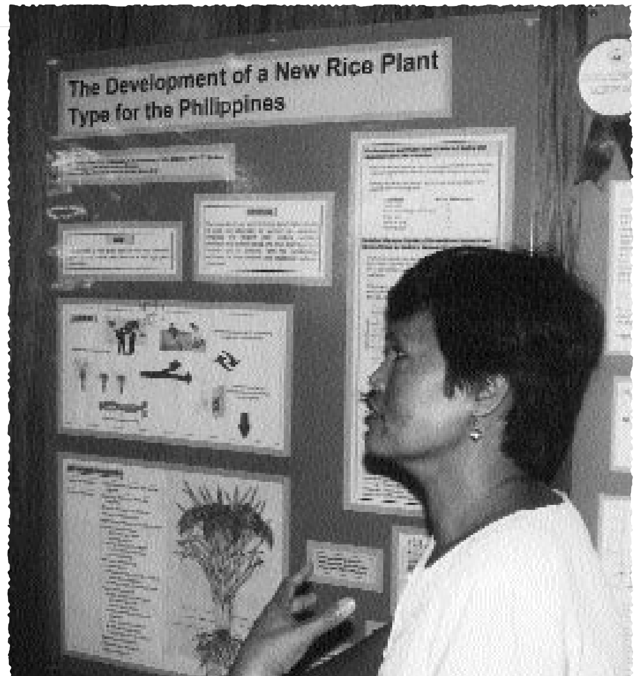
Complex, diverse and risk-prone agriculture

Peasant farmers have historically been displaced, as described above, into marginal zones characterised by broken terrain, slopes, irregular rainfall, little irrigation, and/or low soil fertility. Being poor they are victimised by pervasive anti-poor and anti-small farmer biases in national and global economic policies. As such, their agriculture is best characterised as complex, diverse and risk-prone.

In order to survive under such circumstances, and to improve their standard of living, they must be able to tailor agricultural technologies to their variable but unique circumstances, in terms of local climate, topography, soils, biodiversity, cropping systems, market insertion, resources, etc. For this reason such farmers have over millennia evolved complex farming and livelihood systems which balance risks. Typically, their cropping systems involve multiple annual and perennial crops, animals, fodder, even fish, and a variety of foraged wild products.

Repeating the error of top-down research

Such farmers have rarely benefited from 'top down' formal institutional research and 'green revolution' technologies. Any new strategy to truly address productivity and poverty concerns will have to meet their needs for multiple suitable varieties. Formal research methods are not able to handle the vast complexity of physical and socio-economic conditions in most third world agriculture. This stems from the discrepancy between hierarchical research and extension systems, which value monocultural 'yield' above all else, and complex rural realities. In reality seeds have multiple characteristics that cannot be captured by a single yield measure, and farmers have multiple site-specific requirements for their seeds, not just controlled-condition high yields. These interconnections stand in direct contrast to formal breeding procedures. Given such conditions the inescapable conclusion is that a different approach, participatory breeding by organised farmers themselves, which takes into account the multiple characteristics of both seed varieties and farmers, is essential. Miracle seeds will not just be developed in laboratories and on research stations and then effortlessly distributed to farmers. Yet genetic engineering is in direct contrast to participatory, farmer-led research.



Will the "super" rice presently being developed by IRRI meet the needs of small farmers? Photo: Bert Lof

Proponents of genetically engineered varieties are repeating the very 'top down' errors, which led first generation green revolution crop varieties to have low adoption rates among poorer farmers.

Yet it is clear that the biotech juggernaut is moving ahead a full speed. What then, are the risks associated with 'forcing' genetically engineered varieties into complex, diverse and risk-prone circumstances?

Risks for poor farmers

The most common transgenic varieties available today are those that tolerate proprietary brands of herbicides, and those than contain insecticide genes. Herbicide tolerant crops make little sense to peasant farmers who plant diverse mixtures of crop and fodder species. Chemicals would only destroy key components of their cropping systems.

Transgenic plants, which produce their own insecticides – usually using the 'Bt' gene - are rapidly failing as pests build up resistance to insecticides. Instead of the failed "one pest-one chemical" model, genetic engineering emphasises a "one pest-one gene" approach, shown over and over again in laboratory trials to fail, as pest species rapidly adapt and develop resistance to the insecticide present in the plant. Bt crops violate the basic and widely accepted principle of "integrated pest management" (IPM), which is that reliance on any single pest management technology

It is not a lack of technology that holds farmers back... photo: Bert Lof

tends to trigger shifts in pest species or the evolution of resistance through one or more mechanisms. In general, the greater the selection pressure across time and space, the quicker and more profound the pests' evolutionary response. Thus IPM approaches employ multiple pest control mechanisms, and use pesticides minimally, only in cases of last resort. An obvious reason for adopting this principle is that it reduces pest exposure to pesticides, retarding the evolution of resistance. But when the product is engineered into the plant itself, pest exposure leaps from minimal and occasional to massive and continuous exposure, dramatically accelerating resistance. Most entomologists agree that Bt will rapidly become useless, both as a feature of the new seeds and as an old standby natural insecticide sprayed when needed by farmers that want out of the pesticide treadmill.

At the same time, the use of Bt crops affects non-target organisms and ecological processes. Recent evidence shows that the Bt toxin can affect beneficial insect predators that feed on insect pests present on Bt crops, and that windblown pollen from Bt crops found on natural vegetation surrounding transgenic fields can kill non-target insects. Small farmers rely for insect pest control on the rich complex of predators and parasites associated with their mixed cropping systems.

In fact Bt retains its insecticidal properties after crop residues have been plowed into the soil, and is protected against microbial degradation by being bound to soil particles, persisting in various soils for at least 234 days. This is of serious concern for poor farmers who cannot purchase expensive chemical fertilisers, and who instead rely on local residues, organic matter and soil microorganisms (key invertebrate, fungal or bacterial species) for soil fertility, which can be negatively affected by the soil bound toxin.

When the Bt genes fail, what would poor farmers be left with? It is entirely possible that they would face the serious rebound of pest populations freed of natural control by the impact Bt had on predators and parasites, and reduced soil fertility because of the impacts of Bt crop residues plowed into the ground. These are farmers who are already risk-prone and Bt crops would most likely increase that risk.

In the Third World there will typically be more sexually compatible wild relatives of crops present, making pollen transfer to weed populations of insecticidal properties, virus resistance, and other genetically engineered traits more likely, with possible food chain and super-weed consequences. With massive releases of transgenic crops, these impacts are expected to scale up in those developing countries, which constitute centres of genetic diversity. In such biodiverse agricultural environments, the transfer of coding traits from transgenic crops to wild or weedy populations of these taxa and their close relatives is expected to be higher. Genetic exchange between crops and their wild relatives is common in traditional agroecosystems and transgenic crops are bound to frequently encounter sexually compatible plant relatives, therefore the potential for "genetic pollution" in such settings is inevitable.

In sum, these and other risks seem to outweigh the potential benefits for peasant farmers, especially when we consider the factors that currently limit their ability to improve their livelihoods, and the proven agroecological, participatory and empowering alternatives available to them

No role for GM crops

It is not a lack of technology which holds such farmers back, but rather pervasive injustices and inequities in access to resources, including land, credit, market access, etc., and other anti-poor policy biases. Two approaches make the most sense under such conditions: 1. technologies, which have pro-poor diseconomies of scale, like agroecology and 2. organisation into social movements capable of exerting sufficient political pressure to reverse policy biases. There is little useful role that genetically engineered crops can play.

The next time we hear of the latest 'magic bullet' invention altruistically developed in private sector labs for the benefit of the poor, we would do well to keep in mind the true causes of hunger, poverty and lagging agricultural productivity in the third world.

Genetic engineering: not the only option

"Genetic engineering is often justified as a humane technology, one that feeds more people with better food. Nothing could be further from the truth. With very few exceptions, the whole point of genetic engineering is to increase the sales of chemicals and bio-engineered products to dependent farmers."
David Ehrenfield, Professor of Biology, Rutgers University, USA

The Gene Revolution

A new agricultural revolution is taking place: the "genetic engineering revolution". For the first time it is possible to break through natural species' barriers, systematically moving genes from one species to another that do not combine in nature. This is done by transferring genetic material, for instance, from bacteria to plants. Proponents of genetic engineering (GE) claim it will provide new plants and animals that would lead to a more environmentally-sound agricultural production with crops that produce their own pesticide thus reducing the use of chemical pesticides. They also promise crops that produce medicine, plants tolerant to salt and drought and enriched food to restore micro-nutrient deficiencies. Many see GE as "the" solution to hunger, poverty and many health problems. Some advocates go a step further by accusing opponents of genetic engineering as 'colonialists who withhold technologies from poor farmers' (p.36).

It sounds too good to be true. But when we begin to look behind the façade of this promise-filled development, many important questions emerge:

- Who benefits from genetic engineering and who loses?
- What are the risks and who will bear them?
- What are the alternatives to genetic engineering?

This issue of LEISA Magazine and the accompanying journal "Biotechnology and Development Monitor" attempt to explore these questions.

Genetic Engineering is different

GE, also known as genetic modification or manipulation (GM), is part of what is termed "biotechnology" or "biotech" in short. Biotechnology is a very inclusive term, ranging from natural fermentation, to safe and relatively cheap practises like in-vitro propagation to genetic engineering. A good starting point to understand the different types of biotechnology is the article by Visser on p.9. It gives an overview of the potential, costs and expertise required by each of them.

In this issue, the focus is on genetically modified crops as they have far-reaching implications on sustainable agriculture in general, and farmers' livelihoods in the South in particular. Genetic engineering is sometimes presented as just another step in a continuous process of agricultural development. In other words, there is no reason to worry. However, this argument cannot be justified. Genetic engineering is radically different from previous technologies because it allows for the moving of genes between different species across natural boundaries, which makes the risks unpredictable.

Ecological concerns

Despite many reassuring words by companies, researchers and some governments, many concerns about the implications of GM crops remain. Major concerns relate to the consequences for the ecological systems into which they are being introduced. These concerns are often neglected by the GM seed industry, the authorities approving their access to the market and the farming communities making use of the proposed technologies. For instance, the insertion of Bt (*Bacillus Thuringiensis*) genes was thought to be a silver bullet, a permanent solution to insect problems. But the model of "one pest – one solution" does not work forever, as is the case with pesticides; sooner or later resistance builds up. Similarly, building of herbicide resistance in plants is headed for trouble as it unleashes basic ecological reactions. Excessive use of herbicides as a major or only tool of weed management, will eventually reduce the sensitivity of weeds to herbicides and create an even worse weed problem. It is "to a large extent a victim of its own success". Recently, more and more evidence is being brought to support the fact that these concerns are not negligible. Yield decline in GM soybean, for instance, is being traced to reduced root development, nodulation and nitrogen fixation.

Another effect is related to the unexpected impact of gene transfer and its consequences. One example from USA tells how genes from one bacterium *Xanthomonas* were transferred to another soil bacterium, *Kebsiella planticola*. The new organism was meant to ferment stubble into alcohol, thus providing farmers with an extra source of income instead of burning the stubble. However, a test by the authorities found that wheat planted in the soil containing the new organism was killed by it.

In Europe, scepticism is widespread due to the many ecological concerns that surround the introduction of GM crops. A de facto moratorium on releasing genetically modified organisms has been in place since 1998 (p.13) One can draw no other conclusion than that, in many countries, GM crops have been brought too early into the market and that precaution should prevail.

Private companies appropriate farmers' livelihoods

One thing that makes the development of GE unique in the history of agriculture is that it is almost fully controlled by private companies. Transnational corporations (TNCs), often with their roots in the production of agro-chemicals, carry out the laboratory research, field trials, production and sale of GM crops. They spend enormous amounts of money on developing herbicide-resistant crops that are being sold to farmers as a package inclusive of both the herbicide and the seeds. Through patents these TNCs keep competitors at bay. It appears that GE technologies are not being developed because of their problem-solving capacity, but because of the patent - and thus profit - it can bring to the companies. For instance, in the 1980s, Monsanto was not interested in genetically engineering virus resistance into plants, as it would bring minimal profits. In the "old days" public-funded international or national agricultural research centres could have stepped in and carried out that research. However, the public research centres seem to be loosing ground in access to the knowledge and genetic material, thus widening the gap between public and private research. Recently, private companies have been pushing further, trying to get exclusive rights over nature's genetic resources as in the case with Monsanto's application seeking patent protection related to (wild and domesticated) soy beans.

Terminator technology takes the issue further. This technology, in which genes are manipulated to be able to switch seeds on and off by treatment with chemicals provided by one and the same GM seed company, effectively prevents farmers from keeping their seeds for replanting. Strong public opposition has forced the companies to give up this line of research, but they still hold the patents to the technology.

These examples illustrate very well what kind of agricultural development these companies promote, namely high-input, highly industrialised monoculture systems, which force farmers to buy packages of inputs from just one company. In this context it is rather shocking that, in 2001, the US government generously funded biotechnology research and development in agriculture with a budget allocation of US$ 310 million, whereas support for organic farming was less than US$5 million. Farmers have expressed their concern about these developments, as can be concluded from the citizen's juries conducted in many parts of the world (p.27). Rossett also clearly illustrates that GM crops have very little to offer to farmers in risk-prone, diverse and complex agriculture (p.6). It is expected that GM crop research will be very slow in responding to the needs of low-input agriculture.

Contamination: No guarantee that crops are GE-free

The contribution from the Louis Bolk Institute (p.12) shows that the organic movement does not consider GM crops as organic. It accepts conventional breeding and the new technologies available to assist it, but finds manipulation at the cell level and below as unacceptable. The article describes how the debate on GE has led organic farmers to reconsider their dependency on seed companies that focus on high-input agriculture.

But how can farmers be sure that they grow GM crops, considering that seeds and pollen spread by wind, water, birds and insects. Large areas can be contaminated by the introduction of GM crops by a single farmer. In the US, contamination by GM crops is now such a big problem that organic farmers find it almost impossible to get GM-free seeds. Tests have shown that "organic crops" from the US are often contaminated with engineered genes despite farmers' efforts to stay GM-free. Consequently, the international organic movement (IFOAM) is considering refusing certification of organic crops from the US. But who will pay for the damage inflicted on the organic farmers in the US?

Who bears the risk?

With the introduction of agricultural genetic engineering, the costs of contamination and other costs of reduced market shares are being imposed on farmers, consumers and the environment as a whole - not only in Europe or North America, but also in the South! Will GM seed companies bear the risk of releasing these crops in the South? What will happen if things go seriously wrong, e.g. a GE crop turns out to have negative health effects or becomes a serious ecological threat?

The GM crop in question may be banned but that does not mean it will stop existing. This situation is not comparable to that of an agricultural chemical which turns out to have unanticipated side effects after a number of years. The effect of such chemicals will eventually disappear from the environment. Not so with GM crops that are likely to survive in the wild and spread their genes through crossing with other plants. This is already taking place in Mexico where wild relatives of maize have been contaminated with genes from GM crops (p.25). Since Mexico is the centre of maize diversity, such contamination constitutes an irreplaceable loss. The wide variety of genes in wild plants and in traditional agriculture is the main insurance we have to cope with new demands on crops – whether caused by new pests and diseases, increased salt levels or changing climates. In Southern Brazil, estimates are that despite the ban on GM crops, 30% of the soybean acreage is already contaminated, thus threatening Brazil's GM-free status (p.19).

The risk of an unintended introduction of GM crops is more threatening in countries where no legal framework exists, as is the case in many African countries. For instance, one expert from Zambia expressed his concern that illegal trade in GM varieties is most likely once neighbouring countries have it. Again, who will bear the risk?

Alternatives

But do we really need GM technology to combat malnutrition, to improve local production and to make agriculture more productive. Has the introduction of GM crops contributed to the reduction of poverty? The FAO (United Nations Food and Agricultural Organisation), in a recent report, indicated that "for the world as a whole there is enough, or more than enough, food production potential to meet the growth of effective demand, i.e. the demand for food of those who can afford to pay farmers to produce it." This implies that "any residual hunger problems will be largely poverty, rather than production-related", which means that reaching the goal of food security for all should be based on a premise other than genetic engineering. Alternative approaches to agricultural production are, therefore, essential.

Over the years, LEISA Magazine has documented a wealth of agro-ecological, low-external-input alternatives to agricultural production. The articles in this issue confirm, once again, that the potential of LEISA is far from exhausted. The case of natural crop protection from the Andes (p.23) indicates that there are many plants in nature, which provide us with clues for better pest management. During a forum in the Netherlands, an Indian journalist informed the audience that agricultural research in India is only making use of 3% of the total of 3000 rice varieties that are known. Research done in Thailand indicates the potential that exists in nature for selecting and breeding varieties with desired characteristics such as salt tolerance (p.16). Many ecological principles that are still being overlooked, underestimated or sidelined, deserve more attention as they provide relatively cheap, controllable and low external input solutions to many problems that farmers face. The System of Rice Intensification (SRI) is an example of the many roads to sustainable agriculture that are hardly explored (p.15). Moreover, these approaches are not accompanied by the many risks - both economic and ecological – that GM crops are posing.

The push-pull system in Kenya (p.17), organic cotton production in Senegal (p.21) and zero-tillage no-herbicide soybean cultivation in Brazil (p.19), are examples of ecologically-sound alternatives that already exist. They are not a danger to the environment, nor do they make the farmers dependent on agricultural supply companies. Third world farmers will certainly be much better off if research efforts and resources are dedicated to agro-ecological approaches that have wide-ranging possibilities.

C O N T E N T S

If poverty and hunger in the world are to be reduced, then the reasons for these problems need to be understood. Starting with a short historical background, the author traces the changes that have taken place in national and global governance mechanisms, leading to some of the most pressing problems faced by small farmers today. In his opinion, GM crops will not address the principal constraints faced by farmers; in fact the risks they face far outweigh any benefits. The author emphasises that it is not a lack of technology that holds farmers back, but pervasive injustices and inequities to resources including land, credit, market access etc.

Among the many different approaches to pest control in maize, the push-pull system shows great potential for small holder farmers. Repellent plants intercropped with maize "push" the insects out of the fields into trap crops outside the field that "pull" the insects in. The system makes optimal use of existing biological interactions, offers long-term stability and requires no expensive inputs. In Kenya, the grasses selected by the farmers as repellents and as trap crops have the added benefit of providing fodder and in suppressing the vicious weed Striga. The system has now been released officially in Kenya and is getting a very positive response from farmers.

ILEIA is the Centre for Information on Low External Input and Sustainable Agriculture (LEISA) in the tropics. ILEIA seeks to promote the adoption of LEISA through the LEISA Magazine and other publications. It also maintains a specialised information database and an informative and interactive website on LEISA (**http://www.ileia.org**). The website provides access to many other sources of information on the development of sustainable agriculture.

LEISA is about Low-External-Input and Sustainable Agriculture. It is about the technical and social options open to farmers who seek to improve productivity and income in an ecologically sound way. LEISA is about the optimal use of local resources and natural processes and, if necessary, the safe and efficient use of external inputs. It is about the empowerment of male and female farmers and the communities who seek to build their future on the basis of their own knowledge, skills, values, culture and institutions. LEISA is also about participatory methodologies to strengthen the capacity of farmers and other actors to improve agriculture and adapt it to changing needs and conditions. LEISA seeks to combine indigenous and scientific knowledge, and to influence policy formulation in creating an environment conducive for its further development. LEISA is a concept, an approach and a political message.

27 Citizens' juries on GMOs and farming futures in India

Michel Pimbert, Tom Wakeford, P.V. Satheesh

Over the past quarter century a number of participatory methods have been developed to democratise policy-making. Citizens juries is one such method that is being used widely to get farmers involved in the debate on GMOs, which has a direct impact on their lives and livelihoods. This article describes two such juries conducted in India, in Karnataka and Andra Pradesh. In both instances, the farmers clearly said "no" to GMOs, and supported localised food systems instead.

23 Plants protecting other plants - an alternative to pest-resistant GM crops

Luis Gomero Osorio

Peru, like many other countries in this region, is endowed with many plants that can be used for pest control. With the introduction of chemical pesticides, the use of these plant-based substances has gradually decreased. However, the genetic engineering of crops to build-in resistance to pests has brought the discussion of natural protection methods back on the agenda. Some of these plant-based pest control agents are well known and are available commercially, but there are many more possibilities, considering the diversity of plant species.

DEAR READERS

There is hardly anyone, from producers to consumers, who will not be touched by the latest technology in agricultural development - genetic engineering of crops and animals. It is a subject that is raising much debate and controversy today, all across the globe, and at all levels of society. It is therefore quite obvious that ILEIA should dedicate an issue of the LEISA Magazine to the subject of biotechnology and GM crops, but then from the vantage point of small farmers and sustainable agriculture. As it is still very uncertain what benefits small farmers will gain from GM crops and what risks are involved, it would not be wise to focus all development efforts on genetic engineering. This issue, therefore, especially explores some of the many alternatives to GM crops.

We are very glad that we could join up with the "Biotechnology and Development Monitor", a journal that specialises in issues of biotechnology related to development, and thereby give you additional and useful reading on the subject. The Monitor's selection of articles related to small-scale farming systems, i.e. legislation and regulation of GMOs, complements those of the LEISA Magazine very well.

Of course, such a joint venture would not have been possible without the support of donors to meet the extra costs. ILEIA and the Biotechnology Monitor are extremely grateful to the Dutch donor organisations HIVOS, ICCO and NOVIB for their generous contribution toward this project.

This double-pack of the LEISA Magazine and Biotechnology Monitor is going out to a combined readership of nearly 20,000 people. Although we have tried to ensure that addresses are not duplicated, there is a good possibility that some of you may receive more than one pack. Please pass it on to a colleague or friend who could make use of the information, and if interested, become a future subscriber.

We hope that the information in these articles will give you more insights into genetic engineering and available alternatives and help you make the right choices. **We also take this opportunity to wish you much success in all your endeavours in the year 2002 in working towards a socially responsible and environmentally friendly agriculture.**

LEISA

Magazine on Low External Input and Sustainable Agriculture

GE – not the only option

Readers and ILEIA staff discussing what they learned from the LEISA Magazine. Photo: Flemming Nielsen

ILEIA visits Ethiopia

During the first half of September Anita Ingevall and Flemming Nielsen of the ILEIA team spent two weeks meeting several readers of the LEISA Magazine in Ethiopia, assisted by Yohannes GebreMichael. Here is a short report on their visit.

The skies were dark grey and the rain poured down as we trudged along in search of some of the readers that had responded to the questionnaire we sent out with the LEISA Magazine 17.2. In this questionnaire we asked our readers in Ethiopia how they actually use the information they get through the LEISA Magazine. We wanted to know if we could establish a link between the information provided in the Magazine and what people actually do in their work; in other words, we were trying to ascertain how the Magazine impacted people.

We know from earlier evaluations of ILEIA that our readers appreciate the Magazine very much and find it useful. But what does this mean concretely? Does the Magazine actually have an impact at field level? Does it influence people and change their perceptions, ideas and actions? Does it have an impact on policy level? We wanted to gain some insights into these questions, and find out who our readers are and what they do with the information.

We chose Ethiopia for this study as it is home to more than 2000 regular subscribers, one of the largest readerships we have. The country is still heavily dependent on agriculture and regularly struck by famine. For the past 25 years many different donors have been active in trying to improve the productivity of Ethiopian agriculture through different programmes and different approaches. In spite of these efforts the natural resources continue to degrade and a breakthrough in agricultural productivity has not been achieved.

Getting in touch with the persons we had selected, based on the questionnaires, proved more difficult than expected. Bad telephone lines, sickness, job transfers etc. were some of the odds to be dealt with in getting to people. But nothing could have prepared us for the truly positive responses we received once we actually got in touch !

We visited people in and around Addis Abeba, North of Debre Berhan and in Tigray, South of Debre Zeit and around Awassa, from different backgrounds and with different tasks in agriculture. Among them were farmers, policy makers in the government ministries in Addis Abeba, workers in NGOs or people involved in research, training and education. What struck us was their resourcefulness and dedication to really make a difference in agriculture. Interested, reflective and innovative they were managing to do a lot more than what their circumstances allowed.

We found examples of direct implementation of technologies described in the Magazine. Frequently, the Magazine was used as a source of training material at different levels and as a point of up-to-date references. Some of the articles had inspired people to write research proposals. Several people told us that their ideas on how agriculture should be done had changed completely after reading the Magazine for some time, and others how their approach to farmers and indigenous knowledge had changed fundamentally as a result of ideas presented in the Magazine. Most of the persons we met considered the Magazine as a resource that was directly relevant to their own conditions. It kept them informed about similar developments around the world, which made them feel part of a larger 'movement' and which confirmed that 'they were on the right track', as one reader put it.

We found that most readers share their copy of the Magazine with friends and colleagues and that the articles often served as a basis for discussions. We were convinced that the Magazine should remain free of charge for those who wish to receive it. This allows individuals to subscribe, thus increasing accessibility and preventing the Magazine from being locked up in an unused library or in the boss's room. We learnt that clear instructions on subscriptions and renewals could reduce a lot of confusion. What we also found was that most of our readers are men. Not a surprising finding as technical personnel in agriculture and forestry most often are men, although agriculture as such involves the whole family and in many situations puts the major load on the women. As we consistently try to increase the number of articles that features women in the LEISA Magazine, we would also like to see our number of female readers increase. So, please, inform your female colleagues about the Magazine and how to subscribe!

We would like to thank all the persons we met in Ethiopia for sharing their time and experiences with us. For us it has been an invaluable and very inspiring experience, which will keep us going and which will certainly have an impact on the Magazine. ■

This study was made possible through the generous contribution of the Swedish International Development Co-operation Agency. The findings will be made available in a report. ILEIA will also produce a small booklet to document the work of a number of Ethiopian readers met during this study.

A keen reader of the LEISA Magazine. Photo: Flemming Nielsen

New themes for LEISA Magazine

Issue 18.2, May 2002.

Rural communication and information management for sustainable family farming.

Rural communication and information management play an important role in spreading information on successful farmer innovations and in getting access to new knowledge. Participatory development programmes increasingly use rural radio, TV and other mass communication media as tools for farmer-to-farmer exchange. In some places, farmers even use mobile phones to get information on market prices. The use of internet and CD-ROMs by development workers, researchers and even farmers for networking and information exchange is gradually increasing as communication facilities improve. Yet, in many rural communities, traditional methods of communication continue to have a significant impact on the spread of information. What practical experiences have been gained with new as well as with more conventional approaches to rural communication and information management to enhance the expansion of farmer movements towards sustainable agriculture? How can access to electronic information and communication technologies be enhanced? How can these technologies be made into participatory tools? What experiences have been gained with local centres for information and farmer exchange? These are some of the practical questions that we wish to raise in this issue.

First deadline for contributions: 1st of February 2002.

Issue 18.3, August 2002

Ecological soil management, key to sustainable agriculture

Many problems in agriculture are related to soil and soil fertility management, i.e. soil erosion, low efficiency of fertilisers, nutrient imbalances, soil borne diseases, pests and weeds, soil compaction, farmer induced drought, water pollution, etc. Successes in raising productivity and ecological sustainability in agriculture often come from improvements in soil management. More insights are being gained into ecological soil and soil fertility management in the tropics. What do we know of ecological soil management? How do (traditional) farmers look at soil management and what can we learn from approaches such as organic agriculture, agroecology, natural farming, integrated soil fertility management, zero tillage and integrated pest management? Can traditional and organic technologies be combined with chemical fertilisers? As organic soil management technologies can be very labour demanding, appropriate mechanisation can be important. What experiences have been gained in this regard? Ecological soil management is site and crop rotation specific. What experiences have been gained with fine-tuning ecological soil management for specific conditions and rotations? Your practical experiences are very welcome.

First deadline for contributions: 1st of May 2002.

You are invited to contribute to these issues with articles (about 800, 1600 or 2400 words + 2-3 illustrations and references), suggest possible authors, and send us information about publications, training courses, meetings and websites.

Launching the new LEISA website:

www.ileia.org

We are proud to present the LEISA Website – the entry to LEISA resources on the internet.

- **Do we need genetically modified crops?**
  Voice your opinion and read what other people think in the Themes section.
- **Want to search the specialised database on LEISA documentation with 9,000 records?**
  Then try ILEIADoc.
- **Tired of wasting hours searching for links to LEISA information on the Internet?**
  Then check the Links section for the best links to other LEISA-related sources.
- **Looking for a particular article in the LEISA Magazine? Then go to the Magazine section.**
  All articles since 1995 are available for you to read, download and print!
- **Wonder what LEISA related conferences are coming up? Check the Events section.**
- **Do you have a LEISA question that needs an answer?**
  Post it at the Open Forum where the LEISA community will help you find an answer.
- **Want to order a book, subscribe to the LEISA Magazine or change your mailing address?**
  Check out the Subscribe section.

Community Integrated Pest Management

http://www.communityipm.org/Concepts/sustliveo1.htm

The words of Mochtar Lubis *"never in my wildest dreams did I think that a programme about 'bugs' would bring the dawn of democracy and liberation to Indonesian villages"* explain the importance of this very good and informative website on Community IPM, a starter activity for development of sustainable livelihoods. The website provides information on concepts, cases, country programmes, events and makes many links with other organisations on IPM. There is also a Newsletter and many downloadable documents: case studies, training materials and scientific papers, among them the longer version of the article by Russ Dilts on p.18.

Future Generations

http://www.future.org

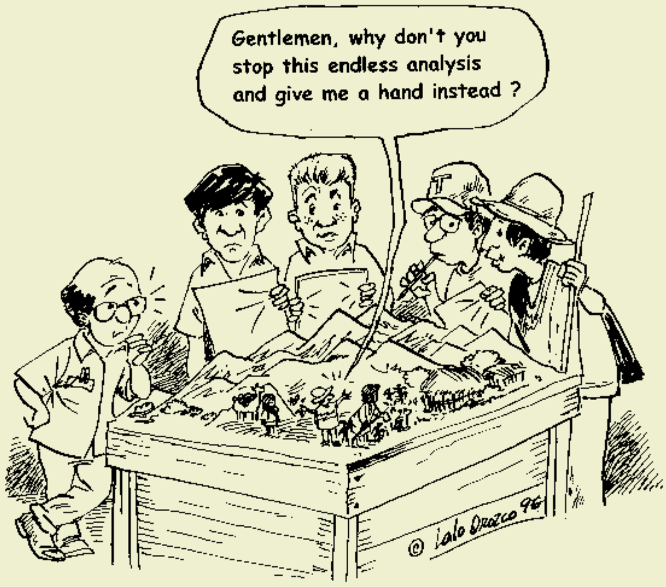
Future Generations has a remarkable track record as an international non-governmental organisation sharing knowledge and experience of how communities can change sustainably and equitably. Future Generations currently works on both sides of the Himalayan range - in the Tibet Autonomous Region of China and the states of Arunachal Pradesh and Utteranachal in India. The Future Generations model of community-based conservation and sustainable development can and should be applied around the globe.

The approach permits development success from one community to expand (or "scale up") quickly to other communities. The process of "going to scale" facilitates a rapid yet site-specific expansion of community progress that remains sensitive to local ecology, culture, and economics. The Future Generations website provides useful information on sustainable development, including a resource page with multimedia material and a variety of reports, among others '**The Future Generations model for community change**' and several pre-published chapters from the new book by Taylor-Ide DC and Taylor CE, **Just and lasting change: when communities own their futures** to be published by John Hopkins University Press (see Taylor p.14).

Scaling up participatory approaches

http://www.gtz.de/agriservice/areas/topics/topic6/topic_6d.html

This page on scaling up participatory approaches is found on the website of GTZ (Deutsche Gesellschaft für Technische Zusammenarbeit). Participatory approaches in community development are designed for use at local level. Participation implies that the number of people involved is small. However, scaling up is necessary to use these approaches in overall development programmes. Two questions are addressed on this page: how can participatory approaches (PA) be institutionalised in research and extension organisations and how can PA become general practice, to benefit large numbers of people.



Smart Library on Scaling Up

http://scalingup.smartlibrary.org/

This website contains a lot of information on scaling up of organisations. Text from a number of documents that handle issues of scaling up are available with a bibliography of the documents used. Scaling up processes in NGOs are discussed in detail. Information on why and how NGOs scale up and what problems can be expected is also available on the website. An easy and fast information source, but does not tackle the issues in depth.

Indigenous conservation tillage system in East Africa with an example of their evaluation from South West Tanzania

by R. Kayombo, J. Ellis-Jones and H.L. Martin, 1998. Available on:
http://www.fao.org/ag/ags/AGSE/ agse_e/3ero/Namibia1/c12.htm

This paper, available on the pages of FAO, documents existing indigenous conservation tillage systems in water scarce conditions and in semi-arid zones, and analyses the usefulness and shortcomings of indigenous conservation tillage in a case study from South West Tanzania. It provides 20 pages with information on these farming systems in East Africa,

The World Bank, participation, community driven development

http://www.worldbank.org/participation/
http://www.worldbank.org/wbi/sourcebook/sbhome.htm

These two World Bank sites provide information on participation in development programmes. The first page contains case studies and reference literature on the subject; the case studies are ordered country wise. There are also links to other information sources. This site is a rich source of information on community driven development, participatory monitoring and other related topics.
The second site provides a sourcebook on participation. Participation is a process through which stakeholders influence and share control over development initiatives and the decisions and resources that affect them. This Sourcebook is primarily intended for readers who have already decided to use participatory approaches in their professional work. The book is meant to strengthen ideas about participation and how to put it into practice. The ways of working presented in this manual can improve projects, contribute to the development process, and help reach the poor.

Conservation Agriculture

http://www.fao.org/landandwater/portals.htm

The FAO Land and Water portal has a section on conservation agriculture (conservation / zero / no tillage). Among its contents is an overview paper on experiences with conservation tillage: 'Frontiers in conservation tillage and advances in conservation practice' by R. Derpsch. This portal also gives access to the African Conservation Tillage Network.

Gender, land, and livelihoods in East Africa: through farmers' eyes by Verma R. 2001. 261 p. ISBN 0 88936 929 1. International Development Research Centre (IDRC), PO Box 8500, Ottawa, ON, Canada K1G 3H9 / www.idrc.ca/books/

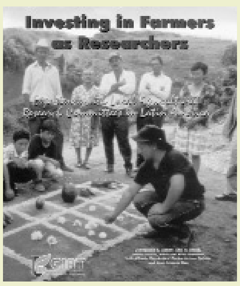
Research into the relationship between gender and natural resource management in Sub-Saharan Africa has taken a step forward due to people like Ritu Verma. Her analysis of the relationship between people and land recognizes the extraordinary complexity of soil management in an era of macroeconomic change. It centers on the social relations that dictate land use practice in Maragoli District, W.Kenya. A large part of the book is dedicated to the case study, which focuses on the complex gendered dimensions of soil management, farming and livelihood strategies of individuals who are differently positioned.

Part one is an introduction to the research, part two gives the historical background of the region. Part three, four and five present the research findings and gender analysis of the case study. The book illustrates the complexity and diversity of women's lives with extensive use of personal narratives and photographs from the farmers of Maragoli.

Interesting reading for researchers, practitioners, and professionals in development organizations, grass-roots organizations and government working on issues of gender, soil management, land tenure, income generation, and off-farm livelihood strategies. (WR)

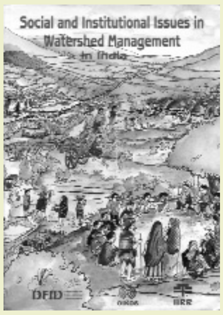
Investing in farmers as researchers: experiences with local agricultural research committees in Latin America by Ashby JA, Braun_AR [et al.], 2000. 199 p. ISBN 958 694 030 6 USD 40.-. CIAT, Publications Distribution Office, Apartado Aéreo 6713, Cali, Colombia / L.Garcia- CIAT@cgiar.org, www.ciat.cgiar.org. (CIAT Publication no 318).

This report describes experiences with an approach to participatory research and development in Latin America appropriate for poor farmers, called Local Agricultural Research Committees (CIAL spanish abreviation). The CIAL is a farmer-run research service that is answerable to the local community. The community elects a committee of farmers, the CIAL. The CIAL conducts research on priority topics and reports its results back to the community. Both the CIAL members and the community benefit from this approach.



The report describes the history and results of a number of CIAL's in Equador and Colombia. It is an impressive example of how poor farmers can help themselves and their community to increase their food security. The report ends with a long list of research topics investigated by CIALs throughout Latin America. The main topics are development of local crop varieties, resistant to pests or adapted to local soil conditions (potato, maize, cassava etc.) and evaluation of livestock diets for poultry, pigs etc. There is also a bibliography with training materials and manuals. This report is a source of useful information for anyone involved in agricultural research and development. (WR)

Social and institutional issues in watershed management in India, 2000. 407 p. ISBN 0 942717 86 4, OIKOS, India and International Instutute of Rural Reconstruction (IIRR), Y.C.James Yen Center, Silang, Cavite, Philippines / information@iirr.org financed by DFID-UK.



This resource book produced during a workshop held in India, in March 2000, has brought together "tried and tested" experiences in dealing with social and institutional issues in watershed development. The purpose in putting together this collection of resource materials is to provide trainers, project/field managers, local government officials, researchers and policy makers with a handy, user-friendly resource book on social and equity issues in watershed management. Oikos and IIRR has succeeded in making a comprehensive and user-friendly resource book with a lot of instructive illustrations focused on an extensive number of topics related to participatory watershed management. Fortunately, attention is also given to establishing partnerships and linkages between governmental, non-governmental, technical, social and credit institutions. This is important for sustainability of watershed management as well as for scaling up. (WR)

Nature in war; biodiversity conservation during conflicts : international seminar by Blom E, [et al], 2000. 174 p. USD 20.-. Werkgroep Ecologie en Ontwikkeling,programme of the Netherlands Committee for IUCN, Plantage Middenlaan 2B, NL 1018 DD Amsterdam / mail@nciucn.nl. (Mededelingen Nederlandse Commissie voor Internationale Natuurbescherming ISSN 0923-5981 no. 37).

This publication is the output of a workshop organised by a Dutch-based group of independent international nature conservationists called "nature in war". Members of NGOs from regions that experienced conflict situations illustrated the enormous damage to natural resources and rural areas caused by war. But at the same time they stated that conservation measures are possible and very important for the local situation. Recovery after the conflict is greatly favoured by nature conserving measures during the conflict situation. Nature conservation can prevent the total destruction of the environment of local communities. This publication gives recommendations for all stakeholders in conflict situations, governments, NGOs, humanitarian organisations etc., on how to avoid destruction of biodiversity and other natural resources. (WR)

Understanding diversity in farming practices in Tigray, Ethiopia
by Beyene A, Gibbon D, Haile M, 2001. 18 p. NUTNET programme, International Institute for Environment and Development (IIED), Drylands Programme. (IIED Managing Africa's Soils, ISSN 1560-3520 ; 24). Drylands Programme, IIED, 3 Endsleigh street, London WC1H ODD, UK / drylands@iied.org ; www.iied.org/drylands.

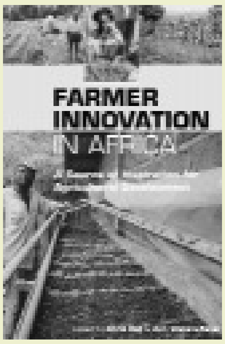
This paper presents the results of a study undertaken in Tigray, Ethiopia, to explore local people's perceptions and understanding of their land resources, and the way that their views influence natural resource management. The findings of the study indicate that the cultural and social meanings attributed to specific areas play an important role in the physical condition of fields. The conclusion of the researchers is that policy makers therefore need to pay more attention to the relationships between people and land, and to the value that farmers attach to different fields and plots. (WR)

Improvement of Neem and its potential benefits to poor farmers
by Childs FJ, [et al.], 2001. 32 p. ISBN 0 90534 29 8. HDRA the organic organisation, Ryton Organic Gardens, Coventry CV8 3LG, UK / www.hdra.org.uk/research , enquiry@hdra.org.uk Forestry research Programme of DFID.

This extensive review on the use of neem (Azadirachta indica) as a multi-purpose tree contains a list of published and unpublished literature, a consultation during a global electronic workshop and information obtained through fieldwork in Ghana and India. Research shows that the main use of neem is for medical purposes, with only a few farmers using neem in crop protection. Constraints for the use of neem in crop protection have been identified and possible solutions are suggested. The report gives an overview of the possible uses of neem, the constraints at the moment and possible interventions for increasing the benefits of the neem trees. The report comes with a neem database on 3.5 inch disk with bibliographic references relevant to the study. (WR)

The overstory book : cultivating connections with trees by Elevitch CR, Wilkinson KM (eds.), 2001. 414 p. ISBN 0 970254415 USD 49.95. Permanent Agriculture Resources (PAR), P.O.Box 428, Holualoa, HI 96725 USA / par@agroforestry.net, www.agroforestry.net.
This hard copy of the first 75 editions of the electronic journal "The Overstory" is a rich source of information on agroforestry. For people working with agriculture, trees, forests or sustainable resource management the book can function as a manual, filled with useful information in easy-to-read, single-subject articles. The articles are arranged content-wise so that interresting chapters like: saving water, soil and fertility; growing trees for forestry; seeds, seedlings and tree basics; animal assistants etc. form the contents of the book. Subscribers of the journal already know the value of the articles, but this arrangement of the articles together with the "learning more" bibliography and the good index with an additional index on botanical names of trees gives the book added value. Every article ends with further reading suggestions and weblinks and even the articles within the book are linked by a "related chapters" list at the end of each chapter. (WR)

Farmer innovation in Africa - a source of inspiration for agricultural development edited by Reij. C. and Waters-Bayer.A., October 2001. ISBN 1 85383 820 9 UK£ 16.95.-. Earthscan, 120 Pentonville Road, London N1 9BR, UK. E-mail: earthinfo@earthscan.co.uk www.earthscan.co.uk
One of Africa's major untapped resources is the creativity of its farmers. This message comes through very clearly in this volume of studies on how, in spite of adverse conditions and lack of appropriate external support, small-scale farmers - both men and women - are able to experiment and innovate in order to improve their livelihoods. Numerous lively examples show how a participatory approach to agricultural research and development - one that builds on local knowledge and innovation - can stimulate the creativity of all those involved, and not simply the farmers themselves.

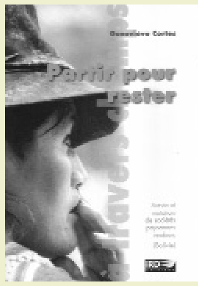


This rich source of case studies, written primarily by African extension workers, researchers and farmers, analyses how agricultural and development policy can be changed. Among the contents are: Farmer innovation and remarkable innovators; Building partnerships for innovation in land husbandry; Farmer innovation: process, evidence and analysis; Evaluation and extension of local innovations, Raising awareness and mainstreaming. The book will be invaluable for development workers, researchers and policy makers, as well as for students and teachers of agriculture, environment and sustainable development.

Municipal solid waste management, involving micro and small enterprises : guidelines for municipal managers by Haan HC, Coad A, Lardinois I, 1998. 154 p. ISBN 92 90493 65 8 : GBP 18.00. Publications Department, International Training Centre of the ILO, Viale Maestri del Lavoro 10, I-10127 Turin, Italy, SKAT. Intermediate Technology Publications, 103-105 Southampton Row, London WC1B 4HH, UK / itpubs@gn.apc.org.
This handy manual about urban solid waste management is meant for municipal managers and others interested in municipal issues. The book is divided into several sections that answer specific questions like "why involve the private sector" or "what policy decisions must be made before starting". It covers the "why" and "how" of involving new entrepreneurs and small community-based groups in the collection of garbage. The last part of the book, "the annexes" contains case studies from Latin America, South-east Asia and Africa , sample contracts and backup information. (WR)

Weed management in the humid and sub-humid tropics by Rijn PJ (van), 2000. 234 p. ISBN 90 6832 123 4 USD 32.50. Royal Tropical Institute (KIT). KIT Press, P.O.Box 95001, 1090 HA Amsterdam, the Netherlands / publishers@kit.nl ; www.kit.nl.
This thorough book on weed management is written by three scientific experts in weed management in tropical crop systems. The abundant growth of weeds can cause high losses in tropical crop yields if no control methods are practised. The first part of the book deals with the nature of weeds, ecology, control, cropping systems and main weed species. The second part deals with weed control methods in general and in various crops. A variety of control methods, also mechanical and biological/ ecological, are described per crop. The last chapters are on weed control in pastures and on aquatic weed management. (WR)

Partir pour rester : survie et mutation de sociétés paysannes andines (Bolivie)



by Cortes G, 2000. 414 p. ISBN 2 7099 1459 X FF 150.-. Institute de Recherche pour le Development(IRD) éditions, 213, rue la Fayette, 75480 Paris cedex 10, France.
Geneviève Cortes is a French researcher in rural development and migration dynamics. She has written this study about migration and the complexities it brings about in Andean smallholder economies. The book in French has summaries in English and Spanish. The work sheds light on the economic and sociocultural changes of rural areas in the Andes (Bolivia) analysed in relation to migration. The way in which spatial mobility of smallholder farmers moulds new relationships with space and with home territories is explored, and also the role of migration in agricultural production, modes of consumption and food systems. The study combines both quantitative methods like socio-economic monitoring of households, and qualitative approaches like observations and participation. (WR)

Participation of the poor in development initiatives : taking their rightful place by Long C, 2001. 192 p. ISBN 1_85383_761_X : GBP 15.95. Institute for Development Research (IDR). Earthscan Publications, 120 Pentonville Road, London NI 9JN / earthinfo@earthscan.co.uk / www.earthscan.co.uk.
This book is an analysis of the progress made by donors and governemental agencies during the past decade to embrace participatory development approaches and incorporate it in their policies and procedures. NGOs in different parts of the world use participatory development as common language for decades, but large donors like the World Bank and USAID have changed their policies in favour of primary stakeholder participation only in the last decade. The book describes this process of incorporation. (WR)

NGO's, states and donors: too close for comfort? by Hulme D, Edwards M (eds.), 1997. 309 p. ISBN 0 333 66582 1 (pbk): GBP 12.99. Save the Children. (International Political Economy Series). Intermediate Technology Publications, 103-105 Southampton Row, London WC1B 4HH, UK / itpubs@itpubs.org.uk
The contributors to this volume have presented a wealth of experiences, data, concepts and competing analyses of what is happening in the relationships between NGOs, states and donors. Donors have poured funds into NGOs, governments have allocated them major responsibilities and their number and size have grown. This book raises the question as to whether this popularity has helped them to solve the problems of poverty, or whether it has changed them to become part of the "development industry" that they used to criticise. The picture that emerges from the general reviews and detailed case studies of African, Asian and Latin American NGOs is a complex one. However, the authors warn that NGOs are getting closer to donors and governments and more distant from the poor whom they seek to assist. (WR)

Farmer-led extension : concepts and practices

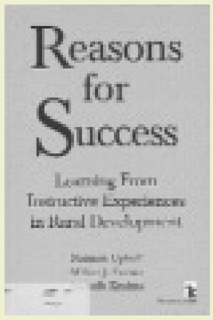
by Scarborough V, Killough S, Johnson DA, Farrington J (eds), 1997. 214 p. ISBN 1 85339 417 3: GBP 12.95. Overseas Development Institute (ODI), Regent's College, Regent's Park, Inner Circle, London NW1 4NS, UK. Intermediate Technology Publications (ITP), 103/105 Southampton Row, London WC1B 4HH, UK.
This book presents the outcome of an international workshop held in the Philippines, promoting farmer-led approaches to agricultural extension. The workshop distinguished between truly farmer-to-farmer extension, extension undertaken and controlled by farmers themselves, and approaches aiming at a greater involvement and influence of farmers in extension organised by others, governmental or non-governmental organisations. Based on a very rich collection of cases from all parts of the world, the book formulates lessons and recommendations on both forms of farmer-led extension. According to the authors the second form of farmer-led extension may be applicable on a wider scale but only if public sector extension is really prepared to give up part of its power and become responsive to interests and initiatives from farmers. (LvV)

The inter-group resource book: a guide to building small farmer group associations and networks by Lawrence T, Rouse J, Thomas G, 2000. 104 p. Food and Agriculture Organization of the United Nations (FAO), Viale delle Terme di Caracalla, 00100 Rome, Italy / www.fao.org
This publication of FAO is the third in a series of field manuals on small farmer group development, and deals with the topic of developing inter-group associations. As a development strategy small groups have been promoted in order to strengthen the collective self-help capacity of small farmers. However, individual small groups often do not have the resources needed to pursue broader objectives. In such cases some sort of inter-group cooperation is needed to achieve results. With this publication FAO aims at helping groups to build inter-group associations that are capable of financing and managing their own activities, using their own resources and without need of outside help. The manual provides practical information on this subject, in the form of guidelines that cover the whole process of establishment to management of an association. This manual is available for free, downloadable from internet, and FAO encourages users to translate it into their own language and to adapt its contents to their own conditions. (WR)

Learning together through participatory extension : a guide to an approach developed in Zimbabwe by Hagmann J. [et al.], 1998. 59 p. Department of Agricultural, Technical and Extension Services (AGRITEX); German Development Cooperation (GTZ); Intermediate Technology Development Group, Zimbabwe (ITZ). Universum Verlagsanstalt, D-65175 Wiesbaden, Germany.
This booklet, written for field staff and middle-level extension managers, describes a community-oriented approach to rural extension based on farmer experimentation and learning. The action-learning cycle integrates four main phases: social mobilisation through a situation analysis carried out jointly by insiders and outsiders, community-level action planning, implementing of activities and farmer experimentation, and monitoring and evaluation through sharing experiences and ideas. A major focus is on local institutional development. The process in practice - with all its steps - is described and clarified through examples from the field.

Scaling up participatory watershed development in India: lessons from the Indo-German Watershed Development Programme
by Farrington J and Lobo C, 1997. ODI Natural Resource Perspectives nr 17
http://www.odi.org.uk/nrp/17.html
Upscaling individual successes to a large-scale programme calls for a perspective of macro-management which, at the same time, has to be rooted in and responsive to the micro-level. This paper describes the experiences of the IGWDP in semi-arid India with the upscaling of participatory watershed development over wide areas. Both the involvement of stakeholders at international, national, district and local levels and the field level collaboration of NGOs, community-based organisations and government departments are discussed and criteria for selection are given. Micro-level watershed rehabilitation reverses environmental degradation and permits a shift in sustainable productivity in the lower slopes of watersheds. This report contributes to the search for participatory but rapidly replicable approaches to micro-watershed rehabilitation. (WR)

Reasons for success: learning from instructive experiences in rural development by Uphoff N, Esman MJ, Krishna A, 1998. 232 p. ISBN 1 56549 076 2 (pbk): USD 19.95. Kumarian Press, Inc., 14 Oakwood Avenue, West Hartford, CT 06119-2127, USA / kpbooks@aol.com.



This book is written as a companion volume to "Reasons for Hope", a collection of case studies of programmes that have succeeded in improving prospects of rural households. Successful large-scale and sustainable programmes for rural development are much more the exception than the rule. These books focus on rural development programmes that have had important impacts in their countries and some even beyond their national borders. A wide range of successful experiences in developing countries all over the world is described. In "Reasons for Success", the authors analyse not only how these initiatives have become successful, but also how to generalise these often local initiatives. The most important aspects that contributed to the success of the initiatives are dealt with in the different chapters of the book: the learning process and assisted self-reliance; the importance of good leadership; local organization and participation; knowledge about how to take better advantage of the available resources, natural, physical and human. This readable book is a rich source of information that shows ways to improve people's livelihoods whilst sustaining the environment. (WR)

Sustainable rural livelihoods: what contribution can we make? by Carney D (ed.), 1998. 213 p. ISBN 1 86192 082 2. Department for International Development (DFID), 94 Victoria Street, London SW1E 5JL, UK. (Issues).
The main papers of the Natural Resources Advisers' Conference on sustainable rural livelihoods organised by DFID in 1998 are collated in this book. The book opens with an informative introduction on definitions and explanations of sustainable livelihoods, written by Diana Carney, the facilitator for DFID's Sustainable Rural Livelihoods Advisory Committee.
The papers in the Key Issues part relate to policy consistency. The Entry Point papers go into some detail about the contributions to the sustainability of rural livelihoods that can be made by involvement in any particular area (biodiversity, ethical trade etc.). This book marks a starting point for thinking about a relatively new policy direction and the opportunities it presents. (WR)

Livelihood transformation in semi-arid Africa 1960-2000 : policy lessons from farmers' investment choices in Kenya, Senegal, Niger and northern Nigeria. 2001. Drylands Research, 17 Market Square, Crewkerne, Somerset TA18 7LG, UK / mikemortimore@compuserve, mary@marytiff.demon.co.uk; www.drylandsresearch.org.uk. (Drylands Research Working paper, ISSN 1470 9384 ; 40).
These are the proceedings of a workshop organised by the Overseas Development Institute (ODI) and Drylands Research in the series "Transformations in African agriculture" held at the London School of Economics in January 2001. It is part of a study that aims to relate long-term environmental change, population growth and technological change, as a follow-up to the well-known study by Mary Tiffen, Mike Mortimore and Francis Gichuki in Machakos District: "More people, less erosion: environmental recovery in Kenya". The hypotheses and policy recommendations generated by that study were tested in four other African dryland environments: Makueni District, Kenya; Diourbel Region, Senegal; Maradi Department, Niger; and Kano Region, Nigeria. Farmers' investments over time were compared in order to increase understanding of the effects of government policies on farmers' strategies and their choices between farm and non-farm activities. For each study area, several working papers and a synthesis were prepared. An overall synthesis was discussed at the workshop as reported in these proceedings. The results confirmed that rural people are innovating and finding solutions and opportunities in response to market and environmental conditions, but have often been constrained in these efforts by inappropriate government policies that do not give space for local dynamics. The working papers and syntheses can be obtained from Drylands Research or at the website (address see above), which contains the abstracts of all the working papers. (AWB)

Information revolutions: how information and communication management is changing the lives of rural people by Mundy P, Sultan J. 2001. 234 p. ISBN 92 9081 2289. Technical Centre for Agricultural and Rural Cooperation (CTA), Triops, Hindenburgstrasse 33, D-64295 Darmstadt, Germany / triops@net-library.de ; www.net-library.de.
This publication of CTA is also available in French (Les révolutions de l'information) and an electronic version can be found at www.cta.nl. With this book CTA addresses an important topic. The possibilities for information gathering and sharing are rapidly increasing at the moment due to fast technology development. But what perspectives does such development have for rural people. Efforts to use communication in rural development have three aims: provide information to audiences; help audiences find information and facilitate dialogue among audiences. This book comprises success stories of projects that promote information exchange in rural areas of Africa. The book is divided into nine sections, each with up to six stories about particular institutions or sets of institutions. There are sections on radio and television, newspapers and newsletters, literacy and local languages, computers and telecommunications, farmers' groups and markets, farmers' knowledge, research and extension links, research networks, and libraries. The stories are carefully chosen; only proven local or national initiatives that really contribute to communication are included. Therefore the book is very useful to everyone who wants to profit from information technology development. (WR)

Participatory watershed research and management: where the shadow falls by Rhoades RE, 1998. 20 p. International Institute for Environment and Development (IIED), 3 Endsleigh Street, London WC1H 0DD, UK / sustag@iied.org. (IIED Gatekeeper series, ISSN 1357-9258; SA 81).
Professor Robert Rhoades, who has more than 30 years experience in international development, warns in this paper of the pitfalls in the conceptualisation and operationalisation of integrated participatory watershed projects. He mentions a number of problems, which he calls "landmines" that can be expected on the way of implementing participatory watershed management. All these landmines are discussed with remarks on how to avoid them. The paper closes with urgent steps to be taken and an appeal to share experiences and to learn from mistakes. (WR)

Cover crops in smallholder agriculture: lessons from Latin America by Anderson S, Gündel S, Pound B, 2001. 152 p. ISBN 1 85339 530 7 USD 22.50. ITDG, Publishing, 103-105 Southampton Row, London WC1B 4HL UK, orders@itpubs.org.uk / www.itpubs.org.uk

Lessons learned in Latin America about the use and dissemination of cover crops in different agroecosystems need to be made more widely available not only in the Spanish-speaking, but also in the Anglophone regions. That is the aim of this workshop report. It concentrates on smallholder agriculture in developing countries where cover crops could provide an appropriate technology for risk-prone and resource-poor farming situations. The selected case studies from different countries within Latin America, which have been analysed during the workshop, form the skeleton of the report. The numerous experiences and variety in lessons learned for a wide range of agroecosystems makes this report a useful reference tool for extensionists, researchers and NGO workers around the world. It is well written and easy to understand. (WR)

Economic conditions for sustainable agriculture
A new role for the market and the state

Ruerd Ruben

Field research by the Development Economics Group of Wageningen University on various agro-ecological practices used by farmers in Central America (Nicaragua, Honduras, Mexico and Costa Rica), East Africa (Kenya, Ethiopia, Zanzibar) and West Africa (Mali, Burkina Faso, Benin) provides interesting comparative results regarding the economic effects in different settings. For this research, four specific criteria were used to assess the economic attractiveness of different types of agro-ecological practices: (i) profitability, e.g. the contributions to farmers' income and consumption, (ii) effect on input efficiency, (iii) consequences for labour use, and (iv) impact for risk management. On the basis of these findings, recommendations for policy reform are discussed.

Profitability
Adoption of agro-ecological practices can only be expected when farmers attain higher and more stable income and consumption opportunities. Contrary to what is usually expected, farmers are likely to apply yield-increasing and sustainability-enhancing inputs for commercially-oriented production activities. In the cotton belts of Southern Mali and Burkina Faso, fertilisers, crop residues and animal manure are mainly used for cash crops that guarantee sufficient monetary returns to warrant these costs. Similarly, animal traction and improved tillage yield higher returns when applied on more fertile fields where commercial crops are grown. In the Central Chiapas region of Mexico, crop residue mulching only appears to be profitable when combined with animal traction on fields devoted to intensive market-oriented maize activities.

Although we found that agro-ecological practices are likely to be adopted by subsistence-oriented, medium-size farmers in remote regions where opportunity costs are usually low, farmers' engagement in market exchange can still be considered an important condition for profitable and sustainable agriculture. Engaging in trade provides financial resources for the purchase of complementary inputs and consumption goods. Market development enhances the willingness to invest, while involvement in market exchange generally improves farmers' responsiveness to price incentives.

Input efficiency
Agro-ecological approaches are strongly based on the substitution of chemical inputs by integrated nutrient and pest management systems. High costs of inorganic fertilisers and other agro-chemicals often drive farmers to rely on locally available resources. Reducing the reliance on purchased inputs implies that good substitutes can be found and that complementary relations between different inputs are recognised.

Prospects for sustainable agricultural intensification strongly depend on the possibilities to improve *input efficiency*, e.g. the marginal returns derived from an additional unit of (organic or inorganic) inputs. Nutrient efficiency (i.e. fertiliser uptake) is determined by the availability of complementary micro- and macro-nutrients, notably soil organic matter and phosphorus. Nutrient recovery and the efficiency of uptake can be enhanced through (i) soil and water conservation measures, and (ii) frequent nutrient applications at times required by the crops (e.g. shortly after sowing and with sufficient rainfall). Both activities are highly labour-demanding and can hardly be mechanised. Input efficiency tends to be low when complementary inputs are not available at the right time or in sufficient amounts.

Organic and chemical inputs are not full substitutes, and combinations of locally available resources with selectively applied external inputs often yield the best results. We found that farmers hesitate to refrain completely from the use of purchased inputs, because it permits better timing of activities, reduces the demand for labour in critical periods, and contributes to a better appearance of the products in the marketplace. Given the low nutrient content and the delayed nutrient availability from organically produced fertilisers (green manure, mulch, dung, compost), chemical fertilisers are gradually reduced but not completely abandoned.

Labour productivity
Most analyses of sustainable practices devote attention to short- or long-run yield effects without acknowledging labour requirements and returns to labour. Family labour is thus wrongly considered as an 'abundant' resource. For most small farmers labour is scarce and strong limitations exist for substituting external inputs by labour. For a systematic evaluation of the attractiveness of such practices from the farm household's perspective, returns to land and labour need to be compared simultaneously. Agroecological intensification can only contribute to poverty alleviation when returns to land and labour increase simultaneously. When agroecological practices are analysed, attention has to be given to *marginal* returns compared to other activities (i.e off-farm employment; hiring-out of land).

Agroecological practices can be relatively intensive in the use of labour. Physical soil conservation measures promoted in the Central American hillsides and West African lowlands have resulted in yield increases, but require large amounts of labour for construction and maintenance and involve substantial costs for the purchase and transport of materials. Given their high labour intensity and long gestation period, returns to labour of such measures are mostly critical. Similarly, green manure practices and crop residue mulching in Mexico and Honduras require additional labour for harvesting, transport and under-ploughing. Mixed cropping and agroforestry systems in Central America and East Africa show low returns to labour due to high establishment, maintenance and harvesting costs. Production of fodder crops for livestock in West Africa improves the availability of manure and enable farmers to recycle crop residues, but demand considerable labour investment. Labour requirements for integrated pests and disease management in Zanzibar are equally high due to the substitution of manual for chemical operations. Mechanisation is not a feasible option due to very sloping terrain and the small scale of operations.

We found that high labour intensity can be a major limiting factor for adoption. Labour tends to be scarce in semi-arid areas during the periods of soil preparation, weeding and harvesting and competition for labour occurs when mulching, manuring or crop residue recycling are introduced. Resource-poor farmers are likely to derive part of their income from off-farm activities that have to be reduced when labour-led intensification of their farming system takes place. Farmers are likely to adjust their production system only when the additional income derived from those activities favourably compares to labour's opportunity cost. Some practices, notably physical soil conservation measures, can be executed in off-season periods, but take up leisure time that may be reserved for social or communal purposes.

Risk-coping

Resource-poor farmers prefer to rely on fairly diversified patterns of activities to ensure appropriate levels of risk management. Farmers facing risk prefer immediate revenues and therefore investment activities with long gestation lags are not popular. Diversification of cropping and livestock production and their integration with (agro)forestry, aquaculture and improved fallow practices could reinforce the resilience of farming systems through processes of nutrient recycling, biodiversity management and integrated pests and disease control. Consequently, yield levels tend to be more stable and dependency on purchased inputs can be reduced.

Risk management can also take place through farmers' engagement in off-farm and non-farm activities. The revenue streams derived from these activities are far less dependent on variable weather conditions and thus provide an adequate insurance against shocks.

Policy Reforms

Agroecological practices are widely promoted by farmer groups and NGOs to reduce the dependency on purchased inputs and to reinforce ecological sustainability. On the long run, genuine sustainability requires that these practices become economically feasible and independent of external support. To facilitate sustained adoption of agroecological practices, the following economic policy conditions should be in place:

Stable and remunerative *market prices* for agricultural products are effective as incentives to mobilise resources towards sustainable production systems. Massive adoption of new cropping systems could, however, lead to pressure on market prices and loss of initial returns.

Agricultural intensification also implies that land, labour and capital resources can be effectively mobilised. Secure and recognised *land and water rights* are an important condition to enhance farmers' willingness to invest. Well-defined ownership, use and transfer (inheritance) rights permit farmers to invest in land improvements and input purchase, and provide a suitable collateral for lending.

Rural *financial systems* are necessary to facilitate farmers' borrowing for investment, input purchase and insurance purposes. While formal banks are usually less inclined to lend to smallholders, local credit and savings schemes could contribute substantially to reduce transaction costs and risks for rural investment.

Reinforcement of the market environment can be considered as an important incentive for investments in sustainable agriculture. However, incentives should be related to '*farmer needs pull'* rather than '*technology push'*. Market prices should reflect real scarcity relations as perceived by the farmers and must not be distorted by improper interventions by the state or local NGOs. Subsidies on inputs or credit are not useful to enhance the lasting adoption of agroecological practices. Subsidies on demonstration plots are less convincing to farmers compared to experiments conducted on their own fields and investments made with own resources. In a similar vein, financial support systems based on farmers' own savings proved to be far more sustainable than subsidised credit systems.

Interventions to improve the market environment in favour of agro-ecological practices:

- Increasing the prices of imported inputs like fertilisers and other agrochemicals through adjustment of the exchange rate (devaluation) and elimination of input subsidies;
- Improving the efficiency of input delivery and output marketing systems, looking for a reduction of the transaction costs involved in market exchange through (public and private) investments in services and infrastructure provision;

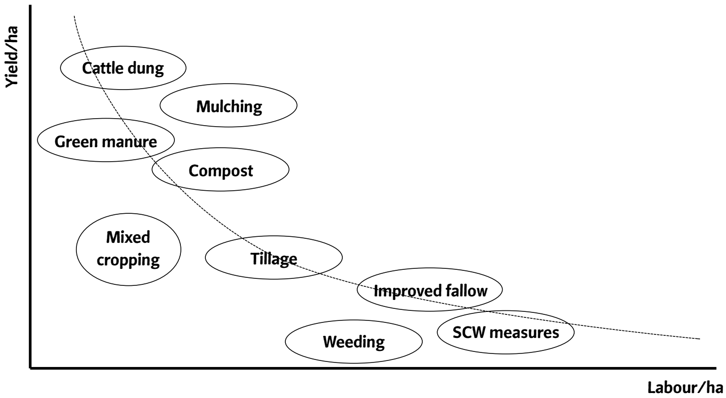


Figure 1: Factor intensity and yield effects of major NRM practices

The figure provides an overview of some agro-ecological practices used by Central American farmers, taking into account expected yield effects and labour requirements. The final selection of suitable practices made by the farmer is likely to depend on the labour/output price relationship.

- Introduction of user charges and fees for water, roads and technical assistance to facilitate the rationing of scarce resources towards the most efficient farmers, and to guarantee the institutional sustainability and maintenance of these services;
- Creation of more competitive markets through reduction of the market entry costs, including the establishment of farmers trading co-operatives, market information services, etc.;
- Improving value addition in agricultural production and marketing through investments in agro-processing, trade centres, product certification, etc.;
- Enhancing the backward and forward linkages of agricultural production, promoting integrated agro-commodity chains based on delivery of improved implements;
- Diversification of factor and commodity markets, enabling farmers to gain access to off-farm and non-farm income sources that will enable the intensification of their farming systems.

Public investments in infrastructure are required to support the development of local factor and commodity markets. Market development and reduction of transport costs are the most important requirements for sustainable agricultural intensification, since exchange relations favour access to complementary inputs and provide incentives for investment. Improving poor farmers' access to physical infrastructure represents a major condition for equitable and sustainable rural development. Without such efforts, low-input technologies tend to be restricted to medium-size farmers who are only marginally engaged in market exchange.

How successful is the Wadi model?

Sharad Mahajan, Madhuri Newale, Pratap Pednekar

In 1982, the BAIF Development Research Foundation initiated a programme to improve the living situation of tribal communities in South Gujarat affected by environmental degradation and labour migration. In direct interaction with the tribal communities the *Wadi* (orchard) model, which combines improvement of human and ecosystem wellbeing, was gradually developed. Today, over 25,000 families from 300 villages have adapted the model. It is now to be implemented in Maharashtra and Rajasthan to cover an additional 20,000 families. In ILEIA Newsletter Vol.16.1 (pp18-19) the *Wadi* model has been presented and would be useful reading for those interested in a more detailed description. This article discusses the impact of the Wadi model.

Women obtain an additional income from tomato cultivation. Photo: Sharad Mahajan

Assessing the Dharampur Experience

Dharampur is one of the major tribal blocks of South Gujarat (India) situated in the forest. The area covered under forest is 46 % and is declining due to area brought under cultivation (a part of which turned into wastelands) and land used for settlements. The block consists of 237 villages comprising 287,600 people of which 98% belong to scheduled tribes. The hilly region has poor land and water resources as well as infrastructure facilities. The tribal population consists of small and marginal farmers (land holding less than 2ha) and the landless. The farmers use the land for production of food grains. Most of the tribals migrate to urban areas in search of work as hired labour.

The *Wadi* model has been taken up in the Dharampur block since 1995. 11478 families from 145 villages have adopted the model during the last 5 years.

The effect of the interventions was assessed using community based indicators. Focus group discussions with members of Planning Committees (*Ayojan Samitees*) of the Village Development Forums (*Gram Vikas Mandal* - GVK) were organised to develop the appropriate indicators. Discussions were centred around the perception of the community about development, the current situation and their vision. Information on selected indicators was gathered through household surveys, special studies related to cropping pattern, land use, status of development of GVKs and access to services. The overall effect of the model has been assessed through the 'Barometer of Sustainability'. The results are as follows.

Investing in orchard development

The participating families have established orchards on 4260 ha without disturbing the traditional cultivation area. The major part of the orchards are planted on wasteland (18%) and marginal lands (75%). The orchard plantation includes mango and cashew together with multi-purpose forestry tree species along the borders of the orchard. Farmers have planted 225,000 mango trees, 450,000 cashew trees along with 5 million forestry trees.

Almost half of the total area under orchards is treated with appropriate soil and water conservation measures. These include trench-cum-bunds for gentle and medium slope lands and tree platforms with upstream trenches for steep slope lands.

Each family establishes an orchard on their own marginal or wasteland. Core support for orchard development is provided in the form of material (good quality inputs e.g. grafts, saplings of forestry plants, fertilisers, organic manure, farm tools etc.) and training. Considering the long gestation period, the participants are encouraged to work on their own plots for land shaping and aftercare of the orchard. A token cash support is paid to the family for the labour it invests. It helps families to sustain and ensure proper maintenance of orchards. Participants also receive additional support to develop water resources as a group for income generation activities. The support is provided as a partial grant and credit (25%). The costs involved for orchard development on 0.4 ha are about US$450 see table 1.

Table 1: Per family costs for development of 0.4 ha orchard model

Particulars	Cost (Rs.) Material	Labour	Total	Period of support
Orchard establishment	3150	1030	4180	One time cost incurred during first year
Land shaping		3500	3500	One time cost incurred during first 2-3years.
Orchard maintenance	8040	2100	10140	Recurring cost indicated from second to seventh year of orchard development
Water resources development and irrigation	1450		1450	Utilisation not for individual basis but on user group basis
Credit component	On an average 25% of the above costs for income generating activities, water resources development, irrigation systems etc,			
Training and health component	About 5 % of the total cost per family for five years			
TOTAL COST	Rs. 20,000/ -(rounded off) i.e. approximately US$450			

Improved utilisation of land and water resources

The combined effect of orchard development, land shaping and utilisation of available water has led to a change in the cropping pattern.

- Establishment of orchard and cultivation of crops has increased the land use in the range of 30 -75%. About 40 % of the families have taken up winter cultivation (earlier only rainfed agriculture in summer). The visible impact of the cropping pattern change is crop diversity. Major crops cultivated before the programme were cereals (paddy, coarse millets), pulses (pigeon pea, gram), oil seeds (niger). Farmers added new crops: vegetables (brinjal, tomato, chilli, cucumber, etc) root crops (onion, turmeric, sweet potato), watermelon, wheat, banana, etc.
- About 55 % of the families have increased the average paddy area from 0.36 to 0.5 ha. Rice is the main staple food. Growing of other crops for the market is observed in areas having appropriate water facilities. Cultivation of perennial crops is also increasing. This includes coconut, guava, lime, jackfruit, ber, etc. An overall change in the cropping pattern is observed on 51% of the total area under cultivation.

Settlement in own environment

Tribals see orchard development as an opportunity to build some assets in the existing subsistence living condition. They take every care to make it successful. In many orchards, elderly family members are engaged in watch and ward throughout the day. About 55% families have either shifted or planned to shift their houses into the orchards. Thus, a resource once considered as written-off has now become a shelter for life.

Families have not only started building and utilising productive resources but also acquiring new skills. The baseline situation indicated that only 13% of their income was generated from local productive sources and the economy was primarily dependent on labour migration. Orchards have now started bearing fruits, the cropping pattern has changed, the use of inputs (seeds, fertilisers) has improved and subsidiary agricultural activities such as mango grafting, nursery raising, etc are being initiated. This has brought about a complete reversal in the sources of income and about 60 % of the families now generate more than half of their income from local productive resources.

Improved quality of living

Settlement of tribals in their own environment and opportunities for developing own resources is reflected in the improvement of their living conditions. The visible changes are observed in a considerable reduction in migration, self sufficiency in food grains and improved access to safe drinking water and health services.

Reduction in migration. The baseline situation indicated that 85% of the families were migrating for an average period of 68 days. The people engaged themselves in labour work at construction sites, chemical factories, grape gardens, vegetable packaging centres etc. Women migration was also a common feature in the area and was observed in 35% families. This situation has changed and about 76% families have reduced the migration period (of which 50% have stopped migration). Migration of women has also come down to 15%. People now look forward to increase productive sources of income and simultaneously augment their income through opportunities of local labour.

Self-sufficiency of food grains. On an average the families were procuring food grains worth Rs.1680/- annually, constituting 40% of the cash income. Now, the families have directed their efforts towards achieving self sufficiency in food grains. This has been observed as an immediate effect of land treatment. The area under paddy cultivation has increased. More than 93% families have reduced their food grain purchases of which 57% do not purchase any more. In fact 29% families have even generated income through sale of food grains.

Availability of fuelwood. Another significant requirement of families is fuel wood. The families were dependent on forest resources to meet the same. Various fuel-wood species namely *Leucaena leucocephala, Acacia auriculiformis* and *Gliricidia* trees have been planted around the orchard. These plantations can fulfil fuel wood requirements up to 60 % depending on the number of established forestry trees. Promotion of energy saving devices such as improved cook-stoves has slightly reduced the fuel-wood requirement. 26% of the families are using these improved cook-stoves.

Development of support services (Primary Health Service, Safe Drinking Water and Credit). Usually the families had to travel up to 10 km to avail even primary treatment. Travelling within the area is difficult due to lack of transport and infrastructure facilities. As a result, families used to get treatment from traditional healers and Primary Health Centres wherever easily accessible.

Local youth (especially women) trained as Village Health Guides have not only improved access to health care but also made the communities more aware on health related aspects. This is quite indicative from the fact that Village Health Guides have been the first contact for primary treatment. The first trimester registration of pregnant women has increased from 27 % in 1996 to 42 %. Also, national campaigns such as Pulse Polio have succeeded with over 95 % coverage for immunisation.

The only safe source of drinking water available before the programme was hand pumps, as open wells were not chlorinated.

The fruits of the orchard plantation, ready to harvest. Photo: Sharad Mahajan

Women have learned how to care for the fruit trees. Photo: Sharad Mahajan

Yet 31 % hand pumps were not functional. Regular chlorination of open wells, awareness generation among families for home chlorination and putting non-functional hand pumps into use through repair and maintenance has ensured safe drinking water to about 80 % families.

There were only two banks in the area catering to the needs of people from 145 villages. The limited availability of resources together with poor access to credit reduced the scope of development. The programme interventions have brought improvements in the existing resources use. The GVMs are empowered to mobilise and manage the resources in terms of savings and credit. Credit facilities for consumption as well as production purposes are now available in 109 villages.

Building local action

The *Wadi* model has become a common thread for participating families and provides them a group identity. A total of 1790 *Ayojan Samitee* members from 143 GVMs are directly involved in the management of all village level activities. Development of the GVM is linked with a feeling of ownership among members, operational regularity and consistency, self-management capacity, resource mobilisation and responsiveness to people's needs. This is seen from actions like establishment of community dwellings, initiation of regular savings, grain banks, organisation of community marriages, literacy classes, collective procurement and sale of produce, etc. The credit facility available through the GVMs has provided easy access to timely and adequate credit to the participants and ensured sustainability of the development in the long run.

Due attention is given to women as well. All the orchards have joint ownership of husband and wife. Women are organised into self-help groups and take up supplementary income generation activities with regular savings and credit. Simultaneously, need based activities to reduce workload and drudgery of women are taken up.

The field functionaries are engaged in mobilising the people and promotion of technologies for common use through demonstration and training. These functionaries, being local, have an advantage of better understanding the people and the village situation. The training and work experience has given them an opportunity to acquire a special status – "a helping hand" in the village and confidence in dealing with external agencies. There are 114 field guides, 111 Village Health Guides, 250 self-help group leaders, 120 barefoot accountants, 71 hand pump technicians, 87 oil engine technicians and a number of nursery technicians.

The strong cadre of local functionaries, *Ayojan Samitee* members and self-help group leaders has boosted the local initiatives and enhanced the management capacity of people.

Score on the "Barometer of Sustainability"

The "Barometer of Sustainability", a tool developed by the International Union for Conservation of Nature (IUCN), is used to combine indicators related to human wellbeing together with ecosystem wellbeing. It treats both people and ecosystem equally on two scale axes as shown in Fig. 1.

The scale is divided into five sectors in an ascending manner from unsustainable (bad) to sustainable (good). Conclusions about conditions of people are expressed as a point on the human wellbeing axis as an index of human wellbeing. Similarly, conclusions about conditions of ecosystem are expressed as a point on ecosystem wellbeing axis as an index of ecosystem wellbeing. The intersection of two points provides reading of overall wellbeing and progress towards sustainability. The tool implies that improvement in human wellbeing should not be at the expense of a decline in ecosystem wellbeing.

Fig 1 indicates the current stage of development in the tribal region of Dharampur due to the model interventions as discussed above. The regeneration and effective utilisation of available resources - mainly land and water - are considered as important dimensions of ecosystem wellbeing. In order to bring about these changes, settlement of tribals in their own environment, changes in quality of living and building local action are crucial and thus these factors are considered as part of human wellbeing.

The intersection of human wellbeing and ecosystem wellbeing scores falls on the border of the intermediate to almost sustainable band with the final score at 60. This indicates a balanced growth at the end of five years. This five-year phase can be considered as a formative phase for reconstructing the resource base and building confidence among the people. The programme has not just remained planting trees but has offered a basket of opportunities to shape the people's future. This is quite evident from actions such as families shifting their houses into

Fig 1. Barometer of Sustainability

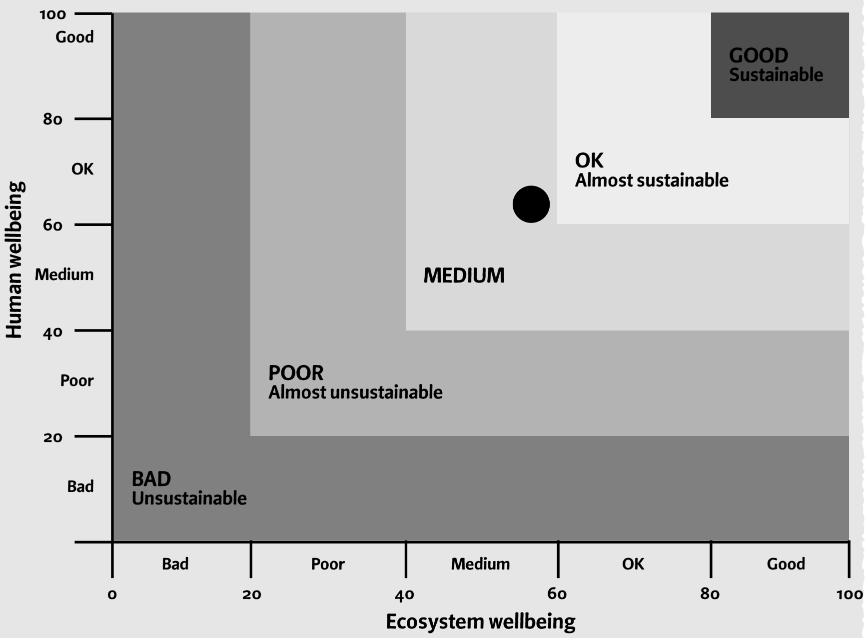
Building local action	67
Ecosystem Wellbeing	
Land	63
Water	50



the orchards, becoming receptive to new concepts and techniques (mango grafting, nursery raising, composting, appropriate irrigation systems, immunisation, etc) and thinking towards optimum utilisation of available resources. The GVM has taught people to look beyond self interest.

The key to these changes is: linking the development of people and the environment. The synergetic effects of these efforts lead to sustainable development. There is a direct co-relation between the quality of ecosystem and human wellbeing. The status of health, wealth and quality of living are dependent upon diversity, productivity and nature of the ecosystem of which people are an integral part. The wellbeing of an ecosystem depends on people's actions which in turn flourishes people's lives.

Well established cashew orchard of a tribal family.
Photo: Sharad Mahajan

Reasons of success

Families, initially sceptical about the interventions, start realising the potential of developing a life time asset soon after seeing the initial results. Planting of trees develops hope in the minds of tribals which further stimulates thinking to make better use of available resources. This becomes the turning point in the life of tribals. Soon families start building check-bunds, nurturing the orchards, land shaping and cultivating new crops.

The regular interaction, exposure to new technologies, visits to innovative and progressive farmers, sharing and learning from one another's experiences increases the awareness and knowledge of people. These actions help build the receptivity to newer concepts and techniques. As a result, tribals once knowing more about harvesting trees than planting them, learn the art and science of plantation and orchard management. Traditional wisdom and the new knowledge assimilated not only helps to establish the orchard but also brings change in agricultural practices, health seeking behaviour and women's status in the family as well as in the village.

The newly found identity as "*wadi* owners" inspires them to come together and the process of development gets a boost through collective action. The GVM becomes the vehicle of "people-owned, people-managed development". Thus, development takes the shape of a mass movement with mass village participation.

A cadre of local field functionaries gets associated with the GVMs to facilitate extension of services in the areas of agriculture, health, record keeping, funds management, etc. The GVKs initiate the process of building resources through savings, credit and support services development (grain banks, agro service centres etc.) to fulfil the people's needs. The increased trustworthiness, credit worthiness and self-confidence enable tribals to gain access and control over resources.

With the passage of time, an entry with a single activity (orchard development) leads to comprehensive community development, individual thinking is replaced by collective action and the tribals once trapped in a dependency syndrome enjoy freedom and power. Thus, the model carves out a new family with the help of already available sources, inspiration and perspiration.

Replication of the model

The time-bound, result oriented model that started with just 42 families, from eight villages in 1982 in the tribal block of Vansda in South Gujarat, is replicated in tribals blocks of Maharashtra, Gujarat and Karnataka covering about 25,000 families from about 300 villages. It is also to be implemented in Maharashtra and Rajasthan to cover additional 20,000 families.

The model has received worldwide recognition. The project was presented as a successful replicable model for poverty alleviation at the UNDP Forum of Ministers for Poverty and Environment in NewYork, USA in 1999 and at the Global Dialogue in Hannover, Germany. Various government agencies in India are now involved in promotion of orchard development and a few of them have supported NGOs taking up the model. BAIF is also engaged in providing techno-managerial support to development organisations. For this it has received the support from Government agencies such as National Wasteland Development Board, National Rural Employment Programme, Tribal Development Department, District development agencies, Banks and various international agencies.

The model has evolved over a period of time considering peoples' needs. Agencies adopting the model should consider its comprehensive nature and use it with suitable changes considering local conditions to achieve maximum benefits.
A multidisciplinary team comprising of professionals from agriculture, community health, engineering, social science and extension workers is required to manage the large-scale programmes. It is necessary to develop forward and backward linkages considering resource development and utilisation. These include banks, markets, credit institutions, research organisations etc. The agencies must use participatory strategies, emphasise on capacity building of people, bring in gender development and promote local institution development to achieve sustainable development.

Poor infrastructure limits the pace of development even after successful orchard development. Proper roads, availability of electricity, banking structures, inputs supply centres, market information and development of marketing facilities are the key areas in which government agencies could provide support. Also governments need to mobilise resources to provide long term and timely financial support.

Conclusion

The magic of *wadi* is that it provides self-employment and thereby creates confidence among tribals for self-reliance. It provides opportunities for tribals to make a decent living on the strength of natural resources in their vicinity and within their reach. The *wadi* model has proved that the poor, the illiterate and the oppressed can be idealised through mutual co-operation and collective efforts.

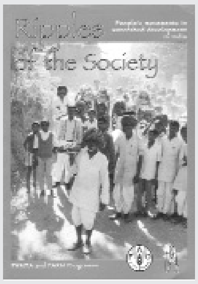
Designing and scaling up productive natural resource management programs: decentralisation and institutions for collective action

by Talib Esmail, 1998. Rural Development Department, World Bank. Available on: http://www.fao.org/waicent/faoinfo/sustdev/ROdirect/Rofo0036.htm

Practical guidance is provided for programme planners on how to design community-based Natural Resource Management programmes that can be scaled-up. It is based on a review of programmes that have achieved some degree of success in this sphere. Recommendations are put forward on policy preconditions, programme strategies, structure of programme implementing agencies, and appropriate financing mechanisms.

Ripples of the society: people's movements in watershed development in India.



Sheena, Ghandhi Peace Foundation / Sharma PN (editor) Participatory Watershed Management Training in Asia Program FAO. 1998. 128 pp. For copies write to: Environmental cell: Gandhi Peace Foundation, 221 Deen Dayal Upadhaya Marg, New Delhi-2, India, or, Dr. Prem N. Sharma, FAO, PO Box 25, Kathmandu, Nepal.

The document is based on eight case studies from the Himalayas and the rainfed desert areas of India. Traditionally, watershed management has been a way of life in the Indian mountains and rainfed areas. The analysis puts the experiences in a historical context to explain why efforts started dying out in the recent century. This happened as the society lost its ownership and control over the process of watershed development due to interference of an alien culture, which continues to impose hypothetic solutions even today without any regard to the native culture. This situation continues to accelerate the loss of confidence among the people in their own capabilities. The analysis shows how to revert this situation so that the national efforts can result into sustainable efforts where the official efforts and the people's efforts work in tandem to make the present day watershed development efforts sustainable (Sharma). A booklet with inspiring stories of endogenous development.

Scaling issues in Integrated Natural Resource Management: Conceptual considerations

by J. Lovell, A. Mandondo and P. B. Moriarty, 2000. Available on: http://www.inrm.cgiar.org/documents/workshop_2000.htm

A description of "lessons" learned from all over the world with two scaling types, the first related to 'scale', the second to 'scaling-up'. The paper discusses the conditions under which INRM is most likely to be successful, and the need to reconcile current top-down and bottom-up approaches, both of which are needed to achieve effective delivery in a structured programme beyond the scale of a few villages or isolated success stories.

Scaling up: Critical factors in leadership, management, human resource development and institution building in going from pilot project to large scale implementation: The BRAC poultry model in Bangladesh

by Md. A. Saleque, 1999. Available on: http://www.husdyr.kvl.dk/htm/php/tune99/5-Saleque.htm

BRAC's poultry program in 1999 reached more than one million poor women following a model that is now known as the Bangladesh or BRAC-DLS model. This paper has documented the model's potential for creating income for the poorest women. Learning on the basis of feedback from the users has been a key element in its evolution. The model is now applied in 380 of Bangladesh's 460 Thanas.

Grassroots development and the issue of scale: a Colombian case

by Steven D. Pierce. Available on: http://www.iaf.gov/jrnl19-2/pierce.htm

The Inter-American Foundation has chosen to meet the challenge of scaling up through outreach strategies in Colombia. Recognising that structural poverty can only be overcome through broad-based alliances among local people, their organisations, the State, the private sector, and the non governmental organisations, the Foundation has sought to establish strategic partnerships with key Colombian entities. The partnership with Fundación Social, a unique case study of how to scale up, is described in detail on this website.

Scaling up successful agroecological initiatives in Latin America and the Caribbean

by Miguel A. Altieri, Daniel Buckles, Rolando Bunch, Simon Carter, Antonio Casanova, Paul Engel, Ruben Figueroa and Carlos Venegas. Available on http://nature.berkeley.edu/~agroeco3/sane/index.html

In this article the authors present their scaling up research project. The agroecological approach to rural development, promoted by the Latin American Consortium on Agroecology and Sustainable Development (CLADES) and other NGOs in Latin America, emphasises the need to consider environmental, social, technical and cultural aspects of sustainable rural development. In Chile, Cuba, Peru and Honduras, members of this consortium have been promoting agroecological initiatives for several years with tangible benefits to food security and natural resource conservation in specific rural communities. Given the benefits and advantages of such initiatives, two basic questions emerge: (1) why these benefits have not disseminated more widely and (2) how to scale up these initiatives to enable wider impact?

The research proposed by this project will test a series of strategies to scale up successful agroecological experiences in specific areas of four countries. The areas chosen have contrasting potentials in terms of institutional capacity, social organisation and environmental and economic conditions.

The main hypothesis of this proposal is that scaling up is possible if NGOs are able to:

- network more effectively with farmers' associations and other institutions
- strengthen links, training, dissemination and validation at a farmer to farmer level
- strengthen the role of rural promoters
- improve the participation of farmers in niche markets.

The goal of the project is to initiate and monitor these four scaling up experiences, undertake a comparative analysis to evaluate the impact of the different strategies employed, and systematise lessons learned (IDRC).

Financing the future: options for agricultural research and extension in Sub-Saharan Africa

by Beynon J [et al.], 1998. 163 p. ISBN 1 902477 00 6. Oxford Policy Management, 6 St Aldates Courtyard, 38 St Aldates, Oxford, OX1 1BN, UK / admin@opml.co.uk

The objective of this book is to review options for sustainable financing mechanisms for agricultural research and extension to meet the needs of smallholder farmers. The study focused primarily on assessing the situation in, and seeking policy proposals for, Sub Saharan Africa, but reviewed a broad range of international experience reaching conclusions that are of much broader application. The outcome is a clear and well-constructed essay on financing research and extension. The summary table of operational guidelines at the end of the book is helpful for readers who want to compare the numerous options for alleviating financial constraints described in the text. (WR)

Kalakhoont village's spin out of the poverty cycle began on a rainy day in June this year. Four days of rain filled up to the brim the long-forgotten tank in this nondescript village of Jhabua district in Madhya Pradesh (MP), India. Crippled by two consecutive droughts, when an NGO, Action for Social Advancement, offered to renovate the tank, it was hard for the residents to decide to contribute 25% of the renovation cost. Three-metres of silt was removed in the renovation. The decision has paid rich dividends and now promises to change the lives of the villagers forever. "There is enough water for the next three years," says an excited Nana Basna, president of the lift-irrigation society formed to regulate water use in the village. "The stored water will be enough to irrigate more than 61 hectares (ha) of land".

20.000 villages secured food production by reviving rainwater harvesting. Photo: Ganesh Pancare / CSE

A story of hope and of major change

For the first time in 50 years, several state governments are dealing with drought in a different way - moving away from drought relief to drought mitigation. The droughts of 2000 and 2001 have seen Andhra Pradesh, Gujarat, Madhya Pradesh (MP) and Rajasthan undertake major rainwater harvesting programmes - getting people to conserve rainwater that falls in their villages.

This year the MP government organised the world's biggest ever rainwater conservation programme — *Pani Roko Abhiyan* (Stop the water campaign). Chanting *Gaon ka paani gaon me, Khet ka paani khet mein* (Water of the village in the village, Water of the farm in the farm), some 706,304 water harvesting structures were created from February to June.

In the four states put together, there are probably over 20,000 villages today undertaking rainwater harvesting seriously. The good rains of June and July this year have already filled up tanks, ponds, *johads* (traditional earthen check dams) and other structures built by people with support from government and non-governmental organisations (NGOs). There is jubilation.

But this achievement also poses several challenges for governments and NGOs. Firstly, how will they ensure that the many thousands of structures are properly maintained? Experience shows that when communities harvest rainwater for 5-8 years and keep groundwater recharged, they can withstand as much as three years of consecutive droughts. However sustainability of the structures is crucial and depends solely on who manages these structures. Government apathy has led to the death of millions of the country's water structures. Where communities are in control this does not happen easily.

In MP, people will be given absolute ownership of the structures to which they contributed one fourth of the costs. The state government is incorporating certain structural changes for transfer of ownership to the *gram sabhas* (village assemblies) who will be responsible for the maintenance of the structures. Yet, the Gram Swaraj Act that gives power to the village assemblies seems almost ineffective. In Rajastan, the minister of irrigation, Kamla Beniwal, ordered the demolition of a *johad* built by the community of Lava ka Baas being of the opinion that: "People do not have the right to tamper with the flow of water... as water resources belong to the government".

Secondly, the experience of villages like Ralegan Siddhi in Maharashtra, and Sukhomajri in Haryana, which started water harvesting in the 1970s, shows that this is just the beginning of rural ecological and economic regeneration. Water improves agriculture, improved agriculture improves animal husbandry and once people begin to harvest water they begin to take care of their watershed, which means more trees and forests. The combined incomes from improved agriculture, animal husbandry and tree wealth have the potential to not just alleviate, but literally eradicate rural poverty. How will governments and NGOs ensure that water harvesting leads to total ecological and economic regeneration of our villages over 10-15 years?

To make water conservation a sustainable social movement the government needs to put in prolonged efforts. Most of India's poverty eradication programmes have failed because they have been short-term interventions. Even India's largest watershed programme in MP is set to withdraw from villages after only four years, and will as in previous experiences undo the advantage of drought proofing. Ecological regeneration only brings prosperity when it is managed with mature community institutions that need time to be built up.

And, finally, what does this mean for people's rights over water? India's water laws, mindless derivatives of the colonial laws, give too many rights to the government. As a result, when chief ministers want water harvesting structures built, the irrigation departments look away. But not when a village or a NGO wants to do so. Will the government get rid of its 19th century hangover and hand over the rights of rainwater to the people in the 21st century?

Towards sustainable pond farming

Michiel Verweij

"Before we had these farm ponds we could only farm in the wet season and everybody migrated to make money to survive. Now with these ponds we can work on our own land, year round, and we produce a surplus to sell at the market. These ponds give us hope for our community and children" said Máximo Gonzales in the April 1996 issue of the ILEIA Newsletter (Maita and Verweij 1996). This article described an unique system of interconnected farm ponds in the Oloy community near Cochabamba, Bolivia. The development of the farm pond system unleashed a process of fast change in peasant farming. Peasant families improved their farming system by developing new strategies to produce vegetables, grains, fruit trees, aromatic herbs, and to raise animals. Now, farm pond farming is spreading fast and integrated agriculture is promising to become a sustainable production system suitable for small farmers on Andean slopes. Based on the experiences of CORACA, a peasant organisation that has contributed significantly to the promotion and development of family farm pond farming, the author analyses further the development and spread of the system.

History of pond farming

The population of the Quechua-speaking community of Oloy is concentrated in the lower parts of the region, on the gently undulating 'pampas' with silt-clay soils at an altitude of about 2100 metres above sea level. The climate is semi-dry, with an average annual rainfall of 450 mm between November and March. Until the farm ponds were built, rainfed maize was the main crop.

The first farm ponds date back to the eighties, when small water reservoirs that the peasants themselves had dug out (k'hochas) were enlarged with the help of heavy machinery that political parties made available to the communities. Rainwater is collected in these farm ponds, taking advantage of the runoff from the higher slopes or water from a nearby watercourse during rainy weather.

Between 1990 and 1991, on the request of community members, the PDAR programme to prevent migration to coca-growing areas built interconnected farm ponds in Oloy. This work was complemented with a rock-cement diversion dam in the Yuraj Yuraj watercourse, to fill the ponds during the rainy season. This dam and the 5 km long conveyance ditch connected and filled 20 family ponds (storage capacity about 1000 m^3) and 2 community ponds (storage capacity about 10,000 m^3).

Given the lack of other permanent water sources, farm ponds have become a source of water for domestic use, drinking water for animals, supplementary irrigation of summer crops and for small-scale irrigation of highly valuable dry season crops. The water in the family ponds is used to irrigate up to 0.25 ha of farmland on which onion, garlic, tomato, beans and other vegetables are grown. Some farmers even have enough water to grow fruit trees. It is common practice to protect the irrigated area and farm pond from cattle by building fences around them with thorny branches, barbed wire or stone or brick walls (see figure 1). The land inside the fence can range from 0.3 to 4 ha.

There is no clear category for these farm ponds in terms of irrigation or soil and water conservation. Rainfed farm ponds are usually referred to as a means of preserving water and soil and for collecting water. This is fair enough if the water runs off the slopes above the pond, but in many cases it rains further away from the production area, therefore the water is obtained from other parts of the small valley catchment. This is why some authors refer to irrigation (Pacey & Cullis; 1986, p8).

In recent years, the area under irrigation was expanded considerably and production was intensified by increasing the number and size of the ponds. In the community of Aiquile, for example, more than 1000 new ponds were constructed in the nineties. Now, a large number of government organisations, municipalities, NGOs and peasant organisations are digging, with the use of earthmoving tractors, hectares of farm ponds in many Bolivian communities. Many different designs are used for

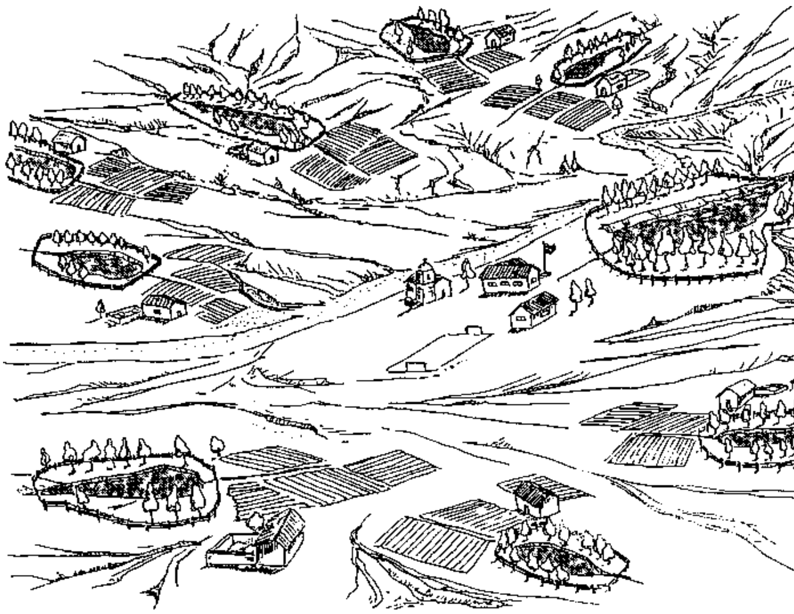

figure 1: Overview of farm ponds in the community of Tarija (Verweij, 2001)

the construction of these ponds. The costs of the ponds differ from US$ 300 for a simple small pond of about 300 m^3 to US$ 2000 for a larger and more sophisticated pond, and up to US$ 4000 for a 5000 m^3 pond. The funding arrangements also differ per organisation. Funds come from the local municipality, the national government or a foreign funding agency. Farmers normally pay a contribution of 10 - 20 % of the total costs in advance.

Different strategies of farm pond farming

Once water is available, a part of the new farm pond users (about 25% of the farmers in CORACA's operational area) concentrates on growing crops like onions, tomatoes and potatoes for the market. These ***market farmers*** tend to grow one or two crops intensively and then leave the land to lie fallow after the harvest, when the water runs dry. Their production system is intensive and yields are high: more than 40 tons per ha. of tomatoes and 30 tons of onions. Without much help from outside, they sell the produce in their own town as well as in Sucre and Cochabamba. In 1999, when prices of tomatoes were high, tomato farmers earned up to US$1800 from a 2000 square metre plot, spending US$425 on fertilisers, pesticides and transport. They had never before had so much money in their hands and earned back their initial investment in one year! But prices are not always high and increasingly farmers start to feel the economic and ecological problems related to monoculture market farming.

A second but increasing group of families are producing on a less intensive and lower-cost basis and largely for home consumption. Their production conditions are often less favourable and they do not accept the high costs and risks involved in market agriculture. Compared to traditional rainfed farmers, these farmers have increased the number of crops (vegetables, grains and fruits) they grow and the amount of surplus products they bring to the market. For these ***conservative improvers*** the farm pond is very important to secure water for human use, their animals and some food crops during the dry period. It has enhanced their quality of life, improved their diets and increased their income. Finding markets for surplus products is sometimes a problem, but with the help of CORACA (who has the contacts) these farmers always find a buyer.

Towards sustainable pond farming

In general, yields in pond farming are up to 4 times higher than the regional rainfed production levels and the contribution of pond farming to regional food security is increasing fast. It is, therefore, obvious that the sustainability of the system is crucial.

However, not every farmer knows how to take care of these systems, which means that the euphoria of earning money from tomatoes did not last long. Those who planted tomatoes year after year have noticed that their soil is getting depleted and that the presence of pests and diseases is increasing. Production costs are increasing every year as more fertilisers and pesticides are needed to maintain the same production level. Unfavourable market prices cause even more frustration. These farmers now realise that the production and sustainability of their farming system depends on much more than just water. They realise that working with some factors and neglecting others is counterproductive. It is no use having water on the plot if the soil is deteriorated or eroded. Nor is there any sense in producing high amounts of products for the market if these can neither be sold nor transformed.

Fortunately, insight into alternative, ***integrated farming*** is increasing. About 10% of the farmers with a farm pond are experimenting with this third farming strategy, which is gradually being developed. These farmers diversify their cropping system and integrate livestock as well. Their plots are turning into regular orchards, with over 25 species of vegetables, grains, fruit trees, forage, aromatic herbs and flowers. There is a growing tendency to keep small animals like guinea pigs, hens, ducks, partridges, bees and fish. These families use their small plots to a maximum by growing crops around the borders of their farm pond and fruit trees, forestry species, ornamental plants, shrubs or forage alongside the fences. Since these plots are fenced in to keep animals out, wild vegetation grows in the corners and on the borders of the farm pond (fig.2).

The families are very fond of their farm ponds and gardens. Based on their own ideas and available resources, they create irrigation systems using gutters, pipes and aqueducts. They also protect their borders with grass and stones, adorn their gardens with flowers, obtain all kinds of fruit seeds and seedlings and build terraces or bench terraces to make their small plots as productive as possible. Their infectious enthusiasm is creating an interesting and innovative type of competitiveness. However, many of these initiatives lack a technical basis, which is why the results still leave much to be desired. Adequate monitoring and backstopping by expert technicians would guarantee even better results.

By having a diverse small-scale production system financed with own and local funds, farmers can produce a larger variety of products and can make the peasant economy more secure. The fact that they can increase control and lower costs is an additional advantage. This is very evident as far as agro-chemicals are concerned; these farmers use only one third of the amount used in irrigated plantation agriculture in Santa Cruz. Integrated farming is a more balanced strategy of farming, which combines market and self-sufficiency objectives within a more ecologically sustainable, overall approach.

Further improvements needed

In fact, development of family farm pond farming has just started. Farmers with access to farm ponds listed the following demands for improvement at a workshop:

1. Community/farmer organisation (production and marketing, awareness of collective values).
2. Soil and water management (farm planning, soil and water conservation practices, irrigation canals, gully control)
3. Integrated Pest Management (training, development of local practices).
4. Marketing (seeking markets for local products and opportunities for new crops, establishing relations with companies, seeking and creation of opportunities).
5. Financial management (loans, help in calculating production costs).

An increasing demand for technical support has been noted since farm pond construction was initiated. Often, farmers start to pay attention only when they encounter real problems. For example, the demand for high quality seeds (see box 1) is coming up only now after many diseases have been spread. Still, farmers express their need for holistic monitoring from a peasant farmers' perspective. Once the problem of water shortage was solved, questions arose about a more sustainable, ecological and healthy way of production, applying integrated pest and soil fertility management methods.

Having worked on productive aspects, peasants are also looking towards processing, transforming and marketing of their products, which is something they cannot do on their own. Developing the farming community means that all these aspects have to be worked on. Anyone who intends to support this process has the moral obligation to go beyond farm ponds and technological packages. That is why today's agricultural scientists and rural instructors must have a more complete understanding of sustainable agriculture and the food production chain. They also should be versatile and take an active part in peasant struggles.

Social Capital

Experience showed that it is fundamental to raise the self-esteem of peasant farmers before they can do anything for improving

Box 1. Production of high quality seeds

The farm pond garden is a farm jewel because water is assured. Yields tend to be more than 4 times higher than in rainfed conditions. Products are more regular and of better quality. In order to capitalise on the production potential, irrigated plots deserve only the best inputs, i.e. seeds, fertilisers and manpower.

For example, what happens if inferior quality seeds are sown in the plot? First of all, production would be lower and secondly, the farm would be infected with diseases, nematodes and insects. This will reduce the productive potential of the land for a long period, as some pests and diseases, and nematodes in particular, are difficult to eliminate. The saying "seeds are half the technological package" means that one must start with an excellent seed in order to get a good harvest.

For this reason CORACA formulated a proposal to multiply high quality, basic potato seeds in irrigated plots. It is enough to sow small areas because the high yield makes rapid multiplication possible. This saves the buying of expensive seeds and guarantees good seeds for use in rainfed areas of the farm or for sale. More than 13 bags of good quality seeds can be obtained from one bag of basic seeds. The same strategy could be applied to other crops.

(Based on the presentation of Gonzalo Reynaga at a CORACA Seminar)

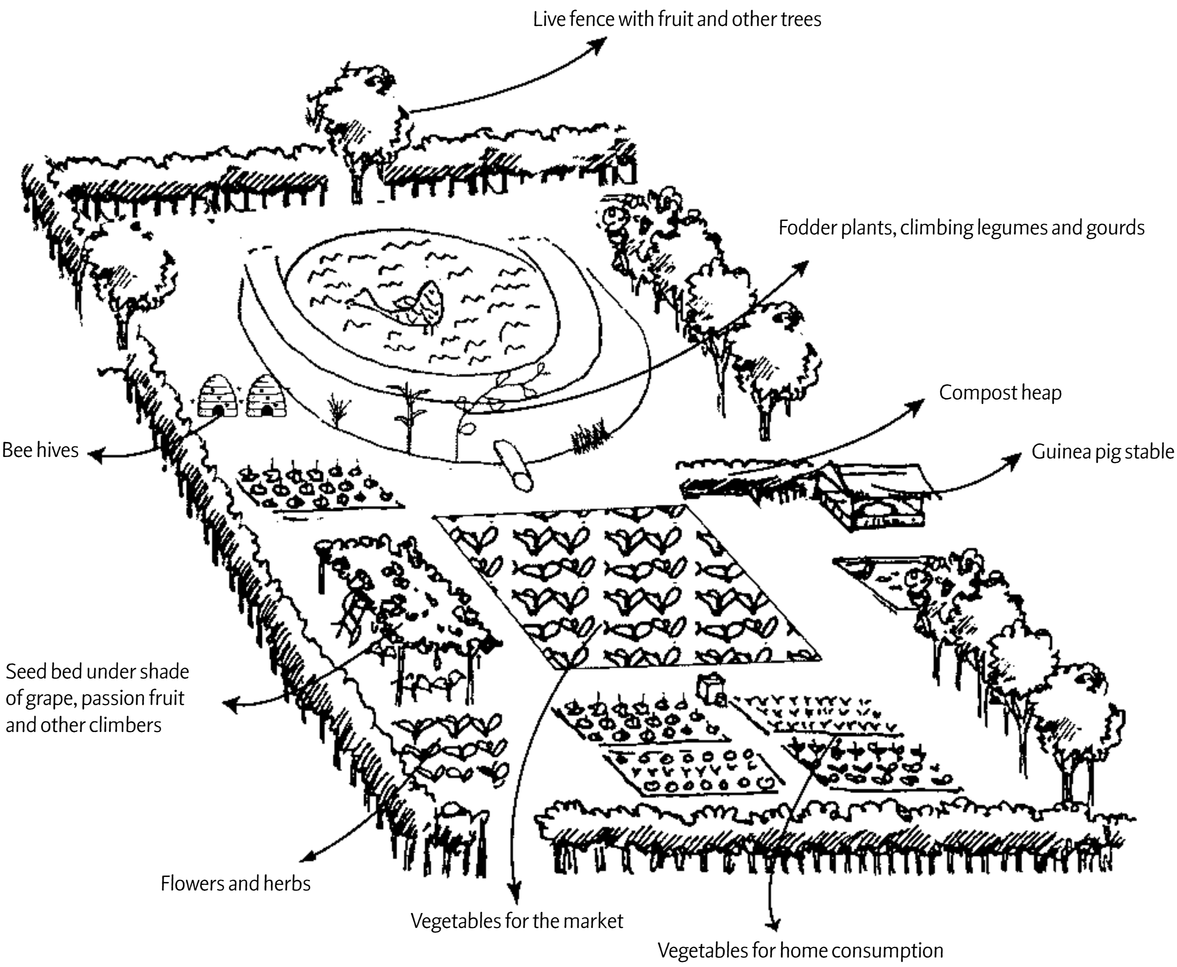

figure 2: Diversified pond farm (Verweij 2001)

their situation. They must be made aware of their valuable know-how, skills and potential and realise that they are capable of making changes. Peasants can evaluate examples and alternatives and apply them, provided that they have the information, inputs and instruments, and, above all, self-confidence.

Social capital was identified as an essential precondition for working together in a change process. Social capital, in terms of self-esteem, credibility of the support agents involved, mutual respect and confidence between peasant families and the support organisation, and shared background and responsibility, is needed to obtain tangible results.

Social capital creates the belief that things can actually improve. If there is ample social capital, peasant farmers will have the courage to demand training and advice on issues that are important to them, copy successful examples and demand the right conditions to carry out joint experiments with technicians.

Growing institutional concerns

Paradoxically, many small support organisations are withdrawing from regions with adverse development conditions, either because they have lost their funding completely or are fighting to survive and avoid more cut-backs. Meanwhile, the highest international development co-operation authorities have discovered the key to development: good governance and institutional development at macro level. But their strategy stops at that level with no connection to the peasant farmers and their support organisations at micro level, which means that peasant demands will not be heard nor met. Times are hard for support organisations at micro level because they are not considered sustainable, democratic nor representative, and therefore do not justify financial support, whilst peasant organisations have to finance themselves to become sustainable.

It is indeed necessary to work at macro-level to develop regional development plans, favourable economic policies for agricultural development, strong national institutions and international trade relations, but without support to local NGOs and peasant organisations there will be no credible and concerted development efforts at micro or at macro level. In many cases the construction of farm ponds has helped to build up social capital between peasant families and support organisations. Advantage must be taken of this social capital to synchronise development initiatives at macro and micro level to make further practical development of sustainable family farm pond farming feasible. ■

Scaling up participatory development in agricultural settlements

Chesha Wettasinha

The Promoting Multifunctional Household Environments (PMHE) Project was operational in Mahaweli System C, Sri Lanka, from 1991 to 2000. It was a bi-lateral development cooperation between the governments of the Netherlands and Sri Lanka, with consultancy services provided by ETC. During this period, it developed and scaled up a strategy for sustainable agricultural development based on farmer participation.

Introduction

The Mahaweli Development Programme (MDP) is considered the most ambitious development initiative undertaken in Sri Lanka in the recent past. Five major dams constructed on the largest river "Mahaweli" supplied irrigation water to an area of 144,000 ha, deemed unproductive due to lack of water. Nearly 125,000 families were settled in the downstream areas during the early and mid '80s – many of them poor, landless peasants who left their homelands and journeyed to the "promised land" with the dream of becoming proud owners of a plot of irrigated paddy land. Each settler family was entitled to 1 ha irrigated lowland and 0.2 ha. rainfed highland for a homestead.

The Mahaweli Authority of Sri Lanka (MASL) was the government agency set up for the sole purpose of making this programme work. It played a central role in the construction of irrigation and other infra-structure, in human settlement and in the development (also agricultural) of these vast settlement areas under its purview. Administratively, the area is divided into Systems (B, C, G, H etc), Blocks and Units. An Unit is more or less comparable to a village with an average of 150 resident farm families. Several units form a Block, and several Blocks form a System. Around 11,000 employees arranged in a strictly hierarchical order managed this vast programme until the agency underwent restructuring in the late '90s and 60% of them were made redundant. Yet, the MASL remains to be one of the biggest government agencies, which as a river-basin authority, will continue to be involved in management of these areas in partnership with farmers and other stakeholders.

The PMHE Project entered the Mahaweli arena in the early '90's, when the "Mahaweli dream" had begun to blur. Initial euphoria amongst settler farmers had given way to grievances and apathy – they were far from prosperous; in fact many of them were deep in debt and some had even lost the right to their land. Increasing costs to counter falling yields and poor market prices made paddy farming unprofitable. Socially, too, the settlers were severely affected. There was hardly any feeling of community; disconnected families struggled in isolation to make ends meet. And it was in this context that PMHE was given the task of developing a strategy for sustainable agricultural development for the Mahaweli settlements.

Identifying bottlenecks to development

A 9-month action-research undertaken in close cooperation with settler families in 2 units of System C helped PMHE get a deeper understanding of settler life and identify the specific bottlenecks to development. These were classified under the following broad categories: inability to adjust to new surroundings due to background and origin; blue print approach to development adopted by the MASL which did not meet site specific requirements; insufficient income from paddy farming leading to serious indebtedness; poor social cohesion and lack of organisational capacity among farmers; dependency on the MASL due to prolonged assistance given in an attempt to cushion the "settling in" process.

Developing a strategy for participatory development

These problems that hindered settler development and methodologies to overcome them formed the basis for the 3-year implementation phase that followed. PMHE worked in 12 settlement Units in 6 Blocks of System C during this period.

Most of the work was at grassroot level and of an experimental nature. Experiences gained in the field contributed to developing, through continuous adaptation and together with farm families, a strategy for participatory development that was suited to the specific socio-economic and ecological conditions of the area and its inhabitants. It hinged on the principles of LEISA, participatory methodologies including PRA and PTD, organisational development and gender. The strategy consisted of two main interventions at farmer-level - ***sustainable resource management and community strengthening*** – following a process approach. Farm planning, farmer experimentation, farmer to farmer exchange, community mobilisation through small self help groups and farmer organisation strengthening were the key components of these interventions.

The changes that took place in the 12 Units were evidence to the success of the strategy. Integration of crops and livestock on the farms resulted in improved family nutrition, higher family income and a better microclimate; farmers were gaining more confidence in finding site-specific solutions to their agricultural problems through experimentation. Small groups proved to be an excellent forum for building self-reliance, forging a collective spirit and forming the basis for community strengthening. Small group members were gaining the confidence and the ability to bargain for better prices, demand for services, set up enterprises, build linkages for development purposes etc. In short, a process of sustainable agricultural development based on farmer participation was set in motion.

Sustaining and spreading participatory development

Having demonstrated that sustainable agricultural development can be achieved within Mahaweli settlements, it was now important to find ways of sustaining and spreading the process of participatory development. Real success was in ensuring that the many thousands of farm families in Mahaweli settlements would have similar benefits. As such, much of PMHE's energies in its final phase (1996-2000) was focused on creating the conditions in which the strategy would be adopted and adapted by the important development actors in Mahaweli settlements, particularly the farm families and the staff of the MASL. Three large lines of action for scaling up can be distilled from PMHE's experience:

- Strengthening the capacity of settler farmers to sustain and spread elements of the strategy
- Institutionalising the strategy for participatory development within MASL
- Sharing the experiences with a wider circle of development actors beyond MASL

Strengthening the capacity of settler farmers

Providing farmers the knowledge and skills to support other farmers in activities such as farm planning, farmer experimentation, group building etc. was a very effective way of sustaining the process of participatory development. Several methods were used.

a. Farmer to farmer exchange, as an integral part of most interventions, ensured that farmers passed on their experiences and innovations. Farmer to farmer exchange took a variety of forms: group discussions, inter-group events, cross visits, visits to resource farmers, farmer presentations etc.

b. Developing the skills of selected farmers to be village level extensionists/ facilitators was another way of ensuring the horizontal spread of the strategy. This also took several forms, depending on the motivation and interests of the farmers. ***Praja Sevakas*** or community servers were those men and women who had a vision and were interested in being facilitators of the process of community development. As such they were given an all-round training and regular backstopping for an extended period of time, so that they could carry on the process of

Interaction between farmers and trainees at a training session of MASL staff. Photo: PMHE

community development even without external assistance. Community mobilisation, Farm planning and experimentation, participatory development and the use of relevant tools, basic accounting and financial management, village development planning and monitoring, small scale business development were among the many topics covered in their training. These Praja Sevakas took an active role in building their communities. Most importantly they were able to identify and analyse problems with the people, find suitable solutions, plan and implement activities, get the services required, monitor and evaluate activities collectively and share the experiences with others. ***Resource farmers*** on the other hand were farmers who were interested in sharing their knowledge and experiences in a particular area of activity like experimentation, livestock keeping, crop husbandry. These farmers were given additional support in further developing their skills, not only in agriculture but also in aspects such as communication, group moderation etc. Some among them were trained as facilitators of farm planning and were able to work with groups of farmers in developing sustainable farm plans. Others were able to function as village level livestock extensionists capable of providing basic veterinary services, supporting farmers in building marketing linkages etc. The capacities of the *Praja Sevakas* and Resource Farmers were recognised and acknowledged not only by their fellow villagers, but also by the MASL and many outsiders. Respected as trustworthy and able leaders of the community, they were appointed to office in farmer organisations and looked after the interests of the community. Their technical prowess had earned them a reputation far from home – they were approached not only by farmers, but also by private companies, NGOs etc. who needed farmer-level liaison to support their development ventures in the region.

c. Farmer seminars and workshops were yet another way of getting more farmers involved. *Praja Sevakas* and Resource Farmers often took an active role in such events. Unlike the small-scale farmer to farmer exchanges, these events attracted much larger numbers of farmers from a wider geographical area. Considering that most of the Mahaweli systems are newly settled and sparsely populated areas, these events were excellent for making new contacts and forging new partnerships.

Institutionalising the strategy within MASL

The process of participatory development could not be sustained within the Mahaweli systems, unless the MASL supported it. Having mentioned earlier the strictly hierarchical nature of the organisation, its blue print approach to development and its paternalistic attitude towards the settlers, taking on an approach to development based on farmer participation required fundamental changes. These changes had to be brought about at all levels – enabling field staff to take on the role of development facilitators through a process of training and backstopping, assisting middle-level staff to manage participation and lobbying at the higher-level to bring about favourable conditions for participatory development.

a. Training and backstopping of staff: *Training* was a key element of the capacity building process. Nearly 100 training workshops were conducted in the period January 1995 to June 2000. The main subject areas covered by the training were Participatory Rural Appraisal, Farm Planning, Participatory Technology Development, Community Mobilisation, and Organisational Development. The curricula for these training programmes were tailor-made to the requirements of MASL staff, with aspects of Participatory Monitoring and Evaluation and Gender built in. Training was initially undertaken with those officers who worked in direct contact with farmers at Unit and Block level and then worked up and across the many layers of the hierarchical structure to the top. Contents of the training programmes varied according to staff category - field level training was usually much longer with a large component of field-work, whilst shorter workshops or seminars were used for managerial levels. However, most training events included an opportunity for trainees to interact directly with farmers. Training of trainers was done simultaneously in order to build up the capacity for training in participatory methodologies within the organisation. Another important activity in this regard was the preparation of systematic training manuals, which could be used by the MASL trainers. *Backstopping* followed training as another key element of the capacity building process. It facilitated the application of newly gained knowledge and skills. It took many forms and evolved over the period to consist of sharing sessions for trained staff, post-training refreshers, joint monitoring of post-training assignments, on-the-job guidance to trained staff in routine activities and training impact assessment. *Support to the Human Resources Development Unit* of MASL was a crucial activity that tied up, in a sense, all the input into capacity building of staff. As the unit responsible for all training activities within the organisation, it was important to provide them with the knowledge and skills required not only to continue training and backstopping, but also to adapt training to meet the changing requirements of the organisation and its staff.

b. Support to manage participation: Field Officers who adopted a participatory working style needed to be understood and supported by their superiors. Within the MASL hierarchy, this was primarily in the hands of Block Managers, who supervised all field staff in a given Block. Institutional Development and Organisational Strengthening (ID/OS) was considered a very useful tool for Blocks Managers in stimulating the changes required towards managing participation. Being trained in ID/OS, Block Managers were provided backstopping in a variety of applications, ie. analysing the activities of the Block office in relation to all actors in the community and finding areas for networking, analysing the tasks and skills of Block staff to determine a more efficient use of human resources, incorporating participatory action planning for preparation of annual and seasonal Block plans etc. This intervention brought about noteworthy changes - farmers' priorities were being incorporated into plans, collaboration was sought with other actors (NGOs, government line ministries and farmer organisations) in development activities, Block staff were working more effectively and barriers among them were being broken down as collective goals were pursued.

c. Creating conditions to sustain the process: The full potential of all changes at field and middle level could only be realised if the strategy for participatory development was fully integrated within the MASL. It was only then that the benefits could reach settlers in all Mahaweli Systems. Here again PMHE worked on many fronts and with many key persons, mainly at the higher levels of the organisation. *Seminars and workshops* were specially prepared to provide decision-makers with a clear picture of field developments and raise issues that needed attention. These were also occasions in which farmers were given an opportunity to discuss matters directly with higher officials of MASL. *Close collaboration with sectional heads* was very important in keeping a continuous and open dialogue about the process of participatory development and its implications. Such dialogue helped to incorporate their views and led to strong support for the strategy. Many openings for integrating elements into routine MASL programmes were found. For instance farmer to farmer extension as a means of sharing experiences and farm planning as a tool for sustainable resource management were integrated into many field level agricultural programmes. *Policy advocacy* was another step in creating the legal framework for further expansion of the strategy into other Mahaweli Systems. It built on the foundations laid through awareness raising and dialogue and resulted in key elements of the strategy being included into MASL policy for rural development. The new agricultural extension policy of the MASL, for instance, incorporated participatory analysis and farm planning for identifying crops and extents to be cultivated in a given season, farmer experimentation as a means of finding site-specific solutions, farmer-to-farmer extension as a means of sharing experiences, participatory monitoring and evaluation methods for end-season evaluations etc. Similarly, the small group approach to community mobilisation and the participatory analysis and planning approach to strengthening farmer organisations were integrated into MASL's guidelines for Farmer Organisation strengthening.

Sharing experiences with a wider audience

Although MASL was the main focus of PMHE's efforts to institutionalise participatory development, it certainly did not exclude others who could benefit from shared experiences.

A Praja Sevaka conducting training for a small group of farmers. Photo: PMHE

Networking, workshops and seminars, visits of interested persons and documentation were some of the main activities undertaken for this purpose.

a. Networking: Two networking experiences deserve special mention as being very fruitful. The first is the *PID/PRA* (participatory interactions in development/ participatory rural appraisal) *Network* in which PMHE played a very active role for many years as a member of the working committee. The Network consisted of organisations and individuals, practitioners and trainers in participatory methodologies involved in a variety of sectors – health, agriculture, rural development, relief and rehabilitation. This meant that a wide range of experiences was made available for sharing. This Network made a considerable contribution to promoting participatory development in Sri Lanka by sharing and publishing experiences, grooming national trainers and providing access to resources. MASL was introduced to the Network by PMHE and together were able to share some of the unique experiences in using participatory methodologies for development in the Mahaweli settlements. The PTD (participatory technology development) Working Group is the second successful networking experience. PMHE and two other projects working in the field of sustainable agriculture founded the Working Group, which grew to accommodate other projects, government as well as non-governmental organisations. Apart from sharing experiences and learning from each other in a very systematic manner, the Working Group was instrumental in creating a pool of national trainers in PTD. PMHE made a significant contribution to this training effort, which was also used to train MASL staff. These efforts of the PTD Working Group was commended in a study undertaken by a leading university in Sri Lanka to ascertain the effectiveness of training in participatory extension methodologies on the working styles of government field extension officers.

b. Workshops and seminars: The workshops and seminars that fell into this category were mostly at national or regional level. Some were joint initiatives of the above-mentioned networks, and the others were organised by PMHE alone. But all of them had the purpose of bringing the message of farmer participation in sustainable development to those who had a stake in policy formulation and decision making, among them politicians, directors of government agencies, representatives of the donor agencies, heads of research institutes, academics etc. A notable feature in all these events were the presentations of farmers, which gave much more credibility to the message that was being promoted.

c. Visits of interested persons: Although it appears an insignificant aspect, visits were actually a very tangible way of promoting participatory development. Unlike in any of the other options for sharing, visitors could go right down to where things were happening – to the field and talk to the farm families. Despite certain logistical constraints, visits were by far fact the best exposure to the facts. Even the hardest of sceptics were unable to leave without having food for thought.

d. Documentation: Apart from documentation that was prepared with a specific focus on the MASL, resource material of a general nature was created for the purpose of scaling up. The lack of relevant material in the national language *Sinhala* prompted PMHE to take on the *translation* of a number of key books that covered the basics of participatory development and were simple enough for use by field workers and farmers. *Case studies* of farmers' experiences published in several periodicals reached a wide audience within and outside the country. More comprehensive information on the strategy as a whole, or important elements thereof, were written up in *reports, books etc*. that were widely distributed. Special mention in this regard should be given to the video produced by PMHE that provided a concise account of how the strategy was developed and efforts in scaling up within the MASL. The original made in English was versioned into Sinhala for use in Sri Lanka, and in German and French to fulfil the requests of many who wanted to use it in other parts of the world. The video has been screened at many events, national and international, and been distributed to many development organisations worldwide.

Some reflections on scaling up

In reading an article of this nature, there is a tendency to imagine that scaling up was indeed a logically-arranged package of activities which were implemented quite straight forwardly. This, however, was not the case at all. Much of what is written in this article evolved over a couple of years and through a process of action and reflection. Yet, PMHE gained a good measure of success in scaling up - starting with a few farm families in 2 Units of System C the strategy was adapted by the MASL for implementation in all Mahaweli areas, counting direct or indirect benefits to thousands of settler farm families.

In evaluating the success of such a programme, attention would usually be given to the more obvious aspects such as the training of field staff, systematic documentation, capacity building of farmers etc. But there are certainly other, less significant aspects, which deserve mention.

Flexibility - PMHE, like any other bi-lateral project, had its objectives, interventions, activities etc. set out in neat planning matrices. But in implementation, PMHE was able to adopt a flexible approach that allowed for responding to changing conditions, capitalising on new opportunities and finding the right entry points.

Perseverence - What PMHE undertook was primarily a task of transforming people - changing their attitudes and perceptions through an intensive process of capacity building, the results of which are hard to show and quantify in the short term. This was at times a dilemma for PMHE as a time-bound, donor-funded project. It was only sheer perseverance and commitment that enabled PMHE to get the time it needed to complete, satisfactorily, the task it had begun.

Meeting felt need - The strategy developed through PMHE interventions filled a vacuum in the Mahaweli settlements - it found solutions to the most pressing economic, social and environmental problems of the settlers. As such it found favour, not only in the eyes of settler farmers, but also the MASL.

Shared ownership - Although PMHE invested substantial energy in developing the strategy, it avoided falling into the trap of claiming total ownership to it. In a true sense of participation, it created an environment in which farmers and MASL staff could say, "we did this ourselves". This is not to say that PMHE was not proud of its achievements, but rather to emphasise the importance of not holding on to findings in a way that hinders the spread.

Conclusion

What better way to conclude this article than with the words of a farmer who wrote this poem in farewell to PMHE:

"All the efforts that PMHE took
to support and guide us, to make us aware
To motivate us towards sustainable development
We will values as precious gems

The farmers who were fallen
Got strength to stand up
We respect immensely
PMHE's input in this

Even though you leave us now
What you gave us will live on
And be given to the next generation
As a heritage that lives on"

■

The author wishes to acknowledge the farm families and MASL staff who so enthusiastically and untiringly worked together with the project in making this experience a success.

Farmers are looking for more options and more species, not only for soil fertility improvement, but also for fodder, grain and other benefits. Photo: ICRAF

Scaling up fallow management innovations

Freddie Kwesiga, Andreas Böhringer, and Glenn Denning

Southern Africa has a fast growing human population, making food security a major challenge. Over 70% of the population live in rural areas and depend largely on rain-fed traditional agricultural practices. The climate is characterised by unimodal highly erratic and unpredictable rainfall lasting four to five months from November to April, followed by a severe dry season. The average annual rainfall ranges from 500-1200 mm. The eco-region is mainly an undulating plateau landscape, with a mean altitude range of 600-1200 m above sea level. Maize constitutes the predominant food crop. Livestock production (cattle, goats and pigs) is extensive and traditional communal grazing is widespread.

Fertilisers and improved germplasm that fuelled Asia's "Green Revolution" have generally not worked throughout Africa. There are some commercial farmers in Zimbabwe and South Africa who have utilised the Green Revolution approach. However, the Green Revolution has by-passed the majority of peasant cultivators (80% of the regions farming communities) Here, agricultural production is dominated by complex, diverse and low-input farming systems characterised by infertile soils, unreliable rainfall and low yields. The majority of these farmers live in remote villages with little or no access to research and extension services, high yielding seed varieties, capital and credit, fertilisers and pesticides.

Farmers resort to cheaper options over which they can exercise greater control. In the densely populated areas such as the Shire highlands of Southern Malawi, mixed intercropping of maize with *Cajanus cajan* is common. Other strategies practised include crop rotation using cereals and legumes, application of crop residues and manure and traditional fallowing.

Fallow management research in Eastern Zambia

Fallow management and other agroforestry interventions have been the subject of the International Center for Research in Agroforestry (ICRAF)'s research since 1985. The most promising amongst them are improved fallows with *Sesbania sesban, Tephrosia vogelii, Gliricidia sepium and Leucaena leucocephala.* Results from Zambia show that *Sesbania sesban* is the species most preferred by farmers. However, on-station research has shown that coppicing species, particularly *Gliricidia sepium,* has a high potential to complement *Sesbania*. In general the coppicing species are able to suppress the striga weeds, diversify biomass resources and produce fuelwood on farm. If the clay content in the soil is less 10% S*esbania* fallows will not grow well. Sandy soils, root knot nematodes and the crop damaging leaf beetle *Mesoplatys* can be major constraints to the widespread use of *Sesbania sesban.*

Sesbania improved fallows have a great potential to increase maize yields with or without application of inorganic fertilisers. Maize grain yields of 5 and 6 t/ha were obtained in 1990 and 1991 following 2 and 3 year S*esbania* fallows, respectively. This was in comparison to 4.9 and 4.3 t/ha from continuously cropped maize with fertilisers (112 kg N/ha) and 1.2 and 1.9 t/ha without it. In addition, 15 and 21 t/ha of fuelwood were harvested after 2 and 3 year fallows, respectively (Kwesiga et al,1999). If the Sesbania biomass at the end of the fallow is above 9 t/ha, a farmer can grow maize for 3 years before going back to the fallow phase. For biomass yields of approximately 7 t/ha, a maize growing period of two years and then reverting the field back to fallow is recommended.

Economic analyses revealed that these improved fallow systems were feasible, profitable, and acceptable to farmers. The returns per labour day were very similar to those of the fertiliser option. After six years the returns from one year and two year fallows were considerably superior to the control option of continuous maize cultivation without fertilisation (Kwesiga and Coe, 1994)

The demonstrated potential to increase maize production without applying inorganic fertilisers has excited thousands of farmers who are enthusiastically participating in the evaluation of this technology. The number of farmers who are testing and using a range of improved fallow practices in the Eastern Province of Zambia has increased dramatically: from 200 in 1994/95 to about 10,000 in 2000. There are 100,000 farm families in Eastern Zambia who could potentially benefit from this innovation and 120 million farmers in the wider Southern Africa Development Cooperation (SADC) region. The challenge now is to scale up the adoption of this technology.

Scaling up improved fallows in Eastern Zambia

Farmer involvement initially followed the classical technology-transfer approach of diagnosing farmers' priority problems followed by on-station research and then on-farm research. Since 1992, on-farm research became the main vehicle for assessing the biophysical and economic performance of the technology, with farmers gradually taking over the design and management of trials in their fields. Nevertheless, farmer designed and managed experiments were characterised by intensive farmer-ICRAF interaction and substantial support was provided to individual farmers in terms of information, training and technical backstopping visits. This support extended to individual farmers could be considered as the minimum incentive necessary for making a technology like improved fallows to be adopted in the first place. In fact such incentives are necessary for an innovation like agroforestry which takes a long time to provide tangible benefits. Scaling up is about people and not technologies alone. Our approach to technology dissemination is demand-driven, being highly dependent on private sector equipment manufacturers, seed and seedlings producers, retailers, and farmers for its success.

The enthusiasm generated by increases in maize yields after *sesbania* fallows has triggered a large demand for the technology by farmers. Dissemination and farmer experimentation with improved fallows has now evolved into a true client-driven process.

Why and how farmers adopt the technology

A participatory study to understand why and how farmers decide to adopt improved fallows was undertaken with 81 women and 40 men in four villages. The main findings are:

- Exhausted soil fertility and lack of alternative innovations are the driving forces for trying improved fallows;
- Awareness and information about the potentials of the improved fallow technology are pre-conditions to use. Women have less access to information, less formal education and hence should be given special attention when disseminating improved fallows;
- The current use of the technology appears to be spread evenly by both men and women farmers;
- Better off farmers are more likely to test first, presumably because they are better able to cope with risk, however out of the poorer ones that are testing, women are more successful and more likely to expand planting of improved fallows on their farms;
- Among women users, the largest numbers come from female-headed households where women can take their own decisions on land management choices;
- Men are more likely to test for the first time only after hearing about the potential of improved fallows, whereas women are more likely to test after seeing first hand for themselves, ideally from peer farmers.

ICRAF's main strategies for scaling up

Working with government extension service

Government structures are often rigid, hierarchical and autocratic and have a natural tendency for centralisation, bureaucracy and control. In spite of these draw backs, working with government to scale up may be more beneficial to the poor because governments:

- remain largely responsible for social services including health, education and agricultural extension on which the poor rely;
- remain the ultimate arbiters of wider political changes on which sustainable development depends;
- are seen as the only providers, especially in Africa.

Constraints and difficulties of the government system - resources in short supply, lack of motivation due to low salaries, poor conditions of service - have to be recognised and accepted beforehand. Inevitably, if progress has to be achieved, it will be slow. Thus, agencies that undertake to work in partnership with governments must be committed for a long time. ICRAF, for instance, has a memorandum of understanding with the government of Zambia, to conduct agroforestry research and development work in her territory. In return, ICRAF gets land for experimentation, scientists on secondment, access to field sites without interference, and an enabling environment to work with the rural poor. The improved fallow technologies were developed in partnership with government research agencies and extension services.

A Sesbania sesban improved fallow plot on a farmer's field. Photo: ICRAF

Personalities and relationships between individuals are a vital element in successful government–NGO partnerships, without which no amount of money or advice will make a difference. In Eastern Zambia, ICRAF still enjoys very good relationships with the political establishment; from the office of the provincial minister to chiefs and village headmen who allocate land and influence local policies. ICRAF's good relationships with the provincial and district agricultural offices have enabled access to the district Farm Institutes to demonstrate technologies and get feedback from farmers. The camp extension officers were attached to the project to learn and be trained in agroforestry technologies as well as to select farmers with whom to conduct initial on-farm trials. This pathway is still one of our main strategies for scaling up. Furthermore, ICRAF has access to the government media to disseminate technologies, and hopes to impact on government policy and practice when the conditions for influence become favourable.

Networking and partnerships with NGOs

World Vision International (WVI) in Zambia and ICRAF share the objective of addressing food security through increased farm productivity. Whereas ICRAF had developed the technology, it lacked the capacity and mandate for wider dissemination. ICRAF's capacity to mobilise at the grassroots level could only reach very few farmers carrying out on-farm research. At the same time, its traditional partners, mainly government extension services, had limited understanding of natural resource management strategies since they were largely commodity based. They were also constrained by limited budgets that curtailed their day to day functioning including training.

Therefore, to move forward in a manner that would benefit smallholder farmers, ICRAF needed partners with the willingness to understand her technologies as well as the capacity and credibility to operate at grassroots level. WVI has a grassroots network of staff and volunteers trained to facilitate extension. It also has networks with churches, women's organisations and other community groups. World Vision was aware of the potential of agroforestry interventions and had, at a small scale, already tried out using improved fallows.

With both parties acknowledging that they needed each other, it was easy to find common ground. A jointly designed 5-year project aimed at introducing improved fallow technology to 12,000 small-scale farmers in the Eastern Province of Zambia. For its part, ICRAF agreed to provide the technical aspects, which included training in nursery development and management, supply of initial seed, training of trainers and guidance to farmers, provision of laboratory support and soil etc. In general, ICRAF would be on hand to answer technical questions from WVI staff.

The project included components such as introducing agroforestry to communities that had not been reached by ICRAF and government extension agencies, crop diversification, soil moisture conservation, improved farmer access to agricultural extension and markets. By the 1999/2000 planting season, the project was working with over 3000 farmers. The number of farmers adopting and planting improved fallows is expected to increase sharply once the main groundwork has been laid.

Building grassroots movements to replicate successful projects
ICRAF facilitates exchange programmes for introduction of new technologies between farming communities that have experience in agroforestry. The main objectives are empowerment of farmers as trainers, knowledge transfer from farmer to farmer, farmer assessment of technology performance and farmer-to-farmer backstopping of activities. The more intensive farmer-to-farmer capacity building programmes usually last 3-5 days in host villages. Planning and organisation of programmes including content is largely carried out by host farmers. ICRAF provides some logistical support like transporting farmers, while the host farmers organise accommodation, meals and entertainment in the village for the trainees.

We have found that one participant of such a farmer-to-farmer capacity building programme reaches an average of 6-10 fellow farmers at home, who again will plant agroforestry trees on their land. This, together with the low costs involved, makes the farmer-to-farmer exchange pathway a very attractive one for achieving sustainability and wider impact. The advantage of the farmer-to-farmer training linkages between the Eastern Province of Zambia, the Central & Southern Regions of Malawi and the bordering areas of Mozambique is of interest. We call this area the "Chichewa Triangle", as language and culture are the keys for successful dissemination. Further geographic diffusion by building bridges to other neighbouring languages and cultures in the region is anticipated.

Influencing policy reform: Linking with grassroots organisations
In addition to the dissemination efforts highlighted above, ICRAF has organised workshops for different levels of policy makers to promote the adoption of agroforestry. The policy makers range from village headmen in traditional authorities to paramount chiefs, elected officials, senior civil servants and the private sector. These workshops have been very useful and have helped to produce strong recommendations (by-laws) that protect and promote on-farm cultivation of trees. The large number of stakeholders in natural resource management issues and the existence of groups with conflicting interests necessitate the involvement of various levels of policy makers in these processes. For example, in Eastern Zambia institutional arrangements authorise free range grazing of livestock after the harvest of crops. For those land users who may want to establish nurseries and plant improved fallows and other trees in their farms, this arrangement poses a serious threat to the survival and sustainability of the desired agroforestry interventions. In 1998, ICRAF in Zambia facilitated a workshop under the auspices of the local traditional chiefs to identify institutional arrangement that hindered or accelerated adoption of agroforestry technologies and to seek ways of alleviating those constraints. The workshop provided an opportunity for institutional arrangements to be established to facilitate wide adoption of agroforestry. These included:

- penalties on those whose livestock damaged agroforestry trees and crops because they did not herd their animals during the cropping season
- time periods when bush fires can be set–early burning after harvest
- prolonged tenure on leasehold land if the land user planted trees
- by laws empowering the local authority to prevent crop cultivation on hill sides if soil conservation measures were not adhered to.
- revisions to the chiefs act by the government to reinstate some of the powers of the chiefs and other traditional authorities.

Factors contributing to the current achievements
Development is a process whereby people learn to participate constructively in the solving of their own problems. The driving force is people's enthusiasm for change. People who work with development programmes must motivate farmers through results rather than by promises. Our current achievements so far can be attributed to:

- Correct diagnosis of farmers' problems from the onset of the programme;
- Involvement of farmers and extension staff in the research process from the inception of the programme. The scientists, like the camp extension staff, spent much time interacting with farmers and could respond quickly to the needs of farmers;
- Starting small and using local knowledge in the design of solutions;
- Demonstrating easily recognisable results;
- Testing a wide range of management options with farmers (e.g., offering different species with intercropping and pure stand options) and then allowing them the freedom to modify, innovate, and improve the prototypes;
- The technology that could be used by men and women alike (half of the participating farmers are women) It also appears to be attractive to different types of farmers, e.g., high income and low income, ox-and hoe-cultivators.
- Working with partners at all levels: government research and extension services, local farmer groups and big NGOs like World Vision who shared a similar vision with ICRAF;
- The funding of the research programme(thanks to Sida and CIDA) has been adequate and for a reasonable length of time,
- Ex-ante economic analysis helped identify key features of the technology that make it financially attractive, e.g. bare-root

seedlings and the superiority of a two-year fallow over one- and three-year fallows;
- Development of an adaptive research and dissemination network for testing and extending the technology in new areas.

Constraints to scaling up agroforestry innovations

- ***Erratic and low seasonal rainfall during establishment*** means that many of the agroforestry seedlings planted will fail to establish, and those that do, will not grow very well. This diminishes the impact of the fallows on maize yields. Farmers are more cautious about establishing sizeable nurseries and instead prefer to make smaller ones so that less effort is wasted if a season of poor rains occurs. The lack of sufficient water is a further disincentive to the establishment of nurseries.
- ***Seed availability*** is a major bottleneck for scaling up the adoption of agroforestry technologies in the region. Even though most farmers are producing their own seed, the demand for seed remains high. ICRAF is developing a seed strategy that will establish the amount and variety of seed available now and make projections for future demand. The strategy will provide guidelines on collecting tree seed and establishing seed orchards. It will also provide clear seed quality control and pricing guidelines within the region and for each country. This work will be undertaken in collaboration with competent seed centres, which also have the mandate to produce and certify seed. In addition, the project will create awareness aimed at increasing the involvement of farmers and the private sector in seed production, distribution and marketing.
- ***Initial support to farmers and NGOs.*** As the project builds up momentum for scaling up it will need adequate technical backstopping capacity for the various farmer trainers, groups and organisations. ICRAF's present capacity in not sufficient to provide backstopping to all partners, who need to go through at least one cycle of the technologies before they gain the confidence and know-how to manage the scaling-up process on their own.
- ***Weak extension services***. Throughout the region, government research and extension services are largely enfeebled or paralysed through lack of staff, low salaries, low morale and lack of operating funds. It is left to the project to catalyse the relevant government services. On the other hand, farmers are enthusiastic and actively helping in scaling up. The issue is how to keep them motivated with different options that generate results and address their food needs.
- ***NGO constraints***. NGOs offer very good collaboration to the project and the opportunity to tap personnel, community contacts, financial resources and geographic coverage that the project by itself would be unable to achieve. However, the NGOs are rarely able to manage the dissemination of project technologies alone due to high staff turnover, short life spans and coverage of small areas. Besides, these NGOs usually have priorities other than agroforestry in their programmes, and most are unable to provide any technical backstopping as they usually have no relevant research capacity and few technical skills. In recognition of these weaknesses, ICRAF will continue to provide training and technical backstopping to empower these important partners in scaling up.
- ***Diversity of agroforestry technologies***. To date the project has developed and successfully tested appropriate technologies that help small farmers to replenish soil fertility, and to grow woodlots and fodder on their farms. The soil fertility improvement technologies are simple, yet essential for sustainable farming and to eliminate the annual food deficit in the region. Woodlots and fodder offer the opportunity to create cash flow in the farming system. Although each technology was developed in a different country they are all relevant and adapted throughout the region. But, attempting to extend multiple technologies at the same time will reduce the rate at which farmers are contacted.
- ***Lack of funds***. It requires only US$ 20 per month to motivate a field extension Camp Officer and US$200 to hold a community field day (about 200 farmers). It is such small amounts of funding at the farmer level that are required to undertake effective dissemination and scaling up of innovations. At the moment, project budgets for field dissemination activities are very small as dissemination is only being undertaken in a few target areas. Increased dissemination budgets for field activities will be required if dissemination is to be directly stimulated by the project on a significant scale.

Reflections on scaling up

Scaling up is about people and meeting their needs by delivering appropriate technologies to those who need them most. Our experience on scaling up the improved fallow innovations in Eastern Zambia shows that this is feasible. The involvement of farmers in the research and development process has been highlighted as a very important element for the achievements realised so far. However, we have noted that the task of scaling up from thousands to millions requires the following to be in place:

- exciting results;
- willing farmers;
- seed and seedling production and distribution networks;
- smart partnerships with government, and NGOs, farmers and farmer groups, traditional leaders and policy makers all working together to make it happen;
- enabling policies and markets since technologies on their own cannot be effective in the absence of such incentives;
- farmer feedback and research backup to address second generation issues such as pests and diseases.
- leadership and the will to make it happen.

The impact of research on the lives of poor people is usually highly localised and often only produces islands of success. NGO programmes tend to be good but limited in scope. In contrast, governmental development efforts are often larger in scale but limited in their impact. It is only a synergistic partnership among all parties that can produce greater impact or scaling up as demonstrated by the collaboration between ICRAF, the government and WVI in Zambia.

The authors acknowledge with gratitude, the continued support of this project by the Government of the Republic of Zambia, the Canadian International Development Agency (CIDA), the Swedish International Development Agency (Sida) and the thousands of farmers participating in this project.

Scaling up the Landcare and NRM planning process in Mindanao, Philippines

Delia C. Catacutan, Agustin R. Mercado, Jr. and Marcelino Patindol

The International Centre for Research in Agroforestry (ICRAF) has been conducting research on contour hedgerow technologies for the past decade in Claveria, Misamis Oriental, assessing the management strategies that address key technical constraints of the system. Since adoption of the technology by farmers was low, ICRAF refocused its efforts in finding alternative systems that address the technical and institutional issues of conservation farming. Natural vegetative filter strips (NVS) provided simple solutions to the technical constraints of soil conservation on sloping farms. These are buffer strips laid out on the contour in which natural vegetation is allowed to re-grow into thick, protective cover. NVS also provided the foundation for complex agroforestry systems with fruit and timber trees. This system is being widely adopted, enhanced by a dissemination approach called "Landcare".

Landcare is a movement of farmer-led organisations supported by local governments with backstopping from technical service providers - they share knowledge about sustainable and profitable agriculture on sloping lands while conserving natural resources. This dynamic voluntary movement has grown to include more than 5000 farmers in 250 groups from five municipalities in northern, central and eastern Mindanao. Today, Landcare has become the melting pot for farmers and others who discuss issues, share lessons, invest talents, skills and other resources geared towards better land husbandry and protection of the environment from degradation. It threads a path for constructive, long term and practical action at a community level for tackling environment and sustainability issues for the well-being of people and their communities.

Experiences with and strategies for scaling up the Landcare approach and the locally-led natural resource management planning process are described here.

Farmer innovations in erosion control

ICRAF's project sites are located in two adjoining provinces in northern Mindanao, namely Misamis Oriental and Bukidnon, in the municipalities of Claveria and Lantapan respectively, with similar biophysical conditions. Rainfall is about 2200 mm/year and soils are degraded, acidic (pH 4.5-5.2) with low availability of P (Mercado et.al, 2000). Sloping fields in Claveria experience up to 200 t/ha of soil loss annually. About 95% of the cropping activities (mostly maize and some vegetable) take place on lands of more than 15º slope.

Contour hedgerows of pruned leguminous trees or Sloping Agricultural Land Technology (SALT) had been promoted in Claveria since the early 1980's by the Philippine Department of Agriculture (DA). It aimed at providing effective soil erosion control, organic fertiliser to the companion crops, fodder for ruminants, fuelwood for farm families, and restoration of water quality and quantity in the watershed etc. In spite of these benefits, farmers' adoption was not widespread due to high labour in establishment and maintenance of the hedgerows, resource competition between the hedgerows and associated crops, limited added value from hedgerow pruning, and poor species adaptation.

However, farmers began to adapt the technology. Some placed their crop residues in lines on the contour to form "trash bonds". These accelerated the growth of native grasses and weeds and soon formed stable hedgerows with natural front-facing terraces. Others laid out the contour lines but didn't plant anything. These contour lines eventually evolved into natural vegetative strips (NVS) that controlled erosion but needed less maintenance and labour than the tree based contour hedgerows.(Mercado et al, 2000).

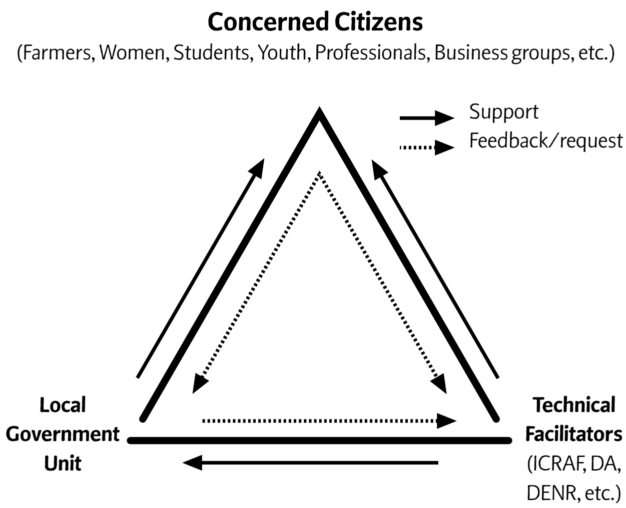
These simple innovations attracted many farmers in the area. In 1994, it was estimated that 150 farmers had adopted contour hedgerow systems while the number of pruned tree hedgerow fields decreased after 1990. The new wave of hedgerow systems was predominantly NVS with contour ploughing replacing up-down tillage.

The evolution of Landcare

ICRAF also developed and put into test an extension programme that rapidly and inexpensively diffuses conservation farming and agroforestry technologies using the group approach. This approach was found effective in strengthening government extension programmes and expedited the dissemination process. It also encouraged local governments to provide technical, leadership, logistics and policy support. At the beginning farmers came together to exchange knowledge and skills on soil conservation and agroforestry practices. With time they felt the need to be more cohesive and to look at other degradation issues - a process of group development that required leadership skills. This key institutional innovation for technology dissemination gave birth to “Landcare”, a land conservation approach and movement, which has its origin in Australia (Campbell and Siepen 1996).

What is Landcare?

The Landcare approach is based on effective community groups being in partnership with local government. Such groups respond to issues affecting them and are more likely to find and implement solutions independently, rather than follow those imposed by external agencies. Landcare is about people and the key to success is based on a mature social capital and a close bond between and among farmers ‘communities’ and governments. The tripartite relationship of key actors in Landcare: grassroots Landcare groups, local government units (LGU) and technical service providers and facilitators (ICRAF, Department of Agriculture (DA), Department of Environment and Natural Resources DENR, others) is indicated in the figure below. The success of Landcare as an approach is dependent on how these 3 key actors interact and work together.



In 1996, we started our technology dissemination programme in response to farmers’ requests for technical assistance in conservation farming. 25 farmers requested for training on the establishment of NVS and decided to form a group and share the technology with other farmers. That group of 25 farmers made the history of Landcare in Claveria. Today, there are more than 250 Landcare groups in Claveria and Lantapan. Most of them are based in the sub-villages *(sitio or purok)* and are federated at the village *(barangay)* and municipal levels. More than 3000 farming families are involved and have successfully extended conservation farming technologies to more than 2000 farmers and established more than 300 communal and individual tree nurseries (Mercado et al 2000). Thousands of fruit and timber tree seedlings are planted on the NVS, on farm boundaries, on buffer zones of protected areas, on riparian areas, and some are planted on small-scale tree plantations. Some groups have also linked with other service providers, including the business sector, for funding of their nursery activities and livelihood projects.

Who is involved in Landcare?

Landcare is a voluntary group that is currently represented by a large number of farmers. However, interests from other sectors - women, students, youth and professionals - are emerging. This implies a wider applicability of Landcare for a range of community groups in varying situations. They are:

1. Concerned citizens in the community who are:
- Willing to share their talents, skills and other resources
- Usually resource poor and want to improve their livelihoods
- Willing to learn, share experiences and employ new sustainable farming techniques
- Committed to resource conservation and protection and the creation of workgroups for the purpose
- Tillers, non-tillers, owners, tenants of the land

2. Local Government Units (LGUs) who can provide:
- Policy support for the institutionalisation of conservation farming, agroforestry and other practices for sound environment and natural resource management, and budget allocations through creation of local ordinances.
- Leadership in facilitating Landcare groups and related activities
- Capacity-building programmes for the overall development of Landcare
- Financial support for Landcare activities

3. Technical facilitators (ICRAF and other line-agencies) who can provide:
- Appropriate technologies for sustainable agriculture and natural resource management
- Facilitation for Landcare group formation and their activities
- Information, communication and education programmes
- Network support for Landcare groups

What are the aims of Landcare?

The issues in Landcare are varied and usually location-specific, and form the basis for defining goals. Generally, however, Landcare aims at:

- Protecting, conserving and restoring the resource base: soil fertility by controlling soil erosion and other conservation technologies that increase and sustain farm productivity.
- Engaging in field level action research that addresses other issues on sustainable agriculture and natural resource management.
- Developing marketing strategies for agroforestry and environment-friendly farm products
- Strengthening and empowering local people to think, create and initiate activities that improve livelihoods as well as protect the environment from degradation.
- Sharing technical knowledge among researchers, extension agents, local officials, farmers, students, women, professionals, business sector, civic groups and other members of the community about sustainable agriculture and natural resource management.
- Seeking technical and other forms of assistance from government and non-government agencies as well as private companies.
- Drawing support from all sectors for the common interest of land care.
- Fostering and safeguarding the welfare and interest of its members.

Steps of the Landcare approach

During the gestation and evolution of Landcare in Claveria, we identified the following steps in developing this approach as summarised below (Garrity and Mercado, 1998).

1. Select sites with good potential

This is to bring conservation farming technologies to where it is most needed—on sloping lands where soils are prone to erosion. It also involves meeting with key leaders in the local government units, interested farmers, and other stakeholders. Their understanding of the issues to be addressed and their willingness to support and complement the programme are crucial to the success or failure of Landcare at a given site.

2. Expose key farmers to successful technologies and organisational methods

The aim is to develop strong awareness among prospective key actors - especially innovative farmers and farmer leaders - of the opportunities to effectively address production and resource conservation objectives through the new technologies. The success of the activities can be measured though the enthusiasm developed to adopt the technologies within the community. Exposure activities include:

- Cross visits to the fields of farmers who have successfully adopted the technology
- Training experience for farmers in the target communities to learn about the practices through seminars in their villages; and
- Opportunities for farmers to try out the technologies through unsubsidised trials to convince themselves that they work. If so, these farmers become the core of a conservation team to diffuse the technology in the municipality

3. Organise conservation teams at the local level

Once it is clear that there is a critical threshold of local interest in adopting the technology and a spirit of self-help to share the knowledge among the villages of a municipality, then the conditions are in place to support the implementation of a municipal conservation team. The team is composed of an extension technician from the Agriculture Office and possibly from the Environment and Natural Resource Office, an articulate farmer who has experience in applying the technology, and an outside technical facilitator. The team will initially assist individual farmers in joint implementation of desired conservation farming practices. Later, they can conduct seminars and training at the village level if sufficient interest arises. During these events, the team can respond to requests for the organisation of formal groups.

4. Evolve Landcare farmers organisation

If and when the preconditions are in place for a Landcare farmer organisation, then the facilitator may assist the community in developing a more formal organisation. A key ingredient for success is identifying and nurturing leadership skills among prospective farmers. This may involve arranging for special training in leadership and management for the farmer leaders and exposing them to other successful Landcare organisations. Each village may decide to set up its own Landcare Association and a Village Conservation Team. A village may organise Landcare Association sub-chapters in their sub-villages. A sub-village conservation team usually includes a local farmer technologist, the sub-village leaders and the councillor assigned in that sub-village. The sub-village conservation teams are the front liners in conservation efforts providing direct technical assistance, training and demonstration to farmer households. They are backstopped by conservation teams at the village and municipal levels. At the municipal level, the Landcare Association is a federation of all village level Landcare groups. The municipal conservation team is part of a support structure, which also includes other organisations that can assist the chapters for the organisational set up of the Landcare Association.

5. Attract local government support

Local governments can provide crucial political and sustained financial support to the Landcare Association in meeting its objectives. The municipality has its own funds earmarked for environmental conservation. These can be targetted to Landcare activities that enhance natural resource conservation. The municipality can be encouraged to develop to a formal natural resource management plan, which can help guide the allocation of funds.

The villages can also allocate financial resources from their regular internal revenue allotment. These funds can be used to organise the conservation teams and Landcare Association activities at the village level. The municipality can complement the funds of the villages, just like it happened in Claveria. The municipality allocated 50,000 pesos (about 1,250 US$) to each village to support Landcare activities. External donor agencies can best support Landcare development by allocating resources for leadership and human resource development, communication equipment and transportation to enable the Landcare leaders to make maximum use of their time.

We noted that Landcare performed impressively in villages whose activities were mostly funded by the local (village) government. Here the village officials made sure that the activities were well implemented so that their investments paid off, as compared to those that were in part funded externally. This implies that when the investments are coming from local funds to support self-help activities, it is likely that local people ensure the gains of their investment, resulting in good and successful projects, and sustained actions.

6. Monitor and evaluate

Monitoring is a necessary tool to assess the progress of the activity and use outputs for strategising activities or planning actions to make the programme more dynamic and relevant to the needs of the target community. For monitoring purposes, ICRAF has been keeping records of all those who have attended a training or had been assisted with establishing NVS on their farms, as well as farmers who requested assistance. Details on farming and conservation practices, training and follow-up needs are recorded on a diagnostic card, which is updated on regular follow-up visits by ICRAF staff. The leaders of the Claveria Landcare Association (CLCA) chapters and sub-chapters have been supporting this activity by facilitating the distribution and collection of the diagnostic cards to and from the sub-villages and new CLCA members.

Scaling up the natural resource management planning process

In 1996, the local government of Lantapan embarked on a bold step to develop their "natural resource management and development plan". It was probably the first of its kind in the history of local development planning with emphasis on natural resource management. The planning process was designed by the local government and technically supported by an international research consortium in which ICRAF is an active member. The plan drew national recognition and emerged as a model for a local government-led, participatory and research-based planning process. Today, the plan is vigorously implemented through public-private partnership. This means, everybody involved in either research or development activities within the area need to streamline their programmes towards meeting the objectives of the plan.

Based on the experiences in Claveria and Lantapan, different scaling-up modalities were developed (Catacutan et al. 2000).

MODALITY 1: ***Scaling up through the local development planning process*** *(From Claveria to Lantapan)*. This mode requires an engagement with LGUs in their local development planning process, resulting in the institutionalisation of the project at the planning stage as in Lantapan. Landcare is embedded in the bigger NRM and development plan of the municipality.

MODALITY 2: ***Scaling up through "integration" within the conventional extension programme of local government line agency: Municipal Agriculture Office (MAO)*** *(from Claveria to Malitbog, Bukidnon)*. The local government of Malitbog invited ICRAF to help them develop their Landcare programme.

Landcare was then embedded in the extension programme of the MAO in Malitbog that provided both human resource and financial support. Local champions – persons committed to Landcare – play an important role.

MODALITY 3: ***Scaling up through the local development planning process and integration in existing local programmes*** *(Lantapan to Manolo Fortich, Bukidnon)*.

This modality is a marriage of the two modes cited above.

MODALITY 4: ***Province-wide scale scaling up through integration of programmes implemented by government-line agencies and special local warm bodies at the provincial level*** *(Lantapan and Claveria to other municipalities in the two provinces)*. This mode requires a review of the different line-agencies and special warm bodies operating within a provincial scale and involves an understanding of their mandated programmes and identifying committed local champions who can mobilise programs on a provincial scale.

MODALITY 5: ***Scaling up through networking, collaboration and integration in existing special projects implemented by both public and private sectors*** *(for provincial, regional to national levels)*. We identified pathways whereby NRM can be streamlined in the development goals of different government line agencies from the provincial level down to the municipalities such as the Protected Area Management Board, Provincial Planning and Development Office, National Government Agencies such as Department of Environment and Natural Resources (DENR) and the Department of Interior and Local Government (DILG) and the League of Municipalities. The challenge was to contextualise NRM in respective programmes and mandates of these agencies.

We also have had interaction with other development service groups engaged in this issue, such as the Governance on Local Democracy (GOLD) project of the Associates in Rural Development Inc., and recently again, the Philippine Watershed Coalition. A potential partner for future scaling up is the Forest Management Bureau in implementing the Philippine National Watershed Management Strategy.

Keys to Success

In our experience, there are key principles that should be applied when scaling up technologies, concepts or processes. These are:

1 - Identify your strategic partners. You can do this, by critically examining your potential entry points that can be government officials, government offices, government programmes or NGOs, POs and their programmes. Be sure to get as much knowledge about your potential partners - their programmes, skills and even their personal interests.
Be conscious of the different personalities of people.

2 - Build that strategic partnership. Partnership is about relationship. It is important to approach the relationship as equal partners and be open on what each partner can invest. We are very careful as we carry the banner of an International Centre. We usually begin by saying, "we are here, not as a bank, a donor, or a sponsor, but—we are here to share our experience and our little successes".

3 - Use opportunities to build upon the programme.
Don't create confusion or chaos in an already organised system. Refrain from being identified as "Organiser" but as "Innovator and Facilitator". Avoid creating foreign structures. The key word is "Refinement" not "Re-engineering". Your proposed programme should be put in the context of already existing programmes by reviewing their working structures and relations and building on it. Be subtle and kind, and don't impress upon them that you are there to solve their problems. At the end of the day, they should claim ownership to the programme.

4 - Be flexible. Flexibility is very important in partnership building, from conceptualisation to implementation, but avoid "double standards". Each locality has its own unique conditions. Your scaling-up modes and even the project level approaches for the delivery of outcomes should vary according to local conditions.

5 - Maintain good communication and a friendly attitude. Just as in any relationship, communication is essential to success. Occasionally, socialise with your partners, but don't loose the limits. Be respectable by avoiding broken promises - don't promise anything you are not able to deliver.

6 - Be dynamic and innovative. Make things exciting by bringing in new and relevant information to your partners from time to time. Don't forget to be humble - yet show that you know something and that you are willing to share it with them.

7 - Be reflective and encourage your partners also to reflect on issues, problems and past events. It is always important to evaluate how things were delivered and look forward to mid-course corrections, if necessary. This can be a mutual learning exercise by the partners themselves.

8 - Networking. Invest in network building and maintain a supportive role to the network. Building networks is like building relationships - it is therefore, important to show an untiring effort and sincerity to potential networkers.

Challenges and future plans

Our analysis indicates that there is more to be done in further releasing the power of the Landcare concept. The public and non-government sectors can assist in facilitating group formation and networking among groups, enabling them to grow, develop their managerial capabilities, and enhance their ability to capture new information from the outside world. They can also provide leadership training to farmer leaders to ensure the sustainability of the organisations. Cost-sharing external assistance can also be provided. For this, the use of trust funds can be emphasised, where farmer groups can compete for small grants to implement their own local Landcare projects. This has been remarkably successful in the Australian Landcare Movement. We envision that the Landcare approach may be suited to other locations in the Philippines and elsewhere, providing a national focus for the sustained management of resources by farmers with minimal local government support (Mercado et al, 2000). On the other hand, the NRM planning process manifests a strong basis in the implementation of provisions mandated in the Philippine Local Government Code. Both Landcare and the local NRM process exhibit the essence of local governance. The modalities for scaling up provide more options for project implementers to contextualise approaches for scaling up on the basis of opportunities and build the blocks for accelerated progress in that local condition.

Farmer recommendations after 15 years of innovation

Güinope was the site of a highly acclaimed people-centred development project in the 1980s. The ACORDE / Ministry of Natural Resource / World Neighbors' Integrated Development Program (IDP) was unique for its time, since it promoted local innovation for generation of responses to needs rather than relying on technology transfer. Furthermore, it was one of the first efforts in Latin America to employ villagers as principal agents of change. Fifteen years after the inception of the IDP and ten years after its completion, the authors interviewed farmers in their fields and held a series of participatory workshops with 10 former farmer promoters (FPs), now influential farmer leaders. The results of this study were published recently in *Agriculture and Human Values* (see end). Some reflections of the FPs on rural development programmes are summarised here.

In 1982, the IDP felt that soil conservation and the development of FPs offered the greatest opportunity for community progress. Fifteen years later, FPs expressed the need for development organisations (DOs) to give attention to new priority areas. Community populations have become increasingly transitional. This has drastically changed traditional mechanisms of learning, leadership, and organisation. External cultural influences have placed new pressure on local norms and behaviour, and agricultural modernisation emphasising export-oriented and extensive agriculture is threatening the sustainability of smallholder production systems.

The FPs felt that the most effective projects were those that facilitated community participation. Projects should, they said, include men, women and youth, begin with local interests and experience, rely on available resources, and ultimately permit the community to direct change. It was also important for DOs to enable leadership and to collaborate through local leaders. They added that such leaders should be chosen based on their ability to learn, success in applying innovations, and demonstrated volunteer spirit.

Projects, they said, should not focus on single-answer solutions or technical themes, but rather embrace the local complexity. They argued that the best way to achieve this was through cultivating the "human farm": the head (ability to think), the hands (ability to implement ideas), and the heart (motivation to initiate and complete tasks). Further, they encouraged DOs to become facilitators, enabling communities to develop and implement independent initiatives by assisting them in organising, getting access to information, representation in political circles, and logistical support.

The FPs mentioned that present priority areas demanding support were marketing of commodities, irrigation, credit for investments, and attention to the development of new leaders in the community, especially women in leadership roles. They also sought conditions that would permit children to become independent farmers or entrepreneurs, rather than labourers. Such changes would demand new platforms for the community's voice in government decision-making and the formulation of policies.

Ultimately, the local leaders downplayed the role of technologies in rural development and called for special attention toward enabling communities to confront external pressure, particularly recent government "modernisation" policies they felt threatened community livelihoods.

The FPs presented their ideas to a forum of 30 representatives from 12 DOs as well as 15 farmers from the Güinope area. An open discussion followed the presentation, and the group summarised nine essential project attributes and strategies for more effective development work (Table below).

Essential project attributes and strategies for more effective rural development

Attributes	Strategies
1. **Increasing participation**	Begin with local priorities Be inclusive (include women and other disadvantaged groups) Work with local knowledge and available resources Increase involvement of local actors in decision-making and ultimately permit community control over initiatives.
2. **Avoidance of paternalism**	Avoid using external incentives (e.g. gifts and subsidies) to motivate Use success to inspire increasing involvement and participation
3. **Integrated human development**	Attend to the "Human farm" (development of knowledge, skills, and motivations) View technologies as tools and their use as means rather than ends
4. **Community-oriented flexible projects**	Respond, do not lead Develop projects and methodologies in collaboration with communities Grow with the changing needs, interests, and abilities of intended beneficiaries
5. **Collaboration with multiple institutions**	Involve the entire range of local organisations Develop abilities to work together Build linkages among multiple development organisations and coordinate efforts
6. **Start small**	Begin with small, manageable projects that permit people to build confidence and abilities without involving them in substantial risk
7. **Quality agents of change**	Employ extensionists and promoters who are: • experienced in farming • competent with agriculture, teaching, and organising • genuinely sensitive to the local situation
8. **Local leadership and innovation**	Enable local leadership and achieve change through leaders Chose leaders who: • have thirst and ability for learning • have successfully applied innovations on farms • demonstrate volunteer spirit Promote democratic (rather than autocratic) leadership styles Promote independent learning (experimentation, analytical skills, and self-discovery)
9. **Local initiative**	Encourage communities to generate projects Provide organisational support Facilitate access to information, teaching materials, and provide logistical support

Scaling up sustainable agriculture

Lessons from the Campesino a Campesino movement

Eric Holt-Giménez

For thirty years the *Campesino a Campesino (CaC)* movement of Mesoamerica has been hard at work developing Sustainable Agriculture, patiently, empirically, step by step. What started as a village alternative for a small group of Cachikel Mayans in the Highlands of Guatemala has spread through Mesoamerica in spite of (and sometimes because of) military conflict, widespread agrarian failures and chronic economic crisis. Presently there are well over ten thousand practising farmers in Central America alone.

The effectiveness of the agroecological practices promoted by the movement were made clear in the aftermath of Hurricane Mitch: thousands of "agroecological" farmers survived the century's most destructive hurricane with more topsoil, less erosion and fewer crop losses than their neighbours practising conventional agriculture. (LEISA Magazine 17.1, p.18-20).

A Campesino a Campesino workshop, Santa Lucia, Nicaragua. Photo: Eric Holt-Gimenez

The essence of Campesino a Campesino

CaC is more than a wide-flung, loosely related collection of NGO projects. It is not simply a horizontal methodology for learning or technology transfer. It is a social *movement* based on the belief that farmers are capable of developing their own agriculture (Holt-Gimenez, 1996).

The CaC movement **"walks"** on the legs of 'innovation and solidarity' by experimenting on small, local scales and by widely sharing knowledge, creativity, experience and wisdom, farmer to farmer.

The movement **"works"** with the two hands of 'production and protection'. By focusing on overcoming limiting factors to production and on strengthening the weak ecological functions in the agroecosystem, farmers first reduce and then substitute external for internal inputs. To the extent possible, they gradually eliminate inputs altogether by redesigning the farm system to rely primarily on ecosystem functions. Protection of the environment then becomes crucial to the productive function of the farm. Watershed hydrology, habitat and biodiversity become key considerations for on-farm soil and water conservation and pest management, thus linking farmers' collective watershed management to their individual farm management.

The movement **"sees"** with the shared visions of farmer-led sustainable agriculture. In its **"heart"** members of the movement are motivated by deeply held beliefs in the divine, in family, in nature and community. The shared expression of these beliefs in practice has led CaC to reaffirm the cultural capabilities and the social imperative of farmers' contribution to sustainability, both locally and globally (Holt-Gimenez, 1997).

Basic principles of Campesino a Campesino

The basic principles of CaC evolved from Roland Bunch's concept of "people-centred development" three decades ago:

- Start small, go slowly
- Small-scale experimentation to overcome limiting factors and stabilise ecological functions
- Multiplier effect
- Limit introduction of technology
- Teach others
- Reduction, substitution, redesign: 3-phase conversion to sustainability
- Vertical and horizontal integration of production

Lessons from experience

Experience over the years has brought out a number of activities and methodological/ organisational lessons. First is the centrality of campesino culture. Farmers learn from each other by sharing wisdom, creativity and knowledge, not just information and techniques. Rather than simply transferring technologies, farmers first and foremost "make culture" - sharing that leads to action builds a culture of sustainable agriculture. Technology transfer is actually just one (and not always the primary) component of this cultural matrix.

Part of farmers' enthusiasm for developing agriculture comes from the sense that they are actually contributing to and shaping society. This subjective, but very powerful motivational force has been nurtured through **cross visits**, "**encuentros**" (farmer gatherings… sometimes similar to scientist's symposia) and the inclusion of farmer-promoters in workshops held by national and international agencies for agricultural development.

Farmer promoter teams have played a key role in CaC. Teams have the advantage of spreading the knowledge, time, talents and risk among several like-minded promoters. They also allow for entry and exit of farmers from promoter duties and the continual renovation of the team itself. Teams are peer mentorship programmes for young or new promoters, as well as a reservoir of expertise for NGOs who frequently hire experienced promoters, (either on short or long term basis) to open new programmes. Teams also ensure an installed capacity for a wide range of social, economic and technical activities that work directly and indirectly to help sustainable agriculture scale out (geographically) and up (i.e., research, organic certification, Fair Trade, etc.). Promoter teams usually rely on an agricultural technician from an NGO for technical, logistical and/or some form of economic support for their activities. Field days, study sessions and workshops that are held continuously have been broken down to modular 1-3 day activities to make them more accessible to farmers. Some teams have found it important to arrange themes and experiments seasonally to coincide with the cropping calendar of local farmers.

A more sustainable agriculture

This combined approach of developing pools of local expertise and sharing experiences widely has accomplished three important tasks in the development of a more sustainable agriculture:

1) It has generated and adapted locally-based alternatives that are easily incorporated to the ecology of each particular area, increasing agroecological diversity and resilience,
2) It has spread simple, adaptable technologies at low cost to thousands of farmers and has improved the capacity to innovate,
3) It has developed farmers' social and agroecological capabilities.

The widespread adoption of Velvet Bean (*Mucuna pruriens*) and other green manures in Mesoamerica is largely due to farmer to farmer innovation and solidarity, as is the knowledge and practice of soil and water conservation technologies (ILEIA Newsletter 13.3, pp.12-13). These farmers have often been the first and/or most successful in converting to organic practices, in diversifying their markets, and in vertically integrating production.

While over 10,000 farmers identify in one way or another with the movement, thousands more have been influenced. (The numbers are undetermined because these farmers fall outside the NGO areas of influence). Likewise, many professionals within NGOs have adopted parts of the CaC methodology or technologies without specifically identifying with the movement. In fact, the movement has profoundly influenced the technical and methodological agenda of many NGOs in Latin America (ILEIA Newsletter 16.2, p.26).

Success not the only key for spread

In the recent Central American study on Farmers' Agroecological Resistance to Hurricane Mitch (Holt-Giménez, 2001), one thousand practising farmers indicated that their reasons for adoption of sustainable practices included:

- Need (highly degraded agroecosystems, high cost and diminishing returns on credit and external inputs)
- Access to farmer to farmer training
- Consistent technical assistance
- Access to appropriate credit and market opportunities

However, while these factors help explain CaC's success, the question remains, "If it works so well, why hasn't it spread more?" One thousand conventional farmers from the same study indicated that their lack of adoption was due to:

- Insecure access to land
- Too much land (can afford to degrade the agroecosystem)
- Access to credit for external (chemical) inputs
- Lack of time/labour (engaged in pluri-activity)
- Ignorance
- Apathy

At this juncture, the limits to scaling out appear to be related to the structural problems of scaling up. These problems have less to do with technologies and methodologies than with national policy contexts and institutional behaviour. The CaC movement provides a perspective on these factors as well.

Factors that impede scaling out

Lack of documentation: There has been little "*sistematización*" or documentation of the movement done in a way that actually provides feedback to technicians, promoters and farmers. This has meant that the sharing of most of the agroecological, methodological and organisational knowledge in CaC is limited to farmer to farmer exchanges. While these horizontal learning networks are of prime importance for building the culture for sustainable agriculture, the lack of documentation prevents these lessons from scaling up into institutional networks. This in turn limits institutional learning, resulting in many projects "re-inventing the wheel." Further, lateral learning by government and private sector institutions is virtually non-existent, resulting in little headway for CaC outside the informal social networks connecting remote villages and the NGO institutional world.

No effect on formal research: Several interesting studies regarding technologies and methodological approaches have been undertaken. Some national and most international centres for agricultural research (NARIs and IARCs) have a small section or project that deals with sustainable agriculture, in general. Yet, CaC has not significantly affected formal agricultural training and research. In fact, lately, privately-funded research in biotechnology has begun to dominate IARC research agendas, dwarfing sustainability-oriented projects, which remain isolated and wield little influence.

Lack of appropriate training: Not only is formal research for sustainable agriculture largely out of touch with the farmers who are actually practising it, relatively few agronomists or technicians are being trained to work in agroecology or with campesinos. While it is true that over the last ten years, many technicians have learned about sustainable agricultural techniques, (primarily on the job, many from campesino promoters), very few have any grounding or formal training in agroecology. Thus they have difficulty applying basic ecological principles to solving a changing array of complex agroecological problems. This also limits their ability to design effective on-farm agroecological experiments, hampering innovation.

Adoption with no integration: Success and the lack of a fixed organisational focus encouraged many NGOs to adopt CaC methodologies (and its rhetoric if not its ideology). However, this has not always translated into greater farmer input or control over programmes, nor has farmer-led sustainable agricultural development necessarily become a guiding approach for NGOs. NGOs are still primarily accountable to donors, and few of them have direct mechanisms for accountability to farmers. While it is true that farmer participation is a key indicator in most project evaluations, "participation" continues to mean the participation of farmers in the NGOs' projects, and only rarely considers the nature of the participation of NGOs in farmers' processes for development. The conflation of "participation" and one-way accountability prevents clear strategies for farmer organisation and empowerment (beyond technologies and/or markets), particularly in regards to influencing the policy context for sustainable agricultural development. Claims to partnerships

Don Pedro Rodriguez, promotor, Nicaragua explains how CaC walks on the legs of solidarity and innovation, works with the hands of production and protection, has a heart that loves family, nature and other campesinos, and eyes for a campesino vision of the future. Photo: Eric Holt-Gimenez

notwithstanding, campesinos remain "clients" of most development programmes, rather than "constituents" of organisations working for social change.

Inability to influence decision makers: Despite its extensive presence in one of the largest farmers' unions in Central America, CaC has not been very successful in scaling-up its agenda within national and regional farmer organisations. Basically, promoters from CaC have been unable to penetrate decision-making circles (boards, directorships, etc.), dominated by medium and large producers interested primarily in conventional agriculture. Consequently, while some farmers' unions can boast of CaC projects (this is important for obtaining international funding), the lack of power sharing and the dominant conventional strategies for agricultural viability precludes these unions as lobbying agents for sustainable agriculture.

Rogelio Sanchez Ledesma, a Mexican promoter helping Jose Jesus Mendoza (now a well known Nicaraguan promoter) to establish the first terraces on his land in 1987. Photo: Eric Holt-Gimenez

Conflicting economic interests: The importance of economic viability has led many CaC groups to establish international linkages for Certified Organic and Fair Trade marketing. While both Fair Trade and the Certified Organic market have proven a windfall for many campesino groups, neither is *necessarily* agroecologically sustainable or *intra*-generationally equitable. Farmers anxious to obtain quick certification have chopped down forests for access to fertile, uncontaminated soils. Others have shifted from diverse agroecosystems that produce food for local consumption to organic monocultures geared for export. Finally, many NGOs, eager to attract farmers to their projects, substitute broad-based organising efforts around food security, autonomy and sustainability, for short term, market-oriented strategies. This has drawn in farmers interested more in profits than sustainability and has excluded those farmers whose factors of production do not permit farming for the international market.

Establishing linkages with the international market does not in and of itself develop local or inter-sectoral linkages with urban, consumer, or environmental interests. But these linkages on local, national and regional scales cannot be ignored if scaling up itself is to be sustainable. This does not mean that sustainable agriculture must operate outside the market or that Certified Organic and Fair Trade should not be pursued. Simply, it means that programmes for sustainable agriculture cannot afford to push market options uncritically.

Unfavourable institutional and policy contexts: The decentralised, informal and horizontal nature of CaC has given tremendous resilience and diversity to the movement, whose reticular development has allowed it to establish effective technical and methodological alternatives for sustainable agriculture over a broad geographical area. The knowledge-based, farmer-driven approach has been especially appropriate to the ecosystem-specific nature of sustainable agricultural development. However, it appears that CaC has found its limits in the unfavourable institutional and policy contexts that do not favour sustainable agriculture or farmer-led development. There are many credit and market mechanisms that could be brought in to improve the conditions for sustainable agriculture, as well as research, training and extension programs - just as they were for the Green Revolution. However, the lack of effective political will on the part of governments and research centres makes this a remote possibility. Developing this political will depends in large part on pressure from civil society. For the CaC movement to successfully influence decision makers reluctant to sustainable agricultural policy, institutional mechanisms for this expressed purpose must be developed. How much of this can or should happen within the NGO, academic, or private (market) sectors should be a subject of serious debate. It is likely that all avenues should be pursued in some form.

Movements and alliances for scaling up and out

To be an effective social movement for sustainable agriculture, CaC may well need to establish broad social alliances for sustainability with other sectors and with actors from Central America's new social movements (gender, environment, urban dwellers, social justice, etc.). Given that many NGOs working in sustainable agriculture also address many of these issues (either within the agricultural project or within the organisation itself), there may be good opportunities for this. However, it should be noted that while NGOs have been very good at introducing issues, technologies and methodologies into civil society, until now, they have not necessarily pursued a strategy for building movements or alliances for social change. Many professionals working within NGOs see their organisation or their project as and end in itself, and not as a means to enable social change. On the other hand, Central America's rich (if violent) political history has meant that activists once involved in movements for social change are still around, many of them are in NGOs working for sustainable agriculture. Experienced or not, these professionals can help develop strategies for "scaling out" through movements such as CaC*,* and "scaling up" through farmer-led, inter-institutional alliances.

CaC illustrates the importance of farmers' movements for developing sustainable agriculture on the ground. Perhaps the most pressing lesson is simply that agriculture in general will change not only when farmers change, but when farmers (and their allies) are capable of changing the institutions that hold change back. We still have much to learn about just how to do that. The formation of international and regional alliances for influencing agricultural research and development may provide a useful way to overcome the present policy impasse in sustainable agriculture.

■

Scaling up, and further scaling up participatory development

Jean Marc von der Weid

Since 1995, AS-PTA has facilitated a successful family-farmer programme in the central-southern part of Paraná, **Brazil**. Thousands of farmers have gone through a process of discovering solutions to their farming problems and thereby improved their understanding of the principles of ecology and agroecology.

This region of Brazil is part of the Atlantic Forest, a very diverse and rich rainforest with a subtropical, cool and humid climate. Average rainfall varies between 1,300 and 1,700 mm per year. The area is hilly to mountainous, with small flat stretches at the bottom of the watersheds. Family farms of less than 50 ha, constituting 90% of all farms in the region, are concentrated on a third of the farmland. Large haciendas account for the remainder. Diverse crops are grown on these farms. Beans and tobacco are the main cash crops, followed by onions, potatoes and *erva mate* (a kind of native tea). Corn is grown by most farmers mainly for home-consumption and fodder. Horses play an important role as draught animals and nearly all family farms have a few heads of cattle, some pigs and poultry.

The farming systems mix traditional and modern features, chemical or organic fertilisers are used depending on the farmer's resources. With generally low average yields, family income varies from US$ 660 to 1020 per year.

The programme initiated by AS-PTA covers 22 municipalities (about 13,000 sq. km) with a population of 250,000 people (roughly 55,000 family farmers).

Farmer experimenters testing herbal herbicides. Photo: AS-PTA

Major problems

Inherent natural conditions like soil acidity and low phosphorous content together with small farmland holdings and reduced fallows, cause a number of social, economic and environmental problems. The lack of financial resources does not allow farmers to take measures to deal with the tendency of soil nutrient depletion and decreasing yields. Steep slopes and heavy rainfall, combined with "up-down" tillage practices causes significant soil erosion. The replacement of traditional bean and corn varieties by improved ones has had devastating effects on agro-biodiversity and crop efficiency. Last but not least, indiscriminate use of agro-chemicals has given rise to toxic contamination among farmers and in the environment, without any significant reduction in pests or crop diseases. Difficulties in access to credit and markets also contribute to low income patterns in the region.

The approach adopted by AS-PTA was to identify major constraints in agriculture through participatory methods and to develop technical solutions through participatory research involving all farmers. Agroecological alternatives were presented by AS-PTA's technical team and by the farmers. These suggestions were then tried and adapted by the farmers on their own fields in small-scale experimental plots designed by them.

Technological innovations

Dozens of possible technologies were tested according to the choice of farmers, either as individual or joint efforts. While any one of these innovations can be adopted on its own (this is not a technological "package"), they proved to be most efficient when applied in combination with each other. Each farmer, having to deal with specific conditions, therefore can chose which innovations to adopt and how to adapt them to his/her concrete situation. At community and regional meetings, the results of these tests were presented and discussed by farmers. Field visits were used to illustrate the better technologies to other farmers. This encouraged others to take up new experiments thus engaging more farmers in the process of discovering more complex and adapted solutions. New participants engaged in the experimentation as information on the first group's results spread through initiatives undertaken by AS-PTA. In order to structure its work, AS-PTA has grouped the proposed technologies into three main technical programmes, along with a few minor ones.

The most widespread programme is on **Genetic Resources** and involves nearly 5000 farmers. It tries to identify traditional varieties of maize, beans and potatoes and to bring them back into general use amongst farmers. The purpose is to seek greater adaptability to a range of environmental conditions and to the farmers' different goals and systems. Genetic diversity of crops has been lost due to strong incentives and policies aimed at the introduction of improved varieties. Such "improvements," however, did not provide the anticipated yield increases as they required a rich soil and a host of external inputs. Farmers could not afford to apply the entire Green Revolution "package," and were, therefore, unable to gain all its benefits. Meanwhile, traditional varieties were disappearing and farmers were left with no option but to use poorly adapted "modern" varieties.

The Genetic Resources programme involved older farmers, some of whom still had seeds of traditional varieties, and tried to encourage farmers to test these varieties for selection. The next step was to identify farmers' seed-production methods and evaluate the more efficient methods. This local knowledge-based process was also used in breeding new varieties and in establishing methods for seed conservation and storage.

The second major programme aims at **Ecological Soil Management**. A broad range of innovations was tested. Many of them have been adapted by farmers in different ways and combinations. These include managing crop stubble without burning, the cutting of native vegetation after fallow periods also without burning, planting along contour lines, the use of winter and summer green manure crops, improvement of fallow land with green manure, changes in spacing for inter-crops, the use of an organic leaf fertiliser known as a biofertiliser (produced by the community itself), the use of a compost produced by bio-dynamic farmers to accelerate the decomposition of organic matter, the use of lime and rock phosphate etc.

As a result, disease and pest problems have reduced considerably since the varieties tend to be selected for resistance and receive more balanced fertilisation than in the chemical NPK system. When needed, copper sulphate (Bordeaux blue) or sulfocalcium applications are used, and the leaf-based biofertiliser also provides protection against pest attacks. Weed control is much more difficult and complex, and is carried out with a locally developed no-till, no-herbicide system.

The third major programme focuses on **Agro-Forestry**. It essentially involves native forestry in the *araucaria* forests (a large pine tree, native to this part of South America), one of the most biodiverse ecosystems in the world. The key crop in this programme is another native plant, the *erva mate*, used to make a tea that is widely consumed in southern Brazil. Official research and rural extension services have been encouraging farmers to abandon their traditional native forestry systems enriched with

Ashes is used to make compost, locally known as 'independence fertiliser' . Photo: AS-PTA

erva mate trees and move to open-field plantations, as used in Argentina and Uruguay. This innovation causes tremendous environmental damage as it stimulates the destruction of native forests while promoting intensive use of herbicides and insecticides.

The AS-PTA worked with a group of farmers with long experience in forestry to find a way of improving the traditional *erva mate* management system. The basic principle lies in accelerating natural plant succession and in combining unexploited forest species with the *erva mate* (see ILEIA Newsletter Vol.16, No.3, pp 17-18). Another aspect of this programme is to stimulate the planting and management of medicinal herbs inside the native forest areas, in conjunction with the production of teas and the dissemination of a system of practical medicine known as "bioenergy".

One small-scale programme that has a great potential for food and nutritional security is the promotion of **family gardens**. Diverse crops are grown in these gardens without the use of chemical fertilisers and pesticides. Women have taken up this initiative as a means of meeting family food requirements.

Strategy, process and methods

From the beginning, AS-PTA ensured that the development process did not conflict with the farmers' spontaneous cultural, spiritual and organisational forms. It was clear that the communities' own histories were fundamental to understanding what they believe in today. It gave rise to an important process of re-valuing knowledge and beliefs deeply embedded in farmers' world views, which tend to remain hidden and not dealt with explicitly by the modern, technical ideologies that disqualify them. Farmers were able to become partners in their work with the AS-PTA because they were respected and understood within the framework of their ideology, culture, knowledge and beliefs.

AS-PTA began its work by creating relations with the leadership in the region's family-farming communities. This was facilitated by hiring local extension agents who had deep knowledge of the social dynamics of central-southern Paraná. Along with the local leaders, AS-PTA chose three communities in which to begin its work, involving about 30 families in two of them, and a hundred in the third. A **participatory diagnosis** about their agroecosystems helped to identify the key problems and their causes, as well as to motivate farmers and their families to get involved in this local development work. This resulted in an intensive process of **participatory experimentation** with the different options provided.

The practices that were being tested and selected in the first three communities were **disseminated** in different ways to other farmers. This included presentations by farmers or technical workers at church services, visits between communities to exchange experiences, collective planning of municipal and regional activities and joint participation in seed fairs and public-policy mobilisations. These efforts aroused varying levels of interest in the region's different communities, resulting in the formation of farmer-experimenter groups and trainers within the region, who then took the message to other communities, trained more experimenters and stimulated more and more exchanges of experiences. There is now an intense movement of farmers around the region, organising itself independently of AS-PTA, and making demands for support whenever necessary.

Training is an essential aspect in this approach, which is not limited merely to techniques taught by the AS-PTA staff, but also seeks to stimulate creative observation and the ability to innovate and adapt. Great value is placed on the farmers' own knowledge of agronomic practices and their ecosystems, which is then combined with new information introduced by the technical staff. One of the technical solutions that raised the interest of other communities was the re-introduction of traditional crop varieties, with selection and breeding done in community test plots. The AS-PTA provided training to a group of interested farmers, who then took it region-wide and made it a common learning experience.

This regional group, now made up of about 45 farmers, took on the training of other experimenters, who in turn went on training their neighbours. Significantly, it is not only the techniques (how to set up a seed field, breed maize, etc.) that are shared, but also the reasons behind the different innovations, and how to test it freely in order to improve and adapt it to each farmer's specific conditions.

Moreover, a Regional Development Forum was created with 15 municipal Farm Workers' Unions and approximately 200 Community Associations, women's and youth groups. The Forum took over the leadership and management of local development and has displayed a tremendous capacity for mobilisation, as was seen in the presence of 30,000 people at a regional event in 1999, called the Land Procession.

One interesting impact of this extraordinary activity of social interaction in the region was the breakdown of cultural barriers amongst communities of different ethnic and religious origins. Joint activities have brought the communities together and created a social identity of family farmers taking on their own development.

Without the intense participation of farmers in the process of producing and disseminating new knowledge, it would have been impossible for the programme to take this impressive leap. In five years, this approach allowed AS-PTA to reach out from three initial communities to 160 farmers, and then to 5,000 farmers.

Impact

Agronomic and economic impacts have been very significant considering that the process is far from reaching all the benefits it has to offer these farmers. On-farm seed production has increased substantially, with significant financial savings for at least 10% of the region's farmers. The diversification of traditional varieties has led to the re-introduction of 112 varieties of maize, 98 of beans, 10 of potatoes and 16 of rice (a secondary crop in the region that was not a priority in the Genetic-Resources programme).

Yields of these traditional varieties compare very well with commercial hybrids and the varieties bred at experimental stations run by the State (Instituto Agronômico do Paraná-IAPAR) and federal (Empresa Brasileira de Pesquisa Agropecuária-EMBRAPA) governments. Simply cultivating the best-adapted traditional varieties, with no other changes in farmers' productive systems, brought increases of up to 50% above the regional average, reaching 3600 kg/ha for maize and 1800 kg/ha for beans. Farms that adopt other agroecological techniques in addition to traditional varieties have attained yields of 5000 kg/ha for maize and 3000 kg/ha for beans.

There are no precise records for the impact on tobacco, onions and potatoes, but the farmers' impression is that the results have been just as positive, even though they are more risk-prone crops. More advanced farmers state that they can market high-quality organic produce, including tobacco, with yields comparable to conventional systems.

Qualitative evaluations done by farmers for *erva mate* yields in the new forestry system indicate that they are higher than in the traditional system and that the quality of the product is much better than in the modernised open-field system. Farmers infer that their yields are close to those of the modernised system mainly because major borer attacks have caused damage to open-field plantations, but no precise field surveys have been done to collect data for proof.

Farmers claim that **savings on inputs** are as much a motivation as are yield gains. For example, the introduction of no-till, no-herbicide planting in maize and bean fields on one farm that plants 5 hectares (average for the region) of these crops produced an average gross gain of US$563. The investment for the introduction of this technology costs US$400, meaning an immediate net gain of US$163. Once the no-till, no-herbicide system is established, yearly expenses are a little over 10% of the average fixed costs. This means that, from the second year on, a farmer can obtain a net gain of over US$500, just in maize and beans.

Another advantage of agroecology highlighted by farmers is the system's **greater resilience**. There is a higher tolerance to and lower occurrence of pests, fungi and nematodes, and less vulnerability to occasional dry spells. Tobacco, potato and onion farmers – who use the most insecticides and pesticides – show great interest in the human-health gains from replacing these inputs due to the many poisonings in the region. Less use of these inputs also implies a reduction in labour costs. Farmers who have a low investment capacity and break-even in the traditional system are attracted to these technologies that have a lower dependence on purchased external inputs.

Exchange of information on traditional maize varieties. Photo: AS-PTA

What is interesting about this programme is the wide adoption of techniques that were not essentially new to the region and its farmers. In fact technologies like green manuring and no-till planting had been promoted for a long time by public research and rural extension agencies without wide acceptance by farmers. Now, over 5,000 family farmers are directly involved in using the techniques, along with an unknown number of others who have been "contaminated" by the participants.

Conditions for the successful results so far

Well-established **community structures** in combination with the recent dynamics in social and political life at municipality and regional levels have been the basis for the achievements of the programme.

Another important factor that could be described as "ideological" is that the conventional Green Revolution model had reached its limits for many local farmers. In addition, the political and social dynamics of the 1980s that had demanded for greater access to Green Revolution facilities had already run its course. In its place, the alternative development model presented by the approach of agroecology and self-reliance has raised the expectations of farmers.

Partnerships between the local technical staff and farmers, and very clearly amongst the farmers themselves, complemented by external expertise, were the key to success. The AS-PTA core staff played an intermediary role in the search for new knowledge that could be assessed, adapted and incorporated by the farmers. Visits to other NGOs in southern Brazil helped to build up a pool of technical options to be experimented with locally.

Partnerships with research institutions were built slowly, and now include collaboration with the University of Londrina (genetic resources), IAPAR – the Agronomic Institute of Paraná (no-till planting), EMBRAPA-CNPAB –National Centre for Research in Biological Agriculture (green manure) and the UFRRJ – Federal University of Rio de Janeiro, Agricultural Development Research Centre (CPDA, public policy assessment). These partnerships are useful for the scientific assessment of techniques and results, and for the identification of bottlenecks and possible solutions or improvements.

According to one external technical evaluator who visited the programme, most of the techniques in use do not involve major innovations, but the way they are used, combined and adapted can be considered revolutionary.

Obstacles and limitations

The programme is currently facing two major limiting factors along with others of secondary importance.

Firstly, the farmers' lack of **access to capital** and the totally inadequate credit system slows down the process of incorporating new technologies. Although these innovations are inexpensive and do not demand recurrent expenses, farmers often cannot afford the investments. Adopting the no-till, no-herbicide technique, for example, demands an initial investment of 40-60% of the average annual family income.

Access to seeds for green manure. Seeds for green manure are expensive and hard to find in Brazil, especially considering the great diversity of species (over 30) used in the programme's experiments. Farmers depend on the on-farm multiplication of green-manure seeds, and therefore take a long time to transform their farms. The AS-PTA provides small amounts of seeds for farmers' test plots. Each of them is responsible for passing on a certain amount of seed to others for experimenting, and to multiply seeds for their own use.

A third major limiting factor has to do with the **market**. A handful of intermediaries control the buying of beans, onions, potatoes and tobacco, leaving farmers totally dependent on them. Consequently, prices are so low that they discourage production. "Why work so hard to change, if the profits end up in the middleman's pocket?" is a common question posed by farmers. These middlemen have also imposed the use of two high-input demanding bean varieties, sold by Monsanto and IAPAR, based on the preferences of supermarkets in Rio de Janeiro who buy most of Paraná's black beans. Trials done with one medium-sized supermarket outlet, however, have shown that consumers are interested in buying traditional bean varieties as long as they are mixed in "blends" with the same cooking time.

The same problem exists with other products, particularly potatoes and tobacco. For potatoes, size, shape and the absence of spots on the skin are more important than taste or nutritional value. With tobacco, the cigarette industry totally controls its contracted farmers, by supplying them with inputs and strictly controlling application thereof. Whatever the quality of the leaves, farmers who do not use the industry's "package" have no chance of selling their harvest.

Other constraints to scaling up the programme are related to the funding available with AS-PTA to support learning and exchange among farmers, to the limitations farmers face in buying small equipment, e.g. a grain dryer; and to public authorities creating countless problems, eg. making loans conditional to the use of "technological packages" or distributing commercial seeds for free.

Proposals to scale-up the programme

Credit will be a key to accelerating the process of adoption. On the short-term, there is no chance that market credit policies for family farmers will change. But, a larger-scale experience in this region with an alternative credit programme could help stimulate changes in the official credit program. The credit agents should be the Community Associations organised in a centralised support structure that would raise and distribute funds. This would simplify access to credit with each farmer's collateral guaranteed collectively, in solidarity, by the community. A loan of US$ 400 per farmer is enough to convert an entire farm. Under normal conditions the gains from the first year's harvest will be enough to pay back the loan.

Also organisation and administration of this flow of funds, including the training of community agents, will be important. There are already some experiences in the region on which to draw upon for organising and training work. The rate of expansion will also depend on increasing the farmers' ability to extend the social dynamic of training and experimenting. This means that the core of experimenters/trainers who lead the region's development process has to be increased.

The third important aspect in gaining scale is market access. To overcome the monopolies limiting the local producers' marketing potential, the family farmers' small cooperatives must have more infrastructure, as well as equipment to process the harvests. This means community grain dryers, drums for seed storage, humidity gauges, scales, sacking machines, sewing machines, elevators, conveyor belts, silos, corn threshers, huskers, greenhouses, *erva mate* processors, classifiers etc. The investment cost, about US$100 per farmer, could be supplied by loans as well. The operating costs of most of this machinery can be covered collectively by participants, as is already the case in today's smaller-scale experiences.

This investment is not aimed at replacing existing commercial agents, but at breaking down monopolies and obliging them to negotiate better prices with the farmers. Channels for direct access to supermarkets in Rio de Janeiro have already been opened, through which farmers' organisations could sell about one third of the total 100,000 tons of black beans produced in the region every year.

Conclusions

Our experience in central-southern Paraná shows how the work of one organisation through intensive social participation has been able to increase, 30 fold, the number of beneficiaries within 5 years. Further scale-ups will depend on greater investments in these new directions for Brazil's rural development. However, this budget is lower (around US$ 35 per year per farmer) than the amount spent on public rural extension services and the cost of agricultural research in Brazil (around US$ 1,000 per year per farmer).

AS-PTA's proposal for central-southern Paraná can point the way to new approaches for rural credit, as well as for public research and extension services. If implemented, the impact of these new approaches on sustainable family farming in Brazil will by far surpass the meagre results shown by the huge volumes of funds spent today in this social sector that includes a great majority of Brazilians now living in poverty.

MERCI (thanks) to our French readers!

In January 2001, ILEIA published a French version of its issue on "Grassroots Innovation" (vol 16.02). This special issue was sent out to over 3000 addresses in French speaking countries of Africa. Of the 1300 that included a reply form, around 200 were returned to us. The response is very encouraging. The French readers complimented the LEISA Magazine with "very well done", "an efficient tool for participatory development", "the Magazine helps researchers and farmers to collaborate closely for a better tomorrow" and many more. They also gave us some good suggestions for improvements and stimulated us to continue with the idea of a regular French language edition of the LEISA Magazine. Meanwhile, we have approached a number of funding organisations to get this project off the ground. We hope to make a start, together with our African partners, early next year.

MERCI, once again, for your stimulating response!
And AU REVOIR

From zero tillage to conservation agriculture

An unexpected success

Sandrine Vaneph and José Benites

Conventional farming systems based on intensive and continuous use of the plough are difficult to sustain in several climatic zones as they cause degradation of the soil. Tillage-induced erosion in developing countries can exceed 150 t/ha annually and soil erosion is responsible for 40% of land degradation worldwide (FAO, 2001). Moreover, yields are beginning to stagnate or even decrease whilst inputs are increasing. In the early 1970s, farmers in Santa Catarina (Brazil) tried conventional terracing as a solution to the problems of continuous erosion and declining yields. The inconsistent results led farmers and researchers to tackle the problems at their source, trying to find solutions to avoid the direct impact of rainfall on the bare soil and to improve water infiltration. What began as green manuring has now evolved to residue-based zero tillage for maintaining a permanent soil cover (FAO, 2000; ILEIA Newsletter 1995, no.3, pp16-17). In 2000, the global area under zero tillage was estimated at 57 million ha, including 9.2 million ha in Argentina and 13.5 million ha in Brazil (FAO, 2001).

Principles of conservation agriculture

Zero tillage (or direct seeding), crop rotation and green manure cover crops (GMCC's) are essential elements in the successful expansion of conservation agriculture in Latin America. Farmers have realised that zero tillage alone is an imperfect and incomplete system in which disease, weeds and pests tend to increase and profits tend to decrease. Research conducted in southern Brazil also shows that zero tillage practices in combination with suitable crop rotations consistently reduce weed infestations (Derpsch, 1999). Based on this observation, a more integrated approach to zero tillage evolved which FAO now calls "conservation agriculture".

This approach implies conformity with the following principles (Benites and Ashburner, 2001):

- No mechanical soil disturbance – direct seeding or planting
- Permanent soil cover – making particular use of crop residues and cover crops
- Judicious choice of crop rotations

Implementation may vary according to the local conditions, problems and means, but zero tillage (direct seeding) is the key technique in the system. Direct seeding implements and tools are often adapted by the farmers themselves or, like in Brazil, by means of collaboration between farmers, technicians, researchers and the private sector (FAO, 2000). Crops are sown directly into a permanent soil cover which can be either residues from a previous crop (or imported straw) or a live cover crop. The permanent soil cover reduces the damaging impact of rain drops on the bare soil, retains soil moisture, regulates temperature, provides organic matter and is a potential source of nutrients.

Zero tillage applied within a conservation agriculture framework has proven to be a feasible farming practice applicable under a wide range of climatic, soil and social conditions, both for large and small-scale farmers.

The farmers-driven adoption process

Conservation agriculture is attractive to farmers for several reasons: it saves time and money, it makes available a longer period for planting, it leads to greater drought tolerance and generally higher yields. Despite these major advantages, farmers are still wary in adopting such radical changes. But in Brazil, the main reason for the rapid expansion of this system is that the farmers themselves are extremely active in promoting them. From the beginning, they have been involved in creating associations and networks, which also involve technicians and researchers from the Brazilian Zero Tillage Association for the Tropics (ZTAT) or the Clubes Amigos da Terra (CAT). These groups and networks provide support to members and have become very effective in farmer-to-farmer spread and acceptance of the ideas and the technologies. They have also begun to develop into significant local pressure-groups pushing for improvements in the policy and institutional environment as well as for political and legal support for their initiatives (FAO, 2001).

Supports to farmers' and NGOs' actions

Since 1995, the Brazilian government has been strongly involved in the process. Several ministries and research institutions are now collaborating with NGOs such as ZTAT and CAT and provide financial support, training of technicians, research support, integration of training sessions in universities, etc. Further support for zero tillage promotion was generated by collaborating with ABEAS (Brazilian Association for Higher Agricultural Education) and the University of Brasilia in the first graduate-level correspondence course in zero tillage in Brazil, in 1999 (Landers, 2000).

However, most agricultural policies still focus solely on increasing production, usually associated with packages of external inputs and technical interventions. In many cases, these policy frameworks are the principal barriers to the spread of more integrated, sustainable and productive agricultural systems (FAO, 2001).

From farmers' field schools to community IPM
Scaling up the IPM movement

Russ Dilts

A people-centred IPM movement has grown in Asia over the last ten years, and is now spreading to parts of Africa, Latin America, and the Middle East. During this period, many variants have evolved, and continue to evolve, within the specific natural and operational environments of different countries, cultures, and communities. From the first Farmer Field Schools consisting of 25 farmers each to a people centred IPM movement, which counts several millions of farmers in many countries (e.g. more than one million farmers have been trained in Indonesia alone), the IPM programme has indeed gone to scale.

Farmer Field Schools - from extension to education

The IPM Farmer Field School programme emerged out of a concrete, immediate problem. Farmers were putting their crops, their health, and their environment at severe risk through massive abuse of highly toxic pesticides promoted aggressively by private industry and government. Pest species were becoming resistant and in some cases resurgent. What was called for was a large-scale decentralised programme of education for farmers wherein they would become 'experts' in managing the ecology of their field – bringing better yields, fewer pest problems, increased profits, and less risk to their health and environment. "Grow a Healthy Crop" is the first principle of the IPM programme.

The basic framework for the educational approach addresses three fundamental learning domains (adapted from Habermas.J):

1. Technical domain of work: If one has ever seen the look on the face of a farmer who doesn't comprehend why he lost his crop, despite all his hard work, one can readily understand the empowerment that occurs when a farmer regains control based upon direct understanding. From this emerged the entire '**Farmers as experts**' approach underlying the Farmer Field School (FFS). In Field Schools farmers themselves learn to conduct experiments independently, create learning materials on their own, manage a 'field laboratory', and plan for special sessions such as 'IPM Field Days' or 'IPM Popular Theatre'. Farmers do not master a specific set of contents or 'messages', rather they master a process of learning that can be applied continuously to a dynamic situation: the ecology of their field.

2. Practical domain of interaction and communicative action: Farmers do not work in a vacuum. Their attitudes, decisions, perspectives, and practices are greatly influenced through their interaction with their peers and community. From the outset the Field School intentionally included processes and methods that would provide such interaction. Participants work together in small groups to collect data from the field, generate analysis through discussion, present results, conduct experiments, and make group decisions for field management. For many farmers, unaccustomed to even speak in front of groups, this confidence building and process mastery is the most important outcome of their Field School experience.

Interaction skills are also addressed directly through exercises in communication, collaboration, group problem solving, and discussion/analysis techniques. The processes used for analysing social reality are in essence the same as those employed in 'discovering' ecological realities in the field. These skills are applicable not only to IPM, but also to everyday life

Members of a farmers association in Central Java reading their IPM newspaper PETANI. Photo: FAO

in the community. These skills do not come overnight, but must be practised and reinforced, and elaborated upon over time. This is assisted by the length of the Field School which lasts across an entire season and is begun with preparatory meetings which also include participatory methods of problem analysis and participant selection such as labour analysis, mapping, and joint 'learning contract' formation.

3. Domain of emancipatory action for empowerment: Emancipatory learning is the next step, in which people examine their internal or group constraints and options as they relate to a larger social, political, economic, and ecological environment. In this sense, the initial Farmer Field School, and even follow-up activities such as Farmer-to-Farmer training, farmer action research/field studies, etc. are just 'starters' for empowerment and local institution building. Further efforts are needed to allow for the evolution of empowerment within the community. Gaining control of one's fields is a first step, but soon farmers run into forces and systems outside their immediate control that must be addressed through other kinds of action.

Going beyond Field Schools - farmers as experts

Through evaluations and case studies we found villages where the cadre of trained farmers had 'captured' their entire community as they continued to spread and deepen IPM. However, in other locations we found that, even where good quality Field Schools had taken place, the programme had vanished with little trace. Based upon this, early in the programme a number of activities we started aimed at strengthening the roots of the programme within the community. Our goal was sustainable farmer initiative and the 'institutionalisation" of IPM at community level - this meant going beyond field schools.

- ***Farmers as trainers*** - We postulated that if farmers could master the process of 'discovery learning' in their own fields, they could also facilitate other farmers in their learning. The first 'Farmer to Farmer' IPM field schools emerged spontaneously. They were then built in as an integral part of the programme. Currently, nearly 50% of all IPM Farmer Field Schools are organised and run by IPM farmer trainers. Over 20,000 Field School graduates have gone on to be trained as farmer trainers and conduct Field Schools for other farmers.

- ***Farmer Researchers*** - Most believed that farmers would be limited to simple experiments and 'demplots'. However, in hundreds of locations farmers are currently engaged in field scientific investigations of complex local problems. Farmers are undertaking programmes previously thought impossible, such as the rearing, breeding, spreading and maintaining of complexes of bio-control agents (parasitoids, virus, bacteria) while training other farmers in their use. Now, IPM 'farmer researchers' are often invited to national research meetings on IPM to present their findings and their programs. Needless to say, researchers unfamiliar with the independence, intelligence, and diligence of IPM farmers are initially shocked.

Community IPM - from expert farmers to empowered communities

Again, we found that while this increasingly complex array of farmer-based activities was of great help in broadening and deepening IPM, the programme still resembled a 'menu' of follow-up activities and dependency upon central and provincial project funds remained high. Institutionalisation of IPM at community level had to be pursued.

- ***Farmers as strategic planners and organisers*** - In many locations networks of active IPM farmers had been established, and many of the functions previously done by government or NGO fieldworkers had been taken over. However, the organisers of most activities, except at village level, remained with outsiders. Within Community IPM, activities were developed that would provide trained farmers with the skills and opportunities to build their own institutions. For this, a number of different fora were initiated, at first funded by the national program. These included seasonal planning meetings for IPM farmers from villages and sub-districts. Herein farmers were trained in participatory planning methods while making actual plans for their groups, allowing plans and planning skills to be honed through interaction with other farmers. Groups were linked across communities and across villages into networks where they could discuss their plans and share experience. Farmers were also trained in methods of 'lobbying' local government and applying effective demand through organising. Once again, the farmers surprise people in their ability to develop thorough and detailed *strategic plans* incorporating problem and social analysis, 'vision', 'principles for action', strategy, tactics, and operational plans.

- ***Farmer policy making*** - As the 'Reformation' period in Indonesia has begun, so has IPM Farmer involvement in local politics since their networks represent one of the few organised institutions composed of true farmers. Most of these activities were focused at the sub-district level, which is seen as a *'strategic universe'* for farmer organising. In Indonesia, the sub-district is the interface between government and other services (banks, markets, etc.) and rural communities. Villages are often too small to provide the scope of institutions that farmer organisations need to interact with to improve their access to resources.

- ***Institutional diversity*** - An array of IPM farmer institutions has sprung up across the country. These vary from single-village focused activities to province-wide 'IPM Farmer Congresses' involving thousands of people. Some IPM farmer institutions have taken the form of networks, with meetings and leadership revolving across specific geographic areas. Others have formed more formal 'associations', some even with the official legal status of 'foundation'. Some have made close links with local government at various levels and serve as training/service agencies for government programmes. Others have linked to local political or social forces, such as Islamic organisations. In the last 6 months, some have even begun to dabble in the heretofore forbidden realm of 'practical politics', organising campaigns and getting IPM farmers elected to village head positions.

  As a point of principle within Community IPM, the training, education, funding, and other opportunities and resources provided do not foresee or proscribe any specific

IPM farmers from Cikoneng in West Java analyse their soils. Photo: FAO

  institutional outcome. The job of outside organisers is to provide tools, methods, skills, experience and opportunity only. It is up to the farmers themselves if they want to organise, for what, and how. At present various forms of IPM farmer organisations are still emerging, growing, dying, evolving, stalling, prospering, disappearing. Current efforts from the 'facilitators' involve bringing farmer organisers into the analytical dialogue through programmes geared to provide farmers themselves with the ability to document and analyse, to 'map' the progress of their institutional initiatives and to formulate ways to further strengthen their efforts.

- ***Institutionalisation and civil society*** -The goal of community IPM is the institutionalisation of IPM at community level. The Gerung case (see box p.21) provides a look at how alumni in one sub-district in Indonesia are working to institutionalise IPM in their villages. Specific organising activities include reactivating farmers groups, organising a sub-district alumni association, and taking advantage of water users associations. The farmers groups are planning and conducting a variety of activities to help farmers overcome specific field problems. The alumni association and water user associations serve to spread the results from field studies to all farmers in the sub-district. Apparently the leadership skills of farmer IPM trainers, their ability to facilitate open processes and group decision-making, has been recognised by local farmers. The farmer IPM trainers have been elected to leadership positions of farmers groups and maintain prominent positions in the water user associations. Local governments have provided funds to support Field Schools conducted by farmer IPM trainers. The provincial agriculture service believes that the activities of IPM alumni will lead to a sustainable agricultural system in Gerung. And having put themselves on the local institutional/ organisational map, alumni organisations are becoming institutionalised through the legitimacy accorded to them because of their activities.

A farmer field school in China. Photo: FAO

An important outcome of community IPM activities as they accomplish institutionalisation of IPM at the village level is that civil society in a given village is also strengthened. Government, non-alumni, and other local organisations are legitimising IPM and the IPM organisations being established in Gerung. This institutionalisation will influence behaviour patterns for all local organisations in Gerung. Hence, the conditions common to a strong civil society are being established. The civil society that evidently is taking root in Gerung will enable the community of farmers in Gerung to better manage the ecological and social conditions in which they live. This will in turn ensure greater stability in food production in the communities of Gerung. Community IPM leads to civil society and civil society will enhance local food security.

Keys to successful upscaling

Despite going against "conventional wisdom and conventional approaches", IPM has grown to be a farmer-driven movement in Asia. Looking closer at the process of scaling up, some keys to success can be found:

- Trusting in people as being able and willing to take control of their lives, communities and environment and capable of dealing with the ecological and social complexities of the programme
- Having a concrete entry point addressing a multi-faceted problem
- Pressing on realising that nothing worthwhile succeeds overnight.
- Developing a shared vision through continuous dialogue and reflections on accumulated experience
- Being aware that methods and approaches are not "neutral" and allowing for human views to be incorporated
- Making efforts to push down roles which reside "at the top" as in the case of strategic planning which is now done at community level by farmers
- Giving room for leadership to emerge, be built up, shared and rotated to maximise "human capital"
- Building "social capital" by helping people to learn to organise towards achieving goals that are worthy
- Tolerating, encouraging and enjoying diversity as the stimulus for learning.

Community IPM as an entry point for Sustainable Livelihoods

For the last 10 years, IPM training programmes in Asia have been pursuing multiple objectives with considerable success - farmer empowerment, conservation of biodiversity, food security, community education, protection of human health and policy reform amongst them. These multiple objectives have arisen from a growing recognition – among governments, NGOs, donors and farmers themselves - of the interdependence of different aspects of development, and the need to put people at the centre of the development process.

These concerns have given rise to the concept of 'sustainable livelihoods'. Within a Community IPM programmes, participatory approaches (including farmer-to-farmer training, action research and policy dialogue) are being used to transform a range of assets (including *natural, human and social capital)* into a number of livelihood outcomes, including security of incomes, food supplies and health, and improvements in rural civil society.

Initiatives of farmers in spreading the message

Experiences from Gerung Sub-district

IPM National Programme efforts established a critical mass of IPM alumni in Gerung. Since 1996, IPM Alumni have been organising several types of activities that, for the most part, they have funded themselves. They have been very active and creative in informing others about IPM and in establishing their own organisational network. They have forged steadily ahead in the development of a local farmer-led IPM Programme.

Farmer conducted field studies - Alumni conducted field studies have increased farmer understanding of ecological issues, to adapt and test out recommendations in local conditions, and to increase alumni confidence regarding their understanding of specific practices.

> "Farmers get worried during the first couple of weeks of soybean growth because of the appearance of bean seedling flies. Although only five percent of the plants may be lost, farmers begin spraying at this time. So that we would know when and at what levels damage could be sustained without significant loss in yields my friends and I set up this study. Planting distances are also important to this issue so we have worked with the farmers of Kebun Ayu Village who are conducting a planting distance study. We will use this study to establish a set of basic practices among the farmers in our Farmers Group in the planting of soybeans."
> - H.Fatuchorrohman, IPM Farmer Researcher

Alumni helping others to learn about IPM - IPM Alumni in Gerung have used all means, formal and informal, to help educate other farmers in the villages about IPM.

- **Religious training as a vehicle for IPM dissemination** - Twenty-nine year old Rusdi Aminullah, a farmer IPM trainer from Lembar Village, serves as a religious teacher at the Madrasah Nujumul Huda in his village. In the classes that he conducts he usually finds a way to incorporate IPM into his lessons.

> "I don't necessarily rely upon the curriculum or the school's schedule. Every time a topic arises that is connected to the environment, nature in general, or health I discuss the basic principles of IPM with my students. I hope to plant the seed of love for the environment that was created by God for the enjoyment of humanity not for humanity to destroy. If I can plant this seed now, they will grow to appreciate the importance of nature. I would be thankful if at the very least they will be able to influence their parents."

- **Dissemination of IPM by women through informal groups** - Women often take advantage of informal situations to discuss household issues with each other. Ms. Syifa'iyah of Lembar Village, an IPM alumni says,

> "I often gather with other women in the bruga (meeting place) and talk about IPM. I also teach at the Madrasah and every time we hold religious instruction for women I slip in information about IPM. I have told them that in this world, if you have rice plants you surely are going to have pests. But if there are pests, there will also be natural enemies that prey upon them. These natural enemies are there to help farmers. I have also talked about the danger of pesticides to the environment and to people."

IPM farmers organising - IPM Alumni have taken their own initiative to create a multi-tiered structure of semi-formal and formal groups. They have established an IPM Alumni Association through which the groups keep in touch with each other. The goal is to develop a system to sustain the IPM movement in Gerung. These efforts are independent of outside agencies.

- **The Bruga as the foundation for an IPM movement** - The custom of people gathering in the bruga of a household has been taken advantage of by IPM alumni to create a foundation for a semi-formal IPM network. The bruga of households are being used as meeting places for IPM discussion groups. These groups form the backbone of a farmer controlled IPM Network. According to Bachriandi, farmer IPM trainer,

> "Spreading information about IPM via bruga is appropriate, we farmers don't much care for formal meetings. At the bruga we can talk about IPM in a relaxed and informal manner without worrying about protocol. Farmers usually gather in the bruga in the afternoon as it starts to cool for a cup of coffee. While families have always had bruga, the role of the bruga has expanded in village life. The bruga serves a greater social purpose. With the advent of IPM an additional role has arisen for the bruga; they now serve as neighbourhood forums to support the spread of information about IPM and to strengthen the understanding of farmers regarding IPM principles. The bruga has given birth to farmers who embody the spirit of IPM. They are changing how they farm."

- **Farmer groups reorganised** - The farmer IPM trainers and other alumni in Gerung Sub-district have provided the leadership to breathe life back into inactive farmer groups. Alumni note that their FFS experience provided them with new ideas and a new perspective on how to work effectively as a group. As alumni brought new energy to their farmers groups, farmers in general learned that alumni had something new to offer both in terms of knowledge and motivation. They have helped members of their farmers groups to improve their farming practices by involving them in learning through field studies. IPM alumni, including farmer IPM trainers, have become the heads of their farmers groups and as such the nodes of an IPM movement. Among their roles as heads of farmers groups, the farmer IPM trainers have worked to connect one farmers group with another via the IPM network that has grown up. Farmers groups have become the second tier in the organisation of an IPM movement in Gerung Sub-district. The farmers groups provide bruga discussion group members with a forum for discussing IPM issues among a larger group of farmers. Farmers groups provide a context in which farmers can plan and effectively manage a variety of activities that respond to their needs.

- **Sub district level organisation** - The next tier of alumni organisations is at the sub-district level.

> "Along with other farmer IPM trainers and IPM alumni we are in the process of creating an IPM Alumni Association at the sub-district level. We feel that the primary activity of the association will be to expand the application of IPM by farmers via the implementation of field studies in response to field problems identified by farmers.",

says Rizalihadi, a farmer trainer involved in setting up the organisation.

- **A mega-tier** - Bachiariandi and Rizalihadi have promoted a new initiative - the inclusion of water groups to form a network that is more inclusive and more extensive than an IPM Alumni Association, a collective of farmers groups, or neighbourhood brugas. The same key individuals, IPM alumni and farmer IPM trainers, are in both, but there is a potentially larger audience for IPM by including water users groups. The heads of water users groups meet regularly. This provides a forum that allows for communication amongst all affiliated groups.

> "Rizalihadi and I agreed to try to expand our organising to truly cover all of the sub-district. Fortunately I am still trusted by farmers to co-ordinate the Collective of Farmers Water Users Association for Pengga Kanan and Rizalihadi holds the same position for Pengga Kiri. We will use this opportunity to spread Field Schools throughout the watershed areas of the sub-district. Wherever the watershed includes another sub-district, we will be active there as well. I get really nervous whenever I see farmers using poisons. Many farmers still don't realise that they are playing with fire. If they are unlucky they could die. We need to stop this. We, all of us farmer IPM trainers, are now actively pursuing this."

says Bachriandi. The network has helped farmers groups to take a co-ordinated approach to their activities. It has enhanced the ability of farmers groups to plan and organise activities, establish methods for sharing and exchange of information.

Scaling up social development

Carl E. Taylor

It is apparent that our current models of development are not working, especially when judged by the fundamental criteria of sustainability and equity. Scaling up of social development is our most urgent problem. It is a pleasant task therefore, to share experiences from the health sector about the complex concept of learning to "go to scale" and its possible relevance to the agriculture sector.

A universal process of scaling up

Our Johns Hopkins Rural Health Research Centre was based in the village of Narangwal at a teaching health centre of the Ludhiana Christian Medical College I had started when developing the first department of community medicine in India in the 1950s. In parallel, at the Ludhiana Agricultural University a remarkable team of international consultants was involved in laying the foundation for the Punjab's fantastic success in Green Revolution agriculture. I learned much from agricultural experts in those days of great enthusiasm when they were leaders in doing development at the level of the farm. Then they shifted from the biological growth model to the blueprint and explosion models (see box). Their successes seemed to grow fantastically and rapidly with massive publicity. But, they became more top-down in scaling up. Unexpected consequences and environmental complications followed from problems such as monocropping, overuse of chemical fertilisers and poorly controlled irrigation. The worst result was that the Green Revolution packages favoured the rich since investments cost too much for the poor. Family farms failed and the rich got richer.

Development experts have wasted many decades of rhetoric arguing whether top-down or bottom-up approaches are best. It is time to declare that the argument is false. This is not an either/or dilemma. We need both, but in a flexible and varying balance depending on local circumstances. There are no universal solutions in development, only a universal process to find appropriate local solutions in a biological growth model.

Three basic principles in building up valid processes of scaling up

Principle One – ***Three way partnerships are essential to maintain an effective working balance between bottom-up and top-down action.***

1. *The community must be treasured and always be in eventual control.* This is the bottom-up component.

2. *In a new role, government and NGO officials must learn to support community empowerment.* This is obviously the top-down component and it is here that most development projects fail because all the reflexes of officials are conditioned to demand that they be in control. A basic conclusion is that officials need to make a tremendous shift in their attitudes and values. They should realise that nothing will facilitate their success as leaders so much as delegation of control. As people close to the action take over the routine and dull tasks of management, it permits those higher in the hierarchy to focus on policy and innovation that will eventually set new directions.

3. *Experts must guide the process by learning how to synthesise scientific innovation with traditional wisdom.* The key concept is that the experts' responsibility is to bring the outside-in. They store and apply knowledge from around the world and open new horizons applying the best of modern science and simplifying it for rapid general use in improving human welfare. However, changing their attitudes and values is almost as difficult as re-training officials.

Principle Two – ***Action must be based on locally specific data.***

Growing experience with participatory methods of data gathering and decision-making shows that one of the commonest reasons for failure of development efforts has been the long tradition among officials and experts that they

GOING TO SCALE MODELS AND CHARACTERISTICS

Blueprint
- Experts select successful interventions from local or international experience
- Blueprint is designed by outsiders and imposed with regulations and targets
- Community participation becomes top-down community manipulation
- Tight supervision and incentives achieve quick results but lose sustainability

Explosion
- Focused interventions selected as national or global priorities
- Tight control and efficiency assured by vertical hierarchy for one purpose but usually duplicating management
- Effective in filling infrastructure gaps if then integrated into whole system
- Social mobilisation can strengthen local system but over-riding local priorities often destructive and not sustainable

Additive
- Bottom-up comprehensive and culturally adapted development at community pace
- Stimulated and financed by outside donor (NGO) usually works well in local area-great impact of inter-sectoral action
- Phasing over to local control often difficult because of dependency and being accustomed to outside pay and equipment
- Too slow to rapidly go to scale or fit into national system; need a top-down enabling environment for scaling up

Biological
- Existing successful community-based projects are selected which demonstrate self-reliant empowerment
- Healthy communities are not mechanical structures but replicating organisms
- Each community becomes a biological growth node for exponential and rapid expansion with infrastructure for enabling environment, sustainability and standards for equity
- Integrated inter-sectoral development evolves naturally as communities learn to demand services for their priorities

deliberately and consistently excluded the people from participating in decisions about their own future. Officials have learned the rhetoric of community participation, but it has in recent decades mainly been used in a distorted form for community manipulation. Data gathering for social development has been treated as a simplified version of social science research. People have been excluded from the process to ensure scientific objectivity. Modern experience is clear that the best way of promoting community ownership and empowerment is to get communities deeply involved in continuing data collection. The more important result is that when the people know how the data is gathered they trust the findings, feel ownership and are motivated to act.

*Principle Three – **Changes in community behaviour produce sustainable social change.***

The most sustainable social development depends not on outside inputs of money or materials but on behavioural change among the people. The changes in behaviour must include all partners. We find that the most difficult part of social change is to change the attitudes, values and behaviour of officials and experts. Calling for behavioural change seems to have similarities to preaching about religious revival. It is easy to talk about but hard to do. Behaviours are embedded in social norms. They change most readily when people experience practical demonstrations that meet their basic or imaginary needs and self interest in promoting the welfare of their families and friends. Most convincing are messages about successful innovation that are transmitted by people like themselves. Biological models of scaling up work mainly because they systematise the process of learning, community by community, in exponential expansion as people teach each other.

Three dimensions of going to SCALE

Through fieldwork in many parts of the world we have observed the biological approach to be the most common pattern for large-scale expansion. It unfolds in an organic way that appears at first hard to describe. But after analysing numerous examples, there appear to be three clusters of commonalties which we term dimensions and indicate by acronyms: When development is initiated by local people, action typically begins with community-based **SCALE One**: they try a few ideas, see success, then try some more. When a cluster of innovations are worked out, that community-based action becomes a demonstration for other communities, or **SCALE Squared**, providing formal training to other communities and refining ideas in an on-going way for greater local adaptation. When a larger enabling environment is created to nurture this process, the demonstrations and ideas to spread; the dimension that unfolds then is **SCALE Cubed**.

SCALE One – *Successful Change as Learning Experiences*
Bottom-up social development has gradually spread throughout the world with successful examples of empowered communities in every country and region. In different places the empowerment process started with varying kinds of projects focusing on innovation, in subjects such as: agricultural extension, income generation for women, education for women, primary health and nutrition care, family planning or small-scale crafts and home industry. A combination of factors that clicked with local culture, available resources and indigenous skills created the synergy to empower the community to continue expansion to a variety of other innovative changes.

Each community must start this process from where it is. The challenge is to identify priority issues that are both locally important and do-able. Because community energy grows mostly from success, perhaps the best starting point is a project that can mobilise the greatest energy – perhaps one involving primary health care, credit for women, forestry, emergency services. The starting point need not be an indigenous success. Who initiated the project is not important (for instance, in addition to community, a NGO, university, or government programme could have started the work.) as long as the community recognises the project as a success and accepts it as part of the community. This acceptance cannot be enforced, as then the community will not believe that it has the competence to continue.

Outsiders often press for action to begin with the most needy, but doing so reduces the chances of sustainability. Development is momentum, and momentum cannot be gained when the first step is uphill. Projects should be targetted at the neediest sections only after there is an example of success to build from. The subgroup that can least afford failure, should not be expected to take the lead position of being the first project where the probability of problems is higher and their competency levels are lower for solving those problems.

SCALE Squared – *Self-help Centres for Action Learning and Experimentation*
Few good interventions can be transferred directly from one setting to another, without some degree of adaptation. People adopt ideas and methods most readily when they see them being implemented in conditions similar to their own by people who are like them.

The central source of power in scaling up comes from a cluster of SCALE One communities which are selected as being representative of a whole region and then the motivation, capacity and resource base is provided to form them into a *learning centre*. Here bottom-up, top-down, and outside-in functions come together. Control of their future must remain with communities, but the extension function requires more active roles by officials and experts. This is where experts bring in and try out new ideas. A SCALE Squared centre is both a community-based laboratory and a school without walls. One lesson builds upon another; findings from one demonstration lead to solutions for new problems, as capacity is built and the knowledge base keeps expanding. These learning centres have two functions.

1. *The first function of a SCALE Squared Centre is educational but with a new learning by doing orientation. The action learning function moves communities beyond concern just for their own progress to intentional extension of the change process to other communities.* The SCALE One communities welcome people from other communities to learn how they can help themselves. In these exchanges and workshops both groups share questions as answers are worked out with mutual benefit. Doubts are cleared when visitors see people like themselves solving problems they struggle with every day. Some development projects spend as much as 50% of their budgets on bringing in consultants to draw up plans and do evaluations. Spending that money on arranging for community members to go to parallel projects and learning centres will almost always yield a far higher rate of return. Taking citizens and policymakers on trips may seem extravagant, but it opens doors to new areas of knowledge and provides role models to help them adapt what they see working.

2. *The second function of a SCALE Squared Centre is experimentation.* Experts from many disciplines are brought in to work with community leaders in the new discipline of participatory research. Their synergistic interaction combines

scientific understanding with traditional wisdom. Those of us who have had the privilege of doing this kind of research know that usually the most innovative and usable insights come from the village people and we can mainly supply skills and tools which they simplify and quickly learn to use even without our sophisticated jargon.

SCALE Squared centres should resist the temptation to become showcases. Communities understandably want status, outsiders want to take credit for having a "good" project, and activists in the community want affirmation. But making SCALE Squared centres look spectacularly good often make unreplicable, both them and the lessons they are trying to teach. As SCALE Squared centres become established in regions, it is useful to form a network for sharing among them; here modern technologies can help extend the reach of traditional experiential learning.

SCALE Cubed – ***Systems for Collaboration, Adaptive Learning and Extension***

Expanding social development successes to all communities in a region requires systems for extension based on a network of SCALE Squared Centres. Experience shows that communities left to their own resources usually do not spontaneously learn from each other. The systems needed for bringing about wider impact resulting in regional change include:

1. *System for sustainable collaboration and partnership* using approaches such as: seed grants; opportunities for communication between and with SCALE Squared Centres; objective critiques of ideas and experiences between communities, officials and experts; and special regional events such as fairs, competitions, concerts, festivals and formal workshops to create a sense of being part of a larger, expanding movement.

2. *System for adaptive learning.* The purpose is to provide opportunities for step-wise learning as communities learn about themselves using annual self-evaluation surveys. They develop an annual work plan and evaluate each year's achievements to do better incrementally. The SCALE Squared Centre provides the framework for testing new approaches to learning.

3. *System for extension of innovations.* I have been repeating the theme that the main difference from the blueprint approach is that in scaling up, the expansion of innovations grows biologically not mechanically in radiating ripples around SCALE Squared Centres. Officials and experts should not try to "remote-control" this extension, but let people do it themselves. However, growth will not happen by itself. Officials and experts are needed to create an enabling environment. They need to change their policies, laws, regulations and administrative infrastructure. People must be given control and very small incentives to change by providing simple resources not available locally. They need to change financing mechanisms, which mainly are designed to favour and suit the convenience of the people with money not those who use the money. They need to change basic relationships with the main service agencies: agriculture, health, education, public affairs, etc. Problems of inter-sectoral cooperation disappear when the communities have the right to ask for help. When communities build up capacity to know who can help and how to ask for it, then cooperation is sustainable.

Scaling up must start with successful communities and ensure a systematic process of replication to permeate a whole region so that all communities become SCALE One in being empowered to solve their own problems of social development. Some SCALE One communities will become SCALE Squared Centres. Other SCALE One communities will simply continue to build on their success, supported by demonstrations from SCALE Squared centres and the enabling SCALE Cubed environment.

If a government is out front trying to nurture the rapid spread of change, this community energy can mount very quickly. Expectations soar, people are ready to sacrifice (and others move in to take advantage) but the exponential potential is obvious. This energy can be quickly sidetracked if people begin to see leaders taking advantage of the momentum they have created.

Six criteria are needed to measure progress in social development

Modern management emphasises the need for indicators to measure progress. We have found that seeking universal indicators is unrealistic. Since every situation and community is different the specific indicators should be chosen to fit the local time and place. However, to have a rational framework, six criteria (within which local indicators need to be sought) must be defined.

1. ***Collaboration around a Shared Vision.*** Communities need to agree on the direction they want to go and a shared vision helps internal collaboration. This can evolve from immediate concerns or from underlying causal influences over time as observed in annual reviews.

2. ***Equity is defined as reaching out to those in greatest need and in providing opportunities to those who have been deprived in the past.*** The only way a whole community can improve overall welfare is when the groups, which have the greatest concentration of priority problems are helped to get better living conditions and lifestyle. In most communities local patterns of discrimination are deeply entrenched and outside pressure is needed to make the elite share. This can be done efficiently when top-down standards are set for communities that can be met only by improving conditions for those who have the greatest problems.

3. ***Sustainability is where most social development has failed and it requires measuring from the beginning for benefits that will last.*** Is development exhausting water, forest, and energy sources or increasing pollution? Are debt loads being incurred that cannot be repaid and will be passed onto future generations? Is change undermining treasured cultural values? There are always trade-offs that must be carefully, unselfishly and pragmatically evaluated.

4. ***Interdependence not dependency is essential for a just and sustainable process.*** Dependency produces victimisation and vulnerability to control by outsiders. In many instances outside assistance has been great in satisfying the egos of givers but has been terrible for the self-reliance that happens when capacity building is a primary goal. Development cannot be bought. Donors often want to pay start up costs to accelerate action but this will fail if this creates expectations both in the community and in neighbouring communities. Outside resources are certainly needed but they should be accepted only if they do not remove control from the community-except for the criterion that assistance must give priority to promoting equity.

5. ***Holistic action at community level is automatically inter-sectoral.*** Breaking development indicators into the bureaucracies' use of agriculture, health, education, etc. destroys the basic need for holism in action. Solving combinations of priority problems leads communities to awareness of underlying causes. Synergistic entry points emerge as each activity opens understanding of new potentials. Together they strengthen the fabric of community and family life to produce a "rising tide" of progress, in which the big boats should not swamp the little and leaky boats.

6. ***Iterative action leads to sequential learning and continuing adjustments in interlinked relationships.*** Using annual surveys a community tries one idea, the next try makes it work a little better, more people bring in their own improvements and behaviour changes to produce new social norms. Iteration gives opportunity to identify those loose ends and fix them incrementally until all fit together with growing precision. Action should not wait for precision to be imposed from external quality standards; instead quality control should depend on internal building of capacity. Once people have agreed on starting a do-able action, it should start while interest is high. Then the emphasis should be to recognise that failures will be frequent. But getting the action right is not as important as getting action going and then improving the process. The amazing thing is that in community development this is what succeeds because people learn from each other and the whole is greater than the sum of its parts.

Conclusions

Bottom-up social development has gradually spread throughout the world with successful examples of empowered communities in every country and region. These examples have convincingly shown that bottom-up social development does work. However, efforts to bring them to scale in large programmes invariably failed: the spark that produced the initial empowerment was lost in moving from an exclusively bottom-up to an exclusively top-down approach. What is needed is an approach, which systematises the process of a learning community. Each community becomes a node for exponential and rapid expansion. Healthy communities are replicating organisms. Integrated and inter-sectoral development evolves naturally, as communities learn to demand services for their priorities.

On Social Capital and Partnerships

SOCIAL CAPITAL means "trust" and "cooperation networks". As a form of capital, it is possible to invest on it to save and to stock it – but it is possible to lose it, too. The principal strategies for "investing" in social capital are:

- Create a "common space" among different institutions (social organisations, NGOs, public sector, entrepreneurs) to identify common goals as stakeholders.
- Make transparent the interests of the different institutions in negotiating common goals.
- Identify the "added value" of cooperation through the different types of support coming from each of the stakeholders. The added value is like the interest rate of social capital.

The main OUTPUTS of social capital are:

- Reduced "transaction costs" among institutions
- Increase in the "cooperation values" in a community or region
- Increased competitiveness of the stakeholders in the market.

How Social Capital Influences Scaling Up Efforts

Technical aspects

- Creates environment for farmers to reach agreements in their organizations to support an "inter-learning process" e.g. in sharing successful technologies
- Allows for agreements to be reached among farmers' organisations, NGOs and the public to promote watershed management and forestry programmes and other natural resource management/protection strategies and programmes.

Political aspects

- Makes way for defining and implementing common policies that promote sustainable agriculture in a local/regional context (e.g. tax reduction for NRM projects, laws to punish pesticide use, etc.)
- Facilitates designing and implementing common programmes for sustainable agriculture in a watershed and mobilising institutional resources (human, financial, physical). For example, the "round table" in the Cajamarca project permitted the municipality to multiply its resources through social and private resources by a ratio of 1:3 (three-fold).
- Demonstrates to the national government the importance of cooperation in a region to raise more funds for the decentralisation process.

Economic aspects

- "Social Capital" makes possible new loans from banks to farmers' organisations (social guarantees among farmers can serve as replacement/alternative to collateral requirements in the absence/lack of property rights to land).
- Makes it possible to design and implement new strategies to "reduce the risk" of markets (new roles among municipal governments, farmers organisations, NGOs, local banks and the private sector can increase the efficiency of institutional resources and to create "cooperative guarantees" to attract investments and loans).
- "Social Capital" among social, public and private institutions can increase the competitiveness of a region in the country (competitive advantages instead of comparative advantages).

Juan Sanchez

Ten fundamentals for scaling up agroforestry innovations

Many research and development organisations accept that the priorities and foci of research must be for development. In this light, the ten fundamentals described below provide the logical common ground on which research and development partnerships should be built.

SCALING UP AGROFORESTRY INNOVATIONS

Learning from success and failures
- *To enhance analytical and systematic learning about the performance of agroforestry innovations and the process associated with scaling up, both at a range of different scales and from the perspective of multiple stakeholders.*

Available germplasm
- *To ensure timely availability of quality germplasm to meet development needs.*
- *To analyse and compare the processes and cost-effectiveness of different methods of supplying and producing sufficient quantities of germplasm.*
- *To build the capacity of development partners, and especially farmers, to produce and distribute, disseminate or diffuse quality germplasm.*

Technology options
- *To identify existing technical agroforestry options that are likely to be appropriate in a defined and characterized project area for farmer experimentation, adaptation and adoption.*
- *To define the social, economic and biophysical boundary conditions (recommendation domains) of new potential agroforestry innovations.*

Farmer-centred research and extension approaches
- *Through participatory research, and in collaboration with development partners, to determine the adoption potential of agroforestry innovations.*
- *Through participatory research, build the capacity of farmers and communities to become agents of change and to take over some functions of existing research and extension bodies.*

Knowledge/information sharing
- *To ensure informed, effective and appropriate decision making by a wide range of stakeholders in the scaling-up process through the sharing of knowledge and information.*

Local institutional capacity
- *To create broad-based support and effective local implementation of scaling-up activities through the empowerment of farmers and local communities.*

Facilitation
- *To mobilize both existing and external expertise and resources to support the process of scaling up.*
- *To assist the coordination and integration of the scaling-up process within and between countries and regions.*
- *To ensure the sustainability and multiplier effect of scaling up through the empowerment of local institutions.*

Policy options
- *To achieve a favourable policy climate for the scaling up, adoption and impact of agroforestry.*

Market options
- *To build local and institutional capacity and develop strategic partnerships in the marketing process.*
- *To improve marketing information systems, define successful marketing strategies and product development plans, and help develop an enabling policy framework.*

Strategic partnerships
- *Expand and strengthen links amongst institutions and organisations with complementary agendas, expertise, resources and "reach".*
- *To improve the efficiency and effectiveness of partnership mechanisms.*

A project design framework for scaling up NRM research

Sabine Gündel, Jim Hancock and Simon Anderson

The overall question addressed during the workshop in Whitstable, UK, was "*what can research contribute to scaling up*". The mix of participants from relevant projects in Nepal, Uganda, Bolivia, Colombia, UK and the Philippines, from the North and the South, from academic and development backgrounds helped to bring out key issues, which contributed significantly to the process. During the workshop the participants discussed the importance of a framework for scaling up and identified strategic elements. The workshop was part of a wider review process facilitated by the Natural Resources Institute on which a report is available.

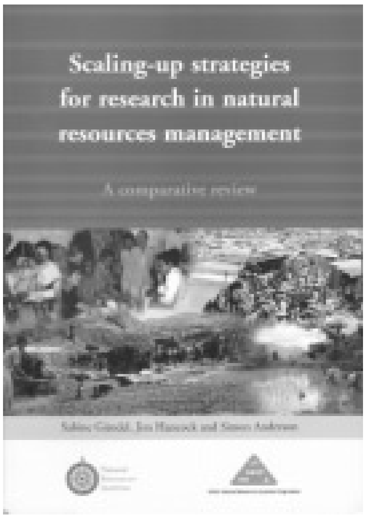
A project based framework

Creating impact from research results has in the past focused heavily on the "post-project" stage. However, many of the key strategies which have been identified as prerequisites for successful scaling up need to be addressed more extensively in the "pre-project" and "implementation" phases. Project oriented

Table 1. Activities, strategic elements and attributes of scaling up processes for NRM research

Project phases	Activities relevant to scaling up	Strategic elements towards successful scaling up		Attributes
Pre-project	Situation analysis	Engaging in policy dialogue on pro-poor development agendas.		Inclusive & plural
		Identify community, institutional, and environmental enabling and constraining factors to scaling-up		Recognise differentiation
		Appraisal of institutional capacity of agencies to be involved in scaling-up required.		
	Identifying target groups	Identifying appropriate research objectives and outputs within development processes to ensure widespread uptake		Consultative
	Setting objectives and outputs			Collegiate
	Developing M&E system	Identify indicators and planning, monitoring and evaluation methods to measure impact and process of scaling-up		Participatory
	Collaboration	Building networks and partnerships to increase local ownership and pathways		Constructive
	Funding mechanisms	Develop appropriate funding mechanisms to sustain capacity for expansion and replication		Innovatory
Implementation	Capacity building	Building capacity and institutional systems to sustain and replicate		Vertical sharing
	Institutionalising			Start early
	Partnership forging	Demand, supply & support actors identified.	Other resource organisations contribute with products and by building technical capacity	Collegiate
	Networking			Inclusive
	Awareness raising	Multi-media dissemination of findings.		
	Policy dialogue	Aggregate and assess findings from individual projects and derive policy relevant information		Pro-active
	M&E and Support studies	Central to scaling-up processes in providing evidence to influence policy-makers, in deciding what should be scaled-up and how this might be achieved		Participatory Plural Post-project
Post-project	Exit strategy	Concerted action required on a regional level		Concerted
	Dissemination	Should involve the target group as disseminators		Accessible
	Impact assessment	Built upon M&E. Representatives of target part of assessment team. Technological and livelihoods assessment required.		Participatory

development activities can be criticised for being too donor driven, time bound and often too narrowly focused in relation to the wider context. They do, nevertheless, serve as a primary tool in terms of moving from ideas into action. We have therefore chosen the broad flow of project design to develop a framework for scaling-up strategies.



The full version of the review document can be obtained from NRI

Table 1. shows the proposed framework for guiding scaling-up of NRM research. It links, chronologically, key elements which strengthen the likelihood of successful scaling up. In general, we advocate that scaling up should be considered during early stages of planning research activities. However, the strategic elements, while essentially recommended at the pre-project phase also have a bearing throughout the project and programme implementation phases. They can be used at different entry points in a research implementation process: reviewing ongoing work, as well as finished research projects with existing potentially useful outputs. It may also serve as additional material in evaluations of research programmes.

Key strategic elements for successful upscaling

1. ***Engaging in policy dialogue on pro-poor development agendas***. Research needs to be placed in the context of local, regional and national development agendas as this helps identify key entry points and the major needs. This is ideally done at an early stage so as to shape the overall project design, but can also be done through regular reviews of the project or at other development discussions.
2. ***Doing situational analysis to identify community, institutional, and environmental enabling and constraining factors to scaling up***. The likelihood of scaling up will be increased if key hindrances as well as opportunities are found out at an early stage, thereby allowing key channels for scaling up research activities and development outcomes to be identified. All enabling and constraining factors cannot be identified at the outset and so the research activities (project) will need to build in mechanisms to review new issues and plan around them or with them. This is crucial in terms of addressing the real priorities of target groups, as well as in identifying catalysts for scaling up.
3. ***Identifying appropriate research objectives and outputs within development processes to ensure widespread uptake***. Rather than identifying outputs and forms of dissemination just at the end of research, these should be shaped at an early stage together with stakeholders and users, and subsequently modified throughout the project. These outputs may include identification of solutions, which can be very technical in nature.
4. ***Identifying indicators and planning, monitoring and evaluation methods to measure impact and process of scaling up***. Should be central to scaling up processes in deciding what should be scaled up and how this might be achieved, and in providing validated evidence to influence policy-makers. To manage, learn from and gain credibility, methods and measures for assessing pro-poor and NRM impact on different scales needs to be elaborated. The intermediate supporting processes and institutional changes to achieve this will also need agreed measures and review mechanisms. Various participatory methods are vital to ensure open feedback. A major area of this work is in identifying cost-effectiveness, so as to work towards it.
5. ***Building networks and partnerships to increase local ownership and pathways to scaling up***. In order to achieve the above elements, researchers and their institutions need to develop relationships throughout the process which can then develop into firmer partnerships with development and other institutions, always with a firm link to the grassroots and end users. Personal relationships also foster direct interest and enthusiasm, increasing the chances of institutionalisation and spread of ideas.
6. ***Building capacity and institutional systems to sustain and replicate***. The capacity to manage 'learning through doing' is critical for scaling up to be an on-going and dynamic process. It is also important especially in the implementation and exit stage to internalise new ideas within institutions, especially within communities and government.
7. ***Developing appropriate financing mechanisms to sustain capacity for expansion and replication***. Maintaining flexibility and ensuring funding for softer activities (local and regional networking, capacity building, consultations) is considered in the pre-project stage. At the same time, one has to begin building ownership through clear shared resource commitments to activities. Seek opportunities for self-sustaining results in research outcomes, or at least mechanisms for reducing costs when expanding, replicating etc. Take into account the very real dynamics between technologies and wider economic spheres, and financial constraints facing local and government institutions.

The strategies and framework proposed are not prescriptive and have to be understood as a guide only. The limited number of successful cases in scaling-up research shows no absolute strategies or prioritisation of elements.

Major implications for research

The adoption of the above framework for guiding future research projects and programmes will have major implications for researchers and research programme managers:

- Project calls have to be addressed towards institutions and organisations in the target regions to strengthen the implementation of a demand-led approach.
- Shifting the emphasis of research to partners in developing countries may require the development of regional capacities in terms of demand-led approaches, sustainable livelihoods and scaling up and development of partnerships, and innovative means to fund, monitor and evaluate these strategies.

The implications for researchers and their institutions are:

- The establishment of functioning partnerships with in-country agencies, particularly in terms of working within participatory development processes and producing outputs suitable for addressing and communicating local and regional situations.
- That researchers and their institutions have to become accountable in their contribution to scaling up, which in turn requires the identification of indicators that show research effectiveness in terms of extent of impact.

Going to scale

What we have garnered from recent workshops

Julian F. Gonsalves

Agricultural and Natural Resource Management (NRM) research and development projects often have too little impact in terms of farmers reached, poverty reduced, sustainability of the development process or influence on policy. Researchers and development workers are therefore constantly being challenged by colleagues, funders and policy makers to maximise impact and "scale up" the development process. In the present situation of reduced financial support to agricultural research and development (R&D) the interest in "Going to scale" is growing. Larry Harrington and colleagues (2001), in a paper presented at the NRM research meeting in Penang, warn us that if insufficient attention is given to scaling up, "*we will have failed in our purpose of contributing to poverty alleviation, food security and environmental protection*".

Evaluations of programmes are necessary to understand which approaches to scaling up are most effective or to show the effectiveness of new approaches, for example in participatory development. In the past two years, there have been at least four international events dealing with scaling up. ICRAF sponsored a workshop in September 1999, at Nairobi, looking primarily at how agroforestry innovations should be scaled up within a research and development framework. Two events were sponsored by the CGIAR NGO Committee and the Global Forum for Agricultural Research, (one held in October 1999 at the World Bank in Washington and the other in April 2000 in Silang in the Philippines). The most recent event focussed a bit more directly on NRM research: this was held at Whitstable, sponsored by the Natural Resources Institute UK in January 2001.

The approach, in at least three of the four workshops, was to use cases and participants' own experiences to derive common principles. Although the case analysis did not allow for drawing up any general models, some important principles and lessons were identified at the workshops. The goal of this article is to discuss these principles and lessons with the purpose of improving our general understanding of the process of scaling up. Some references are also made to relevant important literature.

Several of the cases presented in the Philippines workshop are included in this issue of the LEISA Magazine.

What is scaling up?

The first emphasis of scaling up is on reaching *larger* numbers of people. Also, the need to get specific innovations and methodologies accepted by conventional (mainstream) research, development and policy institutes in order to bring about institutional change is sometimes referred to as scaling up or "mainstreaming", especially by proponents of participatory approaches (Long, 1999).

With the renewed focus on poverty alleviation, questions of equity and distribution of benefits are invariably raised. Given the wide interest in the subject, it is probably not surprising that participants in the Philippine and Washington workshops arrived quite quickly at the following multidimensional understanding that ***scaling up leads to more quality benefits to more people over a wider geographic area more quickly, more equitably and more lastingly***. This operational definition has served as a basic assumption and starting point in subsequent meetings.

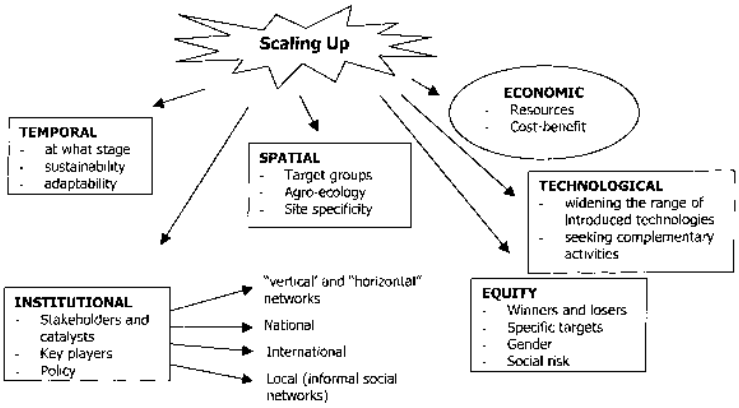

figure 1: A framework to summarise participants' understanding of the contexts of scaling up

Figure 2:
GOING TO SCALE
More Benefits, More People, More Quickly
As one goes up higher the institutional levels (vertical scaling up), the greater the chances for horizontal spread; likewise, as one spreads farther geographically (horizontal scaling up), the greater the chances of influencing those at the higher levels.

VERTICAL SCALING UP is higher up the ladder. It is institutional in nature that involves other sectors/ stakeholder groups in the process of expansion - from the level of grassroots organizations to policy-makers, donors, development institutions and investors at international levels.

HORIZONTAL SCALING UP is geographical spread to cover more people and communities and involves expansion within same sector or stakeholder group. Others refer to it as a scaling out process across geographical boundaries. Achieving geographical spread is also realized through scaling down - increasing participation by decentralization of accountabilities and responsibilities particularly in breaking down big programs into smaller programs/projects.

Types of scaling up

Among the first to discuss types of scaling up approaches was Clark (1991) who, in examining the work of NGOs, distinguished between three types of scaling up: ***project replication***, ***building grassroot movements*** and ***influencing policy reform***.

In their paper to the Philippine workshop, Uvin and Miller discuss in considerable detail a taxonomy of scaling up. They suggest looking at scaling up in terms of structure, programme, strategy and resource base, and propose four types of scaling up: quantitative, functional, political and organisational (Box 1).

Carl Taylor, on the other hand, using primarily his experience in the health sector, has suggested four models of going to scale: ***blueprint***, ***explosion***, ***additive*** and ***biological*** (see box Carl Taylor p.14). He makes a case for what he calls a biological model for scaling up involving a number of stages. Action usually begins at the community level and starts with a few simple ideas. With success more ideas are tested. When a cluster of innovations are worked out, that community based action becomes a basis for learning by other communities. These communities serve as learning centres. Other communities learn from that experience and adapt it further. Finally, when a larger enabling environment is put in place the ideas spread rapidly. These approaches are discussed in more detail in his article on page 14 and in his forthcoming book.

At the Washington meeting, an attempt was made to systematise the various perspectives of scaling up arising from the workshop discussions (see figure 1). There is the spatial dimension wherein technologies spread to larger numbers of farmers over a wider area. However, this should also include helping communities strengthen their ability to solve their own problems. The temporal dimension refers to the need to know when a certain technology or process can be scaled up. The economic dimension reminds us that the cost effectiveness of the effort has to be kept in mind. Does the availability of resources to scale up guarantee that the efforts of an institution will be sustained? The technological dimension often includes the need to diversify the range of technologies or to implement complementary approaches in order to achieve synergism. Scaling up is always multi-dimensional, involving technological, process, institutional and policy innovations.

Vertical and horizontal processes: up, down and out

One of the more easily understood concepts is that scaling up has both *vertical* and *horizontal* processes. The vertical process represents efforts to influence policy makers and donors and is

Box 1. Four types of scaling up (Uvin and Millar, 2000)

Quantitative: A programme or an organisation expands its size by increasing its membership base or constituency through increase in geographic area or budgets.

Functional: A community-based programme or a grassroots organisation expands the number and the type of its activities e.g. from agricultural production to health, nutrition, credit, training, literacy, etc.

Political: The organisation moves beyond service delivery towards empowerment and change in structural causes of underdevelopment. This usually involves active political involvement and the development of relations with the state.

Organisational: Community-based programme or grassroots organisations increase their organisational strength to improve the effectiveness, efficiency and sustainability of their activities. This is through diversifying fund sources, increasing level of self-financing/income generation, assuring the enactment of public legislation earmarking entitlements within the annual budgets for the programme, creating external links with other organisations, or improving internal management capacity of staff.

generally institutional in nature. The horizontal process refers to the spread across communities and institutions and geographic boundaries (see figure 2).

Larry Harrington and colleagues (2001) introduced the following ways of understanding scale as it is applied to NRM work:
- ***Scale of analysis:*** from plant to plot to farm to watershed to regional scales;
- ***Scale of intervention point:*** "high-level" interventions (e.g., policy change, adjustments in institutional arrangements or property rights, fostering of collective action) vs. "low-level" interventions (e.g., programme of farmer experimentation or extension on specific NRM practices);
- ***Scale of investment*** in intervention strategies: small vs. large investments in extension, in farmer experimentation programmes or in efforts to inform policy;
- ***Scale of community empowerment:*** the number of communities with capacity to undertake their own research and adaptation through processes for local learning;
- ***Scale of geographical coverage*** of an NRM practice: whether the practice is limited to a village or watershed, or whether it has attained regional or national significance;
- ***Scale of impact***, e.g., the extent to which desirable outcomes (improved system productivity and resource quality) are achieved through NRM research.

Farmers, NGO and government staff learning about vegetative strips in farmer's field. Photo: ICRAF

The scales are linked and greater impacts are generated from higher levels of investment in suitable interventions or from more efficient use of these investments through reliance on community empowerment leading to expanded geographic coverage of suitable practices.

No to blue prints and cookie cutters

The strong interest in *planning* for scaling up could lead to an undue reliance on predetermined activities and strategies. There were early reminders from David Korten and Carl Taylor (p.14) about the limitations and dangers of relying on blueprints. Carl Taylor warns us that ***there are no universal solutions but only universal processes*** in social development work. At the Washington meeting, Norman Uphoff stressed that what we need is frameworks and not blue prints and that too often we try to find straight line solutions and to routinise innovation. Standardisation is often stressed, but what we probably need is systematisation, which is less "strict". Uphoff warned participants of the dangers of viewing scaling up as merely replication (the cookie cutter approach) since quality scaling should involve multiplication through adaptation not replication. It is probably in this context that the limitations of model and pilot projects are also increasingly being raised. The emphasis on strengthening organisational and learning capacities emphasised by numerous participants (probably the single most mentioned concept) results from an appreciation of the concerns raised by Korten, Taylor and Uphoff.

Building capacities to innovate and the learning process approach

To achieve scale and to also ensure sustainability in programmes of technological enhancement, the strengthening of local capacities to innovate may often be just as or even more important than the technologies themselves. Knowing and understanding the underlying principles are crucial. Strengthening peoples' capacities to innovate were often mentioned in the four workshops as being important in up-scaling and sustaining impact.

Knowing the principles behind a technology and improving capacities to innovate helps communities cope with changing environments and new problems. Many feel that technologies are usually adapted not adopted. One example of wide-scale adaptation by farmers can be seen in the Landcare programme in the Philippines (p.31), where thousands of farmers have decided to adapt a range of soil conservation approaches based on a basic principle of vegetative strips across contours. Farmers utilise the contours in a diverse manner, some letting vegetation establish itself while others enhance the grass strips by planting fruit and timber trees species. Still others plant annual species and short-term perennials or use the contours to raise fodder grasses.

Farmers, communities and local organisations that are exposed to a wide range of available best practices can locate which ones are relevant to their particular situations. The usual approach here is to talk about the value of a basket of technological options. Presenting farmers with options could foster or strengthen the drive to innovate or adapt.

Divergence of methods

Peter Horne of CIAT made a point at the Washington workshop about the value of a divergence of methods. This, he said, was good primarily because of the huge complexity from site to site. He felt that local people needed to be assisted with resources and knowledge to deal with the complexity in their own situation. If the capacities to innovate are to be strengthened, farmers probably need not only a wider diversity of technologies but also a wider diversity of methods or approaches. The ICRAF meeting referring to collaborating institutions indicated that in order to learn from successes and failures with using these diversities of technologies and methods, there was a need to develop an analytical learning culture amongst partners.

The ongoing documentation and systematisation of experiences with wide ranges of technologies, strategies and methods is a useful tool for discovery and dissemination. These best practices must guide the process of scaling up: systematisation of lessons needs to be planned for, if successful sharing is to take place at different levels. Unfortunately there is a lack of documentation on best practices dealing with sharing between farmers, NGOs and different institutions.

Partnerships and alliances

The nature of most efforts to scale up involve a multiplicity of players and it is therefore not surprising that all the four workshops stressed the importance of institutional collaboration and partnerships. Many would argue that partnerships are an essen-

Farmer to farmer exchange: a very effective means of dissemination. Photo: PMHE

tial element of a strategy to scale up: to reach larger numbers of people in horizontal scaling up, a wider range of organisations might be involved. The need for widening the representation of stakeholders, especially policy makers and local leaders was also stressed. Involving a wide range of actors at different levels also helps capitalise on different strengths among various players. In vertical scaling up, efforts are directed towards reaching policy makers and planners, which may need the involvement of a lesser number of organisations.

The ICRAF workshop stressed the value of a strong network of partners with shared and complementary agendas. There will, however, be a need to continually review the agreements on collaborations and exit strategies. Partners must accept that collaboration has its own costs and resources must be set aside for this.

Ownership and social capital

However, as was emphasised in the Washington meeting, merely engaging multiple stakeholders in a consultative process is not adequate to build ownership. Instead, strategic alliances need to involve the participation of a broad range of stakeholders as early as possible and in different stages of the project cycle. The report of the Whitstable meeting (Gündel and Hancock, 2001), which focused on project cycle dimensions, pays special attention to this. It reminds us of the need for flexibility at all stages and the need to avoid rivalry in terms of ownership of innovation as it is not the technologies which matter as much as the process.

It is indeed a reality that competition and mistrust between players exist in almost all situations and that these are considered as impediments to scaling up efforts. Inter-institutional collaboration and coordination is not only important, it is crucial and a prerequisite for maximising impact. However, we are reminded that reaching consensus and gaining commitment from the different stakeholder groups are important first steps. In this context, several references were made by Juan Sanchez at the Washington meeting about the value of social capital (Box, p.17). He emphasised the value of the '*mesas de concertacion'* (roundtable discussions involving community members, their local government and those engaged in R&D). It was felt that efforts to enhance and strengthen the social capital would improve the quality of partnerships and foster increased networking. The value of cooperation is stressed, whether in arriving at common policies or in joint action. Different institutional interests are considered in negotiating strategies. Transparency and accountability of the different partners is fostered.

The driving forces: building upon "sparks" and "champions"

The urge to scale up is often associated with the need to expand initially successful small-scale experiences or pilot projects. From the Workshop discussions, participants identified other driving forces or "sparks" that stimulate technologies, processes, principles, programmes, organisations, etc. to be scaled up. While the initial successes continue to be recognised as providing the sparks, the "timing" (when they come) remains to be properly analysed. Sparks come unexpectedly – and they tend to come from everywhere. They may be generally unpredictable. Examples of such sparks are:

Local champions - people or individuals within institutions can be driving forces to the scaling-up process. These can be people with unique skills within the community who are strongly motivated to initiate and support change.

Development practitioners - to show impact and account for their work, practitioners need to achieve the numbers, i.e., scale up without necessarily sacrificing quality. This desire to reach out to more people in more communities to prove that they can make a difference can provide the sparks for development programme to go to scale. These sparks come about as practitioners try to empower people or shift power or authority towards a desired state or try to be simply of help to farmers.

Support groups - stakeholder groups external to the community, like donors and parent organisations of local groups and the people behind them – development workers, extensionists, researchers, etc. can be sparks as well. These include people who are eager to share with others and consequently get widely recognised.

Success in small-scale initiatives can provide inspiration to go to scale.

Crisis - crisis situations and the raising of questions on where technologies, projects, programmes, etc. should lead to - can also become sparks.

However, Carl Taylor warns us, that in moving from a bottom-up to top-down approach, the spark that produced the initial empowerment can be lost. Experts can "engineer out the spirit and human energy that gives heart, motivation and life to the process."

While recognising the value of champions, many participants cautioned about the fragility of a process championed only by a single person. This is probably why the IDS Participation studies (1999), while reinforcing the importance of champions also reminds us about the challenge for the future to multiply the number and effectiveness of champions, especially local ones. Relying too much on a single champion could affect the long-term sustainability of the effort and limit its expansion to other areas. One has to find and support champions wherever they are - in government, in donor agencies, in civil society etc.

The critical role of markets as driving forces

The Washington and Nairobi meetings put a considerable amount of emphasis on the value of markets in influencing scale. Paul Rice at the Washington meeting had three core messages for participants: 1) all farmers produce to market – they need to produce but they also need to sell and earn; 2) farmers need to organise themselves to achieve economies of scale to produce economically and profitably; 3) consumers are increasingly concerned about social and environmental concerns and are often willing to pay more for quality products. Farmer

organisations can help their member farmers take advantage of the economies of scale and better prices. Co-operations marketing large volumes of produce can negotiate better prices and access distant markets. But, for many farmers it is also equally important to recognise their need to reduce risks.

Participation and scaling up

In all the workshops discussed in this report, the question invariably arose about whether participation is sacrificed during efforts to scale up. Uphoff, Esman and Krishna (1998), in their review of cases, cite the case of the National Dairy Development Board's work in India which indicates that, inevitably, there are risks of "dilution and diminution of effort" and that patterns of organisation and operation were compromised in scaling up. However, the authors emphasised that the criterion of success is whether the capacity for collective action that has been fostered is used by rural people to improve their lives in other ways.

At the Silang workshop, the issue on how to *maintain* not only adequate levels of participation but also how to assure quality in expanded programmes was raised. While believing that participation should not be sacrificed in scaling up, many participants felt it was inevitable. A lack of participation however, could also mean that benefits are not being maintained. It could also suggest the existence of tension resulting from different paradigms of development e.g., top-down approaches used in a government bureaucracy and the bottom-up approaches of NGOs. However, if a right approach is used, a NGO-GO link can help NGOs to *mainstream* participatory approaches that they have developed or are engaged in.

Broad-based grassroot level movements can also provide the pressure to bring about change at higher levels. An initiative like a farmer field school can be important, because these are often precursors of local institutions (e.g., farmers' associations). The large-scale, people-centred IPM programme in Asia has built, over the last decade, local capacities to engage farmers in active learning. A decentralised farmer-led approach, we know, has been useful in tackling location-specific demands of tropical agroecology (see Dilts, p.18). However, this programme also involved a process of large-scale re-education, often using training as the initial strategy.

Planning for scaling up: implications for project design, monitoring and evaluation

The Whitstable workshop raised a concern about the fact that in natural resource management research projects, the issue of scaling up is only addressed in the *post-project* phases. In other words, scaling up is not thought of earlier nor is it planned for. Participants at the workshop in Silang came up with a checklist to facilitate planning. Participants of the ICRAF workshop made an overview of the fundamentals of scaling up agroforestry research (see p.13). The Whitstable meeting identified key strategic elements for scaling up activities in the pre-project, implementation and post-project phases. All of these have implications for project design for which a guiding framework was created (Gündel et al, p.11).

One important implication is the need for donors to fund a pre-project phase where a considerable amount of time and effort is engaged in situational analysis, defining target groups, objectives and outputs and a monitoring and evaluation (M&E) system. This also involves an engagement in policy dialogue on a "pro-poor" agenda. The Whitstable report also suggested that the focus on M&E should be established at an early stage but not necessarily with rigid indicators but "*with initial ideas of what aspects of process and what levels of impact will be addressed*."

In their book, "Reasons for Success", Uphoff, Esman and Krishna (1998) raise concerns about donors being wedded to the project approach despite evidence that this is not a good way to use resources. They believe that if a project is carried out in a learning process mode, many of the pitfalls of a blue print orientation can be avoided. The authors call upon donors, especially when they have confidence in a certain approach to rural development and certain leadership and model of operations, to fund programmes on a "*wholesale*" rather than a "*retail*" basis, allowing for flexibility and complementarity. The bottom line, according to Uphoff, Esman and Krishna, is that while funding is required, "***successful rural development programmes depend more on ideas, leadership and appropriate strategies than money!***"

Lessons for scaling up LEISA

Editorial

In a bid to guarantee food security for all, policy makers argue for a doubling of food production in the next two decades together with poverty eradication. What's more, they expect such increases to be brought about with no added pressure on natural resources. Farmers, as primary producers, want to survive, stay in business and increase their income, and therefore wish to raise productivity, reduce costs and minimise the negative impact of their production systems on human health and the natural resource base. Clearly, policy makers, researchers, development workers and farmers have a common interest to improve agricultural production. However, agricultural development is complex and diverse, and stakeholders often do not agree on the remedies and strategies that are best.

Many research and development programmes try to address the above objectives. Although there are many successful cases around the globe, only a few of them are spreading fast. To optimise returns to effort and spread impact to as many farmers as possible, it is important to analyse which approaches are successful and why. How these approaches contribute to the different objectives of sustainable agriculture, and which research and support methodologies are most effective in enhancing agriculture development and large-scale application should also be analysed. It is increasingly understood that conventional Green Revolution (GR) agriculture and top-down research and development approaches have strong limitations. This explains the growing interest to learn lessons from alternative approaches that have spread to many farmers - 'gone to scale'.

Recent workshops on 'going to scale'

To learn about the factors that influence 'going to scale' of agricultural research and development, leading to '*more quality benefits to more people over a wide geographic area more quickly, more equitably and more lastingly'*, four recent workshops (Gonsalves p.6) brought together information on approaches which are spreading fast. Although these workshops mainly focused on the methodological aspects of research and development and less on impact, the cases collected for these workshops give interesting examples of present success stories, with insights into enhancing and constraining factors for scaling up. In this issue of the LEISA Magazine we include the main findings of these workshops (Gonsalves p.6; Guendel et al p.11; ICRAF p.13) and a selection of the most interesting cases. Several additional cases are also included and reference is made to some cases published in earlier issues of the LEISA Magazine (ILEIA Newsletter).

Success stories

As we see it, there are 3 groups of success stories:

- Success stories from conventional high-external-input agriculture: Integrated Pest Management (IPM; especially in irrigated GR rice in Southeast Asia but increasingly in other crops and parts of the world) and Zero Tillage (ZT; especially in commercial rainfed agriculture in Latin America). These approaches are now being embraced by millions of small and large farmers, some of them combining both. The benefits of these approaches are clear: lower costs and higher income, less damage to human health and the environment (IPM), significant reduction of soil erosion (ZT) and increased production. In Southeast Asia more than one million small and larger farmers have been introduced to IPM in so-called Farmer Field Schools. The focus in IPM is gradually shifting from pest to crop to system management, and from a technical to a community approach, which in Indonesia is becoming a social movement of farmers (Dilts p.18). ZT first spread rapidly among large farmers, but now even small farmers are adopting it, as technology adapted to their conditions is becoming available. ZT in Latin America is basically developed by farmers but is now getting massive support from research and government (Vaneph and Benites, p.22).
- Success stories from semi-subsistence, low-external-input agriculture using entry point technologies such as cover crops (LEISA Magazine 13.3, p.12-13), water harvesting (Verweij p.43; CSE p.46; LEISA Magazine 16.1, p.11-15), natural vegetation strips (Catacutan et al. P.31) and traditional seed varieties (Von der Weid, p.23 ; Zhardhari LEISA Magazine 17.2 p.19). These technologies are spreading among thousands of farmers, often supported by NGOs. The innovation process is strongly driven by participatory farmer experimentation and farmer-to-farmer exchange evolving into social farmer movements for development of agroecological agriculture such as Campesino a Campesino (Central America; p.27), Landcare (Philippines; p.31) and Nayakrishi Andolon (Banglandesh; LEISA Magazine 17.2, p.16-18).
- Success stories from organic agriculture, sometimes in combination with fair trade (ILEIA Newsletter 14.4). This trend is a result of increasing ecological awareness and market demand for 'healthy' organic products, especially from consumers in rich countries.

From natural vegetation strips to agroforestry, Landcare in Mindanao, Philippines. Photo: ICRAF

An overview of the main success stories and their impact has been published by Pretty and Hine (2001): *Reducing food poverty with sustainable agriculture: a summary of new evidence* (see also LEISA Magazine 17.1, p.21).

Towards agroecological agriculture

All these success stories show that situation and farmer-specific entry point technologies are very important as they bring fast economic results, make further investments possible and create the enthusiasm, motivation and self-confidence necessary to further develop more integrated agroecological agriculture (LEISA) and sustainable livelihoods (Mahajan p.48). Later these technologies may become less important, as broader and more flexible sets of technologies are adopted, depending on changing needs, conditions, problems, insights and skills (Sherwood and

Larrea, p.30). Zero tillage farmers in Brazil, for example, have realised that herbicide based no-tillage is still far from sustainable and are now developing a broader approach: conservation agriculture (Vaneph and Benites, p.22). In all these cases, farmers have learned to use local natural resources and ecological processes in more efficient ways, to reduce the use of costly external inputs and to intensify agriculture ecologically. Thus, monoculture systems gradually evolve into integrated systems. In general, ecological intensification also leads to higher ecological sustainability and resilience (Holt-Gimenez p.27). In most cases (except in organic agriculture), farmers do not exclude agrochemicals completely but use them cautiously in a way that is appropriate for their specific economic conditions (Ruben p.52). Reduction of the use of external inputs and development of integrated agriculture, however, may only happen after farmers have experienced the negative impacts of monocropping (Verweij p.43). The drive towards agroecological agriculture is strongest in subsistence conditions where agrochemicals are too expensive to use, credit is not available and farming has to satisfy a wide array of subsistence needs (Von der Weid p.23). Nevertheless, this drive also exists in commercial agriculture where farmers and researchers try to develop integrated pest, disease, weed, soil and water management (Dilts p.18; Vaneph and Benites p.22).

However, farmers' interests are not limited to agriculture. Increasingly, small farmers are investing labour not only in agriculture, but also in non-farm and off-farm income generating activities (Ruben p.52). Development of agroecological agriculture and local healthcare, off-farm income generation and strengthening of local value and knowledge based decision making (see e.g. Mahajan p.48) can be mutually supportive and serve as crucial elements for successful development of sustainable livelihoods.

Participatory development

The participants of the four workshops stressed the importance of participatory development and 'social capital' for successful expansion of agricultural research and development programmes (Gonsalves p.6). Participatory analysis and planning, farmer-to-farmer exchange and learning, farmer experimentation, participatory monitoring and evaluation, and integration of indigenous and scientific knowledge are all important elements of such participatory processes. The Farmer Field School approach, which combines experimentation for learning and innovation, farmer promoters and farmer-to-farmer exchange, is the motor of success in the Community IPM (Dilts p.18) and Landcare (Catacutan et al p.31) movements and is influencing other participatory research and development programmes as well. (see LEISA Magazine 16.2).

Creation of regional research and development platforms for information sharing, planning and coordination is also mentioned as an important tool for 'going to scale', as successfully used in the development of ZT (Brazil, p.23) and the improvement of groundnut production in India (LEISA Magazine 15.1&2, p.72). Consortia of farmer organisations, NGOs, government and international agencies and recognition of the complementary roles these different stakeholders play is clearly important for success as well (Catacutan et al p.31; Kwesiga et al p.35).

Participatory development of site specific agroecological agriculture and sustainable livelihoods requires basic rethinking and relearning of land use and rural development by farmers as well as development staff and researchers. This calls for massive efforts in human resource development. The PMHE programme in Sri Lanka proved that motivation and retraining of government staff in participatory and agroecological approaches is possible, also on a large-scale (Wettasinha p.39).

Supporting farmer movements

The potential of participatory and agroecological approaches to increase agricultural production, eradicate poverty and improve the natural resource base comes out clearly in these cases. The fact that large numbers of farmers are following these approaches already says a lot. Additional economic data, although very difficult to gather because of the complexity of agroecological systems, is providing further insight into why, where and when low-external-input technologies can work (Ruben p.52). Supporting farmers' movements for agroecological and social development such as those in Indonesia (IPM), Brazil (ZT), Central America (Campesino a Campesino) or the Philippines (Landcare) could indeed be the most effective way for 'going to scale'.

However, many forces and conditions work against the spreading of agroecological development as shown by Holt (p.27) and Von der Weid (p.23). Some of the constraints are: lack of awareness about the potential and necessity of agroecological agriculture and participatory development amongst policy makers and researchers; the prevailing Green Revolution and biotechnology paradigm; lack of funding of agroecological and participatory programmes; lack of credit for small farmers, especially for development of agroecological agriculture; lack of appropriate training; clientalism on the part of NGOs which keeps farmers dependent on external support; inability to influence policy makers; lack of participation of farmers in local and national decision making and the lack of cooperation and coordination between farmer, consumer, environment and development organisations. Most agricultural policies still focus solely on increased yield per area, usually associated with packages of external inputs and technical interventions. In many cases, these policy frameworks are the principal barriers to the spread of more integrated, sustainable and productive agricultural systems (Mahapatra et al, p.46; Vaneph and Benites p.22).

Yet it is important to get strong and coordinated support from local and national administration, research, communication, education, CSOs, private companies and funders as confirmed to some extent by the IPM (Indonesia), ZT (Brasil), Landcare (Philippines) and water harvesting (India) movements. But Taylor (p.14) and Holt (p.27) point out, validly, the risk of losing the sparks of innovation when the bottom-up approach is changed into a top-down approach as commonly followed by governmental agencies. It is therefore very important that international policy institutions, governments and research make the switch:

- From reductionist approaches to interdisciplinary, holistic and social learning approaches,
- From commodity-oriented research to system-oriented research at the local level,
- From high-external-input systems to low-external-input systems that enhance agroecosystem functions and optimise the sustainable use of local resources,
- From a centralised, expert-driven approach to a decentralised, agroecosystem-specific approach to science that complements farmer and indigenous knowledge and experimentation, and recognises and enhances local research potential.

To advocate for and contribute to this process, strong alliances between farmer organisations, consumer organisations, development and environmental civil society organisations and researchers, who already have made the switch, are very important (Holt-Gimenez p.27).

CONTENTS

ILEIA is the Centre for Information on Low External Input and Sustainable Agriculture (LEISA) in the tropics. ILEIA seeks to promote the adoption of LEISA through the LEISA Magazine and other publications. It also maintains a specialised information database and an informative and interactive website on LEISA (**http://www.ileia.org**). The website provides access to many other sources of information on the development of sustainable agriculture.

LEISA is about Low-External-Input and Sustainable Agriculture. It is about the technical and social options open to farmers who seek to improve productivity and income in an ecologically sound way. LEISA is about the optimal use of local resources and natural processes and, if necessary, the safe and efficient use of external inputs. It is about the empowerment of male and female farmers and the communities who seek to build their future on the basis of their own knowledge, skills, values, culture and institutions. LEISA is also about participatory methodologies to strengthen the capacity of farmers and other actors to improve agriculture and adapt it to changing needs and conditions. LEISA seeks to combine indigenous and scientific knowledge, and to influence policy formulation in creating an environment conducive for its further development. LEISA is a concept, an approach and a political message.

35 Scaling up fallow management innovations in Eastern Zambia

Freddie Kwesiega, Andreas Bohringer and Glenn Denning

Improved fallows with *Sesbania* and other species have been the focus of ICRAF's research since 1985. These improved fallow systems have a great potential to increase maize yields with or without application of inorganic fertilisers. This fact alone has increased the number of farmers testing and using improved fallow practices in Eastern Zambia from 200 to 10,000 in just 5 years. ICRAF's is now developing ways of scaling up the adoption of this innovation to benefit the many thousands of farmers in Eastern Zambia, and in the South African region. ICRAF is, however, not unaware of the constraints that have to be overcome in order to achieve success.

DEAR READERS

This issue of the LEISA Magazine is on 'lessons in *scaling up* of LEISA research and development programmes, *to bring more benefits to more people, more quickly, more equitably and more lastingly'*.

Case studies and workshop reports from four recent international workshops on *going to scale of agricultural research and development* have been made available to us for this purpose. A selection from this material complemented with several other successful cases makes up this issue. The introductory article (p.6) is written by Julian Gonsalves, the guest editor for this issue and former Director of the Sustainable Agriculture Programme of the International Institute for Rural Reconstruction in the Philippines and proponent of sustainable agricultural approaches for 20 years. He was involved in organising two of these workshops and served as a resource person in the other two. This article provides a summary of the main findings of the said workshops, and together with those of Cooper and Denning (p.13), Gündel et al (p.11) and Carl Taylor (p.14) would be of special interest to planners, managers and trainers of research and development programmes. The rest of the articles, which deal with more practical cases, should certainly be more appealing to the majority of our readers.

The production of this 'larger than regular' 60 page issue was made possible by the additional financial support from the NGO Committee of the Consultative Group on International Agricultural Research (CGIAR), for which we are very grateful.
New themes for the upcoming issues of the LEISA Magazine and the new ILEIA Website and its interactive discussion platform are introduced to you on p.59. Your contributions to these issues and comments on earlier issues are invited and highly appreciated.

On the back cover is a short report on the readers' survey conducted in Ethiopia. This survey is the first in a series that ILEIA hopes to undertake in the coming years to get better insight into what information readers really need and how they use the information that is provided. The findings of this survey were very encouraging - every visit was an inspiring example of how useful the Magazine is to its reader, and in more ways that we could think of. We are rewarded by the fact that the LEISA Magazine is indeed serving its readership.

Lessons in scaling up

“Orphanaging baby corn”

The traditional rice farmers of Chiang Mai’s Mae Tha district took to baby corn growing in 1983 as a way of supplementing their decreasing income. Rice yields had dropped and the harvest could not even feed the families who lived there, leave alone bring an additional income. The companies involved in buying the baby corn from farmers brought in the seeds and fertilisers, and bought back the produce at guaranteed prices, setting off the costs of inputs.

In the early years, farmers grew baby corn twice a year - in the dry and rainy seasons. A family could survive on the income of 1300 bahts from approximately 0.32 ha. By the nineties, when baby corn production had reached its peak, farmers were growing it six times a year, just to make ends meet. Taking around 45 days to be grown, and another 15 days to be harvested, farmers were forced to work day and night, especially at harvest time. With the land being severely exploited, maintaining production meant changing to improved seeds and fertilisers. This increased production costs, but the guaranteed price for baby corn remained static since 1983.

The buyers grade the corn in 3 sizes according to factory standards: small, medium and large. The low exchange rate of the baht caused by the economic slump brought in higher income to exporters who sped up their exporting. Consequently, only the small sized baby corn was bought as dictated by the Japanese and European markets. Harvesting time is crucial to the size of the baby corn. Just a day too late, and the size would not be right, which meant that only about half the harvest would be bought up. The rest would be rejected. Hence, the income dropped whilst the production costs stayed the same. Yet most farmers had no choice - they were pushed to produce the small sized baby corn that could be sold, risking even their health. Sarcastically, farmers began to call the crop “orphanaging baby corn”.

Nevertheless, a few farming families have turned away from baby corn and taken up alternative agriculture: growing mixed types of fruit trees, garden vegetables and plants. Even some of the baby corn growers have started to include trees and other crops in their farms. Many of them have discovered that concentrating on one particular crop is not a good idea, and that farming needs diversity.

Baby corn production in Mae Tha has reached its peak. Ten years of monocropping has so severely damaged the soil that farmers have to buy more inputs to maintain production which they can’t afford. But the only interest of the baby corn exporting factories is a steady supply of raw material and so it’s time to move on, looking for greener pastures. This is very usual of modern-day capital, which moves from one place when all its good things have been siphoned off to another place. With making profit the only target, there is no appreciation or compassion towards the farmers or the land. ■

Themes for next issues

February 2002 Vol.18-1

New ways in smallholder animal husbandry

Never was so much said about animal husbandry than when the Foot and Mouth Epidemic hit Europe during the last months. Following several other animal-related controversies in the recent past, this new epidemic triggered fierce debate and protests. Even governments were forced to agree that there was something terribly wrong in the way animals were managed within the industrialised food system. Are animals simply “production machines”? Aren’t food safety, ecology and the health and well being of animals essential as well?

For families in the South, farm animals are often very important, not only for food and other economic reasons, but also for deep-rooted cultural and social aspects. Should they copy the unsustainable trends from intensive animal husbandry in Europe as often propagated by development programmes? Or should development initiatives build on indigenous practices and involve the people themselves? How could indigenous and scientific knowledge support each other in making animal husbandry healthy and productive? How could cultural and social aspects be dealt with? Is it important to look at gender roles in animal husbandry, especially in terms of access to and control of animal assets and labour division? How should species diversity be maintained, inbreeding prevented and animals upgraded? How can integrated (tree-) crop-animal systems be developed or improved? Should interactions between wild life and domestic livestock be considered? What income generating activities could be developed around animal husbandry to secure the livelihoods of animal keepers? What marketing arrangements are undertaken by farmers and how can these be improved? And what about veterinary services that are so essential to animal husbandry?

All these questions and more have urged ILEIA to take up animal husbandry as the theme for the first issue of 2002. Your experience counts in working towards a more sustainable system of animal husbandry, both for the North and for the South. Please send your contributions to us before 1st January 2002.

Information on the themes for September (Going to scale) and December (Alternatives to biotechnology) issues can be found in issue 16-4 and 17-1, p.36.

You are invited to contribute to these issues with articles (about 800, 1600 or 2400 words + 2-3 illustrations), suggest possible authors, and send us information about interesting publications, training courses, meetings and websites.

Learning together for change: facilitating innovation in natural resource management through learning process approaches in rural livelihoods in Zimbabwe by Hagmann J. 1999. 330 p. ISBN 3 8236 1314 6 : EUR 25.60. (Kommunikation und Beratung, Sozialwissenschaftliche Schriften zur Landnutzung und ländlichen Entwicklung 29) Margraf Verlag, Postfach 1205, 97985 Weikersheim, Germany margraf@compuserve.com

The efforts of the Zimbabwean agricultural research and extension agency Agritex and its partners to pioneer an effective farmer-led extension cum PTD approach in the province of Masvingo have been well documented. (see Farmer Research in Practice p. 153-173 and the ILEIA Newsletter v.13 no.3 (October 1997) "Rebuilding Lost Soil Fertility"). The result has become known as "Kutaraya" or "Let's try". It combines solid participatory agricultural extension methods with those of the social change approach known as Training for Transformation. This was realised through the intensive collaboration of the government agency Agritex and the NGO ITDG, with prolonged funding support of the German Government. In this book, Jurgen Hagmann, one of the key researchers in the Masvingo activities from as early as 1991 and still involved in backstopping Agritex, provides a detailed insight into the developments that led to Kutaraya and its successful application. Even more important is its contribution in linking these experiences with fundamental social science insights and discussions. Following scientists such as Röling, he argues that changes in natural resource management practices are not necessarily inspired by technical expertise alone, but are often a result of interactions between various interests and sets of knowledge. Facilitating joint experimentation and learning among resource users can encourage innovation - just what Kutaraya tries to put into practice. Hagmann's efforts to be thorough and cover all aspects have led to a voluminous publication, yet one of great interest for those who are not just interested in the nuts and bolts of farmer-led agricultural development, but also its theoretical foundations. (LvV)

Incentives in soil conservation : from theory to practice by Sanders DW ... et al. (eds) 1999. 384 p. ISBN 81 204 1347 4 : USD 39.95. World Association of Soil and Water Conservation (WASWC). Science Publisher, PO Box 699, Enfield, N.H. 03748, USA / sales@scipub.net, www.scipub.net

This publication compiles contributions on the use of incentives (direct or food-for-work payments, tax concessions etc.) and disincentives (fines, taxes, exclusion from government benefits etc.) in soil and water conservation programmes from all over the world. The results of such programmes have been mixed, and this book is meant to be an overview as well as a guide for future programmes. The book is divided into three parts: the first deals with the theoretical and conceptual considerations, the second with national and regional programmes and the last presents case studies and projects. It is a combination of experiences that is very valuable. (IHG)

Rural credit and self-help groups : micro-finance needs and concepts in India by Karmakar KG. 1999. 374 p. ISBN 0 7619 9345 2 : GBP 29.99. Sage Publications, 6 Bonhill Street, London EC2A 4PU, UK / orders@sagepub.co.uk / www.sagepub.co.uk

This book deals with the problems and prospects of rural credit in India. The writer has worked as an officer in various banks for over 22 years, and has made an in-depth study of the existing rural credit delivery system. In this book he makes many valuable suggestions for strengthening and restructuring the system, based on Asian financial role models. The book studies the micro-finance needs of the rural poor, and offers the solution of self-help groups to enable the rural poor to aim for economic empowerment. Recommended reading for rural bankers, NGO volunteers and credit specialists. (WR)

Information management for development organisations by Powell M. 1999. 160 p. ISBN 0 85598 410 4 (pbk). (Skills and practice series). OXFAM Publications, 274 Banbury Road, OX2 7DZ Oxford, UK.

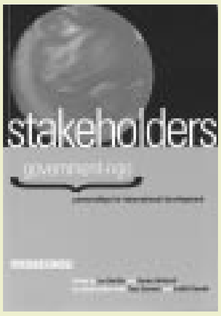
In this era of information and communication, development organisations can feel overwhelmed by the amount and variety of information available, ranging from wage records and purchase orders to evaluation reports and conference notes. This book can be helpful in understanding the links between the various information items available and in classifying them, so that they can be used as a tool for planning, implementing and monitoring. The described approach is illustrated with case studies from community groups and non-government organisations. The book can also be used by people only interested in certain aspects of information management as the different chapters can be read individually. Most chapters conclude with a list of practical issues and suggestions which makes it helpful to check what one's own practice of information management consists of. (IHG)

The distribution and regeneration of Boswellia papyrifera (Del.) Hochst. in Eritrea by Ogbazgi W. 2001. 131 p. Wageningen University and Research Centre (WUR), Department of Environmental Sciences, Silviculture and Forest ecology Group, Droevendaalsesteeg 3, PO Box 342, 6700 AH Wageningen, The Netherlands. (Documents sur la Gestion des Ressources Tropicales = Tropical Resource Management Papers, ISSN 0926 9495 ; 35).

Boswellia is a gum-producing multi-purpose tree that grows in the savannah belt from northern Nigeria eastwards to the highlands of Ethiopia and Eritrea. Despite its economic importance, it has become a threatened species as natural Boswellia woodlands are converted into agricultural fields and unregulated grazing hinders natural regeneration. This paper/thesis research presents distribution and regeneration factors of the woodlands. (IHG)

Tropical forest resource dynamics and conservation : from local to global issues by Wiersum KF (ed). 2000. 172 p. Wageningen University and Research Centre (WUR), Department of Environmental Sciences, Forest Policy and Forest Management Group, Droevendaalsesteeg 3, PO Box 342, 6700 AH Wageningen, The Netherlands. (Documents sur la Gestion des Ressources Tropicales = Tropical Resource Management Papers, ISSN 0926_9495 ; 33).

This book presents an overview of recent social science research in the Netherlands concerning the conservation and management of tropical forests. It describes the three main fields that can be distinguished in contemptorary tropical forest research on the basis of several contributions. The first field is related to forest use by local communities including options for community level management of forest resources (Bulu forest tenure in Cameroon and storytelling to ameliorate communication). The second is research at the macro-level about the economic and political processes that can explain forest degradation and conservation (cases from Senegal, Ecuadorian Amazon, Sierra Leone and a political perspective on a Costa Rican environmental campaign). The third field is the most interdisciplinary: it focuses on the land-use dynamics at the forest fringe and refers to factors and forces both at the local as well as the global level (cases from the Tojobal Highlands, Mexico, the highlands of Papua New Guinea and the Philippines and Indonesia). (IHG)



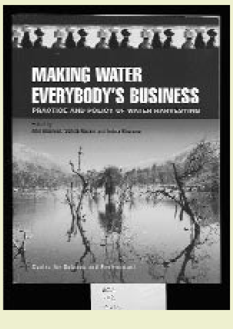
Stakeholders : government-NGO partnerships for international development by Smillie I, Helmich H (eds). 1999. 317 p. ISBN 1 85383 589 7 : GBP 25.00. Organisation for Economic Co-operation and Development (OECD), 2, rue André-Pascal, 75775 Paris Cedex 16, France. Earthscan Publication, 120 Pentonville Road, London N1 9JN, UK / orders@lbsltd.co.uk.
This study provides an overview of the relationships of governments in "Northern" countries, including Australia, New Zealand and Japan, with development-support NGOs in these countries, as well as relationships between these NGOs and both the European Union and the World Bank. The chapter on trends and issues in government-NGO relationships analyses how the NGOs are maturing and becoming more realistic in their dealings with government agencies, but also points to some of the dangers of dependency on government funding. It traces the evolution toward stronger evaluation of NGO activities, a form of evaluation that tends to focus on output rather than process and learning. Also funding relationships have evolved from matching grants to contracts, blurring the borderline between organisations of concerned and committed civil society, on the one hand, and service providers and executing agents of government, on the other. The largest part of the book - the country studies - are useful as reference material, but are not particularly exciting to read. They give a sense of history and trends, and reveal some of the differences in how NGOs are defined in these countries. However, the current information about official policies with respect to NGOs will quickly be out of date. The book is based on a meeting arranged by the Organization for Economic Cooperation and Development (OECD) in January 1998 to promote open dialogue between civil society and governments of the OECD countries. (AWB)

Agricultural terracing : development perspectives by Ojha ER. 1997. 77 p. Ratna Pustak Bhandar, PO Box 98, Kathmandu, Nepal.
This handy, compact and very practical monograph looks at different aspects of terracing. The author, a native of the Nepalese hills, examines evolution, construction, operation, and maintenance of terraces. In many parts of the world, land pressure has been very high for time immemorial given the shortage of arable land and the early demographic pressure. The only solution open to people for survival was by building terraces, no light decision given the tremendous task of constructing and maintaining such structures. Terracing is a last option when all other practices such as contour cultivation, crop rotation and strip cropping have revealed themselves as inadequate in keeping soil erosion in check and maintaining productivity. Different types of terraces are described, the use of which is dictated by the environment as much as by demographic factors and the degree of agricultural mechanisation. Labour is a heavy constraint when dealing with terraces not only for their construction, but also for their maintenance; difficult in case of outmigration or other causes of depopulation. Farmers' participation is of paramount importance in terracing, as illustrated by cases where terraces were constructed through forced labour or when farmers were not convinced of their productivity. The author gives some factors to be considered in a cost-benefit analysis of terraces. There are magnificent pictures in this book giving a glimpse of the enormous toil that must have gone into constructing and maintaining these structures. (WB)

Integrated soil fertility management by Hilhorst T, Toulmin C (eds). 2000. 64 p. ISBN 90 5328 283 1. Ministry of Foreign Affairs, Rural and Urban Development Department, P.O.Box 20061, 2500 EB The Hague, The Netherlands. (Policy and Best Practice Document ; 7).
Food security, poverty alleviation and environmental protection are important objectives of the Netherlands' development cooperation policy. A more sustainable agriculture is vital for achieving these objectives, and it is for this purpose that the Netherlands Ministry of Foreign Affairs issues a series of policy documents, which, so far, includes: Sustainable Land Use (1993), Sustainable Irrigated Agriculture (1998), Water for the Future - Integrated Water Resource Management (1998) and Participatory Integrated Pest Management (1999 and reviewed in New in Print 17.1). This new contribution to the series examines the issues at stake in relation to soil fertility management, the reasons why policy makers should be concerned about soil degradation, the lessons learned from interventions in this field and the type of policies which contribute to a more sustainable management of soils. Up-to-date background information! (IHG)

Dynamics and development of highland ecosystems : highlights on the hills in far-western Nepal by Ojha ER. 1999. 279 p. Walden Book House, PO Box 2071, Kathmandu, Nepal.
This study, with a lot of quantitative data, analyses the agroecosystem of a remote highland region in West Nepal to determine ways and means of improving the socio-economic and environmental conditions of the people living in this typical low-external-input area from which the resources are gradually draining away. The traditional terrace system is well analysed, building on an earlier study by the same author: 'Agricultural terracing: development perspectives' (see above). A list of recommendations is included in the last chapter. (CR)

Making water everybody's business : practice and policy of water harvesting by Agarwal A, Narain S, Khurana I (eds.). 2001. 456 p. Centre for Science and Environment (CSE), 41 Tughlakabad Institutional Area, New Delhi 110062, India / cse@cseindia.org , www.cseindia.org.
After the enormous success of the monumental work "Dying wisdom: rise, fall and potential of India's traditional water harvesting system (State of India's Environment, fourth citizens' report)(1997), about India's traditional water harvesting systems, CSE has published this new impressive book. It continuous from where "Dying wisdom" stopped and provides, besides new descriptions of traditional rural water harvesting systems, many examples of communities which have undertaken water harvesting programmes in the recent past. The focus is widened to examples outside India, and also to urban water harvesting programmes. New technologies which can by useful to safeguard the quantity and quality of water are also presented. It is not only the low rainfall which causes water shortages, but more the heavy reliance on surface and groundwater alone which calls for a revival of traditional water harvesting systems. Another important problem lies in the heavy dependency on the government for the provision of water. The book is a strong plea to let communities to take water management in their own hands and to become involved in water provision as well as the protection of water resources. (IHG)



A package containing Making water everybody's business, Dying wisdom, Water links-2 and the Water harvesting manual is available from CSE for a discounted price of USD 48.00

Slow Food Movement

http://www.slowfood.com

The association founded in Bra, Italy, in 1986 has grown into an international movement with more than 60,000 members in 35 countries on all continents. The manifesto of the movement states, “slow food is the avant-garde response to the fast life that has changed our lives and threatens the environment and the landscape in the name of productivity.” The website of the movement is packed with information on events, courses, publications and information on food and drink. Slow Food Editore, the publishing company of the movement, has two quarterly magazines: “Slowfood” on agroindustrial production and “Slowine” dedicated entirely to wine. The Ark of Taste and Slow Food Praesidia are two projects promoted by the movement to protect biodiversity and the right to taste. Information on these projects is posted on the website. Membership can be obtained by on-line registration.

Centre for Environment and Society, University of Essex, UK

www2.essex.ac.uk/ces

The CES is a trans-disciplinary research centre located in the Department of Biological Sciences at the University of Essex. It is engaged in a wide range of basic, applied and action-oriented environmental research, capacity development, teaching and training, and outreach through publications and seminars. Its web site contains some interesting reports on the ongoing research programmes, amongst others on: Sustainable agriculture; Externalities – the real costs; Sustainable development for local economies; and Community participation. There is also interesting reading on conferences dealing with sustainable agriculture and local economies, e.g. Pretty, 1998. Taking back the middle for local economies.

Food Security Resource Centre of the Institute for Agriculture and Trade Policy

http://www.iatp.org/foodsec/

On this site you will find an events calendar, organisational listings, a full text document library and on-line discussions on a variety of issues including: food security, food safety, the industrialisation of agriculture, the World Food Summit, US agriculture policy and upcoming negotiations on agriculture at the WTO. This is an interactive website, which allows you to instantly add your events, contact information or even upload documents to the library.

Focus on the Global South

http://www.focusweb.org

As reflected in its name, Focus on the Global South directs its attention on addressing issues that affect the whole South, in four thematic areas: economic and financial liberalisation; security and conflict; state, market and civil society; culture and globalisation. Interesting publications on globalisation - bulletins, books and articles - can be accessed through this website.

International Forum on Globalisation

http://www.ifg.org

The International Forum on Globalisation (IFG) is an alliance of more than sixty leading activists, scholars, researchers and writers formed to stimulate new thinking, joint activity, and public education in response to economic globalisation. The website provides contact information of IFG associates, allows access to many relevant publications, gives an overview of upcoming events. Interesting links are available for those who wish to get more information on certain topics or like-minded organisations.

World Bank - environmentally and socially sustainable development

http://www-esd.worldbank.org

This address gets you straight to the World bank’s site that deals with environmentally and socially sustainable development. The pages on Rural Development and Agriculture provide access to information on issues related to globalisation at the policy level. It also allows you to follow the electronic discussion on “Agricultural Trade and the World Trade Organisation” being conducted from June 10 to August 10, the findings of which will be taken to the next WTO Ministerial meeting in Qatar in November 2001. The e-discussion aims to provide wide consultations with public and private stakeholders in both developed and developing countries on emerging trade issues from a development perspective. Join the discussion by sending a blank e-mail to join-ag-trade@lists.worldbank.org, give your opinion and get involved.

Centre for Alternative Agricultural Media CAAM

http://www.farmedia.org

CAAM, the Centre for Alternative Agricultural Media, is a non-governmental organisation in India working towards a farmer friendly communication system. More detailed information on the many activities of the organisation which include writing for farmers, self-help journalism etc. can be found on the website. Interesting cases of farmers developing alternatives to modern agriculture, written from the farmers’ point of view, are posed on the site. CAAM-net is the electronic bulletin of the centre, which is sent out to a network of friends and professionals concerned with pro-farmer communication efforts. You can subscribe to the bulletin by sending an e-mail to caam@vsnl.net with “subscribe” as the subject.

Research Foundation for Science, Technology & Ecology

www.vshiva.net

This Indian based organisation, founded and headed by Vandana Shiva, works on biodiversity conservation and farmers’ rights. The organisation is a strong proponent of the grassroots ‘localisation’ movement, the countervailing citizens’ agenda for protecting the environment and people’s survival and livelihood from economic and political ‘globalisation’. Among its programmes are:

- **Navdanya,** is its main programme on the conservation of biodiversity. It places the farmer at the centre of conservation and empowers her/him to take control over the political, ecological and economic aspects of agriculture.
- **Diverse Women for Diversity**, one of the latest programmes, seeks to herald a global campaign of women on biodiversity, cultural diversity and food security. It seeks to strengthen women’s grassroots movements and provide women with a common international platform to air their views on globalisation, emergency of genetic engineering and patents on life forms.
- **Lok Swaraj Movement** to assert people’s sovereignty over decisions and resources that affect their lives and livelihood – food, seed, land, water and the commons and to save the country being hijacked by a new form of colonialism. **No patents on life, Monsanto quit India** and **Global campaign against biopiracy** are among the many campaigns organised by RFSTE.

There is also information on publications by Vandana Shiva and others. Shiva’s latest publication: **Stolen harvest: the hijacking of the global food supply** (p 30), however, is not included yet. Several interesting articles on economic and political globalisation can be down loaded. RFSTE also publishes a hardcopy magazine, **Bija the seed, a quarterly monitor on Biodiversity, Biotechnology**

and Intellectual Property Rights. Although this magazine has a strong focus on India, it provides interesting background information for other people involved in the anti-globalisation movement as well.

RFSTE, A60, Hauz Khas, New Delhi – 110016, India. Phone: +91 11 6868077; Fax: +91 11 6856795; Email: vshiva@giasdl01.vsnl.net.in ; http://www.vshiva.net

Institute for Food and Development Policy - Food first

http://www.foodfirst.org

For 25 years, the Institute for Food and Development Policy - known as Food First - has been committed to establishing food as a basic human right. As a progressive think tank, it has impacted many people through publications, workshops and courses, and involvement in activist coalitions. Food first's stand against globalisation and trade liberalisation is firm and uncompromising. The well-organised website provides access to many of the organisation's reports, papers, fact sheets and backgrounders, which are a must for anyone interested in knowing how real change is being effected, both in individuals and government policies.

Essential Information

http://www.essential.org

Essential Information is an NGO set up in 1982 with the purpose of getting citizens more active in their communities. Under the banner, "Essential information, encouraging activism", the website provides information to meet this objective. The Multinational Resource Centre, within Essential Information, provides free information to activists, environmental and consumer groups, and other interested parties in Southern countries, who find themselves increasingly exploited by the abuses of multinational corporations. If you need free information on any multinational company that is operating in your city, region or country, then contact MRC by e-mail mrc@essential.org Skillshare is a project of MRC that sets up meetings between activists and experts from the South and the North to help build the capacity of Southern NGOs to take action on incineration, toxics and waste management issues. More information on this initiative can also be obtained on the e-mail address given above.

International Society for Ecology and Culture (ISEC)

http://www.isec.org.uk

ISEC is a non-profit organisation concerned with the protection of both biological and cultural diversity. Its emphasis is on education for action: moving beyond single issues to look at the more fundamental processes that influence and shape our lives. ISEC has worked in more than 12 countries, from the UK and the USA to Thailand and Bhutan. Its programme in Ladakh, India, which started in 1975, has won international recognition for countering the negative effects of globalisation (see page 20). ISEC supports community initiatives to rebuild self-reliance and self-respect; is involved in local, national and international networking and campaigning to strengthen the localisation and anti-globalisation movement; produces books, reports, films and holds conferences to promote locally-based alternatives to the global consumer culture.

Roots of change, one of its programmes, is a guided group self-study on how globalisation is affecting the own local community and other communities around the world and on what strategies can be developed for effective local action.

Publications strongly recommended by ISEC are:

- **Bringing the food economy home: the social, ecological and economic benefits of local food** by Helena Norberg-Hodge, Todd Merrifield and Steven Gorelick ISEC, 2000, US$7.00 It reveals that the globalisation of food is not only undermining farmers and damaging the environment, but also is posing a real threat to human health, food security, local economies and, ultimately, consumers.
- **Small is beautiful – big is subsidised** by Steven Gorelick. ISEC, 1998, US$6.00 It shows how taxpayers' money is used to promote an ever larger scale of economies. Using numerous examples and astonishing statistics, the author demonstrates how the global economy along with the infrastructures it necessitates is a key factor in the increase in a whole range of environmental and social problems – from climate change to the erosion of community.
- **From the ground up: rethinking industrial agriculture** (new edition) by Helena Norberg-Hodge, Peter Goering and John Page. ISEC and Zed Books 2000, see page 30.

Agricultural trade in times of globalisation - workshop proceedings and papers

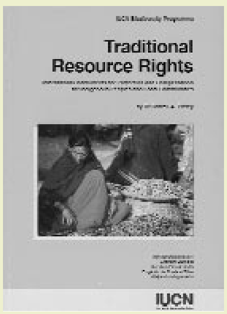
by Silke Spielman (ed).2000. 65pg.ISBN 3-9805354-7-9. BUKO Agrocoordination, Nernstweg 32-34, D-22765 Hamburg, Germany/ bukoagrar@aol.com Website www.bukoagrar.de

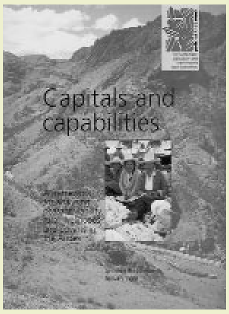
On the invitation of the BUKO Agro Coordination of German developmental action groups, more than 40 representatives of NGOs, farmers organisations, trade unions, churches, and other social movements from all over the world met near Hamburg in October 1999 to discuss "Agricultural trade in times of globalisation". Having discussed a broad range of themes, which are documented as reports from working groups, the participants agreed that agriculture is not just another sector of economic production, but a way of life, which has to be dealt with differently than industrial production and services. Regional development, fair trade, eco-labelling, food sovereignty, national agricultural policies and the WTO are some of the themes. The resolution adopted by the participants for the Third WTO Ministerial in Seattle is found as an annex to the report. It states that they will work together using different ways of influencing the WTO and develop stronger cooperation between farmers, workers, NGOs and other social groups for protecting food security. Although the report is primarily for the participants, its contents could be interesting and inspiring to those involved in trade and development issues. (CW)

Traditional Resource Rights - International instruments for protection and compensation for indigenous peoples and local communities

by Posey D.A.1996. 221 pg. ISBN 2 8317 0355 7 IUCN Gland, Switzerland and Cambridge, UK. Copies available from IUCN Publications Services Unit, 219c Huntington Road, Cambridge CB3 0DL, UK.

Although the UN Convention on Biodiversity recognises the role of indigenous peoples and local communities in enhancing and maintaining biodiversity, it does not provide specific mechanisms to protect their rights to genetic materials, knowledge and technologies. The Traditional Resource Rights (TRR) concept presented in this book is proposed as a guide to the development of *sui generis* (new and unique) systems for protection and compensation of indigenous and traditional peoples for their knowledge, technologies and biological resources. The book provides a detailed overview of a series of International Instruments with the intention of identifying existing support for protection of indigenous peoples and local communities. Key principles are identified across major agreements and declarations. TRR are viewed in the light of guiding efforts to harmonise human rights with trade, development and environmental laws, initiatives and policies. (CW)





Capitals and capabilities - a framework for analysing peasant ability, rural livelihoods and poverty on the Andes

by Bebbington A., 1999. 54pg ISSN 1561-1256 International Institute for Environment and Development IIED, 3 Endsleigh Street, London WC1H 0DD, UK. E-mail bookshop@iied.org

This paper is one of several which provide the contextual and conceptual background to "Policies that work for sustainable agriculture and regenerating rural economies", a collaborative research undertaken by IIED's Sustainable Agriculture and Rural Livelihoods Programme. The paper discusses the limitations to the current debates on the rural sector in Latin America, which have led many to question the future viability of peasant livelihoods in the Andes. It attempts to build a framework that approaches rural livelihoods and poverty without automatically linking its analysis to agriculture and natural resources. The framework looks at resources from a much wider perspective and considers five types of "capital" assets - produced, human, natural, social and cultural capital. Assets, or capitals in this framework, are not merely means through which people make a living, but give meaning to life. They are not simply resources that people use in building livelihoods, but are assets that give them the capability to be and to act. Access is seen as a critical resource that enables people to build sustainable, poverty alleviating rural livelihoods. Particular attention is paid to social capital as an asset through which people are able to widen their access to resources and other actors. (CW)

The subsistence perspective - beyond the globalised economy

by Mies M. and Bennholdt-Thomsen V., 1999. 246 pg ISBN 1 85649 776 3 GBP15.95 Zed Books Ltd., 7 Cynthia Street, London N1 9JF, UK.

The book begins with a conversation that took place between Hillary Clinton, the then First Lady of the US, and a group of women in Bangladesh. Ms. Clinton's intention was to find out for herself whether the success stories of the Grameen Bank projects were true. In the course of the interview she found out that indeed the women were empowered - they had an income of their own, some assets in the form of cows, chickens or ducks, and their children went to school. But when it was Ms. Clinton's turn to answer the very same questions, the women concluded that Ms. Clinton was not empowered - she had no cow, no income of her own and only one child. This story somehow embeds the radical alternative to the current globalised, free market industrial system posed in this unique book - a new economics and politics based on a subsistence perspective. The authors explain subsistence as empowerment based on peoples' own strength and cooperation with each other and with nature. Rather than the endless accumulation of wealth, the aim of the subsistence perspective is happiness, quality of life and human dignity. The arguments in the book together with the cases are convincing evidence that real development only works when it is done from the bottom-up. An insightful book that gives food for thought and action. (CW)

Villages for the future: crops, jobs and livelihood

by D. Virchow and J. von Braun (Eds), 2001. Springer (forthcoming).

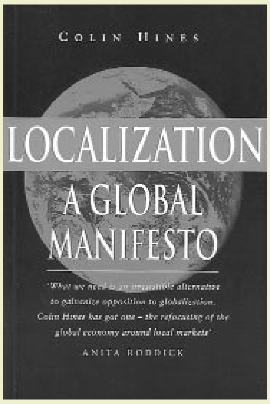
This publication focuses attention on the problems and the opportunities of rural areas worldwide at a time when globalisation impacts deeply on them. It is based on papers presented at the Global Dialogue: "The Role of the Village in the 21st Century: Crops, Jobs and Livelihood" in Hannover at the World Exposition in August 2000. The selection of articles ranges from scientific papers analysing particular issues of rural development to short reports from practitioners describing examples of sustainable solutions for the rural populations in different regions of the world. The contributions are grouped a round four major themes, which can be seen as starting points for further debate:

- political and institutional frameworks to foster rural development;
- natural resources management and related actions;
- broadening the technological base of rural economies;
- improved linkages between urban and rural areas.

The overall message of the contributions is unanimous: there is a promising future for the rural areas worldwide, if adequate policies can be enforced and more efficient and fair institutions can be created.

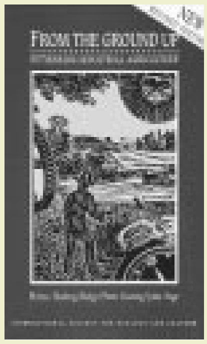
World Development Report 2000/2001: Attacking poverty. World Bank 2000. Oxford University Press ISBN 0-19-521129-4 paperback. Email: books@worldbank.org; www.worldbank.org
The World Bank's vision on rural poverty, the causes and a framework for action: promoting opportunity, facilitating empowerment, and enhancing security – with actions at local, national, and global levels. Actions should be site specific, as illustrated by many case study boxes. The publication contains many references and world development indicators. An impressive publication with many good arguments, but lacking an analysis of what economic transition and economic, political and cultural globalisation is doing to urban and rural people. Therefore, doubts can be raised as to what extent the vision presented in this publication will contribute to end poverty (CR).

Localization - a global manifesto by Hines C., 2000. 290 pg GBP 10.99 ISBN 1 85383 612 5 Earthscan Publications Ltd., 120 Pentonville Road, London, N1 9JN, UK. E-mail: earthinfo@earthscan.co.uk
"To protect the local, globally" is the alternative to globalisation that this book very passionately promotes. The book is laid out in 3 parts. The first "The Problem - Globalisation" examines the downsides of globalisation and provides a brief history of trade. Part 2 "The solution - localisation" looks at localisation as something done by people, not as something done to them and discusses the potential advantages of the local. It also considers in detail what is required to build sustainable communities. The seven chapters of this part are dedicated to seven basic steps to be introduced in making the transition towards localisation. Re-introduction of protective safeguards to rebuild local economies localising production and dismantling transnational companies, localising capital, a localist competition policy, taxes for localisation are some of them. Part 3 "How localisation might come about" looks at the different entry points to be taken in making localisation a reality and is detailed in 8 chapters. The book concludes, controversially, on the note that localisation will bale out the market and calls all those interested to join hands under the banner, "Localists of the world unite - there is an alternative" (CW)



Taking back the middle for local economies by Jules Pretty, 1998. http://www2.essex.ac.uk/ces
An article on the principles and characteristics of local economies and local food systems. Examples are mainly from the UK.

From the ground up - rethinking industrial agriculture by Norberg-Hodge H., Goering P. and Page J. 2001 New revised edition 118 pg. ISBN 1 85649 994 4 Zed Books Ltd., 7 Cynthia Street, London N1 9JF, UK in association with International Society for Ecology and Culture, a charitable organisation based in Devon, UK and Berkeley, USA.



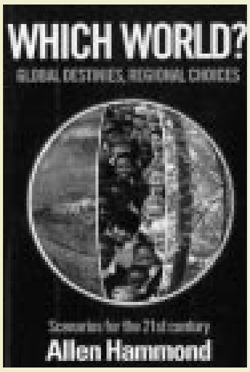
The introduction to the book " From global to local - sowing the seeds of community" gives in a nutshell the essence of its contents. It outlines the global industrial food system, globalisation, free trade and genetically modified organisms and points out the damage in terms of the loss of biological diversity, increased poverty as farmers get pushed out of their livelihoods, and the general decline in agriculture. Having described this rather depressing state of global agriculture, the author brings back hope by showing how people have begun to resist these trends and revert back to what is called the "local food movement". The two parts of the book that follow take up the same discussion, but then in detail. The first, "Industrial agriculture: broken promises" discusses the negative impacts of many aspects such as hybrid seeds, chemical fertilisers, pesticides, mechanisation and biotechnology. The second part, "The new agriculture: back to basics" shows how a move towards more ecological agricultural practices could undo the damage - social, economic and environmental - done by industrial agriculture. Written in simple terms and an easy-to-read style, the book communicates the urgent need for re-thinking industrial agriculture, clearly and without compromise. (CW)

International trade in agricultural commodities - liberalization and its implications for development and poverty reduction in the ACP states, Policy series 5 by Coote C., Gordon A., Marter A., 2000. 79pg. ISBN 0 85954 518 0: GBP5.00. Natural Resources Institute, University of Greenwich, UK. Copies can be obtained from: NRI Catalogue Services, CAB International, Wallingford, Oxon OX10 8DE, UK quoting EP 5.
One in a series that deals with current policy issues of importance to developing countries and countries in transition, this publication focuses on international agricultural trade and developing countries, particularly the ACP (African, Caribbean and Pacific) countries. It aims to provide guidance on ways to make trade policy more pro-poor and builds up the case in four sections. The first section looks at trade liberalisation and poverty. The second gives an analysis of how ACP countries participate in trade and how it effects poverty, livelihoods, gender and the environment. Section 3 looks at ways of increasing ACP participation and benefits from trade, which includes a section on EU trade and development policies. The concluding section provides recommendations for enabling the poor to benefit from agricultural trade. They are grouped into: international action to help developing countries to get the best deal from trade liberalisation; targeting the export sector in developing countries without overlooking the importance of the food sector in its own right; focused interventions to ensure that the poor benefit from improved opportunities for trade. (CW)

Stolen Harvest - the hijacking of the global food supply by Shiva V. 2000 146pg. ISBN 0 89608 607 0 South End Press, 7 Brookline Street 1, Cambridge, MA 02139-4146, USA
This book by well-known author and environmental activist Vandana Shiva describes the negative impacts of globalised industrial agriculture on small farmers, the environment and the food we eat. In each of the first six chapters, the author talks about the many losses that people face due to globalised agriculture - food security, biodiversity, environmental destruction, loss of control and values etc. All arguments in the book are substantially supported with examples from India, but the case made by the author goes beyond India to people the world over who are affected by corporate-controlled agriculture. In the last chapter, "Reclaiming food democracy", the author talks about public action against these destructive modern trends, challenging people to work towards claiming food freedom in their everyday lives. Written with passion and commitment, the book will not only shock you into reality it will also stimulate you to exercise your rights in reclaiming food democracy. (CW)

Which world? Scenarios for the 21st century - global destinies, regional choices by Hammond A., 1998. 306pg GBP 18.99 ISBN 1 85383 582 X Earthscan publications Ltd., 120 Pentonville Road, London, N1 9JN, UK. E-mail earthinfo@earthscan.co.uk

This book is about the future - an attempt to look at the world in the year 2025 or 2050. It is one of the results of the 2050 Project - a study organised by three major research organisations to consider demographic, economic, technological, environmental, social, cultural, political and other factors that may determine the future of the planet. It also draws on the vast experience of the author in studying global trends. The book constructs three possible scenarios of three altogether different visions of the world - a Market World in which current patterns continue; a Fortress World that reflects fundamental but undesirable social change; and a Transformed World that reflects fundamental and desirable social change. The book also analyses critical long-term trends that would shape the future of the world - demographic, economic, technological, environmental, social, political etc. Considering that global destiny is dependent on regional choices, the book discusses several crucial regional choices that would determine whether the world will become peaceful and prosperous or polluted, impoverished, and violent. In closing the author suggests that both optimistic and pessimistic futures will be fully within the range of possibility, given the present long-term trends. He believes that the outcome will depend on the choices human societies make in the coming decades. Yet, on a more personal note, the author is reasonably optimistic that the outcome will be closer to the Transformed World vision and cites some examples that he hopes will stimulate further thought and action. Readers are also invited to join the on-line discussion on this topic at www.hf.caltech.edu/WhichWorld and share their views. (CW)



The case against the global economy & for turn towards localization edited by Edward Goldsmith & Jerry Mander, July 2001. Earthscan, 120 Pentonville Road, London N1 9JN, UK. ISBN 0 85383 742 3, 336 pp. 14.95 (paperback). Orders@lbsltd.co.uk or www.eartscan.co.uk

The new and fully revised British edition explores the greatest political debate of our time: the blind rush towards a single global economy and its devastating consequences on employment, poverty, democracy, human rights, cultural diversity, and the natural world that sustains us. Twenty four leading economic, political, agricultural, and environmental scholars and activists, fourteen of whom are members of the International Forum on Globalisation, argue that free trade and globalisation are producing precisely the opposite effects to those promised. With 70% of global trade controlled by just 500 corporations, only a radical change in direction towards local economy, democracy and self-sufficiency can assure human welfare and prevent environmental and climatic catastrophe.

Beyond Malthus - Nineteen dimensions of the population challenge by Brown L., Gardner G. and Halweil B. 2000. 168 pg. GBP12.95 ISBN 1 85383 656 7 Earthsacn Publications Ltd., 120 Pentonville Road, London, N1 9JN, UK. E-mail earthinfo@earthscan.co.uk

200 years after Malthus' legendary essay on population, the world population has exceeded the 6 billion mark. The earth is more crowded today than ever before. A number of limits to sustainability are being surpassed, or are about to be. This book looks at the consequences of population growth on 19 dimensions of human life - environmental and social. Grain production, fresh water, forests, biodiversity, cropland, housing, jobs, climate change and waste, are some of them. It talks about “demographic fatigue” - the growing inability of poor governments with burgeoning populations to cope with new threats to society. It calls for population stabilisation by intelligent and human social and economic policies and suggests some options like debt relief, family planning assistance to those who lack access, educating young people on the benefits of smaller, more sustainable family units etc.(CW)

Genetically modified crops out of control, organic agriculture threatened

The organic industry in the US is in a crisis. Contamination of organic products, namely maize, soybean and canola, by genetically engineered (GE) crops is being reported consistently. Not only is there evidence of organic products being contaminated, but the very seed stock organic farmers depend upon is now also contaminated. There may not even be enough clean organic seeds of some crops, such as maize, for this planting season. For example, 77 of the 281 seed companies in the US found their maize seed to be contaminated with the genes of Starlink GE maize, which is approved for animal consumption only. A further 68 seed companies are still awaiting the results of their tests. Not surprisingly, this contamination found its way into the human food chain and caused the withdrawal from the market of over 300 products.

The issue of seed contamination strikes the heart of organic standards. Organic standards of the EU and IFOAM, and many others, are quite clear when they state that GE crops must not be used in organic production systems. GE crops are still not permitted for general cultivation in most parts of the world. However, in countries where GE crops have been given free access, the situation could be as serious as in the US. To put a halt to further use of genetically engineered crops, IFOAM has asked for an immediate ban of genetic engineering in agriculture.

ILEIA fully supports all attempts to stop genetic pollution, as this will not only affect organic crops but also conventional crops and their wild relatives. For consumers, this may mean that it will become impossible to obtain GE free products from these crops.

Stop genetic engineering!

“IFOAM calls on governments and regulatory agencies throughout the world to immediately ban the use of genetic engineering in agriculture and food production, while there is still a chance to stop this unwanted pollution. IFOAM further holds genetic engineering industries responsible for the damage they have inflicted on organic farmers. Governments are therefore urged to pass legislation that makes GE companies liable for all genetic pollution caused by the products they own.”

Governance in international agricultural research – time for change

Participatory breeding of crops valuable to small farmers in marginal areas of the tropics is not the mainstream research activity of the sixteen research centres in the Consultative Group on International Agricultural Research (CGIAR). With some exceptions in the form of model projects, the research conducted by the centres is focused on Green Revolution agriculture with biotechnology included recently. Small farmers have benefitted little from this approach as they have different needs and apparently do not see its relevance to increase food production. If research priority setting would be done at regional level, and if regional cooperation and participation of small farmers would become a more basic organisational principle, the poor in these areas could probably benefit more from international agricultural research than they did in the past three decades. Many Civil Society Organisations (CSOs) therefore call for regionalisation of agricultural research.

Although the CGIAR has made certain politically important moves, notably by putting its genebanks under the auspices of FAO, by supporting action against biopiracy and by rejecting the Terminator technology, they have not looked into the negative aspects of Green Revolution agriculture. With pressure increasing after the UNCED in Rio in 1992, a "Renewal" was launched, and at the end of the 1990s, a "System Review" questioned the whole CGIAR system. But few changes have resulted.

To increase the relevance of its research to small farmers, the CGIAR took the initiative of organising the Global Forum on Agricultural Research (GFAR) in Dresden, Germany, 21-23 May 2000. Many CSOs as well as the world's largest organisation of small farmers, La Via Campesina, joined the meeting in a sceptical but constructive mood. The rare opportunity to discuss on equal level with scientists from formal research organisations was considered valuable. They were somewhat sobered when their distinctly different position, especially on modern biotechnologies, was levelled out in a Global Vision, and their offers to collaborate were hardly noticed. However, they backed the idea to have Regional Fora and a Global Forum, where research priorities were to be set, and opted for including development issues in the Fora (1).

A year later, in May 2001, "Change" was on the agenda of the CGIAR biannual meeting of its members, the Northern donor governments and foundations, and a number of Southern governments. Yet, the decisions taken in Durban, South Africa, point to more centralisation, not regionalisation. Part of the future research was to be organised around "Challenge Programmes". And new topics were presented - the impact of climate change on agriculture; water management; and the impact of disease on livestock production and trade – in order to attract new funding, even before a priority setting process was carried out in the regions.

More centralisation is likely to come from the three other structural decisions:

- To abolish one of the two annual CGIAR member meetings, and to establish an Executive Council administered from the World Bank, Washington. The Interim Executive Council consists of a limited number of "shareholders" (CGIAR/GFAR terminology for donors), and representatives of Centres, GFAR, industry and NGOs. Small farmer organisations (SFOs) do not have a seat. The rest of the donors may come as observers, making the poorer South less likely to afford attendance at the foreseen two to three yearly meetings.
- To abolish the FAO-based Technical Advisory Committee, which had a budgetary say and carried out strategic research planning and impact assessment. These functions will most likely be attached to the Executive Council. The functions of the new FAO-based Science Council are under consideration; in the worst case, they may be limited to peer reviewing.
- To increase power to Washington with a new System Office that provides services to the Centres, especially for public awareness and fundraising. The existing CGIAR Secretariat will probably be integrated into this Office.

CSOs presented their ideas on a regionalised agricultural research system, where the role of the CGIAR would be catalytic (2, 3). This was strongly supported not only by the regional research organisations, but also from many donors. Regional priority setting is important to the CGIAR and its donors. But, the GFAR chair R.K. Paroda could report only very slow progress. Broadening the participation from national agricultural research institutes to include other "stakeholders" (CGIAR/GFAR terminology for constituencies), like farmer organisations and NGOs seems to be especially difficult. The CSO regional contact persons who were nominated in Dresden have been only marginally involved. In Central America, two parallel processes are developing: La Via Campesina and the NGO Committee have started regional priority setting by SFOs and NGOs, in addition to the Regional Forum. The GFAR has announced its readiness to integrate the two.

Participation of CSOs at the final CGIAR Mid-Term Meeting in Durban was higher than ever before. The NGO Committee of the CGIAR, after arranging an electronic conference early this year, held an international CSO/SFO workshop in Frankfurt, Germany, that produced a "CSO Declaration for Durban" signed by eighty CSOs (2). An African NGO workshop in Durban, likewise organised by the NGO Committee, supported the issue with a declaration and a press statement; many of the 40 participants were active during the Mid-Term Meeting. The Canadian-based RAFI and the German NGO "Forum Environment and Development" presented a joint paper (3) and commented on the Durban decisions when the meeting ended. CSOs will continue to advocate for the regionalisation of the CGIAR in preparation of the International Centres' Week (renamed the Annual General Meeting) in October 2001.

Farming economically to revitalise agriculture

Jan Douwe van der Ploeg

Many of the attempts to revitalise agriculture in Europe and to create sustainable rural livelihoods involve a shift away from agriculture's traditional 'core' activities - production of food and fibre. By means of diversification 'new' on-farm activities such as farm tourism, care and on-farm processing are introduced. These new rural development practices are often perceived as a 'rupture' with conventional farming practices (e.g. conversion to organic farming). However, a considerable proportion of the alternatives in rural development is emerging gradually from conventional agriculture. This will be illustrated by the example of dairy farming in the province of Fryslân in the Netherlands. Similar examples are found also in other agricultural categories, elsewhere in the country.

Farming styles

In the past four decades, farm development in Europe has been dominated by the modernisation paradigm. Continued scale increase and intensification was seen as the only viable type of farm development.

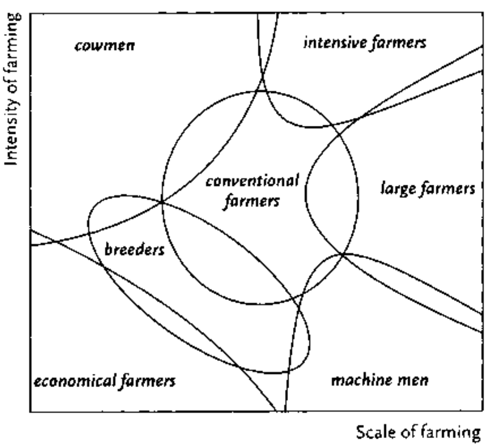

Figure 1. Farming styles in Friesian dairy farming

Several studies have pointed out that the homogenisation of agriculture - envisaged by modernisation policies – through the disappearance of 'non-viable' farms has not, in fact, occurred. Heterogeneity in farm type and structure is a persistent feature of European farming and the indications are that this diversity increased during the modernisation period. The patterns of heterogeneity in agriculture correspond to different farming styles (Van der Ploeg 1994), which are essentially the different strategies applied by farm households in respect of the markets, policies and technologies relevant to them. Figure 1 shows the different farming styles in Friesian dairy farming, they are arranged here according to scale and intensity of the farm enterprise.

Farming economically

Farming economically is the farming style that emerged as one of the most important alternatives and unexpected responses of Friesian dairy farmers to modernisation. Farming economically is basically a strategy to contain monetary costs as far as investments, loans and expenditure on external inputs are concerned. Farming economically, therefore, can be equated with 'low-external-input agriculture'. Central to this farming style is also the mobilisation, use, development and reproduction of internal resources.

In the heydays of modernisation (1960-1990), the strategy of farming economically enabled many farms to remain viable without entering into the logic of modernisation. Today, farming economically seems to have become the dominant style. It provides farming families with a way of countering the increasingly threatening situation of limited milk production quotas, decreasing prices, the high cost of land and milk quotas, and the obligation to farm in a more environmentally sound way.

An example: Hoeksma's farm

Together with his two sons, Taeke Hoeksma runs a farm that is a perfect example of farming economically. Compared to a reference group of some 80 dairy farms, this farm shows a wide range of differences. Taken in isolation each difference is small and may seem almost irrelevant. However, taken together the difference is significant. It should be noted that these individual differences are interconnected.

Veterinarian costs are low on Hoeksma's farm - Euro 38 compared to Euro 67 per cow per year. This is related to a lower milk yield - 6,449 kg compared to 7,526 kg per cow - and higher labour input, which means that more care is given to the animals. In turn, a lower milk yield reflects the fact that less industrial feed is used. One remarkable feature is the combination of high grassland production - 8,453 compared to 7,224 kVEM - and the relatively restricted use of fertiliser - 217 kg nitrogen per hectare compared to 300 kg indicating high levels of technical efficiency. The costs associated with hired labour are also low clearly reflecting the high labour input of Hoeksma and his sons.

As much as on the cost side, there are also remarkable differences on the benefit side. Because of the lower milk yield and the composition of feed and fodder, the fat and protein content of the milk produced on the Hoeksma farm is higher. Combined with a particular distribution of production over the year - winter milk gets a better price - this translates into a higher milk price. When additional revenues from the sale of heifers and cows are also included, the total revenue on Hoeksma's farm comes to Euro 39.41 per 100 kg milk compared to Euro 34.42 for the reference group. The surplus, after deducting all costs except those associated with labour, is Euro 11.12 compared to Euro 5.23. While the labour input on Hoeksma's farm is much higher, the 'nett margin' is the same implying that higher labour input is remunerated according to normal standards.

This concrete example enables us to better understand the concepts of the strategy of farming economically. Agricultural production is built on two resource flows (Van der Ploeg et al. 2000). The first flow refers to the mobilisation of resources through markets in the form of commodities, the second to the production and reproduction of resources within the farm.

Farming economically (low-external-input agriculture) could be specified as the search for the domination of the second, non-commoditised flow over the first, commoditised one. It also involves a search for a high level of technical efficiency - the ratio between the total output and the resources used - without entering too deeply into new chains of dependence, i.e. without enlarging the first flow of commoditised resources. In this way three elements emerge as decisive in the strategy of farming economically.

1. The overall degree of commoditisation is low.
2. The technical efficiency is high due to the centrality of both the quantity and quality of labour.
3. The socio-technical networks through which resources are mobilised contrast with markets as they are primarily based on non-commoditised relations.

All these elements can be found on Hoeksma's farm. Labour and craftsmanship play a central role. The use of external inputs including veterinarian services, hired labour, cattle feed, bought fodder, fertiliser, and animal purchases have been significantly minimised and contrast sharply with practices on farms in the reference group. At the same time the use of internal resources such as grassland and manure is geared to high levels of technical efficiency. In this respect, it is significant that several of the resources available have been developed and specified so they fit within the overall strategy. Hoeksma, for example, uses traditional Friesian cattle rather than the widely used Holsteins. It is also significant that he and his sons participate in several nature conservation and landscape management schemes.

Relevance of farming economically

Modernised farming with scale increases and farming economically at farm level can both lead to a reduction in cost price. Their effects on rural development in the wider sense, however, are very different (see Table 1).

Farming economically generates more income and employment through decreased dependence on external resources that have to be mobilised through the market, and higher levels of technical efficiency. In addition it is a strong response to deteriorating market conditions and may provide an adequate line of defence to further squeezes that result from the forces of liberalisation and globalisation. Therefore, farming economically is an effective way of reproducing farming over time and one that has shown itself to be highly competitive. Because of the strategy of farming economically, more farms - and therefore employment and income opportunities - have been retained in the countryside and this has contributed to its liveability and social cohesion.

The impact of farming economically on rural development, however, goes beyond strict economic parameters. In environmental terms, it tends to be more sustainable than other farming styles. Several studies have pointed out that economical farming results in relatively low levels of nitrogen loss and that further reduction is in line with their farming strategy. Ecological sustainability and economic efficiency do not necessarily run counter to each other. The two can coincide and strengthen each other within the 'low-external-input' strategy of farming economically.

Starting point for rural development

Farming economically developed historically as a multi-purpose use of resources. Economical farmers worked to secure small benefits wherever possible and together these contributed in generating a viable farm income. In the changing context of rural development, continuous adaptation through small steps for risk avoidance appears to be one of the greatest potentials of the style of farming economically. National surveys indicate that the rate at which economical farmers enter new rural development activities such as nature and landscape management is relatively high, 34% compared to 15% for large farmers. Similar differences emerge when other activities such as organic farming, direct sales, multiple activity or mixed farming are discussed. Farming economically appears to offer a viable starting point and reservoir for diversification into other fields of rural development. Several features of this particular farming style, such as its high labour input, the incidence of surplus labour, independence from external inputs and relatively low stocking densities, result in more flexibility when it comes to the opportunity of taking up new rural development activities. Other farming styles – especially those of large and intensive farmers – are much less flexible.

'Protected spaces' needed

Despite the potential for rural development, the prospects for farming economically are somewhat contradictory. As a farming style it runs counter to the dominant 'technological regime'. The interrelated whole of (new) technologies, prescriptions, laws and regulations (especially generic legislation to reduce pollution) and knowledge stocks, for example is evolving in such a way that any room for manoeuvre that may have been available for the economical farmers is being progressively reduced. The Dutch agro-expert system that, for a variety of reasons, focuses strongly on economies of scale plays a crucial role in this process.

The critical factor in the success of economical farmers and their institutional allies will be their ability to develop and consolidate what Iacoponi, Brunori and Rovai (1995) have called 'rural districts'. The rural district is a political, institutional or territorial space that provides the conditions necessary to stimulate strategic innovation and the development of appropriate farming systems. Only when such 'protected spaces' are created within the dominant 'technological regime' can the style of farming economically prosper and unfold further along the lines of rural development. The central question for rural development policies at supranational, national and regional level is whether or not they will contribute to the construction of such 'protected spaces'. Such an approach, I think, would be far more cost effective than a multitude of rural development subsidies.

Table 1: Comparison of the key features of farming economically and modernised farming

Farming economically	Modernised farming
1. Sustain and/or improve income levels by developing and recombining self-controlled resources	1. To sustain and/or improve income levels new resources are mobilised through markets
2. Flexible and multiple use of resources	2. Resource use and allocation is highly rigid
3. Step-by-step development of proportionate nature (built upon available resources)	3. Continuous scale-increase of disproportionate nature (dependent upon external resources)
4. High level of surplus per unit end-product	4. Low level of surplus per unit end-product
5. Tendency towards multipurpose enterprise	5. High degree of specialisation
6. Local innovativeness is central	6. Dependent on availability of new technologies
7. Step-by step changes, learning by doing	7. Pattern of 'turn-key' projects
8. Centrality of family labour and community networks	8. Pursues technological solutions and formal institutions
9. Can influence off-farm prices and be active in building markets	9. Off farm prices and markets are 'fixed' and are to be passively followed
10 Low level of external inputs, low financial costs	10. Labour is replaced by inputs and new technologies
11 Sustainability (to be) grounded on 6,8,10	11. Sustainability (to be) grounded in 7 and 8
12 Farming is (re)-connected to local ecosystems	12. Farming disconnected from local ecosystem
13 Relatively small resource base needed to generate acceptable income level	13. Relatively large resource base needed to generate acceptable income

Family agriculture and globalisation

Farmer organisations need tools to improve their strategic positioning in relation to local and global change. Photo: CIRAD

Bruno Losch

Family farms throughout the world play a central role in the production, processing and commercialisation of agriculture, and in natural resource management. Family agriculture is characterised by the special link between economic activities and the family structure, which affects the decision making process, the organisation of family labour, the choice of activities and the management of family wealth. Family farms are very diverse and operate in a variety of economic, social and ecological conditions. Family farmers can be landless, small-scale or large-scale; they could produce for home consumption and the local or international markets, and are increasingly involved in off-farm economic activities. Having to adapt to new conditions, frequently, has kept them innovative.

Since the eighties, family agriculture is being confronted with a rapidly changing economic, institutional and political environment. Several crucial economic reforms are taking place: structural adjustment, liberalisation and globalisation of trade and development of regional trade zones. These changes are accompanied by radical institutional reforms due to the withdrawal of state intervention leading to reduction of support services to farmers, reorganisation of production sectors, revision of land tenure legislation, decentralisation of administration and planning, etc. Farmers face international competition, the removal of price regulations and subsidies and the closure of national product boards. In most countries these reforms also bring political liberalisation that provides new space and opportunities to economic actors, local institutions, professional organisations, NGOs, and civil society in general, at local and national level. Family farmers and their organisations are forced to adapt to these changes. This

The African Farmers' Academy

The African Farmers' Academy (Upafa) has been created by the APM-Africa Network (Agricultures Paysannes et Modernisation) for strengthening the capacities of farmer organisations to better understand the rapid economic and institutional changes that are taking place, designing strategies that match the expectations and interests of their members with the opportunities and constraints of the new (inter)national market place and improving their skills to take part in consultations and negotiations. The CIRAD-TERA Family Agriculture programme is one of the partners in this project. In February 2001, Upafa started with the first module of an alternating training (combining training sessions and individual work on the participants' own organisation) course in Dakar, Senegal. 25 officials from national, regional and local, sub- and multi-sector based farmer organisations from 12 African countries are participating.

Six 15-day modules have been planned for the coming two years. The modules will focus on analysis of the evolution of the participants' local societies and developments in the national and international context (1), changes of the economic (2) and institutional (3) environment of agriculture; the positioning of farmers organisations in a changing world (4), the objectives and approaches of strategic planning (5) and strategic programming and negotiation (6). The second and third modules will be organised in Mbalmayo, Cameroun and Bohicon, Benin respectively.

The training will place emphasis on the participants' experiences and contributions, and will stimulate reflection and action. Each participant will draw up a professional project during the period of training in relation to his/her organisation. The diverse backgrounds of the participants will enable comparison of experiences and passionate discussion.

This initiative is supported by the French Ministry of Foreign Affairs and the Charles Leopold Meyer Foundation.

More information: Upafa, c/o Réseau APM-Afrique, BP 10008, Yaoundé, Cameroun. (237) 21 53 89, Fax : (237) 20 55 20, email : apm@camnet.cm means improving their skills to analyse the new situation, to develop new strategies, to plan and implement new activities, and to become effective players in the economic and political arena. Professional farmer organisations play an increasingly important role in rural development, taking over services previously provided by the State and engaging in economic and political negotiations.

The Family Agriculture programme of CIRAD

This programme is one of the 28 research programmes of CIRAD, a French governmental institution, which undertakes collaborative research to support agricultural and rural development in tropical countries. The programme has 4 main objectives:

- To analyse adaptation processes of family farmers and their organisations to the changing environment
- To identify technical, economic, organisational and institutional innovations that enable sustainable adaptation of the agricultural production/ processing units and services to the new context
- To study support structures that can give farmers more control over the processes of change, for example, strengthen farmer organisations to take part in consultations and negotiations.
- To strengthen farmers and their organisations to make better use of the opportunities created by the new economic, political and institutional environment.

The research programme follows three thematic lines:
The **first** focuses on the strategies of the actors and the way they take decisions. It deals with the diagnosis of the production units, their objectives, the changing environment and room for manoeuvre. It provides tools to improve diagnosis and decision making by local actors. Among the current projects are studies of the strategies and dynamics of farmers in the irrigated zone in Senegal and in the cotton-producing areas of Western and Central Africa, and the interactions between the climatic and economic risks in the technical choices made by farmers in Brazil and Mexico.

The **second** looks at farmer organisations, agricultural institutions and services. It deals with the reformulation of roles between the public and private sectors and the coordination of stakeholder action. Current projects include the collaborative research-action-education programme (see box p.25), support to the African Farmers' Academy (see box p.24), strengthening the role of farmer organisations in research and extension services in Western and Central Africa, helping farmers to improve cotton marketing in Mozambique, and creating a website on microfinance (http://www.cirad.fr/mcredit).

The **third** line is on value adding and marketing of agricultural products. It deals with analysis of the regional dynamics of production, processing and commercialisation, and ways to support rural agroindustry to improve the quality and commercialisation of local products. In this way it mobilises and strengthens local expertise and production systems. Some projects are: promotion of agrifood resources and culinary expertise in Africa, and assistance to the Latin American rural agribusiness network - PRODAR (www.prodar.org), consisting of 15 national networks of development organisations, research institutes, universities and producer organisations. PRODAR promotes rural enterprises in micro-regions – local agrifood systems – to improve the competitiveness and commercialisation of local products, for instance, *camu camu*, a fruit from the Amazon with a high content of vitamin C and *uña de gato* and *sangre de grado*, plants used as natural medicines.

Farmer organisations deal with the challenge of globalisation

The collaborative research-action-education project 'Farmer organisations deal with the challenge of globalisation' finalised its first phase with an international workshop in Montpellier, France, in November 2000. It brought together the country programme coordinators from Ecuador, Chile, Peru, Uruguay, Senegal, Cameroon, Benin, Zimbabwe and China. Several organisations of farmers and indigenous people were involved in each country. This project is implemented with the networks RIAD (Red interamericana agricultura y democracia) in Latin America and APM-Africa with support from Charles Leopold Meyer Foundation and the French Ministry of Foreign Affairs.

The objective of the programme is to provide farmer organisations with methods and tools to improve their strategic positioning in relation to local and global change. The first phase focused on the analysis of the economic and institutional changes faced by family farmers in the past 15 years, how the farmer organisations perceived these changes and the activities developed by the organisations in response to the new challenges.

The workshop provided opportunity for comparison and reflection on the methodologies used and results obtained by the national and international teams, and formulation of the objectives, activities, methodologies and organisation of the second phase of the project.
It was concluded, among others, that the economic and institutional reform programmes in all countries are very similar in objectives, principles and orientation, though implemented differently. Farmer organisations, therefore, should not generalise the analysis of their situation nor develop uniform strategies. Each situation is different and has to be analysed thoroughly to understand what room for manoeuvre farmers and their organisations have.

In all countries, the economic production environment has become less stable and family farmers tend to respond with short-term strategies. The capacities of farmers to cope with the constraints and make use of the new opportunities created by the reforms differ largely. This causes further socio-economic stratification and competition for land, and sometimes for water. Agriculture in peri-urban zones and sectors of family agriculture not involved in export production are particularly vulnerable. Many family farmers do not have the resources to improve the competitiveness of their products. Thus, the search for competitiveness and the impoverishment of a large part of the rural population is increasing pressure on the natural resources and the employment situation.

The strategies developed by the organisations vary between technical/ institutional adaptation and efforts to change the rules of the economic and institutional games. Two main strategies in the first category are:

- Improvement of the competitiveness and profitability of agriculture and development of a support structure to reach this objective.
- Development of 'alternative agriculture', technically (sustainable agriculture, biodiversity, etc) as well as economically (direct relations between producers and consumers, fair trade, etc).

Sometimes both strategies are combined. In some instances funding agencies have a strong influence on the strategies followed.

In the second phase of the research-action-education programme the Latin American partners will focus on farmer organisations and democratisation (e.g. decentralisation of power, participation in policy making), farmer organisations and sustainable agriculture, food security and regional integration. The African partners will focus on the contribution of farmer organisations to development of a culture of peace for prevention and mediation of conflicts, coordination of farmer organisations at regional and national level, and rural development programmes implemented by farmer organisations with a sectoral and territorial focus.

Strengthening Local Economies and Community Identity

Pascal Molineaux

All over the world, the increasing force of social and economic globalisation has undoubtedly been a phenomenon of great impact in the community-sustaining network of human relations during the last decade. Numerous studies demonstrate how human relations inspired in an essentially competitive spirit with market oriented values - actively promoted by global enterprises whose only goal is short-term maximisation of economic profits - are penetrating into the social and cultural value systems of people, displacing traditional values and eroding essential community-based identity structures.

Historically, the human being has always had a deep-rooted communal identity. Constructed through a complex network of interdependent human relations, based on common beliefs and value systems, trust built through social interactions, a common history and spontaneous solidarity, this identity until very recently still gave orientation and purpose to life. A child grew – and should continue to do so – embedded in and protected by a nuclear family, itself within an extended family in which cousins, uncles and grandparents play a fundamental role, and a healthy community of neighbours and friends. It is in these three social contexts – of the close family members, distant family members and community – that the child develops a sense of belonging, a sense of identity and purpose in life. These, each in their own particular way, serve to educate and guide the child through life.

Organisation and knowledge - cornerstones of education

It is in this context that FUNDAEC's (Foundation for the Application and Teaching of the Sciences) grass roots experience in strengthening local economies and community identity can be analysed. Fundamentally, this experience is centred in the creation and evolution of locally based learning institutions and economically oriented structures that belong, in a true sense, to the local communities themselves. Organisation and knowledge are considered by FUNDAEC as the two main elements needed for people to take charge of their own development and interact as equals with the outside world. The learning institution that evolved in the pursuit of achieving this purpose through education is called the Rural University. It is a community-based system for the development of human resources. The Rural University sets in motion a series of learning processes in which the knowledge generated by rural people helps to create and increase the forces necessary to resist social disintegration and, eventually, to achieve positive change.

Tutorial Learning System (SAT)

The Tutorial Learning System (SAT in Spanish) is a high school equivalent curriculum embedded in the reality and needs of rural life. It is now approved by the Ministry of Education in Colombia and has close to 40,000 students in Colombia and another 2,000 in seven other countries. It offers an interesting experience in the creation of a locally rooted (and relevant!)

educational system connected to a national – and now international – movement of NGOs, public institutions and communities. The local SAT groups, of 15-20 students, guided by a trained tutor from the same community, have demonstrated their potential, as they apply the service oriented principles and concrete knowledge gained through the study of the SAT texts, to become active groups in the strengthening of a community identity. Their activities – which reflect an enormous diversity – cover educational activities with younger children, environmental activities, education, artistic, cultural and sporting events – and directly or indirectly foment a sense of community, of belonging. These activities have shown a great potential, especially among the participants and other youth in the community, in developing a sense of worth, a sense that rural, community based life is possible. This is remarkable in the context of a country known for its high rate of violence and insecurity, accelerating an already high rate of rural outmigration. No doubt, such a feat is, in each local context, a much-needed contribution to peace and understanding.

Moreover, the SAT educational movement strives to connect the participating students and institutions – now close to 50 NGOs and public institutions in Colombia alone – to the reality of a world advancing towards greater levels of unity. Achieving this, which is at once the promise and challenge of globalisation, we believe, can only be done, if the local, regional and national identities and value systems are strengthened and recognised. If not, globalisation will continue to cause havoc in the local economies, traditional value systems and community rooted identity, as it has been doing everywhere. Giving the SAT students – most of them living in marginal and isolated rural villages – access to modern knowledge systems is indeed a tremendous challenge, as this has to be done respecting their own empirical understanding of life's purpose. This is, in essence, what the programme strives at: providing a social learning space in which the students, with their own life experience, can participate in generating and applying knowledge in their own social and cultural contexts.

Positive results

And indeed, the programme is seen as truly revolutionary, providing very positive results. Graduates of the SAT programme emerge with comprehensive knowledge in agriculture, animal husbandry, soil chemistry, and other fields traditionally associated with rural vocations. They also come out with knowledge about how to create micro enterprises and have a greater consciousness of living in and serving their community. As such, they can, and do, initiate and participate actively in community development processes. Rural youth, who would otherwise have left in search of work, are now staying back and setting up small enterprises within their own communities, and earning their own living. SAT graduates have, in many communities, begun to take up some of the key public posts, like running the public telephone office, the public library, the local pharmacy, the kindergarten programme etc. These are the types of positions for which, in the past, the municipalities had to (and still do in many cases) find people from outside the community.

Solidarity groups

The other programme in which FUNDAEC has developed a noteworthy experience is in the creation and strengthening of solidarity groups in a wide variety of rural communities. The programme started in 1990, inspired by the example of the Grameen Bank of Bangladesh, with the help of a long-term loan from the InterAmerican Development Bank. The credit was used as an excuse to create local solidarity groups, in the belief that the traditional values of reciprocity, interdependence, trust, mutual help could be strengthened and thus contribute to enhance, in each community, a sense of collective identity. No doubt the increasing presence of a market-oriented economy and values emphasising the competitive, individualistic spirit have contributed to the erosion of such a collective sense of identity. As the programme has grown, the groups have shown great potential, each group receiving a basic training in solidarity-based value systems and the technical aspects of the productive project they plan to implement. On the one hand, the small productive projects have increased the welfare and given a greater sense of security to the participants. On the other, they have helped to foment, or strengthen, in the participants those essential values that gave – and must continue to give – meaning to the concept of community.

Return to community values

Members of solidarity groups support each other by sharing resources, knowledge and labour. Solidarity, in this case, is not confined to a group, but reaches out to other groups and the community at large. A few examples will suffice. One group member, in the village of Padilla in the Cauca department of Colombia, became aware that an elderly woman, living in a small house, in very poor conditions, had a leaking roof. The rainy season was soon to start. The group decided to provide a helping hand, as they had previously established a small solidarity fund. They all participated, during a whole day, in rebuilding the roof – the women preparing juice (the day was hot!) and food in abundance, each group member bringing some contribution for the reconstruction of the roof – nails, wood, tiles. In one day, the elderly women discovered she was a member of a community that cared for her, the participants rediscovered how powerful the principle of unity is, and the community recuperated a long-established tradition of mutual help – MINGA – that had of late been abandoned to a great extent. Another nucleus of five solidarity groups, in the neighbouring village of La Arrobleda, decided to pool their resources to buy a bull for their thirty or so milking cows. One person was responsible for taking care of the bull and costs were shared amongst all. They also decided to make the bull available to any community member who might need it, for a small fee. In another community, one of the group members lost her cow as it indulged in the sugar cane based sweet she produced. The group members and other members of solidarity groups in the community chipped in, and she was able to renegotiate the reimbursement of credit she had received to buy the first cow and get more credit to acquire a second cow. Again, this was possible because the network of human relations which make up community life and identity were alive and strong, thanks in part to the solidarity based groups established in the community.

Strengthening local communities

FUNDAEC's experience points clearly at two essential aspects to be considered if local communities are to confront the great – and potentially destructive – force of social and economic globalisation. Providing access to knowledge, in all its modern complexity, along with its generation and application as it interacts with locally based knowledge systems, is one. Efforts to create local structures that serve in strengthening local economies, within the context of a community value system and identity, is the other. And they go hand in hand.

Bia Kud Chum

A tool for creating strong, self-reliant communities

Wanlop Pichpongsa, Menno Salverda and villagers

The setting is Kud Chum district in Northeastern Thailand. The Green Revolution and the liberalisation of markets has led to community members becoming more and more dependent on externally set prices for rice, their main crop. They have entered a vicious cycle of debt, lost their community forests and indigenous knowledge, particularly in areas such as herbal medicines. As a result, they now face issues such as health problems and an exodus of village youth to Bangkok in search of work.

Various villages have over 20 years experience in trying to alleviate the problems of debt and achieve self-reliance. Their efforts have led to the formation of many active community organisations such as associations of traditional herbal practitioners, initiatives for integrated agricultural, a community owned rice mill supporting chemical free rice production, cooperative shops, women's producer groups and 'self sufficiency groups'. 'Self-sufficiency groups' aim at healthy production for household consumption, selling only the surplus of their goods. They also promote exchange of labour and tools amongst community members.

Why a community currency system?

In September of 1998, representatives from Kud Chum attended a seminar on community currency systems and self-reliance. They realised the many benefits that a community currency system would accrue: increased production for local consumption and self-reliance in the community; lower dependence on external markets; reduced outflow of money (Thai baht) and other resources from the community; decreased indebtedness as less money/credit is needed; enhanced diversification and sustainability of production; revitalised indigenous knowledge and good social relationships.

This sparked the creation of a local exchange system later named "Bia Kud Chum". In the Northeastern (Isan) language, 'bia' means 'seedling'. The name reflects the aim to develop into strong, thriving communities like small seedlings growing into large trees. As community members in Kud Chum are not very familiar with accounting practices, an user-friendly coupon or notes-based system was chosen.

How it is implemented

A working committee was formed to set up a community exchange system in five villages. It was given three main functions:

a. Accounting, which is carried out by elected managers. The managers facilitate the withdrawals and deposits of bia and administration of bia accounts.
b. Extension activities to support efficient and balanced use of bia between members
c. Monitoring and evaluation of the use of bia.

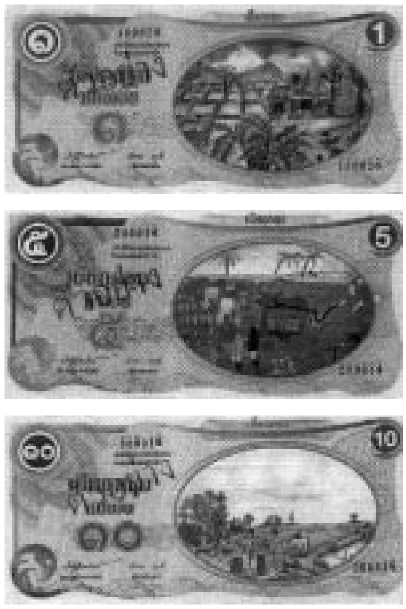
Group members have a credit limit of 500 bia, which they can withdraw from the "Bia Bank" (this name was abandoned due to lack of permission). Bia cannot be exchanged for baht and no interest is charged on bia withdrawn from or deposited into a member's account. Exchanging goods and services in the participating villages can be done using bia only, using bia together with baht or using baht only, depending on what the buyer and seller agree upon. Activities like community markets and skills training to stimulate diversification of local production were organised to support local exchange.

Bia Kud Chum ... against the law?

The community started to use bia for the first time in March 2000, attracting much attention from the mass media and officials. Some feared the use of bia might violate the law or could be a danger to national security. Some even suggested it could be a strategy to create an independent state. Due to this attention and under pressure from the Bank of Thailand (BoT), the use of the bia was suspended at the end of April, after just one month in circulation.

In July 2000, at a meeting of the Board of the Bank of Thailand, it was concluded that the use of Bia Kud Chum violated Article 9 of the Currency Act of 1958. This article 'forbids anyone from making, distributing, using or issuing any material to replace currency, except where permission has been granted by the Minister of Finance'. However, the Ministry of Finance (MoF) is considering the case again.

After a lull of 5 months, the villagers of Kud Chum resumed their activities in October 2000. However, transactions with bia are very limited due to the legal problem.



Community members produced poems and paintings illustrating the local way of life for the bia notes.

What's next?

In their efforts to become self-reliant, the five communities have been accused of breaking the law, an accusation that is far from being justified. Even though the Government has announced its intention to encourage the development of self-reliant and strong community economies, the case of Bia Kud Chum shows how it actually prevents this from being a reality.

"Bia" Kud Chum is indeed a seedling that, as it takes root, will help to bring about self-reliance for communities in Thailand. However, before seedlings can become great trees, and before these communities can achieve self-reliance, they will face many obstacles. The drive to overcome these obstacles requires the collective energies of people from a variety of backgrounds, communities, development organisations and government. There is a need to think, learn and explore alternatives together and to support each other in this quest for more just and sustainable economic systems.

Recently, the Thai Community Currency Systems Project (TCCS) held a meeting on community currency in which academics, NGOs, the BoT, the MoF, and the villagers from Kud Chum participated. There is a strong possibility now that Bia Kud Chum will be developed into a research project.

Catalysing change in Ladakh

Helena Norberg-Hodge

When I first visited Ladakh in 1975, life in the villages was still based on the same foundations it had been for centuries, evolving in its own environments, according to its own traditional Buddhist principles. In the past, the region was protected from both colonialism and Western-style 'development' by its lack of resources, inhospitable climate, and inaccessibility. Change came slowly, allowing for adaptation from within.

One of the first things that struck me about Ladakh was the wide, uninhibited smiles of the women, who moved about freely, joking and speaking with men in an open and unselfconscious way. Though young girls may have appeared shy, women generally exhibited great self-confidence, strength of character, and dignity. Traditionally, most significant for the status of women in Ladakh was the fact that the informal sector of society, with women at the centre, played a much larger role than the formal sector. The focus of the economy was the household; almost all important decisions had to do with basic needs and were settled at this level. The public sphere, in which men tended to be leaders, had far less significance than it does in the industrialised world.

Since about 1974, however, external economic, political and cultural forces have descended on the Ladakhis like an avalanche, bringing massive and rapid disruption of all aspects of the traditional culture. Like so many other cultures exposed to the centralised global economy, Ladakh has become ever more dependent on distant centres of production and consumption. As local economic and political ties have been broken, Ladakhis have become estranged from one another. As the speed of life and mobility have increased, familiar relationships have become more superficial and transient. Villagers have come to be identified with what they have rather than with who they are. As a result of these changes, I have seen the strong, outgoing women of Ladakh being replaced by a new, alienated generation, unsure of themselves and extremely concerned with their appearance. Traditionally, the way a woman looked was important, but her capabilities, including tolerance and social skills, were much more appreciated.

In opposition to these trends, there is now a growing movement at work to restore and promote traditional culture in Ladakh. We at the International Society for Ecology and Culture (ISEC) have been working with an increasing number of non-governmental organisations and Ladakhi leaders to restore respect for Ladakhi culture and to counter the avalanche of forces that have led to a loss of self-respect among Ladakhis. One of these organisations is the Women's Alliance of Ladakh (WAL), which has gained considerable reputation for its work in promoting and preserving the cultural and spiritual foundations of Ladakhi culture. WAL encourages members to retain their cultural identity by challenging the claims of 'progress'. Groups of women from different regions of Ladakh come together to discuss the impact of 'development', their feelings about current trends, and their ideas about Ladakh's future. They talk about how communities and families are being broken down by the psychological pressures of advertising, television, and tourism; about the greed and envy that are now separating people; and about the women who have stopped spinning because it has come to be seen as 'backward'. Ladakhi women have been greatly strengthened by the opportunity to join with others to discuss these issues. Many now have renewed pride in being farmers, and in providing for their families.

The women of Ladakh are both willing and able to take direct, collective action to resist the forces that beset Ladakhi culture. A "No TV Day" has been organised, as well as a demonstration that managed to reverse a rule prohibiting the sale of women's vegetables in the central bazaar. In 1998, the WAL organised a tour of twelve villages in order to discuss the kind of future Ladakhi women wanted for their children, and to speak as a collective voice to influence more effectively the policies of both village leadership and the government. A further objective of the tour was to exchange local goods and to raise awareness about the need for the continued replanting of local crop varieties in the face of persistent government pressure to use "Green Revolution" technologies. As the tour moved from village to village, the group steadily grew in size, as women in each village responded to its message.

All of WAL's efforts, we believe, have had much positive impact on different sectors of Ladakhi society. These efforts have helped fuel a mounting dialogue among members of the community about appropriate paths toward the future and have had, at their core, women working for change for women.

"Barah Anaaj" - Twelve food grains: traditional mixed farming system

Vijay Zhardhari

Introduction

Terrace farming is practised in the UttarKhand district of the middle Himalayas. "*Fasal Chakra*" or Crop Circles is a method of farming adapted to the climatic conditions. Modern agriculture has tried but not succeeded in destroying this tradition of mixed cropping.

Two year rotation and mixed cropping system

Mixed cropping of the twelve food grains is done prior to the *Kharif* season. In different regions, these seeds are sown from mid-May to mid-June and harvested from mid-September to mid-October. These fields are left fallow after that, and are prepared again at the end of March. Farmyard manure is applied. Paddy and barnyard millet are sown and harvested by end September. In the *Rabi* season, wheat, barley and m*asur dal* is grown and harvested by end April. Again in the third year, twelve grains mixed cropping is done.

Twelve food grains mixed system

Ragi (finger millet) is the main crop of this system. Amaranth, *rajma* (kidney beans), lobia, horse gram, *math* (traditional soya), buck wheat, sesame, *mangjeer* (*tilhan* - an oil seed), m*akka*, green gram, black gram, local gram varieties etc. are sown together. In some regions, more or less than twelve grains are grown too. This method is foolish in the opinion of agricultural scientists. But, as it has been developed based on the knowledge and experience of the local people and got accepted from generation to generation, it cannot be unscientific.

Nutritional value of this system

Bread (*roti*) prepared from *ragi* flour supplies energy for a day of heavy work. It is rich in calcium, iron and iodine. *Ragi* grain extract has medicinal properties for animals. *Ragi* malt and extract can be consumed.

Amaranth is used to make bread (*roti*) and sweetmeats during the fasting and festival period. It is rich in fibre and protein. Buck wheat is used similarly. Both crops can be used as greens and have an economic value too. Traditionally, these crops were bartered for salt, but now they have good demand in the plains too.

Amaranth, maize and sorghum plants are tall. Kidney beans climb on these tall plants. These crops do not compete with each other. On the field bunds and rocky parts of the farm, lobia, black gram, local gram, horse gram, green gram and traditional soya are grown. These are consumed as *dal* and are used for other delicacies. Horse gram prevents the formation of stones in the kidney and other organs. And for those with the problem, consuming boiled horse gram water for one month can help cure it without surgery.

Traditional soya is considered the best among the *dals.* It is roasted and eaten like gram and is very delicious. Its flour is given to lactating cows to increase milk production. These cereals, pulses, and oil seeds provide all the nutritional requirements of the farmers.

The crops of the 'Barah Anaaj' system strengthen the inseparable relation between farming and livestock. The crops give valuable straw and husk for animal consumption.

Seeds of the twelve food grains mixed farming system. Photo: Coen Reijntjes

Pest, disease and drought resistance

This system is more or less free of pests and diseases. Even if it exists, only one or two crops in the mixture are affected. The rich biodiversity protects the other crops. Even in the case of heavy wind or storm, only one or two crops are affected. The *ragi*, pulses and oil seeds also show resistance against drought. At sowing time, the fields are very dry and the air is dusty. After one ploughing, *ragi* is sown and it needs only one shower to germinate. *Ragi* can survive even an extreme drought. Again, after a light rain and sunny period, inter-cultivation is done with the help of bullocks and local implements.

Problems with modern agricultural science

Modern agricultural science, however, emphasises only mono-cropping. In the hill areas, the agricultural scientists criticise the "Barah Anaaj" system of cropping as backward and uneconomical. Instead, they promote the growing of soyabean as a monocrop. The Government and the scientists of G.B. Pant Agriculture University promoted soyabean as a cash, oil, fuel and protein crop with free seeds and fertiliser kits.

Save the Seeds Campaign

The farmers in the hill area boycotted such cash crops through *"Beej Bachao Andolan"* (Save the Seeds Campaign). This campaign posed some questions to the Department of Agriculture and the agricultural scientists: Who will process the soyabean crop into oil and milk? For whom is the rich protein? In fact, the soyabean is meant for big industries and multinational companies; farmers selling their own products to the market and buying poor quality from the market for their own consumption. Understanding this trap, the farmers are turning back to the traditional system of farming. The "Save the Seed" Campaign is not only about conserving traditional seeds; it is about saving agricultural biodiversity, organic methods of farming and local traditions. The campaign has been able to conserve about 500 crop varieties. Out of this, the farmers are successfully growing about 100 varieties of paddy, 170 varieties of kidney beans, 8 varieties of wheat, 4 varieties of barley, and about a dozen varieties of pulses and oil seeds every year. ■

Nayakrishi Andolon: Recreating community based organic farming

Farhad Mazhar, Farida Akhter, Jahangir Alam Jony & Rafiqul Haque

Most farmers in the flood plains of Bangladesh shifted to Green Revolution agriculture during the sixties. Farmers began to face ever increasing problems as their survival base was being threatened. Gradually, a group of farmers developed an economically viable alternative to modern agriculture, community based organic farming, which is locally called *Nayakrishi Andolon*. Now, due to globalisation, the economic conditions for small farmers are deteriorating even further, and *Nayakrishi Andolon* is becoming a fast-growing movement of farmers.

New ways needed

Tangail is one of the flood-plain zones in Bangladesh. Every year, the river overflows into the paddy lands, often badly affecting the small farmers of the region. In 1988, they approached the local organisation, UBINIG, for support. In working with the farmers, UBINIG found out that it was not only the flood that posed a great problem for the farmers, but also the practice of so-called modern agriculture. To get a more comprehensive understanding of how farmers perceive chemical-based agriculture, UBINIG undertook a study in 1989-90. A wealth of information was collected through group and individual discussions with farmers. The farmers pointed out that:

- The fertility of the soil was clearly declining. More and more fertiliser was required every year to prevent yield decreases.
- The natural fish and frog populations were declining in quantity and diversity.
- Pest attacks in the fields were more widespread and intense.
- A general decline in livestock and poultry populations, not due to economic poverty, but the lack of fodder. The new HYV rice produce less straw than the local varieties.
- There were fewer birds, bees, butterflies and other insects in the village resulting in poor pollination and low yields of fruit trees.
- The nutritive quality of food was declining as farmers produced nearly no pulses and oilseeds, and a far less supply of fish, livestock products and fruits
- The health situation was worsening, with many more gastric, skin and respiratory diseases, and problems of women in childbearing. Pesticides were seen as killers of human beings, used for suicide and murder of women.

The farmers realised that the total amount of products and income of the farm was declining. In the case of HYVs, farmers figured out that calculating productivity and income on the basis of the yield of a single crop is faulty and misleading.

Nayakrishi Andolon

These experiences led the farmers to search for new ways of food production. Initially, the peasant women took the lead in stopping the use of pesticides, mainly for health reasons. Then, a group of farmers organised themselves to experiment with green manure and compost. Compost made of water hyacinth, available in plenty, became quite popular. This was the first breakthrough - this initial group of farmers became convinced that they did not need to depend on pesticides and chemical fertilisers. Soon '*Nayakrishi Andolon'* (New Agriculture Movement) spread from village to village as a community-based movement going beyond sustainable technologies to regeneration of the life activities and social relations of rural communities. It promoted the joy of living creatively with the entire world: human society and nature, visible and invisible, organic and inorganic.

UBINIG plays an inspirational role and is a source of alternative information for farmers. It interprets currently available knowledge into popular language. Together with UBINIG, farmers test new ideas in practical ways. Care is taken not to suppress the wisdom of farmers in the name of "science", yet farming life and knowledge is not romanticised.

Ten principles

As experience and confidence grew, the farmers developed a set of 10 simple principles for Nayakrishi farming.

Principle 1: Absolutely no use of pesticides. Pesticides do not only kill pests, they also kill other ecologically beneficial living organisms. Monoculture is one of the main reasons for pest attacks. Pests can be controlled without the use of poisons.

Principle 2: No use of chemical fertilisers. The land must be made healthy through alluvial sediments, organic fertiliser, crop mixing and agroforestry, which give natural nourishment to the soil and ensure the presence of living micro-organisms.

Principle 3: Manage pests through conservation and constant regeneration of biodiversity. The practice of multi-cropping has become popular, also for pest management.

Principle 4: Agroforestry with integration of local fuelwood, fruit and various multipurpose trees into rice and vegetable fields. Exotic or imported species are generally rejected.

Principle 5: Calculate total production and income of farming to the household and the community as a whole, not as the quantitative productivity of a single crop. This gives a more accurate view of the overall benefits of the farm.

Principle 6: All domesticated and semi-domesicated animals, livestock, poultry and birds are part of the farming household.

Principle 7: Agriculture is also aquaculture.

Principle 8: Seeds and genetic resources are common resources of the community and must be conserved at the household and community level. The privatisation of seeds and genetic resources, the patenting of life forms and genetic engineering is resisted.

Principle 9: Water is wealth because it brings fertile alluvial sediments.

Principle 10: Stop the use of deep tube wells for irrigation. A lot of harm has already been caused to the groundwater and to the cultivable land.

Farmers are aware that "external" application of inputs is a hangover from the old habits of chemical agriculture. They are constantly innovating new ways to increase the fertility of their soil, without "external" inputs. Nitrogen-fixing species of plants and trees are growing in popularity. Where chemical fertilisers have been used extensively, a gradual phasing out is suggested so that a decline in crop output is prevented.

Village workers are the backbone

The activities of Nayakrishi Andolon are coordinated through centres run by UBINIG in all districts to which the movement has spread. Training programmes, workshops and meetings are organised at these centres. UBINIG coordinates the activities of experienced Nayakrishi farmers training new farmers. The farmers use the centres as their meeting places and for mutual sharing of information.

The backbone of the Nayakrishi network is the *gram karmi* or village workers. They are mostly women farmers, who mobilise and train the farmers in their villages. Apart from networking and campaigning, *gram karmi* maintain audits of the natural resources of the village, which is vital in maintaining and managing the local biodiversity. The information is maintained collectively.

An annual farmers and weavers' fair is organised in Tangail to disseminate information at a wider level. Thousands of farmers, including those who follow conventional practices, participate at this fair. As such, it is an excellent event for debates, discussions and sharing of information between and among farmers of different areas. Cultural functions are an integral part of the fair.

Nayakrishi and biodiversity

Control over seed is the lifeline of the farming community. Women conserve, propagate and germinate seeds. The loss of seeds from the household also means a loss of power for women. The women of Nayakrishi, therefore, have started to rebuild their own *veez sampad* or "seed wealth". The concept strongly contrasts with concepts like "seed banks" or "gene banks". The peasant women are against any centralisation of seed wealth in the form of a "bank". Seed collection, conservation, preservation and regeneration in this context states that :

- Women must regain control over seeds and the associated knowledge and skills. The common seeds should be preserved at the household level.
- A specialised network looks after specialised seeds, or seeds that are not considered economically valuable to the villagers in immediate terms. It conducts investigations and tests to know more about particular varieties. There is interaction within and between villages among the seed-network members. Men can also be members of such a network. Information on seeds and collection cannot be shared with any "unknown" persons or agencies without the consent of the group.
- As an initial experiment, a community seed wealth centre enables Nayakrishi farmers to exchange seeds free of charge.
- The community seed wealth centre is based on the knowledge of the women in seed preservation and germination. It uses earthen pots for the preservation of seeds. The seeds are kept in a place not different from a farmer's house. The impact of the weather is observed closely and a standardised drying method appropriate for long-term preservation is studied.
- All *gram karmi* must maintain a nursery, and conduct nursery activities on a regular basis. Nayakrishi *gram karmi* sell their seeds and seedlings for generating part of their income.
- More research is necessary to evaluate and compare the performance of different indigenous and "high-yielding' varieties (HYVs).

With no more poisons used in the villages, farmers see an increase in varieties of fish and a wide range of uncultivated crops, either as partner crops from the multicropping fields or grown on common land. Local species, breeds and varieties of crops and animals are given priority. The trend is in finding a pattern that is best suited for a particular farm in its totality, with livestock, birds and fish. Raising local breeds of livestock is easy and profitable. Local crop varieties are usually economically advantageous and ecologically suitable. Farmers are not against HYVs offered by the formal sector as long as they can collect and preserve the seed, and as long as the varieties do not need pesticides, chemical fertiliser and water. They are strongly against hybrids which make farmers dependent on seed companies. The HYV seeds that can be cultivated the Nayakrishi way play a key role in the transition from the modern to the Nayakrishi system of cultivation.

Mixed cropping, it is important to find a combination of crops that is best suited for a particular farm. Photo: UBINIG

Nayakrishi farmers give priority to local varieties. Photo: UBINIG

Preservation and use of medicinal plants

The medicinal species and varieties are maintained and managed in the wild, although a few are domesticated. Nayakrishi argues that the medicinal value of a plant can best be ensured if the plant is collected from its own natural habitat. According to this principle, the maintenance and management of medicinal plants is done at two levels: through the structure of traditional midwives, and through women farmers who specialise in medicinal plants.

There are always one or two households in the village, who take the responsibility to ensure that all the common species and varieties are replanted, regenerated and conserved by the farmers. Some women specialise in certain species and varieties. Their task is to collect local varieties from different parts of Bangladesh and to monitor and document the introduction of a variety in a village or locality. They keep up-to-date information on the given species. Such specialisation encourages individuals to develop in-depth knowledge in a particular area. Since this knowledge is highly valued by the group, the person gets much respect and recognition that contributes to the process of building up a collective spirit and knowledge-sharing.

Nayakrishi marketing

The Nayakrishi farmers produce enough food crops to meet their subsistence needs. The surplus of vegetables, rice, pulses and oilseeds is sold first in their own villages, in the local *hat* – the weekly market, and bazaar – the daily market. People are very interested in buying food products that are grown without the use of chemical fertilisers and pesticides. Consumers are willing to pay a slightly higher price for better-tasting products. However, Nyakrishi farmers do not want their products to be considered as exotic or luxury items. They must be for the common people. So the farmers do not charge higher prices if they do not have to.

In one area, the Nayakrishi farmers from several villages have formed their own market. They gather twice a week and sell all their products collectively. They have put up a Nayakrishi banner to attract people to this market, which is gaining popularity.

In Dhaka, the capital, there is demand for local rice varieties husked in the traditional *dheki* – the husking wood. The farmers, in a limited way, are supplying this rice to Dhaka.

Counting the benefits

Around 65,000 families all over Bangladesh follow Nayakrishi principles and the movement is spreading fast. Most important is the general confidence among farmers that Nayakrishi is "economically viable". Besides, the ecological situation is improving, the land is regaining fertility and biodiversity is being enhanced.

Farmers' livestock populations have increased by between 100-200%. Their cash income has increased by around 50-200%. Mixed cropping is seen to be three times more productive than monocultures. It also provides revenue from cash crops. Farmers are economically better off because they do not have to incur the costs of inputs, while the crop output is almost the same as that of HYVs. Besides providing food security, it also is a good risk management strategy.

The community seed wealth centres have also been extremely effective. After the harvest, the farmers are obliged to return two times the amount of seed they took. This condition is waived if the harvest is unsuccessful. Most farmers, however, return more than is required of them because the seeds and the seed wealth centres are "theirs" and they benefit directly from them. The farmers can also sell their seeds in the market. Many local varieties have been collected and reintroduced. One seed wealth centre has collected nearly 70 varieties of jak fruit.

The farming community is more confident than before in their capacity to change their life situation. Without pesticides and chemical fertilisers and with a diverse, nutritious diet the farmer families are a lot healthier. There are also cultural impacts such as reduced incidences of violence against women. The very nature of the relationship Nayakrishi brings into the life activities of the villages empowers women, instead of suppressing them.

Potential for upscaling

Poor farmers, those having less than one acre of land, make up 75% of the Nayakrishi farmers. Among them, more women take the lead in mobilising other farmers. Poor farmers are attracted to Nayakrishi mainly for economic reasons. The prices of chemical fertilisers and pesticides have increased significantly, and they have to use more fertilisers than before. Many of them are indebted and forced to sell land because they are unable to cultivate anymore for lack of money.

Over time, Nayakrishi is also gaining acceptance among the middle farmers with 1-3 acres and surplus farmers with 3-5 acres of land. The representation is 20% (middle farmers) and 5% (surplus farmers). While the poor farmers are joining for subsistence reasons, the middle and surplus farmers have acknowledged the economic viability of the organic farming system as a whole. They have also realised the environmental hazards and the loss of biodiversity due to the use of chemicals and the overwhelming practice of monoculture.

At the national level, Nayakrishi is increasingly being taken up by smaller NGOs in their rural activities. Links forged with agricultural scientists is a significant achievement. The Nayakrishi practice has been able to provoke critical reflection in mainstream agricultural thought. A very co-operative and supportive relationship has been built up between Nayakrishi and the main agricultural institutions of the country.

Although policy-makers in the Ministry of Agriculture are quite aware of the Nayakrishi movement, it has received little support at the national level. UBINIG is now trying to influence them through issues of pesticides, seeds and irrigation. Against all odds, it has proven that there is a viable alternative to the destruction of rural societies by "progress".

Back to the local - no more borrowed concepts

Cosmas Gonese and Raymond Tivafiri

The Zimuto area in Southern Zimbabwe is situated near one of the colonial agricultural institutions, which for decades has promoted market oriented conventional agriculture. Consequently, the communities in the Zimuto area were stimulated to adopt 'modern' agriculture. This, however, was done without analysing traditional 'agri-culture' and the local conditions. Many farmers made an abrupt shift from organic soil management to the utilisation of chemical fertilisers, which over the years has led to soil degradation. Many development agencies that came subsequently into the Zimuto area also rejected indigenous knowledge and replaced it with 'scientific' knowledge. They did not try to understand the culture of the communities in Zimuto either. Despite such external pressure, several traditional methods of farming that are combined with expressions of spirituality have remained alive.

A process to heal the land

The authors of this article were freedom fighters who operated in the Zimuto area during the armed liberation struggle in the 1970s. During this struggle there were concerted efforts to improve environmental conservation for livelihood self-sustenance. The communication and interaction between traditional leaders (chiefs, spirit mediums, influential elders etc.) and the freedom fighters were frequent and especially significant when it came to caring for nature.

In 1980, the new revolutionary government was installed. Initially, this government did not address the most pressing issues that the people had been struggling for, such as land ownership and the position of the traditional leaders. In fact, the laws passed in the early 1980s withdrew the power of the local chiefs, and failed to recognise the role of the spirit mediums. Instead, the government appointed local councillors in the communities. These actions led to a dramatic loss in the quality of woodlands, wetlands and other natural resources - the traditional rules and regulations that had protected them were no longer enforced by local leaders. Population pressure and land scarcity, due to the lack of land reform, worsened the problem.

There was a general feeling of unrest because the development agenda of the new government failed to take indigenous practices and institutions into account. In 1984, in reaction to these developments, a group of traditional leaders and war veterans decided to start a process that would try to 'heal the land'.

AZTREC founded

During the first year, local consultative meetings were held in 7 districts, during which traditional leaders, who were also farmers, met to discuss the issues of ecological degradation, lack of land and food security. They discussed a new strategy that would take into account indigenous practices in natural resources and land use management.

At a general gathering held a year later in Masvingo, the chiefs, spirit mediums and war veterans decided to found the indigenous development organisation AZTREC. Their major objective was the conservation of the environment taking woodland management, wetland management, agricultural land use, reforestation and cultural survival as the basic elements of their strategy. Indigenous knowledge, culture, norms and cosmovision are the strongholds of all the activities, which are guided and presided over by the ancestral spirits. The influential spirit medium Mrs Ambuya Nehanda was appointed as the patron of the new organisation. Since 1985 these general meetings of the traditional leaders are held twice a year to guide and advice the organisation.

Woodland management as a starting point

It was decided to take woodland management as the starting point for activities. This was because of the obvious importance of the woodlands for the farming families. In traditional culture, the woodlands are considered to be the habitats of the spirits, and they provide a place where rituals can be performed. In economic terms, the woodlands are important in the provision of meat from game and birds, materials for construction and crafts, and natural medicines. This is important to most people who cannot afford western medicines and fees for hospitals, and live in places where adequate western medicine is not even available.

To start with the improvement of woodland management, the traditional leaders talked to the village chiefs, or 'kraalheads', in their respective areas. They discussed traditional rules and regulations, and stressed the importance of re-installing and enforcing them again. Together they started to identify the woodlands, springs and wetlands (vleis), as well as the sacred sites in their area, and the rules and regulations that were used to protect them. The chiefs held meetings with their communities to discuss these issues. Soon, the village chiefs began to take over responsibility for the natural resource management, though officially this task was still in the hands of the government appointed councillors, who did not have the full backing of the population. Nurseries with indigenous tree species were started in the 7 districts under the guidance of the spirit mediums.

Initial resistance from the government

As had been expected, this initiative experienced considerable resistance from the government at different levels, for example

Paying respect to the spiritual world at Lamafina wetland spring to recreate the balance between the spiritual, natural and human world. Photo: AZTREC

A nursery for indigenous trees. Photo: AZTREC

the Forest Commission officials. Matters reached a climax when, in 1989, AZTREC decided to become an officially registered organisation and therefore required government approval. At first this request was rejected. Then AZTREC offered indigenous tree seedlings from their nurseries for the 'national tree planting day'. Forest Commission officials, who had initially refused to give due recognition to AZTREC, went to see the nurseries of indigenous tree species. They were very impressed because they had considered it impossible to grow indigenous tree seedlings in a relatively short period.

The indigenous seedlings were used during the national tree planting day on condition that the local chiefs would perform all the necessary rituals in the communities during the planting activities. The ceremonies were conducted and the activity was highly successful. This was the start of the formal recognition of AZTREC by the government.

From tree nurseries to commercial centres

In this way tree planting became a central element in AZTREC's activities, and the tree nurseries the centres of local activities. Once AZTREC was officially recognised, donors could be approached for financial support and extension staff was based in the nurseries. Each community analysed its situation and brought the seeds they considered necessary for the next season. Schoolchildren would come to dig soil, fill pots and prune roots. At tree planting time, the community would take the seedlings to their homes or to the community orchards and wood lots.

This work developed over the years. AZTREC now manages 12 central tree nurseries, and planting is no longer limited to the national tree planting day. The nurseries together provide some 50,000 seedlings each year, with 75% indigenous species and 25% exotic fruit trees, like mango. Since 1985 a total of 500,000 seedlings have been planted in some 280 communities. Moreover, AZTREC gradually took over all the government run tree nurseries in the region from the Forest Commission. Now, many of the wood lots established in the early days have matured, and are providing fruits, medicine, honey, and construction materials. These products are used for home consumption and for marketing. The central tree nurseries have become the commercial centres where these products are processed, stored and sold. These centres also contribute to bio-diversity conservation through rehabilitation of sacred woodlands, wetlands, vleis and springs.

Transformation into 'eco-cultural villages'

Over the past 6 years the tree nurseries have gradually been transformed into 'eco-cultural villages'. They have become centres for training and experimentation with organic farming, cultural promotion and 'eco-cultural tourism' and clinics of traditional health care for humans and animals. A local committee called 'Assembly' guides the transformation process of each eco-cultural village. Chiefs, spirit mediums, as well as representatives of farmers, women and youth groups have a seat in the Assembly. Each Assembly formulates policies and an annual strategic plan for its eco-cultural village. It also presides over cultural events, like rain making ceremonies and the management of sacred woodlands in the area.

In the surrounding areas, the 'kraalheads' are responsible for translating the policies into action. They have formed 'implementation committees', and in each zone these are divided into 'project committees' and 'project subcommittees' headed by local farmer innovators and practitioners. These subcommittees are active in organic agriculture, traditional health care, natural resource management, and income generating projects.

Localised organic agriculture

The concept of organic agriculture is filtering into the communities, as the external inputs for conventional agriculture have become unaffordable. Nearly 40 farmer innovators are developing local ways of organic agriculture by combining indigenous and external knowledge. They are experimenting with and demonstrating the techniques on their own farms around each of the 12 eco-cultural villages.

The farmer innovators have divided themselves into two groups: one group works with vegetable gardens using organic fertiliser, the second group focuses on organic dry land crop production. Traditional pest control measures like growing colourful and aromatic flowers to attract the predators that feed on the pests of the vegetable plants are used in the 13 vegetable gardens. Non-toxic herbal pesticides are sprayed, e.g. solutions from specific flowers. The vegetable gardens have generated considerable income for the families and have led to improvements in their nutritional status. The incidence of diseases related to protein shortage has declined in the communities.

The farmer innovators working on dry land farming are carrying out experiments with organic manure, non-toxic herbal pesticides and inter-cropping for the staple crops finger millet, bulrush millet and maize. Traditional ceremonies are held to ask the ancestors to protect crops from pests and diseases. It was found that organically produced crops could withstand drought better than chemically produced crops. Yields have been good; farmer innovators have harvested between 2.5 and 3 tons on half an acre of each crop where earlier the yields were minimal.

Initially, there was a lot of resistance from neighbouring farmers as well as extension staff from the Ministry of Agriculture. This started to change when the results became visible, both in yields and pest management. Local farmers were invited to see the results for themselves. Slowly, extension staff from the government also became convinced of the value of organic agriculture. Now, they are being trained in organic agriculture by AZTREC.

Healthcare and culture

Apart from their role in natural resource management, agriculture and marketing, the eco-cultural villages have several other functions. In the field of healthcare, demonstrations, exchange activities and clinics on traditional human and animal medicine have been organised. The terrible HIV/AIDS epidemic that has affected great numbers of young and middle-aged people makes activities in the health sector an urgent necessity. The eco-cultural villages actively function as health clinics and traditional pharmacies for the majority of the communities in the area. Patients receive treatment based on plant medicine and payments are made in the form of fieldwork or gifts of a chicken or goat.

Another major objective of the eco-cultural villages is cultural promotion. Many communal activities and festivities take place, including music, songs, folk tales, the use of traditional instruments, as well as an analysis of specific proverbs. Communities also organise meetings to discuss specific problems. A community with a problem, an increased incidence of rape for example, can discuss the situation and analyse how it can be improved. This process is guided by a spirit medium.

In several centres small libraries are being installed in which information on local indigenous knowledge is collected.

Eco-cultural tourism

A new concept is the promotion of educational eco-cultural tourism. National and international researchers come to carry out research on the local cultures. The Zimuto eco-cultural villages are regarded today as 'centres of excellence' of African indigenous knowledge systems, culture and cosmovision. Groups of tourists visit the centres to experience African culture. This venture is being expanded and developed through a relationship established with a tourist organisation in the Netherlands. It sends small groups of 18-20 tourists to stay for one week. The tourists are received and guided by the community and the traditional leaders and have to abide by the traditional rules set by the spirit mediums. They also contribute new ideas, which are selected using spiritual guidelines and fused with local knowledge and experience.

The successful concept is spreading

The concept of eco-cultural villages has been very successful. Apart from ecological regeneration and cultural rehabilitation, the centres are helping to reduce the employment problems amongst the local youth. New jobs are being created in processing and commercialisation of forest and agricultural products, like honey, vegetables and sunflowers, which are brought to the centres. Tourism provides jobs for local groups of dancers and musicians and for youngsters who work as tourist guides. As a result, migration to the towns has been considerably reduced.

In spite of former problems with the government, AZTREC is now officially recognised and supported both at the national and international level. As a non-political organisation, AZTREC has not taken sides in the recent political unrest in which land-hungry Zimbabweans forcibly took back the land that had been confiscated by white settlers during the colonial era. However, AZTREC was appointed by the government Community Based Resettlement Approaches and Technologies programme to assist in land resettlement activities. More than 50 farms have been designated, and AZTREC is involved in structuring resettlement schemes in conjunction with the Ministries of Agriculture and Local Government.

No more borrowed concepts

AZTREC has a strong network with other like-minded non-governmental organisations. Christian churches strongly oppose AZTREC's work, however. They shun initiatives that consider the traditional leaders and spirit mediums as the authentic custodians of the natural resources. Church leaders consider the approach taken by AZTREC contradicting the Christian philosophy. Communities in Zimbabwe and other African countries, however, have reacted positively to the work of AZTREC. Some organisations in Zambia, Malawi, South Africa and Swaziland have started to establish similar eco-cultural villages to address environmental and economic problems, taking their own cultures and indigenous knowledge systems as points of reference.

"The methodology described here is based on a very sustainable form of agriculture and natural resource management, in which indigenous knowledge and external concepts are combined. Because of the high price of external inputs, our own seeds and medicines got a chance to be tried again and to be proven worthy. Of late we feel that even the younger generation has come to realise the beauty of our own indigenous resources, and is deeply involved in all activities. We are convinced of the importance and good results of this strategy. You cannot build development on borrowed concepts - you need cross-fertilisation!"

■

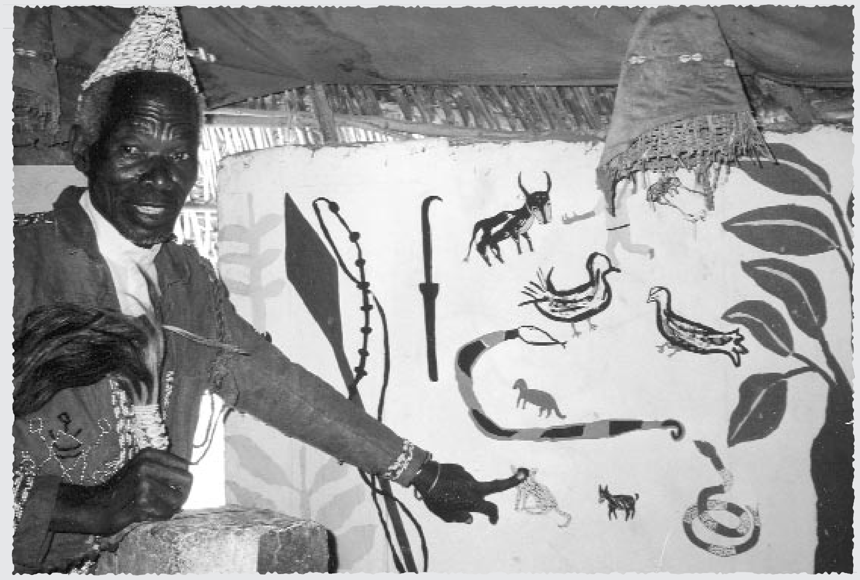
The ENIAKA initiative

Enhancing Indigenous Agricultural Knowledge in Africa



Spirit medium in Iganga, Uganda, explains how the flora and fauna influence healing and farming practices. African organisations met in Uganda to discuss ENIAKA Enhancing Indigenous Agricultural Knowledge in Africa, May 2000. Photo: COMPAS

The African organisations involved in the international Compas programme (see ILEIA Newsletter Vol.14, No.1, pp.26-27), CECIK and AZTREC, have several years of experience with endogenous development based on African culture. The partners agreed that in large parts of the African continent the picture is quite consistent: despite decades of development activities, food shortage and poverty are still widespread and in some cases have even increased. The majority of the rural people are still loyal to their own knowledge, belief and value systems. Though often hidden from the eyes of outsiders, the decisions on farming, health care and use of natural resources are to a large extent based on traditions, and traditional leaders play an important role.

For decades, schools, extension services, development programmes and churches have attempted to introduce new concepts that would substitute rather than build on these traditions. This development approach has often ridiculed and rejected traditional values, and development workers seem to have acquired modern attitudes. The rural people have developed skills to speak the language of the officials, while maintaining their own traditions. Most development professionals live in a dual reality: the African and the Modern.

In order to enhance the effectiveness of development interventions, the African Compas partners have emphasised the need to bridge the communication gap between the rural people and development workers. They have decided to upscale the Compas initiative in Africa in order to introduce the approach to other countries and to influence agencies into taking indigenous knowledge and values seriously. This was the start of the project called Enhancing Agricultural Indigenous Knowledge in Africa, ENIAKA.

Searching for information

During the initial phase of this project, country studies were carried out in Ghana and Zimbabwe. Small teams of local researchers reviewed and analysed the existing information on indigenous knowledge. In both countries less than 100 documents could be found on indigenous knowledge and practices related to soil and water management, crops, animal husbandry and food processing. Meanwhile, during a national workshop, development experts were able to identify more than 50 practices of rural people about which no written information is locally available.

At the same time a literature search was carried out in the major English language databases in Europe. The result was 1663 titles, most of them quite recent. These studies on indigenous knowledge are only available in Western based databases; African national-based development workers have very limited access to these resources. During national workshops in Ghana and Zimbabwe plans were made to fill these gaps. Teams were formed to visit farm families and to document existing indigenous knowledge and practices. The implementation of these plans, however, was delayed by an initial lack of funding.

A pan-African initiative

In December 1999 a pan-African meeting, with representatives of 12 African countries, was organised in Mazvingo, Zimbabwe. It was decided to form three regional clusters for the further enhancement of the initiative: East Africa, Southern Africa and West Africa. A regional co-ordinator was appointed for each region. Plans were made for national and regional follow-up activities.

In May 2000, a national workshop was organised in Uganda. Some 20 NGOs carried out case studies on indigenous knowledge on the basis of a checklist. During the workshop they discussed the outcome and the implications of this for development strategy. They reached the general conclusion that endogenous development has great potential, and agreed that it was necessary to address a number of national policy issues. Proposals for country workshops in Kenya and Tanzania have also been made. At the moment, however, lack of funding has inhibited these workshops and other follow-up activities in Uganda.

Proposal for five years

A five year plan has been formulated for the Southern African region. The activities include in-depth research on the agricultural and environmental knowledge of the rural people, improvement of capacities of NGO staff, establishment of a network for the exchange of information on indigenous knowledge, interregional and international exchange between farmers and rural leaders, and efforts to address national policies on technology development and the role of traditional institutions. Raising funds is the next step in the initiative for the Enhancement of Indigenous Agricultural Knowledge in Africa. AZTREC in Zimbabwe is co-ordinating the ENIAKA activities for Southern Africa, CECIK in Ghana for West Africa and CIOF in Uganda for East Africa.

Compas - Comparing and Supporting Endogenous Development

The Compas Network is a collaborative effort of 22 development organisations in South America, Asia, Africa, and Europe to support endogenous development. Documentation of indigenous practices and cosmovisions are taken as the starting point to revitalise indigenous knowledge systems. Together with the communities, the changes in the knowledge system and the interaction with other sources of knowledge are identified. Options for endogenous development are analysed thereafter and translated into community based activities. The learning processes are exchanged through meetings, the 6-monthly Compas Magazine and a website (www.etcint.org/compas). Free copies of the Compas Magazine can be requested from compas@etcnl.nl or P.O.Box 64, 3830 AB Leusden, the Netherlands.

People's Caravan 2000

Sarah Hindmarsh

Engaging a crowd of over 50,000 on November 30 - one year since the massive protests against the World Trade Organisation (WTO) and its brand of globalisation - the People's Caravan 2000 ended three weeks of activities in India, Bangladesh and the Philippines, with simultaneous events in Japan,Korea and Indonesia. The People's Caravan travelled over 2,500 km through Tamil Nadu, India, Bangladesh and within Manila, the Philippines from November 13 - 30.

The Caravan called for an end to the devastating effects from the globalisation of agriculture and instead advocated genuine agrarian reform, food security, social justice and land and food without poisons.

Over 10,000 people - local farmers, agricultural workers, fisherfolk, students, scientists, teachers, the media, government officials, and anti-pesticide and anti-genetic engineering (GE) advocates - participated in lively discussions at public meetings, press conferences, and educational teach-in's at bus stops, in rice fields, in villages and towns. Food festivals, seed exchanges, songs and street theatre celebrated local initiatives towards more sustainable, healthy agriculture.

The Caravan was organised by Pesticide Action Network Asia and the Pacific (PAN AP); Society for Rural Education and Development (SRED) and Tamil Nadu Women's Forum (TNWF), India; UBINIG and Nayakrishi Andolon, Bangladesh; and Kilusang Magbubukid Ng Pilipinas (KMP), the Philippines; in collaboration with SHISUK, Bangladesh; CIKS and PREPARE, India; Gita Pertiwi, Indonesia; NESSFE, Japan; CACPK, Korea; and Food First, USA.

Rural communities discussed the transition from traditional farming to export-oriented crop production and its impacts on them - increasing landlessness; hazardous pesticide use; and the potential onslaught of unsafe, unproven experimental GE technologies.

Speaking in Bangladesh on land conversion and the erosion of food security, Santi Gangadharan, a pesticide activist with TNWF, said: *"As we travel this country we are very happy to find the fields so full of paddy. In India, most of the farmers have been forced to grow cash crops instead of food crops due to the process of globalisation and liberalisation and because the government wants more export earnings. Now there is no paddy. The fields have been converted into flower gardens for export. Due to globalisation many people in the villages have been forced to leave. They have left their traditional homes, entered urban areas and many of them are without enough food".*

Landlessness is rising among the poor farmers of Asia. This tragedy is particularly evident in the Philippines. Rafael Mariano, chairperson of KMP, is critical of the Filipino government's commitment to the WTO in promoting the World Bank's imposition of market-assisted land reform. This involves joint venture schemes that allow landlords and foreign capitalists to appropriate land for export crop production. "In effect, the schemes reduce the farmers to being farm workers receiving measly wages."

Asian countries, in general, are suffering from a collapsing agricultural sector. Much of this has to do with the use of Green Revolution farming practices, underpinned by monoculture cropping and the use of pesticides and fertilisers.

Farmer Jahanara Begum, speaking in Bangladesh, urged farmers not to abandon their traditional farming practises in favour of industrial agricultural methods. *"We have so many varieties of rice seeds, but instead we are going for the varieties of IRRI (International Rice Research Institute) and the seed companies. These seeds need a chemical package. When we use local varieties we get a yield of 40 kg of rice. When we use pesticides and the companies seeds we get 20 kg more but we also destroy our soil, water and biodiversity".*

She added: *"How many poisons are you using? We have lost our birds, our fish, the wildlife. We have lost all this for 20 kg more and we spend more money on our family's health. Transnational companies - they come, they go. They don't care about our health or our environment. No more, we've had enough! Stop using pesticides and gradually reduce the use of fertilisers. For our survival we have to commit ourselves to land and food without poisons!"*

Sarojeni Rengam, Executive Director of PAN AP, told the crowd that today the pesticides market is a $32 billion industry. With the advent of seeds, genetically engineered to tolerate herbicides or to be dependent on chemical inducers to promote growth and development, the use of hazardous pesticides will only increase.

Speaking on the development of GE rice, Farida Akhter, Executive Director of UBINIG said, *"UBINIG urged all farmers in the rice producing and rice consuming countries of Asia to resist planting GE rice as it is harmful socially, economically, environmentally and also an attack on farmers' sovereignty to produce their own staple food!"*

The People's Caravan also celebrated local initiatives towards more sustainable, healthy agriculture. Agriculture that is in the hands of the people, is for the people, and can really feed them and free them from dependence on hazardous pesticides and other dangerous agricultural inputs and technologies.

In Trichy, India, Tony Tujan, chair-person of the Asia Pacific Research Network (APRN), said: *"As sustainable agriculture practitioners, we have shown the world that we can grow food without poisons. We must all work together to challenge industrialised agriculture and agrochemical TNCs."* ■

"Hybrid seeds, hybrid crops, ... even the children become hybrid", as an elderly woman put it. Photo: AR Vasavi

Loss of the local and spectres of the global

A.R. Vasavi

Farmers committing suicide, ever-expanding groups of people migrating to cities, angry farmers destroying unsold fruits and vegetables, riots at the grain markets as prices collapse, the distress sale of land - all these and more are testimony to the loss of the local and the spectre of the global in agrarian India. While the loss of the local is linked to the loss of local knowledge and social support structures, the spectre of the global looms in terms of the subordination of local agriculture to global market and institutional prescriptions, and the subsequent loss of self sufficiency and livelihoods.

The local undervalued and eradicated

The opening up of Indian agriculture to global capital and markets denotes not only a shift from the policy of agricultural self-sufficiency to one of integration into the market, but also of a substantial shift in the human-nature and human-human relations. Linked to the WTO rhetoric of enabling the nation to become competitive and of engaging in the global arena, the new agricultural agenda overlooks not only the strengths of the local, but also its needs and requirements. As many scholars have noted, agriculture in India is troubled more by the system of unjust access and rights to resources than by a lack of knowledge or capability. Yet, since the economic liberalisation agenda, policies to address the problems of inequitable distribution of resources, including any type of agrarian reform, have been completely overlooked. Instead, the whole body of local agro-ecological knowledge is identified as the basis for problems and is sought to be eradicated. In addition, the State, until now a key player in re-ordering agriculture, is partially withdrawing from agriculture, thereby enabling the emergence of national and international agri-business agencies to become key actors. Currently, in many villages, it is the agents of the agri-business companies whose presence and influence is more visible than that of the state's village and field workers.

Increasing dominance of agri-business

Drawing on their capital and marketing skills, global agri-business companies seek to maximise the low labour costs and eco-specific agricultural production, while retaining the existing pre-capitalist relations of production and work conditions. The establishment of contract-based seed farms in certain areas, such as Haveri and Ranibennur in Karnataka, are examples. Factory-like production conditions have replaced ecological practices, but the existing land-ownership and labour patterns have been retained. And contract farming based on rigid terms, in which the companies stipulate what, how and how much is grown by every contract farmer, signifies the loss of control over their production that agriculturists are subject to. More than HYV

(High Yielding Variety) cultivation, contract farming articulates the dominance of international finance, market and know-how over the economic, social and ecological bases of local agriculture.

Loss of the cultural basis and control

Such intense and significant integration into the agri-business and bio-technology regimes imply not only a loss of the collective, eco-specific knowledge but also of the local, cultural bases of agriculture. Such changes are significantly that of the loss of the veneration of nature, the separation of agriculture from ecology, devaluation of local knowledge, and the re-working of social relations and cultural orientations of people. Each of these is compounded by the new presence of global agri-business agencies, which re-enforce the individualisation of agriculture initiated by modern agriculture. Farmers interact with agri-business agents on a one-to-one basis, often competing among themselves, for access to information, inputs and assurance for sales. Also, as Lewontin (1998) notes, contract farming based on new bio-technologies renders farmers into wage labourers, a trend that aggravates the on-going pauperisation of medium and small-scale land operators.

Disintegration of the collective and loss of autonomy

Biotechnology based agricultural regimes, promoted by global agri-business, lead to a vertical integration of inputs and outputs in the agricultural production processes (Lewontin 1998). Such vertical integration (whereby the agency sells the inputs and also purchases the produce) at this level is matched and aligned with a disintegration of local, collective orientation to agriculture and the loss of autonomy in the production processes. New seed varieties shorten production cycles and increase productivity but deny farmers the ability and rights to reproduce the seeds. Knowledge and know-how must be gained from external sources, often together with the other inputs of fertilisers, pesticides and technology. As agri-business companies gain absolute control over the production process, States, especially in the developing countries, have less hold over such decisions and loose the right to democratic processing of such policies. This has been specifically noted in the context of the promotion of new biotechnologies, including Genetically Modified Crops (GMCs). In certain parts of India, policies to use and promote GM seeds and crops are not debated in public and people are not given any awareness of the potential fall-outs of such programmes.

Expecting high returns, ending with suicide

Yet, farmers are drawn to such programmes as agri-business agencies advertise the easy availability of a good life. An increasingly consumption-oriented public culture further encourages them to take to high income generating schemes. Expecting quick and high returns, farmers submit to such agendas with little or no anticipation of market downturns, loss of genetic diversity, loss of autonomy etc.

But the entry and growth of markets in the life of a community increases the imbalance of power among members of an agricultural community and that between a community and the market. Successful agriculturists not only withdraw from the immediate community of production, but identified as “progressive farmers” they form alliances not with the other agriculturists of their region, but with those who have a similar economic status. Further, in producing for the market with inputs from the market and in terms dictated by the market, agriculturists become subject to the turns and fluctuations of the market itself. While production is based on giving priority to market income over household subsistence, the failure of the market can mean the devastation of the household’s food security and the beginning of a vicious cycle of debt. This is specially so for small and medium agriculturists who, with little or no capital or access to resources, take informal credit at exorbitant interest rates, and are unable to recover basic costs at the end of the production cycle. And, crop loss, like agricultural production, has become an experience borne individually. The spate of suicides among farmers from all over the nation is linked to this combination of debt burden, individualisation and the loss of collective orientation in agriculture.

Lack of a farmers’ forum against globalisation

Though several districts of Andhra Pradesh, Karnataka, Maharashtra, and Punjab have reported suicides related to crop-loss, there is no substantial collective pressure from agriculturists against the state and agencies of capital. And, despite the fact that some Indian farmers’ movements question the globalisation of Indian agriculture, a well-developed and cohesive farmers’ forum against the new agricultural agenda is sadly lacking. In fact, membership in and support for farmers’ organisations are not as wide-spread as it is often made out to be. Instead, caste and religion-based mobilisation seems to be gaining strength, which breeds intolerance and pits communities against communities and some privileged communities against the State. Such mobilisation focuses on either reviving old symbols of heritage or in inventing traditions to counter an opposing group’s claims to exclusive heritage rights. While such cultural mobilisation may result in a limited number of agriculturists becoming political actors, it does not translate into policies that privilege economic or social equity.

Redistribution of resources needed

Though Gandhi largely overlooked the political and economic dimensions of rural communities, and most specifically their role in reproducing a hierarchical and unjust system, he recognised the importance of a decentralised, plural, rural culture. Asserting the importance of agriculture as a vocation, he believed it to be capable of being the seedbed of *Swaraj*; the new ethically and morally grounded system that would enable India to not only break away from colonialism but also generate a new civilisation. Yet, in contemporary India, agriculture and agrarian cultures are increasingly integrated into a global agro-regime that privileges elite consumption and access to capital over ecological and social sustainability. This is generating new tensions. Not only has globalised agriculture disembedded the production system from its ecological base, distanced individuals from the life of the community, rendered local knowledge (Ludden 1997) as “archaic”, it is also fast eroding the very foundational premises of India’s pluralism. While the skewed distribution of land, capital and access to water needs to be addressed urgently, the current trend is to enhance the productivity of select crops, thereby overlooking both the livelihood bases of people and the sustainability of agro-ecological systems. Pre-modern plural agro-ecologies enabled local ecology to influence agriculture, creating a range of agri-cultures. But, individuated, market -oriented agro-regimes lay the foundations for conditions in which the land will be rendered into what Marx (1966) noted as *“cleanly weeded land”* while the dispensed and displaced people will be treated as *“uncleanly human weeds”*.

Trade and hunger

The impact of trade liberalisation on small farmers

A recent publication by John Madeley collates information on the impact trade liberalisation has had so far on food security, poverty, ecological sustainability, gender etc. The survey covers 39 developing countries in Africa, Asia and Latin America. The case studies analyse impacts of the World Trade Organisation's (WTO) Agreement on Agriculture (AoA, signed in 1994), the World Bank/International Monetary Fund imposed structural adjustment programmes (SAPs, going on since 1980) and regional free trade agreements. Some of the key findings , mentioned in the overview, are summarised below.

Trade liberalisation

Under SAPs and AoA, developing countries have to make significant changes in their food and agricultural policies. They are obliged to open up their economies to cheap food imports and to drastically reduce support to their farmers. Most SAPs require more sweeping liberalisation measures than the AoA, and also demand related measures such as privatisation of state-run enterprises, the elimination of subsidies and price controls, and the abolition of marketing boards. By contrast, the AoA centres on trade liberalisation measures – it calls, for example, on member countries of the WTO to reduce tariffs on food imports by 24% over a ten-year period. The 48 least developed countries are excluded from this and other reduction commitments.
The AoA – a deal largely stitched up by the United States (US) and the European Union (EU) under pressure from business corporations – tightens the screw of structural adjustment.
The case studies show that this leads to:

Cheap imports

The majority of people in developing countries belong to farming families. Most farmers are small-scale, with at best a few hectares of land and sometimes much less. Competition from cheap imports, from the US and the EU but also from other developing countries, is putting small farmers out of business. Such imports are coming both through commercial channels and through dumping – food sold below the cost of production to dispose of surpluses. Ghana is just one of many countries in this survey which shows how food imports have demoralised small farmers. Having produced maize, rice, soybeans, rabbits, sheep and goats, the farmers cannot obtain economically viable prices for them, even in village markets. Their produce simply cannot compete with cheaper imports. Domestic food production is at risk as the agricultural sector is placed in jeopardy.

The studies show that liberalisation has led to an increase in the prices of farm inputs, causing huge problems for small farmers. The study of edible oils in India reveals the common problem of farmers paying more for their inputs but receiving less for their crop. In economic terms, trade liberalisation appears to have worsened the terms of trade between outputs and inputs. Consumers may appear to gain from cheap food imports. But they only do so if they have the money to buy, which many people in developing countries don't have. Cheap food imports damage the livelihoods of small farmers and also the countries' most basic economic sector – its food-producing sector. Also, if trade liberalisation gives more power to monopolies, then consumers eventually stand to pay higher prices.

More priority for export crops

Trade liberalisation, as many of the studies show, has resulted in more land and resources being devoted to export crops and less to domestic food production. In Benin, for example, government incentives have led to an increase in land under cotton: cotton exports have increased at the expense of food production and food security. The main study in Uganda points to evidence that the emphasis on exports, both traditional and non-traditional cash crops, has caused a decline in the production of food consumed locally, both in quantity and in variety. This has consequently undermined the food security of households.

Although governments are generally placing more priority on the export crop sector, farmers are not necessarily receiving better prices for these crops. World market prices for many of them are declining – as is shown in the studies on Kenya, Sierra Leone and Uganda. As private traders, and not governmental bodies, are mostly buying these crops, the prices offered to the farmers are related, in some degree, to the world prices. But the power of the traders may mean that the price offered to farmers is far below the world price.

Transnational corporations (TNCs)

Trade liberalisation is proving very beneficial for large entities such as TNCs – this is clearly seen in the studies on India, Philippines, Uruguay and Cambodia. But it is not just proving beneficial to them, it also appears to be helping them at the expense of the poor. The study on cotton in India shows how trade liberalisation is aiding TNCs at the expense of India's farmers. The FAO study included in the survey notes that this process is leading to the concentration of land ownership *"in a wide cross-section of countries"* and to the marginalisation of small producers, adding to unemployment and poverty.

In Mexico, the winners from trade liberalisation are concentrated in the country's fruit and vegetable growing areas where production is predominantly on large-scale, irrigated farms. There is a *"dramatic increase in investment in these areas, with large farms or firms leasing land"*. This finding is consistent with global patterns. The Cambodia study estimates that 10-15% of the country's farmers has become landless since the adoption of a liberal market economy in 1989. More land is being concentrated in the hands of a few.

Women

The studies on Kenya, Ghana, Uganda, Zimbabwe, Mexico, Jamaica and the Philippines all show how trade liberalisation is impacting heavily on women and accentuating gender inequality. In Kenya, as a result of the liberalisation of agricultural trade, many women cannot afford adequate chemicals and fertilisers, and farm output has declined. In Uganda, liberalisation may mean that the local parastatal depot is closed down, and producers have to go out of the village to sell their produce. If not, they are forced to sell their produce at lower prices to village traders who benefit from it.

Women, who produce 60 - 70% of food in most African countries, have been affected disproportionately by the elimination of subsidies, the drying up of credit and the surge of food imports as a result of trade liberalisation. Prices of farm inputs have risen and incomes of farming families have come under serious pressure. As a result, many have been forced to cut back on the quality and frequency of meals.

In Mexico, research has shown how male labour migration increases the workload on women and children, who are often withdrawn from school. It is estimated that women now comprise about one third of all the day labourers working in the Mexican countryside. "*To the extent that liberalisation accelerates these trends, it will exacerbate problems of inequality and rural poverty*", notes the study.

Studies on Kenya, Uganda and Zimbabwe show that trade liberalisation has had some positive effects – in Kenya, for example, it has enabled rural women to engage in micro and small enterprises. But the studies indicate that the negative effects far outweigh the positive.

Unemployment

There are no universal figures on people who have lost their jobs as a result of trade liberalisation over the last 20 years. In Mexico, between 700,000 and 800,000 livelihoods will be lost as maize prices fall, representing 15% of the economically active population in agriculture. In India, the jobs of 3 million edible oil processors were lost. In Sri Lanka there was "*a clear drop in rural employment*", says the FAO study, with 300,000 jobs lost following the decline in onion and potato production. It would therefore not be unreasonable to estimate a figure of at least 30 million jobs lost in developing countries because of trade liberalisation and related factors. When trade barriers are lowered, many small farmers leave their land and head for the cities and towns in hope of employment.

Environment

The cultivation of cash crops for export imposes considerable environmental costs. In the Philippines, for example, the extensive use of agrochemicals in export crop production has increased soil degradation and the loss of biodiversity. Liberalisation encourages producers to abandon traditional and ecologically sound agricultural practices in favour of export monocropping. Also, the encouragement of agri-based export cropping in special development zones creates massive colonisation of critical watersheds and the depletion of water resources in irrigated areas, previously planted to food crops. Trade liberalisation can lead to a more extractive and non-sustainable type of agriculture.

Government services

Under SAPs, liberalisation goes hand in hand with a reduction in government support to farmers, such as investment in agricultural research and extension, controlled pricing and marketing, and subsidies on inputs. Governments withdraw and leave their people to the free play of economic forces. Those with adequate resources may survive but the poor are left stranded. The Philippines is a typical case, where insufficient state support for services such as irrigation, post-harvest facilities and farm-to-market roads has meant that small-scale farmers are unable to improve productivity levels or get their products to market at prices that cover costs.

What price will we get for our groundnuts? Farmers in northern Ghana. Photo: Bertus Haverkort

Food self-sufficiency and sovereignty

The negative impact of trade liberalisation on food self-sufficiency, let alone food sovereignty, comes across in many of the studies. The effects of trade liberalisation on India's edible oils sector are startling. Tariff reductions, allowing for massive imports, turned India from being self-sufficient in edible oils to being the world's largest importer in a mere five years. In a number of countries, the liberalisation of markets has increased participation of private firms and individuals in the trade of food commodities, unlike in the past when public institutions dominated the trade. While, in theory, these activities could generate more employment opportunities, this does not seem to be happening.

Conclusion

As the author of the Thailand study says, *"Many of us have been saying for a long time that unchecked, liberalised global trade is a disaster waiting to happen. No one listened. Now it has happened"*. Small farmers are bearing the brunt of this *"disaster"*. But consumers too are vulnerable.

In free trade theory, production will allocate to where costs are low and consumers – poor as well as rich – will benefit from low prices. Much of the trade liberalisation of the last two decades has been based on the hope that agricultural production in developing countries will switch to high value crops for export, which would enable the import of cheap food to achieve food security. Reality is more complicated, however. The FAO study found that in countries like Ethiopia, Sierra Leone and Bangladesh, trade liberalisation did not bring the hoped-for benefits from exports.

Prices are far too low to make marketing of my wheat an attractive option. Photo: Fritz Berger

Agriculture is the main source of livelihood for hundreds of millions of people in developing countries. If small farmers are out-competed without an alternative source of livelihood, the availability of cheap imported food is not of much benefit to them. According to the studies, governments seem to be misled or pressurised to put too much faith in trade liberalisation, or to do it too quickly, without adequate preparation. Trade-based food security for the poor is – at least for the time being – more a mirage than a fact.

Trade liberalisation is only one factor exacerbating problems for the poor in many countries. The studies often reveal the interaction of factors that affect food security, such as privatisation, domestic economic and financial policies and the incidence of HIV/AIDS. As the study on Thailand points out *"the mess isn't simple"*; devastating weather patterns, massive unemployment, the need to earn foreign exchange *"to bail out an unbelievably irresponsible private sector"* are all factors.

Yet, liberalisation is a policy choice, and is not inevitable. This survey suggests that a fundamental review of the dominating policy paradigm is needed, and that, at the very least, WTO rules need changing so that developing countries can provide domestic support and other regulations to protect the livelihoods of smallholders and promote food security.

Causes of rural poverty

Farzana Panhwar

The Sindhi farmers in Lower Punjab, **Pakistan**, are being systematically kept in poverty due to the low prices they get for their products. This is caused by the policy of the Government to keep the prices of wheat and other agricultural commodities low so that commerce and industry can get cheap labour and high profits.

Presently, the price farmers get for their wheat is about half the world market price and half of what they received in 1950, taking into account the depreciation of the Pakistan rupee. When farmers use the optimal levels of inputs (costing approx. Rs 10,000 per acre) they can produce about 1,400 kg wheat per acre. If farmers get a price comparable to imported wheat they can afford to pay for the inputs and get an additional Rs 3,600 per acre. For a family with 5 acres of irrigated land this is an acceptable level of income for 6 months of family work.

Since farmers do not receive sufficient returns, they reduce on inputs by:

- Replacing deep ploughing and seed bed preparation by one harrowing only
- Replacing tractors by borrowed bullocks and own labour for drilling of seed
- Using poor quality seed produced by the farmer
- Using less fertiliser than the optimum
- Replacing most herbicides by manual weeding
- Using family labour for casual work and harvesting
- Avoiding periodic and precision land levelling
- Avoiding maintenance of water courses

This reduces yields to about 600 – 800 kg per acre most of which is for domestic use, seed for the next year and payment for borrowed inputs. Thus family labour is bartered for wheat needed for food with no accrued profits. Transition from subsistence to commercial farming is very difficult, as the costs of additional inputs are not compensated for by the additional returns from additional yields. As wheat production is insufficient to feed the population due to low yields, wheat is imported at about double the price paid to farmers and provided to the urban population at a subsidised price. Rural poverty, unemployment and insecurity, created artificially by forcing farmers to sell their products at low prices, is leading to unprecedented migration from rural to urban areas. These people, who end up living in ever-growing urban slums, face serious hardships and suffering.

Go global or stay local?
Farmers return to the local economy

Farmers challenging 'globalisation'. People's Caravan 2000. Photo: PAN-AP

Editorial

International trade is growing fast. Products traded internationally are found everywhere in evidence of 'globalisation'. The World Trade Organisation (WTO), World Bank (WB), International Monetary Fund (IMF) and national governments enforce trade liberalistion and the removal of trade barriers with the strong conviction that it offers the best route to increased prosperity. Farmers are promised increasing benefits from free trade if they specialise on those products, which can be sold on the global market most competitively. In line with this thinking, export agriculture, Green Revolution (GR) technology and biotechnology are promoted globally (World Bank 2001; IFAD 2001) as the tools to increase agricultural production, alleviate rural poverty and eradicate hunger.

The negative impact of free trade

However, an analysis of the impact of free trade shows that most small farmers cannot compete on the global market (Madeley p.6). Decreasing prices and growing costs, due to national price policies, cheap imports and a host of other reasons, are forcing farmers to sell below cost price and to deplete their natural resource base (Panhwar p.8). Women farmers are affected disproportionately; this poses a threat to the food security of their families. In some countries, the production of main crops by millions of family farmers, like wheat in Brazil and oil seeds in India, has reached a near full stop and brought about large-scale unemployment (Madeley p.6). Many small farmers have become tied up in debt or in contract production, thus becoming poorly paid workers on degraded land (Hassarangsee p.36). Due to the disintegration of the collective spirit and the feeling that they have lost control, farmers in India often resort to suicide, seeing no other way out. (Vasavi p.9). Clearly, it is large export oriented farmers, agribusiness and especially Trans National Companies (TNCs) that are benefitting most from trade liberalisation.

A recent WB study by Lundberg and Squire found that free trade does indeed lead to income growth among the top 60% of the population, but has the opposite effect among the poorest 40%. Since 1990 the number of poor people is increasing again. Presently 1.2 billion people have to survive on less than 1 US dollar a day (IFAD 2001). 75% of them live in the rural areas, and include indigenous people, small farmers, women and children, who never had a chance to be part of or have fallen out of the global development model.

Globalisation of trade and technology are part of a much broader process of cultural globalisation. Due to the general increase in international trade, travel and mass communication, the Western consumer culture, symbolised by Coca Cola and MacDonald, is spreading fast. This is contributing to the loss of traditional culture, values and knowledge, disintegration of communities, loss of mutual solidarity and degradation of the environment (Vasavi p.9; Norberg-Hodge p.20).

The anti-globalisation movement

In reaction to these processes, a fast growing anti-globalisation movement is strongly manifesting itself. The People's Caravan (p.11) that travelled through Southeast Asia in November 2000 is one such manifestation, which campaigned for food security, land reform and agriculture free of poisons and biotechnology. The warning by IFOAM (p.31) that genetic pollution is spreading fast in the USA shows how important such protests are in raising awareness among citizens.

From 25-30th January this year the World Social Forum had its first global meeting in Porto Alegre, Brazil, to discuss the problems caused by globalisation. The dominance of economic over social interests, the growing inequality, the lack of human rights and respect for nature, and the increasing influence and lack of democratic control of TNCs and international institutions like the WTO were amongst them. But the main outcry of the conference was for a "different" agriculture. It called for an agriculture that produces the food needed locally and nationally, at human scale, with land given back to the farmers. It called also for minimum price guarantees and control given to farmers and nations instead of to TNCs. Ecologically sound agriculture producing safe food in an animal-friendly way was the alternative.

This emerging alternative to 'globalisation' is increasingly called 'localisation' (Hines 2000). As an alternative development approach, it gives priority to endogenous development - building on local concepts and resources, but does not exclude exogenous development - building on solutions from outside.

Understanding globalisation and localisation

It is important that family farmers are aware of and understand present trends of development, and how they are and will be affected by globalisation. They need to know what opportunities they have on the world market, how they could benefit from localisation and what choices they have to make. By strengthening farmers' organisations to analyse their situation, CIRAD (p.24) is helping farmers to design strategies to navigate their lives in a fast globalising world.

An analytical framework can be very useful for this purpose. The framework used by neo-liberal economists cannot explain local economies sufficiently as it looks mainly at the financial aspects. Pretty (1998) and Bebbington (1999), on the contrary, recognise five different capital assets, fundamental for local economic development and welfare:

- Natural capital – nature's goods and services.
- Social capital – the cohesiveness of people and societies
- Human capital – the status and capacities of individuals
- Physical capital – local infrastructure and stocks of produced products
- Financial capital – stocks of money

To understand these highly abstract concepts, one should consider the local economy as a bucket that the community likes to keep full. But, the bucket has holes in it. Every time someone buys something from outside the local economy, money leaks out. Each time natural resources are depleted or polluted, the natural stock diminishes. To balance this, money must flow in from the sale of raw materials, products or services to outsiders, or from migration work, pensions, grants or subsidies from outside. In an open market economy, the inflow of money is maximised by making use of comparative advantages, thereby increasing prosperity. But prosperity can also be increased by reducing the outflow of money and other resources by plugging the holes, preventing degradation of the natural resource base and, in a selective way, raising some additional income from outside, e.g. from niche markets instead of bulk markets (see Box).

Recreating local economies

It is important to note that local economies are not a strategy to create autarchic communities that are only self-sufficient, but totally disconnected from the rest of the world. Rather, it is first to make the best use of available resources (the first four principles), and then to engage and trade with other economies (the fifth principle). OA and LEISA help the local economy in a number of ways. They make better use of available natural and social resources. This is done by minimising the use of external inputs, by utilising and regenerating internal resources (nutrients, water, genetic resources, knowledge, skills) effectively or by combining both (see for example the principles of Nayakrishi Andolon, Mazhar et al, p.16).

Local economies foster deeper community spirit and self-reliance, ensure a better environment and provide more sustainable jobs (Pretty 1998). Where natural and financial resources are scarce, farmers cannot afford to use these resources in an inefficient and degrading way, as in Green Revolution agriculture. Where farmers cannot compete on the market without depleting their resource base and culture, a self-reliant local economy is a viable alternative to protect farmers from ending up in the urban drain. Endogenous development of local economies is not backward at all; it is an artful and knowledge-intensive way of living, as demonstrated, in principle, by many traditional 'agri-cultures'.

Gonese & Tivafiri (p.12), Mazhar et al. (p.16), Zhardhari (p.19), Norberg-Hodge (p.20) and Pichpongsa (p.21) present cases of endogenous development of local economies. After experiencing that their natural, social, human, physical and financial capital assets were draining away due to globalisation, farmers decided to return to community based endogenous development. They are recreating their local economies by building on indigenous culture, values, institutions, knowledge, seeds, medicines, local currency and traditional and organic agriculture or LEISA. These farmers produce mainly for self-sufficiency, but obtain some income from surplus sales on the regional market and from eco-cultural tourism.

Also for market agriculture

Market oriented farmers in economic stress situations follow similar strategies. In the Netherlands and Europe, *farming economically* is becoming an important alternative to the dominant model of large-scale specialised agriculture propagated by the Government. It is basically a way to counter decreasing prices, increasing costs and the obligation to farm in a more environmentally sound way by mobilisation, use, development and reproduction of internal resources combined with a high level of technical efficiency. Low-external-input agriculture taken up by the economic farmers generates more income and employment and tends to be more sustainable. To obtain additional income, economic farmers diversify with new activities such as subsidised landscape management, organic farming, local products, direct sales, tourism and off-farm activities (Van der Ploeg p.26).

Local economies and farming economically in the South and North move towards the 'subsistence perspective' which Mies and Bennholdt-Thomsen (1999) explain to be 'empowerment based on people's own strength and cooperation with each other and nature. Rather than endless accumulation of wealth, the aim of the subsistence perspective is happiness, quality of life and human dignity'. Isn't this truly sustainable development?

Self-reliant sustainable development possible?

But in the end, whether people really can escape from free trade thinking and take charge of their own development again may be a matter of community-based learning and values (Molineaux p.22). Changing the economic, political and institutional system will be a much harder and longer battle, but has to be pursued as well. Small farmer organisations and NGOs are, for example, trying to increase the influence of small farmers in setting priorities for international agricultural research (Gura p.28). These first efforts already give hope!

Five principles to enhance local economies

A – Make best use of local resources

1. Plug the leaks by using local renewable resources rather than externally sourced:
   - Organic Agriculture (OA) or Low-External-Input and Sustainable Agriculture (LEISA)
   - Local food systems and direct marketing
   - "Buy local" campaigns
   - Renewable energy generation
2. Recycle financial resources within the system by buying local goods and services:
   - Local currency and barter systems (Pichpongsa p.21)
   - Credit unions and other micro-finance arrangements
   - Community banks
3. Add value to local produce before it is sold to the outside:
   - Local processing and manufacturing
   - Labelling and accreditation for food and timber
   - Direct marketing, consumer supported agriculture
   - Eco(cultural) tourism
4. Connect people and institutions to build trust, new linkages and more exchanges:
   - "Buy local" networks
   - Democracy and participatory governance for community planning
   - Strengthening of local institutions, farmers' groups and community co-operatives

B – Exchange with other economies

5. Make use of external opportunities to attract external resources, especially money, knowledge, skills and new technologies:
   - Selling of quality products after value adding, e.g. certified organic or forest products
   - Farmer-to farmer exchange programmes
   - Rural radio, internet and other communication programmes
   - Governmental or non-governmental subsidies for rural development

John Madeley

A recent survey covering 39 developing countries in the South describes the impact of trade liberalisation on food security, poverty, ecological sustainability, gender etc. The sweeping changes in the name of structural adjustment have not brought prosperity to the majority of the people. Unable to compete with cheap imports, many small farmers are being pushed out of their livelihoods. Others are being forced to take up export crop production at the expense of local food production and food security. Women are greatly affected by the loss of subsidies, drying up of credit, male labour migration etc. It is startling to note that countries, who a few years ago were self sufficient in certain products, have become key importers of the same products. The survey suggests a fundamental review of dominating trade policy in favour of protecting the livelihoods of small holders in developing countries and providing food security.

Farhad Mazhar and colleagues

It is not only floods that pose a threat to the livelihoods of Bangaldeshi farmers, it is also the practice of so-called modern agriculture. Farmers are well aware of the many negative effects of chemical-based cultivation and monocropping. Nayakrishi Andolon, or the New Agriculture Movement, began as a search for new ways of food production and has a following of nearly 65,000 farmers throughout Bangladesh. Organic farming, conservation of bio-diversity, indigenous knowledge and marketing locally are some aspects of the community-based movement.

ILEIA is the Centre for Information on Low External Input and Sustainable Agriculture (LEISA) in the tropics. ILEIA seeks to promote the adoption of LEISA through the LEISA Magazine and other publications. It also maintains a specialised information database and an informative and interactive website on LEISA (http://www.ileia.org). The website provides access to many other sources of information on the development of sustainable agriculture.

LEISA is about Low-External-Input and Sustainable Agriculture. It is about the technical and social options open to farmers who seek to improve productivity and income in an ecologically sound way. LEISA is about the optimal use of local resources and natural processes and, if necessary, the safe and efficient use of external inputs. It is about the empowerment of male and female farmers and the communities who seek to build their future on the basis of their own knowledge, skills, values, culture and institutions. LEISA is also about participatory methodologies to strengthen the capacity of farmers and other actors to improve agriculture and adapt it to changing needs and conditions. LEISA seeks to combine indigenous and scientific knowledge, and to influence policy formulation in creating an environment conducive for its further development. LEISA is a concept, an approach and a political message.

12 Back to the local - no more borrowed concepts

Cosmas Gonese and Raymond Tivafiri

Market-oriented conventional agriculture has been promoted for decades in the Zimuto area of Southern Zimbabwe. This type of agriculture did not take into account traditional "agri-culture" and the local conditions. In 1984, a group of traditional leaders and war veterans started a process to "heal the land" that led to the formation of the indigenous development organisation AZTREC. It aims at conservation of the environment through woodland and wetland management, reforestation, cultural survival etc. founded on indigenous knowledge, culture, norms and cosmovisions. Having faced initial resistance from the government, the initiative is now well recognised and the "eco-cultural villages" have become showpieces of local agriculture, healthcare and culture.

22 Strengthening Local Economies and Community Identity

Pascal Molineaux

The Tutorial Learning System (SAT in spanish), developed by the Rural University of FUNDAEC, is a high school equivalent embedded in the reality and needs of rural life. Graduates of SAT programmes not only gain appropriate knowledge but develop a greater consciousness of living and serving their communities. Solidarity groups, another programme of FUNDAEC, has helped bring back the tradition of MINGA or mutual help, thus reviving community life. According to FUNDAEC, providing access to knowledge and creating local structures that serve local economies are two crucial aspects for communities to contend with the forces of globalisation.

DEAR READERS

There is a lot of discussion and turmoil around 'globalisation', the complex economic and cultural processes of change that are presently reshaping societies. This issue of LEISA Magazine is on the impact of 'globalisation' on small farmers and their strategies to cope with these processes. The articles herein show that small farmers have great difficulties in being competitive on the global market, that their communities and cultures are falling apart, and that their natural resource base is degrading. Realising that they have waited too long for 'development' to come, communities return to local solutions in order to strengthen their economy and culture. Experiences in many countries in the South show that endogenous development of local economies can be very beneficial for farmers and their communities, as well as for the local environment. Market farmers in Europe, too, are successfully using low-external-input strategies to cope with economic stress, and a growing 'slow food' movement is giving back value to traditional food and regional production systems. In reaction to 'globalisation', civil society and small farmer organisations are calling for 'localisation', not only as an economic solution for small farmers but as a global and general approach to sustainable development.

LEISA Magazine (formerly called ILEIA Newsletter) has been publishing on local solutions developed by farmers to improve agriculture (LEISA) for nearly seventeen years and will continue to do so in the future.

The last issue "Coping with disaster" carried the new design. But as is so often the case, change does not come without pain. Many of you would have noticed the headings that had fallen out. We hope this unexpected printing error, for which we apologise, is resolved by the time that this issue goes to print.

The editors.

DEAR READERS

The moral failure of the European livestock industry

Coen Reijntjes / ILEIA

Once again, Europe is engaged in the mass killing and destruction of farm animals to keep the livestock industry 'healthy'. The present Foot and Mouth Disease (FMD) epidemic follows outbreaks of swine fever and mad cow disease (BSE). It can only be controlled by massive 'preventive' slaughter, or so the public has been told.

Since 1991 European herds have not been vaccinated against FMD. This is a purely financial decision. A choice was made to orientate meat and milk production to the North American and Japanese market and these importers would only buy European products if they were clear of FMD antibodies. Antibodies conferred by vaccination could not be distinguished from antibodies present in animals suffering from FMD – hence the no vaccination policy. By accepting these export conditions, the livestock sector was able to secure a good income even though no animal in the last ten years has had any antibodies to protect it from FMD.

In recent months we have seen the fruits of this policy. More than one million animals: cattle, swine, sheep and goats, have been destroyed in the UK, one of the major advocates of the non-vaccination policy. Only a small percentage of these animals were actually suffering from FMD. The virus has now appeared in the Netherlands and has created panic. There are bans on animal movement and the transport of livestock products and large-scale slaughter of animals has started on and around the farms where the virus has been detected. Throughout the country there is confusion, protest, political wrangling and despair.

The FMD virus is extremely contagious. In general animals recover well and spontaneously from FMD, although milk and meat production may fall temporarily. FMD does not affect humans. In the present situation where export interests have priority, even the threat of FMD is a disaster for farmers, because herds are being destroyed for preventive purpose.

A vaccine exists. In the past, cattle were vaccinated every year. This provided reasonable protection. The best option was to vaccinate every six months. If an outbreak occurred, it could be controlled by quickly vaccinating herds in the vicinity of the affected farms and a few herds were destroyed.

Times have changed. The risk of FMD outbreaks have increased. Animals are kept close together and livestock and livestock products are routinely transported all over the world. The solution to the present outbreak is simple: vaccinate all FMD-susceptible animals. Technically and financially this is a feasible solution. However, export interests prevent implementation.

Once again the break down in moral values within the European agricultural sector gets visible. Within the intensive livestock industry there is little concern for animal welfare, food safety or the environment. More and more people are worried about the safety of industrially produced food or feel ashamed of being part of the present system. Many are turning to vegetarianism or becoming advocates of organic agriculture. Increasing numbers of politicians are aware things have to change. They are coming to recognise that food safety, animal welfare and the ecological soundness of agricultural production are legitimate concerns. It is now possible to discuss less intensive, more ecologically sound and organic ways of practising agriculture. The German Government has taken a firm decision to change its policies in this direction. But what will this mean in practice? Are we really ready to change our values or will entrenched economic interests continue to prevail? Now is the time for change!

Can you imagine this countryside without animals?

Themes for next issues

December 2001 Vol.17-4

Alternatives to Biotechnology

'Terminator Technology', 'Golden Rice', 'Bt Cotton or Maize', herbicide resistant 'Roundup Ready Soya' are the products of modern biotechnology. Some claim that such developments will solve the problem of world hunger and that we need Genetically Modified (GM) crops to meet the demands of a rapidly growing world population. But do we really need these technologies? Do they deliver what they promise? Are large companies investing in these technologies interested in the specific needs and requirements of smallholders in the tropics? Will low-cost and low-risk oriented farmers benefit from these technologies? And are there other biotechnologies not based on genetic modification that provide affordable and complementary tools for improving genetic resources?

In this issue on 'Alternatives to Biotechnology', we would like to focus on the specific claims made in favour of the introduction of the Genetic Revolution in tropical farming, the risks involved and the alternatives that exist around the world. For example, do natural pest control mechanisms in ecological maize or cotton production systems provide good alternatives to high external-input based Bt-Maize or Bt-Cotton? Do people who depend on integrated rice-based systems really need Golden Rice for their daily Vitamin A supply? Are herbicide resistant crops really needed in zero tillage systems? ***Deadline for contribution 1 September***.

Information on the themes of the July (**Globalisation challenged**) and September (**Going to scale**) issues can be found in the December issue of 2000, Vol.16-4, p. 36.

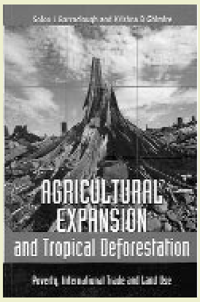
You are invited to contribute to these issues with articles (about 1600 words + 2 illustrations), suggest possible authors, and send us information about interesting publications, training courses, meetings and websites.

BOOKS

Manual on participatory 3-dimensional modelling for natural resource management

by Rambaldi G, Callosa J. 2000. 41 p. ISBN 971 8986 21 9. National Integrated Protected Areas Programme (NIPAP), Protected Areas and Wildlife Bureau (PAWB-DENR), Visayas Avenue, Diliman, 1101 Quezon City, Philippines. (Essentials of Protected Area Management in the Philippines, Vol. 7).

This manual of the Philippines Department of Environment and National Resources (DENR) is intended to assist participatory learning and action practitioners, NGOs, scientific institutions and others, who want to use community-based mapping as a tool for increasing the capacity of local stakeholders to interact with national and international stakeholders, and to express their views and assert their rights. Participatory 3-Dimensional Modelling is a cartographic method which merges Geographic Information System (GIS) generated data with people's knowledge. The manual is a step by step guide to making a relief model of a protected landscape or an ancestral domain in which all stakeholders are involved. The manual is a clear and useful tool, but digital maps and GIS expertise have to be available. This can make the process rather expensive. However, the resulting relief model will be an excellent visual aid for collaborative planning, for collaborative research, for protected area management, for increasing local communications capacity, etc. (WR)



Agricultural expansion and tropical deforestation: poverty, international trade and land use

by Barraclough SL, Ghimire KB. 2000. 150 p. ISBN 1 85383 665 6 GBP 14.95. UN Research Institute for social Development(UNRISD). Earthscan Publication, 120 Pentonville Road, London N1 9JN, UK / earthinfo@earthscan.co.uk ; www.earthscan.co.uk

Tropical deforestation has resulted in the conversion of large areas of tropical forest into other land uses. To remedy this degradation of natural resources, the social origins of deforestation processes and their social impacts have to be considered Deforestation stories that could contribute to the more sustainable use of natural forests have to include the political and socio-economic dimensions, as well as the ecological ones. The writers of this book have tried to do jut this. They draw empirical data from case studies ranging over three continents. They show that agricultural expansion and international trade are important factors in deforestation, but that their roles are varied and contradictory. The book ends with a look at public policy and institutional reforms at different levels that could help to promote more sustainable uses of tropical forest resources. (WR)

The dynamics of irrigated rice farming in Mali

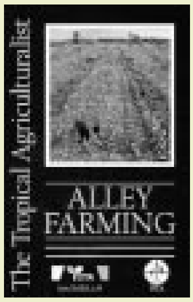
by Kater L,et al. 2000. 25 p. NUTNET programme, International Institute for Environment and Development (IIED), Drylands Programme. (Managing Africa's Soils, ISSN 1560 3520 ; 12). Drylands Programme, IIED, 3 Endsleigh street, London WC1H ODD, UK / drylands@iied.org / www.iied.org/drylands

This study of the Office du Niger, one of the largest irrigation schemes in sub-Saharan Africa, deals with the maintaining of soil fertility by the rice farmers and the risks of expanding the scheme. The rice farmers have recently diversified their production by growing vegetables on the rice fields in the dry season. They still have to add fertilisers because most of the rice stubble is consumed by livestock. In the dry season the herds browse rice stubble, and in the wet season they graze areas outside the scheme.

Expansion of the scheme will increase the pressure on the remaining resources outside the scheme, woodlands and dryland grazing areas. Sustainability can only be achieved when the rice farmers change their livestock management practices, and try to integrate their livestock and cropping systems. (WR)

Alley farming

by Kang BT, Atta-krah AN, Reynolds L. 1999. 120 p. ISBN 0 333 60080 0. Technical Centre for Agricultural and Rural Co-operation (CTA), PO Box 380, 6700 AJ Wageningen, The Netherlands. (The tropical agriculturalist / Coste R.(ed.)).



Alley farming, also known as avenue cropping, hedgerow inter-cropping or contour hedgerow system, is an agroforestry land-use system in which food crops are grown in alleys formed by hedgerows of trees and shrubs (preferably of nitrogen-fixing species). A livestock component may be included in the system as the hedgerow foliage can be used as animal feed. As such it is an excellent LEISA alternative in rainfed areas, particularly on sloping lands, as the hedgerows can greatly reduce soil erosion. Different aspects of this system are dealt with in a concise and practical manner, illustrated with diagrams and photos. This recent addition to CTA s 'The Tropical Agriculturist' series is written by scientists from the International Institute of Tropical Agriculture (IITA), which did research on and promoted the system in Africa. They also ponder over the low adoption rate by African farmers in comparison with Asian-Pacific farmers. (IHG)

Farmers' knowledge of soil fertility and local management strategies in Tigray, Ethiopia

by Corbeels M, Shiferaw A, Haile M. 2000. 23 p. NUTNET programme, International Institute for Environment and Development (IIED), Drylands Programme. (Managing Africa's Soils, ISSN 1560 3520 ; 10). Drylands Programme, IIED, 3 Endsleigh street, London WC1H ODD, UK / drylands@iied.org / www.iied.org/drylands.

In the semi-arid highlands of Tigray, Ethiopia, this survey was carried out to analyse local knowledge on soil fertility and soil fertility management practices. Land shortage and land fragmentation has increasingly forced farmers to abandon fallowing, manuring, terracing and using crop residues. The disappearance of these traditional practices has a considerable impact on soil fertility. One option would be to integrate the livestock and cropping system more closely. Farmers' experimentation with new practices is an important element in learning about integrated soil fertility management. (WR)

Stakeholder participation in policy processes in Ethiopia

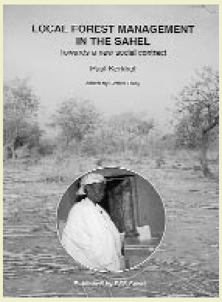
by Tessema W. 2000. 25 p. NUTNET programme, International Institute for Environment and Development (IIED), Drylands Programme. (IIED Managing Africa's Soils, ISSN 1560_3520 ; 17). Drylands Programme, IIED, 3 Endsleigh street, London WC1H ODD, UK / drylands@iied.org / www.iied.org/drylands

Degradation of the environment limits agricultural productivity in Ethiopia. Farmers aware of the problem, employ strategies like soil fertility management practices. This study sets out to examine the perceptions held by different people, institutions and agencies of the problems faced by farmers. It tries to identify possible policies and interventions. (WR)

Participatory integrated pest management by Weel P (ter), Wulp H (van der). 1999. 67 p. ISBN 90 5328 228 9. The Netherlands Ministry of Foreign Affairs, Development Cooperation, P.O.Box 20061, 2500 EB The Hague. (Policy and best Practice Document 3).
Published in the series Policy and Best Practice Documents, these papers are part of the official policy of the Dutch Ministry for Development Cooperation and provide up-to-date background information on topics that are considered important to the Netherlands development assistance programme. They address practical issues in different fields of development and provide guidelines for implementation. The issues in the field of IPM treated in the publication are of benefit to staff at Netherlands Embassies in developing countries who may be involved in identification, formulation, appraisal or review of IPM and crop protection projects, and preparation of policy or programme documents. Given the target audience, the language is non-technical and practical. New trends in the field of IPM stress the importance of participatory approaches now supported by several prominent international policy documents. In addition, the effective introduction of IPM requires a conducive policy environment that does not encourage the use of pesticides. The paper provides guidelines to support participatory IPM, focussing on assistance in the establishment and development of national IPM programmes; assistance to participatory IPM projects; and incorporation of participatory IPM components in ongoing or future projects or programmes. (WB-from executive summary)

Co-managing the commons : setting the stage in Mali and Zambia by Hilhorst T, Aarnink_N. 1999. 80 p. ISBN 90 6832 835 2 : NLG 19,50. Royal Tropical Institute (KIT), PO Box 95001, 1090 HA Amsterdam, The Netherlands / kitpress@kit.nl (Bulletins of the Royal Tropical Institute Series ; 346).
Commons are natural resources that are jointly used by various user groups and include forests, lakes, rangelands etc. In many cases the rights of the users are not well defined and a mingling of traditional and modern legal systems create confusion, resulting in overuse and conflict. This publication deals with a form of community-based management called ‘co(llaborative)- management’, offering opportunities for a more sustainable management of common resources by the establishment of formal agreements between user groups and the government. Two case studies are used to illustrate this approach. The first deals with co-management of forest and rangelands in southern Mali, the second with inland fisheries in northern Zambia. The final chapter dwells on the common elements shared by both cases and ways to facilitate the process of participatory management are explored. (IHG)

Local forest management in the Sahel : towards a new social contract by Kerkhof P ; Foley G, (ed) 2000. 83 p. ISBN 1 901459 28 4. SOS Sahel International UK, 1 Tolpuddle Street, London N1 0XT, UK / mail@sahel.org.uk



This report, also available in French, is the output of a research project in the Sahel, with emphasis on Mali, Niger and Sudan. It starts with a description of the existing methods of local community management of woodlands and the Sahelian forestry tradition partly imported from 19th century Europe. It describes the woodlands themselves, very different from European forests, and the way Sahelian families utilise the local woodlands in their survival strategies. The main developments in decentralisation and restructuring of the role of the state is described, and the report ends with the conclusion that natural woodlands can only be managed effectively on a voluntary basis by local communities operating within certain agreed constraints and restrictions. Local management needs to be negotiated between the various stakeholders involved. (WR)

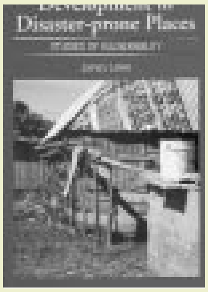
IPM and the citrus industry in South Africa by Urquhart P. 1999. 20 p. International Institute for Environment and Development (IIED), 3 Endsleigh Street, London WC1H 0DD, UK / sustag@iied.org Sustainable Agriculture and Rural Livelihoods Programme (SARL). (IIED Gatekeeper series, ISSN 1357 9258 ; 86).
IPM adoption in citrus is becoming important as part of the international market requirements, esp. in respect to pesticide regulations and criteria of buyers, and the increasing resistance to pesticides. This paper gives a critical overview of the importance of Integrated Pest Management (IPM) for the citrus industry in South Africa in general, and the contribution it can make to rural development in particular. The costs and benefits of IPM adoption for farmers and workers are discussed together with recommendations to encourage the adoption of IPM technologies in citrus at small farmer level. (IHG)

Meeting the challenges of animal traction : a resource book of the animal traction network for Eastern and Southern Africa
by Starkey P, Kaumbutho P (ed.) 1999. 326 p. ISBN 1 85339 483 1. The Animal Traction Network for Eastern and Southern Africa (ATNESA), PO Box BW540, Borrowdale, Harare, Zimbabwe DFID. Intermediate Technology Publications, London.
This book is one of several resource books published by ATNESA after the workshop on ‘Meeting the challenges of animal traction’ in Kenya in 1995. This particular resource book contains papers that address a number of important challenges to animal traction that relate to participation, environment, gender, extension, transport, equipment and animal husbandry. In addition, several papers describe national-level challenges and project attempts to address them. In sub Saharan Africa animal traction has been and still is an important way of increasing the surface area cultivated. Animal traction, placed in a comparative frame with hand hoeing and tractors, has many advantages. Though improper use of animal traction can aggravate environmental degradation, the technology is appropriate to agricultural development. The book also pays attention to post-war re-introduction of animal traction. A valuable resource book for all concerned with the development of animal power. (WR)

A training guide for in situ conservation on-farm : version 1 by Jarvis DI, et al. (eds) 2000. 159 p. ISBN 92 9043 452 X. International Plant Genetic Resources Institute (IPGRI), Via delle Sette Chiese 42, 00145 Rome, Italy CGIAR.
Agricultural biodiversity maintained on-farm by farmers has become an important way to conserve plant genetic resources in a local environment. This manual is written for Ministries of Agriculture and Environment, Universities, Research and Extension Institutions, NGOs and Community Based Groups. In the past, ex situ conservation programmes have been developed with conservation taking place in genebanks or botanical gardens. This guide provides information on expanding these conservation options to in situ conservation of crops on-farm. It mentions the advantages and disadvantages of in situ conservation and deals with a range of topics, from genetics to ecology and anthropology, including sampling, data analysis and participatory methods. The guide presents only the most basic and essential concepts. It is a compact but useful tool for the source group. (WR)

Development at risk? : natural disasters and the third world by Twigg J (ed.). 1998. 24 p. free of charge. Co-ordination Committee for the International Decade for Natural Disaster Reduction (IDNRD), London, UK / eadesa@raeng.co.uk :The booklet can be downloaded from www.gfz-potsdam.de/ewc98 or www.oneworld.org/idndr

This very readable booklet with four important contributions on the relationship of natural disasters and developmental progress is an important basic source of information on the topic. The first two articles look at the scale and nature of the disaster problem. The last two articles deal with ways of overcoming the threat of disasters. Poverty increases vulnerability to natural hazards, and in it the direct connection with development projects. Some people are more at risk than others, which implies that disaster mitigation has to be built on community participation. The booklet carries many examples from all over the world and makes clear why disaster preparedness is worth investing in. (WR)



Development in disaster-prone places: studies of vulnerability by Lewis J. 1999. 224 p. ISBN 1 85339 472 6: GBP 15.95. Intermediate Technology Publications, 103-105 Southampton Row, London WC1B 4HH, UK / orders@itpubs.org.uk

This book addresses the long overdue imbalance in disaster management: an over-emphasis on post-disaster assistance and a lack of attention to vulnerability reduction. Part one deals with causes for vulnerability in rural areas. In part two a number of case studies (Tonga, Antigua, Sri Lanka, Dorset) help to clarify vulnerability mechanisms. In part three the author offers development strategies for vulnerability reduction and increased disaster preparedness. Recommended reading for all those involved in the issue. (WR)

From feast to famine: official cures and grassroots remedies to Africa's food crisis by Rau B. 1990. 213 p. ISBN 0 86232 927 2, Zed Books, 7 Cynthia Street, London N1 9JF, UK.

This book, though not very recent, is still a valuable source on Africa's food crisis. The first part traces the origins of the crisis back to the colonial exploitation of the 19th century. This historical perspective is important to understand why the official cures discussed in the second part do not work. In the third part of the book, grassroots remedies are discussed. The writer states that 'free enterprise' and 'individual initiative' as important rules for the developed world override local realities and indigenous choices in developing countries. Listening to the people is what the author promotes with this book. He cites several examples of how indigenous agricultural knowledge has helped in coping with crises. (WR)

Women feed the world: world food day. 1998. 21 p. Food and Agriculture Organisation of the United Nations (FAO), Via delle Terme di Caracalla, 00100 Rome, Italy / www.fao.org

This brochure of FAO was published on the occasion of World Food Day, 16 October 1998. The fundamental contribution of women to household and national food security and the multiple roles rural women play throughout the entire food chain, from agricultural production to post harvest processing and marketing as well as in nutrition and food safety, was the reason for the publication. FAO believes that the battle for food security can be won only if the invaluable contribution made by women is recognised and supported. The document illustrates the important roles women fulfil and highlight the numerous needs they still have to cope with. The conclusion is that rural women must become visible partners in development and that their voice must be heard on par with that of men when policies and plans are elaborated. Yet, a lot has to be changed before this becomes reality. (WR)

Famine in the Sudan: causes, preparedness and response: a political, social and economic analysis of the 1998 Bar El Ghazal famine by Luka Biong Deng. 1999. 124 p. ISBN 1 85864 265 5 GBP 19.95. Institute of Development Studies (IDS),University of Sussex, Falmer, Brighton BN1 9RE, UK / ids@sussex.ac.uk. (IDS Discussion Paper 369).

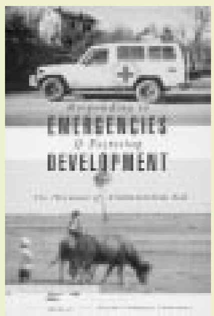
This IDS paper analyses the causes of the Bahr el Ghazal famine as a chain of political, environmental, economic and social factors, as well as a failure of public action and early warning systems. This detailed study of the causes of a severe famine disaster in 1998 shows the complexity of cause and effect when war, drought and failure of management together disrupt society. Even the international relief response was late and inadequate. The paper throws light on how disasters like this famine could happen, but unfortunately not on how disasters like this can be avoided. (WR)

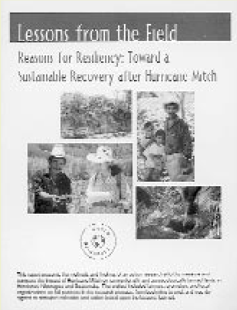
Waters of life: perspectives of water harvesting in the Hindu Kush-Himalayas: proceedings of the regional workshop on local water harvesting for mountain households in the Hindu Kush-Himalayas, Kathmandu, March 14-16, 1999 by Banskota M, Chalise SR. 2000. 101 p. ISBN 92 9115 104 1. International Centre for Integrated Mountain Development (ICIMOD), G.P.O. 3226, Kathmandu, Nepal / distri@icimod.org.np / www.icimod.org.sg

This document discusses, through a number of case studies, the methods of harvesting water throughout the HKH mountain region by a wide variety of people groups with special focus on the efforts being made by local communities. The Hindu Kush-Himalayas is the largest storehouse of fresh water in the lower latitudes. It is the source of major river systems, among others the Ganges and the Mekong. The extreme variability of climate and precipitation patterns as well as the inadequate knowledge on the hydrology of the rivers imposes limitations on the development of HKH waters. It concludes that concerted effort is needed to improve existing systems through community participation while expanding new systems at the same time. An annotated bibliography is annexed to the document. (WR)

Responding to emergencies and fostering development: the dilemmas of humanitarian aid by Pirotte C, Husson C, Grunewald F (eds). 1999. 183 p. ISBN 1 85649 755 0 (pbk) : GBP 14.95. ZED Books, 7 Cynthia Street, London N1 9JF, UK / zedbooks@zedbooks.demon.co.uk

Civil wars, genocide, natural disasters and other emergencies - this book is about how to respond to the fundamental difficulties thrown up by these humanitarian crises. The authors of the book are figures from leading emergency relief and development agencies. They write about their experiences and provide advice on how to act more effectively in the future. The book contains a small chapter on gender and emergency relief. This is an important part because women are often overburdened in crisis situations when they have to be sole providers for their children and families. The book includes many different voices and embodies an open-ended debate about the whole diverse process of international aid. (WR)





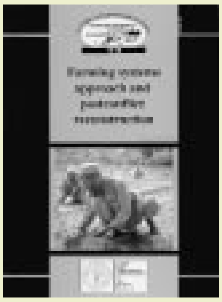
Reasons for resiliency: toward a sustainable recovery after hurricane Mitch. 2000. 32 p. USD 5.-, World Neighbours, 4127 NW 122nd Street, Oklahoma City, OK 73120-8869, USA / www.wn.org (Lessons from the field).
This report presents the results of the study on recovery after Hurricane Mitch in Central America in 1998. It shares the methods and findings of the participatory action research effort undertaken by nearly 2000 farmers in Honduras, Nicaragua and Guatemala. Eric Holt-Giménez's article in this issue focuses on the findings of this study, the conclusions of which are based on the numbers and figures mentioned in the report. This impressive piece of work proves the important possibilities of sustainable agriculture in creating and maintaining a stable ago-ecosystem, especially in disaster prone conditions. The study deserves broad recognition and imitation; at least policy makers in the involved countries should listen carefully. World Neighbours has done an excellent job by publishing the report in English and in Spanish, and making it accessible on the internet (on their web site) for free. (WR)

Changing course: recovery & research after hurricane Mitch.
2000. 17 min. USD 5.-, World Neighbours, 4127 NW 122nd Street, Oklahoma City, OK 73120-8869, USA / info@wn.org, www.wn.org
A video documentary of the above-mentioned research is available both in English and Spanish. Apart from Hurricane Mitch and its disastrous effects, it gives an impression of the field research and the farmers who were involved. It also illustrates the importance of the conclusions. The message is worth advocating. (WR)

Making less last longer: informal safety nets in Malawi
by Devereux S. 1999. 124 p. ISBN 1 85864 286 8 GBP 14.95. Institute of Development Studies (IDS),University of Sussex, Falmer, Brighton BN1 9RE, UK / ids@sussex.ac.uk : www.ids.ac.uk/ids. (IDS Discussion Paper 373).
Informal safety nets are defined in this paper as a subset of the range of coping strategies that people adopt in response to situations of acute food insecurity. Empirical studies across sub-Saharan Africa suggest that traditional practices of 'vertical' redistribution are rapidly disappearing under processes of commercialisation. Yet, 'horizontal' re-distributive practices - transfer to extended family networks and neighbours within poor communities - remain widespread but are highly vulnerable to risks that strike the whole community, i.e. drought. The paper describes studies of household coping strategies in Malawi, which confirm the importance of agricultural labour in rural areas as both a regular source of livelihood and a coping strategy in difficult years. Informal safety nets appear to play a more important role in urban areas than in rural areas, which could probably be attributed to the increased poverty in the latter. The paper ends with recommendations on the design of formal safety nets. The example of aid as inputs-for-work to boost production instead of food-for-work to support consumption is explained and the 'sustainable livelihoods' framework is argued to be usefully applicable to the design of formal networks. (WR)

Reducing risk: participatory learning activities for disaster mitigation in Southern Africa by Astrid von Kotze and Ailsa Holloway. International Federation of Red Cross and Red Crescent Societies, distributed by Oxfam UK, 1996, 301 pp, £14.95, ISBN 0 85598 347 7 .
Despite its focus on Southern Africa, this highly practical training resource can be used in other regions too. It is a collection of participatory learning exercises for people who work with communities at risk.

Risk-mapping and local capacities: lessons from Mexico and Central America by Trujillo M, Ordonez A, Hernandez C. 2000. 160 p. ISBN 0 85598 420 1 USD 18.95. Oxfam GB. (Oxfam Working Papers). Oxfam, c/o BEBC, PO Box 1496, Parkstone, Dorset BH12 3YD, UK / oxfam@bebc.co.uk
This paper describes an exercise carried out by Oxfam GB to map out the range of natural hazards and other risks to which people in Mexico and Central America are exposed. It relates the hazards to the complex social, economic, political, and cultural factors that increase the vulnerability of certain social sectors more than others do. The review of the threats and disasters across the region is very impressive. The maps showing the regional patterns of risk and vulnerability help to appreciate the importance of risk management in order to reduce vulnerability and insecurity and achieve sustainable development. The paper states the importance of fostering a culture of disaster preparedness in the different countries involved, and the importance of community participation in decision making to decrease vulnerability. The paper ends with an important chapter on the needs in disaster management in which warning systems, emergency plans and preparation for protection are discussed. (WR)



Farming systems approach and post-conflict reconstruction
by Schelhas B. 1998. 73 p. ISBN 92 5 104152 0; USD 8.00. Food and Agriculture Organisation of the United Nations (FAO), Viale delle Terme di Caracalla, 00100 Rome, Italy / www.fao.org. (FAO Farm Systems Management Series 14).
In this document, FAO presents important information on the linkages between the farming systems approach to development (FSD) and post-war rehabilitation and reconstruction. It is based on field experiences in development planning, rehabilitation and relief programmes. The aim of this document is to help small farming households in post-war situations to restore and improve agricultural productivity and levels of living in an equitable and sustainable manner, and strengthen preventive factors to reduce future recurrence of wars. The farming systems approach to development is a participatory approach. It is suitable for developing countries but also for countries undergoing heavy transformation processes like the Soviet Union. As an annexe, the booklet contains the example of the application of FSD in Afghanistan. (WR)

Roots up, strengthening organisational capacity through guided self-assessment. Revised and expanded edition.
World Neighbours, 4127 NW 122th Street, Oklahoma City, OK 73129-8869 USA. Fax: +1 405 752 9393; order@wn.org ; www.wn.org , US$ 20.00 plus postage.
The process presented in the guide provides local development organisations with the tools and perspectives necessary to strengthen their capacity by regularly reflecting on their performance, diagnosing internal strengths and weaknesses, identifying priority capacity areas, and designing action plans to improve effectiveness and long-term viability.

World Bank

http://www.worldbank.org

The pages of the World Bank website provide extensive information on disaster management and post-conflict reconstruction. Countries can ask for emergency recovery assistance, and be helped by the bank in financing investment and productive activities. The bank also helps with emergency-preparedness studies and technical assistance on prevention and mitigation measures to strengthen the country's resilience to natural hazards or lessen their impact. The pages are available in several languages, including Spanish and Portuguese. They offer information as well as downloadable reports.

Relief Web

http://www.reliefweb.int/

Relief Web centralises and disseminates information on humanitarian emergencies and natural disasters. This inforchers etc). Its Supplier Guide is an up-to-date and worldwide database of relief products, suppliers and service providers, i.e. you can find a firm, which can supply agricultural tools. Reliefguide provides an online tender area in which aid and development agencies can display their procurement needs. The aim of the Disaster Page is to bring together all parties involved in an ongoing disaster and create an effective exchange of information on aid-related operations and procurement needs. This part is stichers etc). Its Supplier Guide is an up-to-date and worldwide database of relief products, suppliers and service providers, i.e. you can find a firm, which can supply agricultural tools. Reliefguide provides an online tender area in which aid and development agencies can display their procurement needs. The aim of the Disaster Page is to bring together all parties involved in an ongoing disaster and create an effective exchange of information on aid-related operations and procurement needs. This part is still in the pipeline.

Pacific Disaster Centre

http://www.pdc.org/

This Centre is a federal information processing facility that supports emergency managers in the Pacific and Indian Ocean Regions. The page offers information on droughts and rainfall in the region.

International Decade for Natural Disaster Reduction 1990 – 2000

http://www.oneworld.org/idndr

This site provides information on IDNDR, activities, newsletter and an overview of the publications that have been published during the decade. It has been updated in December 1999.

Asian Disaster Preparedness Centre

http://www.adpc.ait.ac.th/

This Asian page on Disaster Reduction for Safer Communities and Sustainable Development provides a lot of information on disaster management, which can also be obtained in printed form. The centre offers courses and training material on disaster preparedness also in regional programmes.

United Nations High Commission for Refugees (UNHCR)

http://www.unhcr.ch

The majority of the world's refugees are found in marginal regions of poor, developing countries. Collecting shelter material and firewood can cause serious deforestation and soil erosion. Natural resources are threatened by the sudden arrival of large numbers of people. UNHCR and partner organisations seek to minimise the environmental impacts of refugee operations. Innovative, alternative solutions are being developed that enable refugee populations to become more closely involved with environmental management and rehabilitation. This site provides important information on refugees and the environment in English and several other languages.

Humanitarian Practice Network

http://www.odihpn.org/

The Humanitarian Practice Network of ODI is a leading information and analysis provider for the humanitarian sector. Its objective is to improve operational practice. The site provides information on this subject.

Disaster recovery, Iowa State University Extension

http://www.exnet.iastate.edu/Pages/communications/recovery/

This site aims to help Iowans make better decisions in tough times. Although tailored for rural families in the U.S.A., the site offers a lot of interesting information on post-disaster agriculture. Practical information, for example on how to manage trees after storm damage and how to store crops, can be very useful to farmers. This site is an example of how the internet can be used in disaster relief and recovery.

Disaster Preparedness and Emergency Response Association

http://www.disasters.org/

Information on emergency preparedness and management of emergency situations is provided by this website. It is available in English, Spanish, French, Portuguese, Italian and German. Besides information and the Disastercom Newsletter on pdf file, it provides many links to a range of organisations in the field of disaster preparedness.

Inter-Action-American Council for Voluntary International Action

http://www.interaction.org/

The page of the Council provides a lot of information and links. The Disaster Response Committee offers information on emergency response activities and reports on investigated emergency situations.
The sustainable development movement tries to promote dialogue, collaboration and action at project and policy levels on priority development concerns of InterAction members and their Southern partners in reducing poverty and achieving sustainable development. This part of the site offers information and links to organisations on sustainable development and agriculture, and on women in development.

United Nations Development Programme (UNDP)

http://www.undp.org

The page on crisis prevention and recovery gives important information on rehabilitation development initiatives.
The Disaster Management Training Programme DMTP offers country-specific training programmes for national governmental and non-governmental institutions and agencies in various areas of emergency management and disaster mitigation, prevention and preparedness. The DMTP also provides training for in-country UN system Disaster Management Teams. Wherever possible, DMTP provides training within a framework of national capacity building/ strengthening in disaster management programming. Unfortunately, information on agricultural rehabilitation is completely lacking.

Food and Agriculture Organisation of the United Nations (FAO)

http://www.fao.org

On the opening page of this very extensive and interesting web site of FAO is news on important agricultural emergencies like Mad cow disease, Foot and mouth disease, AIDS and climate change. It also gives access to the pages of the FAO agenda, special programmes and focus activities like: agriculture, forestry, sustainable development, gender and food security, and publications. The web magazine 'Agriculture 21' featured on the web pages on agriculture contains news, spotlights, archives and provides access to all specialised agricultural divisions within FAO. The part on organic agriculture, with downloadable FAO documents, photos, meetings and a discussion forum is of special interest to the LEISA community. The pages are available in English, Spanish and French.

International Federation of Red Cross and Red Crescent Societies

http://www.ifrc.org

This organisation posts news on recent disasters and aid campaigns from all over the world on its site. It contains an interesting article on a training programme in India on disaster preparedness for volunteers from the Indian Red Cross.

Sustainable agriculture to combat Global Warming

It is now widely acknowledged that the increase in emergencies due to disturbances and change of climate (droughts, floods, hurricanes) is strongly enhanced by 'Global Warming' (IPCC 2001). Global Warming is caused by the emission of 'greenhouse gases' through various human activities such as agriculture.

The 1997 Kyoto Protocol to the United Nations Framework Convention on Climate Change established an international policy context for the reduction of carbon emissions and increases in carbon sinks in order to address this problem. Under the Kyoto Protocol, industrial countries undertook a net reduction of greenhouse gases by 5.2% below 1990 levels by 2012. This implies the need to reduce emissions and increase sinks. Importantly, the Kyoto Clean Development Mechanism also provides incentives – known as 'carbon credits' – for countries that reduce their emissions or increase sinks of greenhouse gases.

In a recent study, Jules Pretty and Andrew Ball analysed the contribution of sustainable agricultural practices to the accumulation of carbon and the additional income this could provide to farmers if 'carbon credits' could be traded as agreed upon in principle in the Kyoto Protocol. The following is excerpted from their report.

Carbon in agriculture

Agricultural systems can contribute to carbon emissions through several mechanisms: I) the direct use of fossil fuels in farm operations; ii) the indirect use of embodied energy in inputs that are energy-intensive to manufacture (particularly fertilisers); and iii) the cultivation of soils resulting in the loss of woody biomass and soil organic matter. On the other hand, agriculture also can be an accumulator of carbon, when organic matter is accumulated in the soil, or when aboveground woody biomass acts either as a permanent sink or is used as an energy source those substitutes for fossil energy.

Long-term agricultural experiments indicate that soil organic matter and soil carbon are lost during intensive cultivation. But both can be increased to higher levels with 'sustainable management' practices. The greatest dividend comes from conversion of arable to agroforestry systems, as there is a benefit from both increased soil organic matter and the accumulation of above-ground woody biomass.

Grasslands within rotations, zero-tillage (or no-till) farming, green manures, and high amendments of straw and manures, also lead to substantial carbon accumulation. Zero-tillage with mixed rotations and cover crops can accumulate 0.66-1.3 t C/ha/year. The rates are higher in humid-temperate areas (0.5-1.0 t C/ha/yr), lower in the humid tropics (0.2-0.5 t C/ha/yr), and lowest in the semi-arid tropics (0.1-0.2 t C/ha/yr). For real impacts on climate change to occur, sinks must become permanent. This raises a core challenge for carbon trading systems, as there is no such thing as a permanent sequestered tonne of carbon.

Income from trading carbon credits?

The first carbon exchange or trading systems have set credit values from US$1.38 per tonne of carbon, though most commonly in the $2.50-5.00 range. For the United Kingdom, it is estimated that carbon sequestration could bring arable and grassland farmers between US$27million and US$220million per year if the government decided to pay for the ecological services provided by farmers. At current prices, it is clear that farmers are not set to become solely carbon farmers. However, systems accumulating carbon are also delivering many other public goods, such as improved biodiversity and clean water from watersheds, and policy makers may also seek to price these so as to increase the total payment package. Carbon, therefore, could represent an important new source of income for farmers, as well as helping to encourage farmers to adopt a wide range of sustainable practices. ■

Organic cotton to mitigate the impact of HIV/AIDS

Sam Page

Zimbabwe has one of the highest HIV infection rates in the world, with more than 26% of the sexually active population living with HIV. The driving force of this epidemic is poverty - it is forcing men to leave their families for extended periods in search of work and women to indulge in prostitution to raise money to feed their children. Local non-government and community-based organisations are at the forefront of the struggle against this pandemic.

In 1995, at the request of some 40 women farmers who could not afford to buy pesticides, Zimbabwe's first organic cotton project was set up in the Lower Guruve area. This initiative has since grown into a larger project, the Zambezi Valley Organic Cotton project, supported by the NGO African Farmers' Organic Research and Training (AfFOResT). Organic cotton and groundnuts are being produced for sale on the local and overseas markets.

The project is addressing a group of farmers who have been largely marginalised as a result of traditional law and agricultural policies: widows, many of them AIDS widows. Although many of these women may be HIV positive, it is the older women who are likely to be safe from HIV infection. As such, some older AIDS widows are responsible for six or more children, ranging from toddlers to teenagers. Many such widows are struggling to survive as smallholder farmers. While in the past widows involved in farming were a relatively small group, today, AIDS widows free of HIV and over the age of 40 are likely to be among the most productive farmers in Zimbabwe.

The impact of HIV/AIDS

The Lower Guruve area of the Zambezi Valley has not escaped the ravages of HIV/AIDS. Already more than one third of the families are headed by widows and there are an estimated 7,000 orphans living in the area. Child-headed households are also emerging. An initial HIV/AIDS impact assessment by the project has found that AIDS widows in particular suffer the effects of increased poverty, reduced availability of labour and the inability to make important management decisions. Interviews with a number of widows revealed the following adverse consequences of HIV/AIDS:

Shortage of labour

Widows suffer from a shortage of labour. Yields of the main crops cotton, maize and groundnuts are generally reduced due to late planting, smaller areas planted and poor management. Weeding seems to be the activity that suffers most. One of the women interviewed said: "*The farm activity most affected is weeding and we were delayed in picking cotton. It's impossible for me to go to the field, and it won't be possible next season either, or until the illness of my husband goes away. No one has relieved me since he got ill.*" Another woman commented: "*There's only me, my 12-year-old son and my mother-in-law who work on the land now. When my husband was alive, we would plough one acre in a day, but now we can only manage to plough half an acre*".

Shortage of cash

Shortage of cash is usually a consequence of the loss of income from either full-time employment in town or sources supplementary to farming, such as ploughing, thatching, carpentry, building or mechanical work. One woman said: "*When my husband was alive, I had my small project of making table mats, but now I can't afford the money to buy the thread*". She also had to reduce her acreage of cotton. In the 1997-1998 season, she planted five acres of cotton, whereas in 1994-1995 she and her husband had grown seven acres of conventional cotton. "*When I returned to the Valley I had difficulty in finding the money to buy seed and pesticides. So, I milked my cattle and sold the milk to buy seeds*." Another woman also suffered from a lack of money to grow her cotton. She had to sell an ox to buy the cottonseed and also to pay for her children's school fees and to buy food.

Lack of financial and management skills

This is a particularly acute problem in households where the deceased husband traditionally made all the important financial and farm management decisions. One woman, for example, mentioned that a cheque they had received from the Cotton company was made payable to her husband, who was unable to travel in order to cash it.

FFSs as support mechanism

Conventional smallholder cotton growing in the Zambezi Valley is usually based on monocropping and the use of five different pyrethroid and organophosphate pesticides. The current cost of these inputs is US$48 per hectare. In Zimbabwe, Farmer Field Schools (FFSs) were introduced in smallholder communal agricultural areas as a means of improving agricultural management practices, including the reduction or elimination of costly external inputs. These FFSs were adapted by AfFOResT to promote organic agricultural production.

Up to 90 farmers, many of them women, were trained by AfFOResT as Farmer Field Workers (FFWs) to facilitate FFSs for more than 900 other farmers over three years. During one month, these FFWs were trained at the Eco-Lab, just outside Harare (see ILEIA Newsletter Vol.13, No.4, pp12-13), in Natural Pest Management (NPM) and internationally certifiable organic agriculture, using a process known as *learning through discovery*. Once they had returned, each FFW held FFSs with 10 other farmers, at weekly intervals, throughout the growing season. Field staff regularly followed up this process to provide motivation and support. The project also managed to conduct *farmer participatory research* (FPR). In this system of research, innovative farmers were encouraged to generate their own research questions, while project scientists gave guidance in experimental design, including data collection and analysis, in a way that ensured that the farmers retain ownership of the results.

The AIDS widows said that they attended the FFSs because they gained strength from the support of other farmers and learnt how to grow cotton, hitherto regarded as a *man's crop*. They said that the system of intercropping and underplanting with food crops such as sorghum, sweet potato, cowpea and water melon, which had been introduced to eliminate the need for pesticides, also suppressed weeds, increased income and improved food security. In time they noticed that soil fertility was enhanced by following the project's recommendations for growing of live fences, conservation of leguminous trees in fields and rotation with groundnut and sunhemp.

Results compared

An analysis of costs and benefits during the 1997-1998 season indicated that organic cotton farmers had higher profits compared to conventional cotton growers. Although the average organic cotton yield was less than half that of the conventional crop in 1998, it gradually improved towards three-quarters of conventional yields by the year 2000. Year by year organic farmers gained a consistently bigger profit (see table). In 1998 and 1999, the farmers who had been certified as *organic* by the Eco-Certification Inspector received an additional 20% premium from the buyer.

It was estimated that the labour requirement was considerably reduced by replacing the 15 hours normally spent doing tasks associated with applying pesticides to conventional cotton, with 2 hours for attending a FFS and one hour scouting for pests and *farmers' friends* such as predators and parasitoids.

One widow indicated: "*I will grow only organic cotton next year because of the low labour requirement. There is less labour needed for weeding because some parts of the field are covered by cowpea. Less labour is needed for spraying too because the herbal sprays are made from plants in the bush nearby. I will not do any conventional cotton production because I have no money to buy inputs*."

It was concluded that organic farming systems have proven to be particularly appropriate for households affected by the AIDS pandemic, as they do not require the purchase of external inputs, they have reduced labour costs and they offer the farmers a premium when sold as a certified organic product.

AIDS prevention

The project has incorporated a component on women's vulnerability to HIV infection and prevention in its FFW training courses. A four-week training of male and female FFWs in May 1999 included two AIDS prevention sessions for men and women. During these sessions, condoms were promoted and the FFWs were invited to take batches with them to the Zambezi Valley to be sold at a small profit to their friends and families as an income-generating activity. The project is also sensitising communities on HIV prevention with the support of a consultant from the NGO Population Services International, who raises awareness on HIV and Sexually Transmitted Diseases and promotes the use of condoms.

NGO difficulties in averting HIV/AIDS

Despite its success in terms of mitigating the impact of HIV/AIDS and development of the production of organic cotton, this project is now on the verge of collapse. Since its inception, the biggest constraint has been the lack of funds. Now, the donor has withdrawn and aspects such as local project supervision, allowances for the FFWs, organic inspection and marketing, are suffering. The hard work of the past three years seem to get lost. This has happened despite a strong recommendation by an external evaluator to continue, and the recent nomination of the project by FAO/UNAIDS as a '*best practice*' in reducing vulnerability to the AIDS epidemic. This illustrates the difficulties local NGOs have in trying to avert the HIV/AIDS catastrophe.

Introducing new crops in a conflict situation: **Gender roles and innovation**

Roger W. Sharland

The ongoing war in **southern Sudan** and the widespread relief effort has resulted in a growing dependency in many communities on relief food. Air drops and other sources of relief food have increasingly become a major coping mechanism and an important component of many food economies. Within this context a number of agencies have been seeking strategies to increase food security through agricultural production.

Differences in food economy

Of the six food economy zones in southern Sudan, the main differences in the basic economy can be seen between the Equatorian tribes on the southern border and the agro-pastoralist tribes of the flood plains. The latter has a long tradition of agricultural production that is secondary to the importance of livestock in their lives, while the former depends almost exclusively on agricultural production. In the past couple of years, many areas of Western Equatoria province have returned to normal agricultural production, while the agro-pastoral areas to the north have remained relief dependent.

Searching for strategies

As part of my input to household food security strategy, I have examined what has enabled Equatoria to return quickly to food security while Bahr el Ghazal has remained relief dependent. One important factor identified in maintaining household food security in Equatoria has been the prevalence of fruit trees, especially mangoes, and the widespread cultivation of root crops (cassava and sweet potatoes) as well as the more traditional grain and oil seed crops. Although introduced into the food economy within the last century, root crops are now part of the established cultivation system of most Equatorial tribes.

Most of the agropastoralist Dinkas, who traditionally rely much more on their livestock for household food security, grow neither cultivated fruit trees nor root crops, and are much more vulnerable in their agricultural production. The disruption of the war over the last fifteen years has led to many changes including the loss of livestock and changes in the gender balance of the population, which has in turn led to large sectors of the population taking on new roles. This in turn seems to have led to an openness to try new ideas and technologies, including new crops.

Introducing new crops

During the 1999 planting season small amounts of planting material for fruit trees and root crops were introduced to a number of farmers in the Malualkon area of Northern Bahr el Ghazal. In January 2000, I facilitated a short workshop with those involved in the agricultural work and women from the local community. A very clear message from the workshop was that with the high population of livestock in the area these new crops cannot be grown in the same way that they are further south in Equatoria, and that local adaptations need to be made with local farmers. The main adaptations relate to three issues, namely the slightly shorter rainy season, and therefore longer dry season, the seasonal flooding that is common to that area and the roaming livestock, particularly in the dry season.

Adapting planting methods

Farmers are used to protecting their annual crops from livestock during the growing season, but both fruit trees and root crops need extra protection. This has led to trying out a new method of production of the root crops, cassava and sweet potatoes, especially in relation to the availability of planting stock. In Equatoria, annual new plantings are made from vines and cuttings obtained from the sprouting of plants that have survived the dry season. Planting material is plentiful and maintaining of stock or nurseries is not required. One of the adaptations made in Malualkon relates to maintaining the planting stock throughout the longer dry season when the livestock completely destroy any exposed plants. With cassava, some farmers have protected part of the area planted with stock proof fencing to provide the next season's source of cuttings. With sweet potatoes, a system of developing nurseries near water holes, which facilitates rapid growth due to well-manured soil, is being tried out for fast multiplication of vines.

New crops and gender roles

Of particular interest during the workshop were the gender roles in relation to the new crops and who to target with teaching. The different roles and division of labour in the production and

Contributions

Combating the consequences of flooding with farmer's innovation and experimentation by NJ Vermaak and D van Niekerk. Institute of Public Management and Development, Disaster Management Unit, Technicon South Africa, Private Bag X6, Florida 1710, South Africa. Email: dvniekerk@tsa.ac.za

The article reports on the devastating floods that occurred in Mozambique and adjacent regions during February 2000. It focuses particularly on the post-disaster period and the adaptations required from farming communities. Subsistence farmers in the Nzhelele region showed considerable potential for restoring their ecological balance by experimenting with new technologies and by taking preventive measures. The flooding disaster re-emphasised the need to avoid overgrazing and to protect natural vegetation. Such measures will improve farmers' resilience and their capacity to recover and sustain their livelihoods.

Foundation of traditions for drought mitigation with self sustainable agri-horticulture system in arid zone by Arun K. Sharma, Central Arid Zone Research Institute, Jodhpur – 3242003, India. Email: aksharma@cazri.raj.nic.in

After 8 years of experimentation the author developed a highly drought resistant, low-external-input agroforestry system based on Jujube (*Ziziphus mauritiana*) intercropped with annual grain legume crops, mainly green gram (see photo). It takes three years to develop fully but income is generated from the first year.
The system has been found to be sustainable with a rainfall of between 200-400 mm/year, provided the rainwater in the field is conserved and nutrients taken out of the soil with the harvested crop are returned in the form of manure. Experience showed that, on an area of one hectare, the system was able to meet the needs of a family of four that had four goats or sheep.

processing of the traditional crops, the different tools used and the preferences of men and women were discussed. This helped to gain an understanding of the gender issues involved in traditional cultivation, and how they could affect the wider introduction of new crops.

Thereon, we looked at the work involved in the production of new crops, which included not only root crops and fruit trees, but also swamp rice. In the case of root crops, particular attention was given to the work involved in protecting them from livestock and in fence building. The division of labour that emerged was based on local knowledge and experience and proved very different from the assumptions based on how the crops are grown further south in Equatoria.

Men's crops and women's crops

Both cassava and sweet potatoes were seen to be crops that require the input of both men and women if traditional roles are to be followed, with sweet potatoes considered more of a male crop and cassava more of a female crop. This is opposed to the experience of the Equatorian tribes, where cassava is the one crop that men frequently cultivate on their own. Division of responsibilities was less in relation to the nature of the crop and its produce (which is very significant in Equatoria) and more in relation to the type of tools used and the type of labour input.

For both crops, men's input was considered very important for the cutting of wood and building of fences to protect them from livestock, but what followed showed a significant division of labour. Sweet potatoes was seen as a crop with more male input because it is grown elsewhere in Sudan on mounds that require either a spade or the east African hoe to dig them, both tools more often used by men. It was also agreed that men should plant the vines, and as it is considered a cash crop that men should harvest it too. The work for cassava involves weeding which is more a woman's role, and the planting of the cuttings was also seen as a more female role, in contrast to that of the vines of sweet potato. For both crops women took on the responsibility of guarding the crop.

Assumptions challenged

The conclusion of this discussion was in contrast to what would be the normal practice in Equatoria. What we would have assumed is that the responsibility for cassava planting material should rest with the men and sweet potatoes with the women. The participants helped us to see that responsibility for cassava should be with the women and that of the sweet potatoes with the men, and that planting materials brought in should be divided accordingly. This is an interesting example of using farmer experience in relation to traditional crops in determining how an innovation can best be introduced from outside.

How farmers, local NGOs and Government are fighting erosion on the island of Flores, Indonesia

by Herman WP Koopman, FADO Indonesia, Jl Letda Kajeng No.22, Denpasar (80234), Bali, Indonesia. Email: fadori@denpasar.wasantara.net.id .

The mountainous island of Flores is seriously affected by soil erosion. In the article soil conservation programmes carried out since the 1950's are discussed. Planting of contour hedgerows of Lamtoro (*Leucaena Leucocephala*) was very successful until 1986 when a major pest of Lamtoro made its appearance on the island - the psyllid *Heteropsylla cubana.* These jumping lice aggressively destroyed all the established leguminous hedgerows planted over a 20,000-hectare area. The very important lesson learned from this devastating invasion was that large-scale propagation of one exotic species is not to be recommended. The risk of pest outbreaks that cannot be naturally controlled are too high. Presently, a new approach has been developed. This focuses on sustainable agriculture as a whole and not just on erosion control. In this approach 'interception terraces' and the establishment of protective leguminous hedgerows of such species as Turi (*Sesbania sp.*) and Gamal (*Glyricidia sepium*) are promoted. It appears that the farmers and NGOs have found a good and effective way of fighting erosion. However, given the huge area, progress (about 1000 ha in the 1998-1999 rainy season) is still too slow.

Rebuilding agricultural resilience: broader issues in rehabilitating rural livelihood systems

by Phil O'Keefe, John Kirkby and Andrew Collins, ETC UK, 117, Norfolk Street, North Shields, Tyne and Wear NE30 1NQ, UK. Email: office@etcuk.demon.co.uk .

Humanitarian assistance to mitigate natural disasters and, increasingly, complex political emergencies has increased twelve-fold from 1990–96. The challenge is not only to provide relief but to rebuild rural livelihood systems and to restore the resilience of agriculture. This is more easily said than done as the culture of humanitarian intervention is significantly different from participatory development practice. Emergency agriculture is much more developmental than humanitarian. There is a need to i) end the relief phase; ii) encourage restoration of local management of agricultural resources and to restore marketing systems, and iii) to increase resilience by upgrading the quality of inputs, especially improved seed varieties and blood stock lines. Emergency agriculture, to be successful, must capture immediate production opportunity. Humanitarian assistance has become much more professional, not least with the establishment of minimum standards in disaster response. Emergency agriculture, however, is not a part of these standards and remains the forgotten child of humanitarian assistance. Based on existing experiences the basic principles of emergency agriculture have to be thought through. This is what the authors have attempted to do.

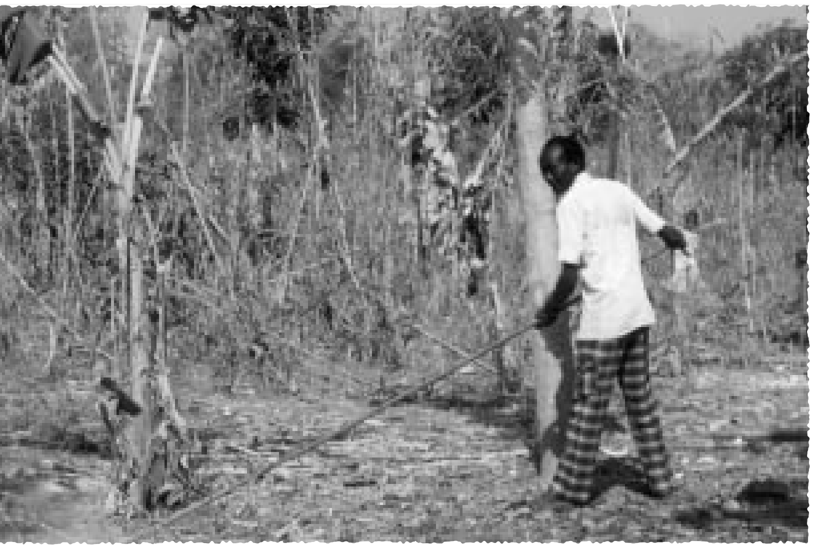
Understanding local adaptation of tools in a relief situation



Farmer using a long handled Sudanese hoe. Photo: Roger Sharland

Roger W. Sharland

Southern Sudan is a region that has seen civil war for all but ten of the last 45 years with many areas of the country dependent on relief aid. As the war has continued, relief agencies have realised the need for not only distributing relief food, but for increasing food security within the region through rehabilitating agricultural production. As people have had to leave their homes in the face of fighting and famine, seeds have often become scarce and tools have been lost. This has led to widespread distribution of seeds and tools by relief agencies.

Hoes and woes

The blacksmith picked up the hoe and threw it into the long grass behind him in a vivid show of disgust. This was not one of the hoes that he had made, but one that had been brought in by one of the many relief agencies in the area, and the recipient wanted the blacksmith to see if he could remake it into something useable. This scene could be repeated in many parts of southern Sudan, and such reaction comes not just from blacksmiths but also from the farmers. This type of hoe is causing frustration among farmers as it is not only the wrong shape but quickly breaks in the hard soil.

The response of the Sudanese blacksmith to the poor quality of a hoe, commissioned by an aid agency to be made by a manufacturer who has no idea as to its mode of use, is one indicator of the local knowledge of what are relevant tools. Blacksmiths make the tools that local people need and know about. They are innovators who adapt what is available to local use.

Why a Sudanese hoe?

The main tool for cultivation in southern Sudan is a flat push hoe, which is fitted to the end of a long handle as much as four metres long. The hoe head is fitted to the handle in the same way as a spear. These tools are not available from any source of mass production, but are made locally to local specifications by blacksmiths from within the various communities.

The push hoe scrapes the soil below the roots of shallow-rooting weeds. The shallow nature of the cultivation has long been a source of controversy by external agriculturalists, but has continued as farmers have experience that it is the most efficient way to cultivate in local conditions. The long handle is important as cultivation is normally done when the grass is at a significant length, and snakes are disturbed ahead of the cultivator. One important characteristic of cultivation in many areas such as the Moru is that most land is not prepared and cleaned before sowing, but sowing and cultivating are done at the same time as one activity. The broadcasting is done into the trash of cultivation.

Local adaptation overlooked

The need for well adapted seed that is suited to the climate and soil is widely recognised by agronomists, though not always given due consideration by those involved in quick response relief efforts. Much less recognised is the way farmers have developed tools relevant to their local conditions. The distinctly Sudanese types of hoes are not used in neighbouring countries such as Kenya and Uganda where agricultural land is short; the predominant tools are the mass-produced ones, uniformly used in the region. These manufactured hoes are easily available for relief agencies to buy, and are often the first choice for emergency tool distributions. The East African hoe is fixed at a right angle at the end of a handle not more than five feet long and uses a completely different action from that of the Sudanese hoe. Many of these hoes have been distributed throughout southern Sudan in recent years, but in most places are not the hoes of choice of the farmers. The action is unfamiliar and in most of the soil types they quickly split from hitting stones or rock hard baked clay during cultivation. They are also unsuitable for clearing large areas of savannah land. They do have uses in the agricultural economy, but not for the main cultivation, and in some areas even these hoes are taken to the blacksmith to be adapted to something more useful. A farmer recently showed me how he had got about half an inch of metal removed from each side to reduce the size to something much lighter, manageable and therefore more useful for his purpose.

Varied responses of relief agencies

As relief agencies have woken up to the fact that the East African hoe is of a completely different design to the Sudanese ones, response has been varied. One response has been to try to persuade people to use the new hoes with teaching that implies that the local hoes are backward and that the East African hoe is superior and is better. Such teaching ignores research done locally within Sudan in the 1970s and 1980s which showed conclusively that the local design of hoe is best suited for local conditions, and enables much larger areas to be cultivated with less energy expended.

The other reaction, which has been somewhat more positive, recognises that the local hoe is what is wanted and therefore should be supplied. Samples of the local hoes have been taken to Kenya and local manufacturers have been commissioned to make them in imitation. The result is the type of hoe that the blacksmith threw into the grass in disdain. I have seen countless of these hoes rejected and broken across the neck in different parts of southern Sudan, because they were not made in relation to the conditions of use.

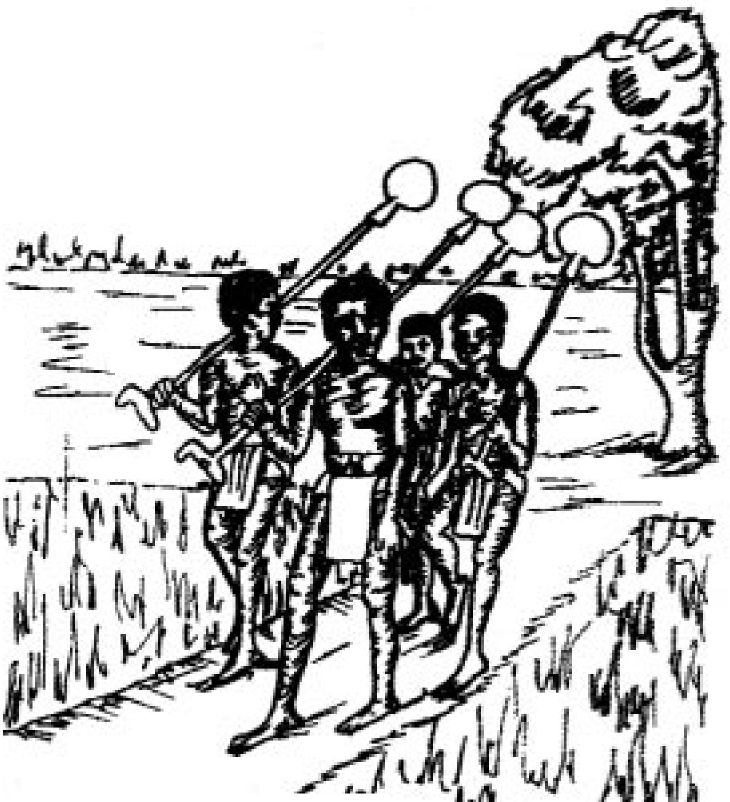
Taking note of local knowledge

The local blacksmiths on the other hand are in the community and use these same hoes and know the exact conditions that they are used in. They are directly accountable to the users, who are their clients and maintain quality control through the marketplace.

A further important observation is that although, superficially, the hoes used throughout southern Sudan have the same general shape and the same action, the actual size and shape of the head varies from area to area. For those who are unfamiliar with the soils and climate it may seem that the shape is merely a matter of local fashion or taste, in the same way that the shape of the drums or stools vary from tribe to tribe. However, on closer study one finds that the shape and size of the hoe used is a response to experience with the local conditions. Some hoes are more rounded, others are flat across the blade, and the size varies both from place to place and in relation to the field type or crop it is used for.

The shape of the tools is in fact a local adaptation to the conditions the farmers face in much the same way that the characteristics of the seeds they grow are. In hard and stony soil the blade wears down fairly fast, but this is taken into account and the use of the hoe changes with its size. For example amongst the Dinka of northern Bahr el Ghazal the new hoe is of a size used by the men in their general cultivation. By the second season this hoe has worn down to a size inefficient for the main cultivation, but which may be used either by the women as they assist the men in this cultivation, or else for the cultivation of groundnut fields in the lighter soils of the higher land. When materials are abundant a special hoe may be made for groundnut cultivation. By the third year, this hoe will be worn down to little more than a stump round the handle and this is the ideal hoe for the women to use in their weeding.

Beyond the different size and shape used in different areas, an important factor is also individual preference of need. Amongst the Moru, for example, many different sizes of the same basic hoe are wanted in relation to the strength (and pride!) of the user. A larger hoe can clear more land if the user is strong enough, but becomes inefficient if too large for the user's strength and skill.



Long handled Sudanese hoe.

So a farmer will order from the blacksmith the type of hoe most appropriate for himself.

Making relief work better

What therefore is the relevant response that relief agencies should be making in this situation? The blacksmiths can easily make tools, but what they are lacking is the raw material to make them. The most relevant response that I have been encouraging for many years is the distribution of quality steel plates, from which the blacksmiths can cut and make the tools to the specification of the local farmers.

As a blacksmith pointed out to me on a recent visit, good quality steel plates can be made into any of the tools needed, and the off cuts can be fashioned into knives or spears necessary for the wider life of the community. With the raw material of steel plates, any tool that is needed can be made by the blacksmith and the community can have greater control in what is most needed. The farmers in conjunction with the blacksmiths have developed the tools best suited to their situation, and recognition of this simple fact could greatly assist agencies to respond in a relevant fashion. ■

Supporting community seed multiplication
The 'Rescue from the Pot' project

Rice seed in Sierra Leone: many varieties are usually found within the same family farm. Photo: Ivan Kent

Ivan Kent and Samuel P. Mokuwa

After a decade of civil war**,** access to a sufficient diversity of seed material is difficult for the small-scale rice farmers of **Sierra Leone**. Valuable stocks have been destroyed, and the disruption of national, regional and community level trading networks has hampered the spread of new technologies and their adaptations. After many years of attempts to provide planting material through emergency large scale aid distributions, there is now a need for a more subtle approach to support the recovery of local seed stocks and the social networks upon which they depend. With these aims in mind, the 'Rescue from the Pot' project, a joint initiative between local communities and the international NGO, Action Against Hunger, was started in March 2000, in the Southern Province of Sierra Leone, an area recovering from conflict.

Rice cultivation in the forest zone

Rice cultivation within the forest-zone of Sierra Leone takes place in a variety of ecological conditions, with upland and swamp environments often found within the same farm (Richards 1986). Farmers often plant several varieties of rice to match a range of soil and moisture conditions. The use of varied environments and cultivars of different cycle lengths allows the harvest to be spread over several months, thus reducing bottlenecks in labour and providing a variety of grains for the household, community and market. Although formal seed markets play an important role in the distribution of the more popular and widespread varieties, many landraces are distributed through informal channels and social networks.

Seed stocks lost due to conflict

Since the beginning of the civil war in 1991, almost all parts of the country have at one time or another suffered conflict or brutal rule by armed factions. Where fighting takes place, stocks of rice seed are lost as a result of looting, extortion and arson; markets and social mechanisms for exchanging seed are invariably disrupted. Maintaining access to particular varieties becomes difficult, especially when traditional source areas become 'off-limits' as a result of on-going conflict. In addition, continuing food insecurity means that seed stocks are often used for consumption.

Emergency distributions

External interventions in the agricultural sector in Sierra Leone, as in other war-torn countries, have been largely based on the delivery of seeds and tools. Dealing with tens of thousands of farming families, these operations provide basic, standardised inputs during the planting season in an attempt to replace lost quantities of seed and to prevent further population displacement or long term dependency on food aid.

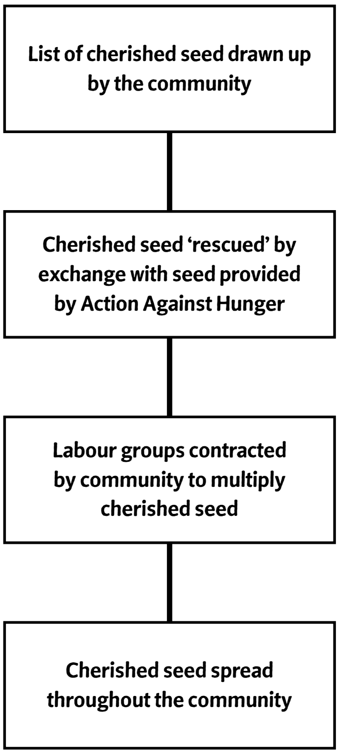
Due to their sheer size and logistical requirements, it is not possible for these operations to take into account the agro-ecologial diversity of each area, or the varied preferences occurring at the village or farm level. In Sierra Leone, programmes are therefore limited to the distribution of a few improved types, notably Rok3, a popular variety developed at the national Rice Research Station at Rokupr, tolerant to both swamp and upland conditions.

The versatility of such varieties make them a good option for large-scale emergency operations aimed at meeting immediate shortages of seed. However, aid agencies face difficulties in sourcing enough seed of sufficiently high quality, and repeated distributions of the same variety over several years do little to encourage the multiplication of more locally adapted and preferred landraces.

Cherished landraces

Three chiefdoms in the Southern Province of Sierra Leone were selected for the pilot phase of the project. After two years largely free of conflict, much of the population that had earlier fled had since returned home. While Rok3 and a handful of popular local landraces were generally available to most farmers, many 'cherished' landraces, suitable for particular ecological niches or cultural functions, were hard to come by.

However, some local landraces could still be found; a survey of 105 farmers carried out in three villages after the 1999/2000 harvest revealed that 16 rice varieties with distinct names were being used. Unfortunately, many of the sought-after or 'cherished' varieties were held only in small amounts by a few families and remained inaccessible to the majority of farmers. Furthermore, because of the still precarious food security situation, little of the cherished seed was saved for the next season. While it was recognised that the resources for multiplying the seed could be found locally, the disruption of social networks caused by the war meant that mechanisms for widening access to seed were missing. In response, chiefdom authorities decided to work with Action Against Hunger in order to rescue some of these cherished varieties.



Preferred characteristics

Once the outline of the project had been agreed upon, meetings were held to draw up lists of the most sought after seed. Through a system of matrix ranking, which included gastronomic as well as agronomic criteria (see box), several varieties were prioritised by each chiefdom. It was agreed that the varieties targeted for multiplication would be limited to those that were highly valued, but in short supply. The three chiefdoms involved in the project selected different varieties for multiplication, reflecting local preferences and varying degrees of scarcity.

Rescued for multiplication

The next stage of the project was to locate the cherished varieties within the community so that they could be 'rescued' for multiplication. It was agreed that cherished seed could be exchanged at a set ratio of 3:2 for a more common variety provided by Action Against Hunger, at designated trading points throughout the project area. Rice was 'exchanged' rather than bought for cash, in order to maintain the food security of households giving up their cherished varieties. At first, farmers were slow to come forward with their rice. However, after 2 weeks, a total of 6.5 metric tonnes of seeds had been exchanged for 9.8 metric tonnes of Rok3 seeds donated by Action Against Hunger.

Labour groups were then invited to grow the cherished varieties on behalf of the community. An agreement was collectively developed and signed by the group leader and master farmer in each group, and witnessed by the Paramount or Regent Chief - the chief custodian of land. A total of 42 labour groups, each with up to 25 members, were formed to multiply the cherished seed in the three chiefdoms. They were paid for their labour with food, and allocated a small percentage of the harvest. During the growing period, field extension officers and community counterparts made farm visits to monitor progress and estimate potential yield. In addition, regular village meetings provided an opportunity for group leaders to give updates on their progress to the chiefs.

Project not without difficulties

At the seed exchange stage, some field extension officers were unable to identify the 'cherished' varieties and some farmers donated and received the wrong type of seed. In one area, seed earmarked for multiplication was eaten on the order of the town chief during a village construction project, and in another the project was suspended indefinitely because armed militia looted the food stocks reserved for the workgroups multiplying the seed. Not all parties agreed on who should benefit from the scheme; displaced populations were not always able to take part in the project, since chiefdom authorities sometimes limited participation to long-term residents. Despite these difficulties, it is estimated that 35.5 metric tonnes of 'cherished' seed were made available to the wider community by the end of the first harvest.

Many lessons learned

The 'Rescue from the Pot' project illustrates the potential for incorporating local knowledge and capacities into the more common distribution-oriented seed programmes of aid agencies. But the transition from emergency seed distribution to community-based seed multiplication requires a set of new skills and a different mode of engagement between local communities and implementing agencies. Extension staff require more locally adapted skills (in both agronomy and conflict resolution); while farmers can benefit from training in seed multiplication and storage to produce good quality material. More importantly, regular contact between all parties is essential to nurture mutual trust and activities such as football matches and music events, as well as seed fairs and formal meetings can play an important role.

In an unstable post-conflict environment, communities are wary of investing in longer-term collaborations with aid agencies that may leave an area suddenly if fighting resumes or funding dries up. But frequent meetings with all actors help to enhance a sense of ownership as well as to re-establish traditional civilian structures disrupted by conflict. Although still in its early stages, farmers in the project area already have access to a broader range of seed types and even after a single season requests have been made for an extension of the 'Rescue from the Pot' project into the following year. ■

Characteristics of preferred varieties

- high tillering ability & large panicle formation
- adaptability to various soil conditions
- high yields
- tolerance / resistance to iron toxicity (for swamp varieties)
- good performance on short fallow bush
- quick maturity (thus shortening the 'hunger-gap')
- palatability
- high swelling during cooking
- attractive grain colour (red or brown pigmentation is preferred in local dishes);
- good storage after cooking

Reducing food poverty with sustainable agriculture: new evidence

In 1998 the SAFE-World project started to audit recent worldwide progress towards sustainable agriculture. A survey of sustainable agriculture initiatives was conducted with the aim of investigating both processes and outcome, and to draw conclusions on whether such improvements could significantly help to feed the growing world population without causing further damage to environment and human health. At the end of 2000, the database contained information on 208 cases from 52 countries involving some 8.98 million farmers on 28.92 million hectares. On this basis it is estimated that on at least 3 % of the farmed land in Asia, Africa and Latin America, farmers are using sustainable agricultural technologies. A summary of the conclusions of the survey has been published on the web, and a book to be launched soon. The following are excerpts from this summary.

Types of improvement for sustainable agriculture

1: Better use of locally available natural resources – in 88% of the cases
2: Intensified use of microenvironments in farm systems (gardens, orchards, ponds) – 21%
3: Diversification by adding new regenerative components – 59%
4: Better use of non-renewable inputs and external technologies – 18 %
5: Social and participatory processes leading to group action - 55%
6: Human capital building through continuous learning programmes – 92%
7: Access to affordable finance (credit, grants, subsidies) – 17%
8: Adding value through processing to reduce losses and increase returns – 12%
9: Adding value through direct or organised marketing to consumers – 15%

Achievements

Of the 208 cases, 91 contain data on yield changes obtained by improvements as presented in the box. The proportional yield increases are generally: 50 – 100% for rain fed crops, though considerably greater in a few cases; 5 – 10% for irrigated crops, though starting from a higher absolute yield base.

Most initiatives report significant increases in household food production – some as yield improvements, and some as increases in cropping intensity or diversity of produce. The evidence shows that:

1. For 4.42 million farmers on 3.58 million ha., average food production per household increased by 1.71 tonnes (an increase of 73%).
2. For 146,000 farmers on 542,000 ha cultivating root crops (potato, sweet potato and cassava), the increase in food production per household was 17 tonnes (an increase of 150%).
3. For the larger farmers in Latin America (av. size = 90 ha/farm), total production increased by 150 tonnes per household (an increase of 46%).

Conducive factors

The successes have been mainly founded on:

- Appropriate technology adapted by farmers' experimentation;
- Social learning and participatory approaches;
- Good linkages between farmers and external agencies, together with the existence of working partnerships between agencies;
- Presence of social capital at local level.

It is concluded that if sustainable agriculture is to spread to larger numbers of farmers and communities, then future attention needs to be focused on:

1. Ensuring the policy environment is enabling rather than disabling
2. Investing in infrastructure for markets, transport and communications;
3. Ensuring the support of government agencies, in particular, for local sustainable agricultural initiatives;
4. Developing social capital within rural communities and between external agencies.

Proud portraits

Both the website and the publication present an impressive list of proud portraits of sustainable agriculture. Two examples:

Most initiatives seek both to reduce soil erosion and to make improvements in soil physical structure, organic matter content, water holding capacity and nutrient balances. One sustainable agriculture technology to spread at extraordinary speed is zero- or minimal tillage (ZT). For example, in Brazil, there were 1 million ha. under ZT in 1991; by 1999, this had grown to about 11 million ha. in three southern states only. ZT has resulted in better input use, water retention, soil management, diverse rotations, break crops for weed control (e.g. ray and black oats between maize/soybeans) and use of green manure and cover crops. ZT also cuts erosion and water run-off, thus reducing water pollution.

Many sustainable agricultural initiatives have reported very large reductions in pesticide use following the adoption of IPM through farmer field schools in rice agroecosystems.

In Kenya, about 2000 farmers have adopted 'push-pull' strategies developed by ICIPE to repel (push) stem borers from the cereal crop (maize and sorghum) using a repellent intercrop (e.g. molasses grass (*Melinis minutiflora*) and silver leaf (*Desmodium uncinatum*)) and to attract (pull) them to intercrop or barrier forage grasses e.g. Napier grass (*Pennisetum purpureum*) or Sudan grass (*Sorghum vulgare*). In this way maize yields have improved by 60 – 70 % in 1998-99. ICIPE has also found that intercropping maize with the fodder legumes silver leaf and green leaf (*Desmodium intortum*) reduced infestation of the parasitic weed, *Striga hermonthica,* by a factor of 40 compared to maize monocropping. This is significantly more than intercropping maize with soybean, sunhemp and cowpea.

Supportive policies are missing

The past decade has seen considerable global recognition of the need for policies to support sustainable agriculture. In most countries, however, sustainable agricultural policies remain marginal. The collected evidence shows that sustainable agricultural systems can be both economically, environmentally and socially viable, and contribute positively to local livelihoods. But without appropriate policy support, they are likely to remain localised in extent.

Measuring farmers agroecological resistance to hurricane Mitch

Eric Holt-Gimenez

In October of 1998, Hurricane Mitch, one of the Caribbean's five most powerful hurricanes of the twentieth century, slammed into **Central America** causing US$ 6.7 billion in damage to infrastructure and industry (primarily agriculture) an amount approximately equal to 13.3% of Central America's GNP. Two meters of rain in less than one week coupled with mudslides and landslides washed away crops, animals, buildings, roads and bridges. Topsoil, lost from hillside farms, silted rivers that overflowed their banks, flooding fields and urban areas. Over 10,000 people died and 3 million were displaced or left homeless. The environmental damages were incalculable. The countries hardest hit were Honduras, Nicaragua and Guatemala. All areas affected by Hurricane Mitch are characterised by an uneasy mix of large-scale plantation agriculture and extensive cattle ranching (primarily for export) alongside small, very poor, subsistence farms. The hillsides and fringes of the large holdings are surrounded by mosaics of hundreds of thousands of poor rural families who eke out an existence by farming basic grains on ecologically fragile land and by engaging in a myriad of other seasonal, part-time, informal rural and urban work. Most observers agree that the unprecedented magnitude of the disaster is the consequence of decades of deforestation, non-sustainable agricultural practices and other forms of environmental degradation that left the region exceptionally vulnerable to an erosive event.

'Sustainable' farms suffered less

While first reports regarding agricultural damage simply indicated that the levels of destruction were massive, subsequent on-site observations began to reveal a more subtle, differentiated pattern. Farms using what are commonly understood to be 'sustainable' practices appeared to have suffered less damage than their 'conventional' neighbours. These farms belonged to smallholders working within a multi-institutional, regional movement for sustainable agriculture (agroecology or LEISA) known in Central America as Campesino a Campesino (Farmer to Farmer). The farming practices commonly encountered in Campesino a Campesino included a wide range of soil conservation and sustainable cultivation methods, tested and promoted by smallholders for nearly thirty years. Most common amongst them were soil and water conservation methods, reduced or discontinued use of chemical inputs, cover crops, agroforestry, in-row tillage, organic fertiliser and pesticides, and different forms of Integrated Pest Management.

An opportunity to compare impact

In general, these sustainable farms exist as islands and archipelagos within a greater, conventional 'sea'. While often localised and geographically fragmented, they provided an excellent opportunity to compare the agroecological resistance to the hurricane of sustainable farms to that of conventional farms. The presence of Campesino a Campesino, made up of farmers and technicians experienced in farm experimentation and farmer to farmer training, also provided the opportunity to carry out an extensive, participatory, action research project in the low, medium and high impact areas of Hurricane Mitch. Several researchers with years of experience working in the Campesino a Campesino Movement designed a study and wrote a proposal. World Neighbors, an NGO working in the region, agreed to sponsor the project, helped to find funding (Ford, Summit, Rockefeller and Inter-American Foundations), and provided administrative support.

Much interest in the study

From February through May of 1999, 40 different NGOs with sustainable agricultural research and development (SARD) projects trained and mobilised 100 farmer-technician teams and 1,743 farmers to carry out paired observations of specific agroecological indicators on 1,804 neighbouring, sustainable and conventional farms. The study spanned 360 communities and 24 departments in Nicaragua, Honduras and Guatemala. The primary objectives of participating in the study were threefold: First, farmer-promoters and NGOs in the Campesino a Campesino Movement were eager to compare their farms to conventional farms because demonstrating a higher level of agroecological resistance would imply a higher level of sustainability. After years of being told that sustainable agriculture was not 'viable', nor 'economical', they were anxious to dispel doubts about the importance and effectiveness of their practices. Secondly, NGOs were very interested in evaluating the effectiveness of years of support for farmer to farmer SARD. Commonly, these projects are evaluated on the level of implementation (number of workshops, participants, terraces, compost heaps, etc.) However, the study gave them an opportunity to evaluate the level of their agroecological impact. Finally, all participants were interested in influencing the agenda for agricultural reconstruction after the hurricane. If farmers could show that sustainable farms were more resistant than conventional farms, then a strong argument could be made for a participatory, sustainable agricultural reconstruction strategy.

A collaborative action

An intensive period of organising, training, data collection and field monitoring began in February of 1999. It was crucial that field data be collected before the onset of the rainy season in late April. Each team had one technician and two farmer-promoters. They carried out observations on the ten best examples of sustainable farms and on the ten neighbouring, conventional farms. Paired observations had to be located in close proximity, in the same position and cardinal orientation in the watershed, have the same general slope and similar environmental surroundings (fields, trees, infrastructure, etc.).

Agroecological indicators included topsoil depth, rill and gully erosion, percent vegetation, crop losses and structural damage. Each team member specialised in specific steps and measurements of the field procedure to reduce and standardise observational errors. The owners of both farms in the paired observations accompanied the team on both sustainable and conventional plots, then signed off on the field sheet indicating measurements and observations had been free of bias. Technicians interviewed farmers regarding their observations of the hurricane, the damage patterns, and the different reasons for any agroecosystem failures. National research coordinators in each country held periodic sessions with teams for feedback, troubleshooting and the correction of field errors.

Significant differences

Field data from the farmer-technician teams was entered into an interactive ACCESS database for each country. Initial results (averages) were processed for distribution among participants. While there was some local variation, the overall results indicated an overwhelming trend of higher agroecological resistance on the sustainable farms. Sustainable plots had 20% to 40% more topsoil, greater soil moisture, less erosion and experienced lower economic losses than their conventional neighbours. Statistical tests showed that some of these differences were highly significant (there was only a 0.0001 probability that these differences were due to chance) and most were acceptably significant (0.02 to 0.05).

Conventional farmers convinced

Fifteen different workshops were held in the countryside to share the results of the field research with participants and key local and municipal actors. Farmers, promoters, technicians and project coordinators collectively analysed the results and gave feedback. Sustainable farms had fewer and smaller gullies and areas of rill erosion. All of these indicators were seen as contributing to both productivity, and to the conservation of the watershed. Further, because of crop diversification, sustainable farms averaged lower economic losses, and in Nicaragua even showed profits, despite the hurricane. However, when correlated to steep slopes (>50%), high storm intensity and other extreme environmental factors, some of the differences between sustainable and conventional farms 'collapsed', indicating that these techniques have thresholds of effectiveness. Finally, the participants themselves indicated what could be the most impressive result of all: over 90% of conventional farmers participating in the study indicated a desire to adopt their neighbours' sustainable practices.

A learning process

Participants enthusiastically claimed that the study had been a highly successful learning experience, and one that had established new bonds of trust between farmers, promoters and technicians. For most farmers, it was their first experience with research, and for others, the first time results of on-farm research had been returned and shared with them.The study also revealed that, at the local level, many organisations and farmer groups had mobilised themselves already in response to the humanitarian emergency situation. Farmer to farmer groups helped to motivate self-help efforts in their communities, rather than simply waiting for outside assistance. This capacity for self-mobilisation among farmer groups indicates that resilience has a social as well as a technical dimension.

Vetiver Grass for disaster mitigation

Last year, around Christmas and New Year thousands of Venezuelans had a miserable time just trying to survive the floods that have ravaged their communities and homes. Although we do not know the details of all the causes behind the flooding and mud slides, we know that when vegetation is removed and the soils become fragile, even moderate rainfall conditions can bring about a calamity.

Vetiver Grass Technology (VGT), if used to stabilise agricultural land, peri-urban building areas, deforested hillsides, riverbanks, levees, and highway embankments, could help to reduce the damage that might occur from future high rainfall in Venezuela. The Vetiver Grass Network strongly urges policy makers and relief agencies to consider VGT as an important tool for rehabilitation and to provide jobs for thousands of unemployed people.

VGT has proven very effective in the Far East for protection against cyclones, just as in El Salvador and Honduras, where it provided near perfect protection against the ravages of Hurricane Mitch in 1998. Some of these stories have been documented and can be found at: http://www.vetiver.org . The website also contains reports from other parts of the world, and information on practical guides such as:

- Training manual of the international training course on the vetiver system. Hard copies of the training manual are available from The Royal Projects Development Board. To obtain a copy email your name and address to Suwanna Pasiri. <pasiri@mail.rdpb.go.th>
- Vetiver grass - a hedge against erosion. The Vetiver Network (TVN) has published a revised (fourth) edition of this book - commonly called the Green Book. Copies available from TVN.

What's needed for scaling up of SARD?

With the aid of drawings, clay models and skits prepared by the participants, farmers then described how their fields and villages should look in three, five and ten years hence if agricultural reconstruction was implemented using farmer to farmer, SARD techniques. Then, farmers analysed the obstacles to the scaling up and scaling out of SARD, and suggested projects and policy ideas for participatory, sustainable agricultural recovery. In general, technology and training methodologies were not seen as limiting to SARD. After all, farmer experimentation, cross visits and farmer to farmer training are the pillars of the Campesino a Campesino Movement. However, it was strongly felt that national credit, market, agrarian and research policies favoured Green Revolution technologies rather than SARD. Although NGOs had been instrumental in establishing SARD alternatives, if SARD was to scale out nationally, and scale up institutionally, proactive national policies were required to push it beyond the NGOs local 'micro-project' sphere of influence.

Sharing of results

Findings from these workshops were synthesised and presented by the participants at national meetings in the capital cities of Honduras, Guatemala and Nicaragua. Key actors in government, relief, development and research institutions were invited. Farmers and technicians presented their findings; the national research coordinators, the methodologist and the principal investigator gave their reports. In-country researchers in agricultural economics and disaster prevention gave topical presentations. Notable figures such as Nobel Prize winner Rigoberta Menchu, several government ministers, and representatives from the United Nations gave keynote addresses. A video of the research project (see below) was shown and distributed.

Potential of SARD demonstrated

The Campesino a Campesino Movement in Central America has demonstrated the social, environmental and agricultural advantages not only of SARD, but also of farmer-led approaches to sustainable agriculture. The study itself demonstrates the tremendous potential for research and development within farmers' movements. While farmer-promoters within the Campesino a Campesino Movement have carried out on-farm experiments and have shared their knowledge across borders for thirty years, this was the first time ever that farmers had collaborated on a regional research project. Participants have expressed their desire to establish national and regional farmer research networks to continue their agroecological research.

Limited impact on national policies

A year after the study, the participating organisations from Nicaragua met to assess the impact of their research. Most organisations reported widespread adoption of agroecological practices at the project level by conventional farmers who had participated in the study or had heard of the findings. A number of NGOs had successfully used the study to persuade international funding institutions to support their efforts at sustainable reconstruction. Some participants were members of territorial committees and used the study to argue for sustainable reconstruction at the municipal level. One organisation gave a workshop on sustainable, participatory reconstruction to donors in Europe, and used the study as an example of the human capabilities in Central America.

This trend of local and territorial impact appears to have been repeated in Honduras and Guatemala. Unfortunately, the study does not seem to have had much of an impact on national reconstruction policy in any of the three countries. While there is evidence of receptivity to the sustainable approach by the government of Honduras, Mitch seems to have been forgotten in Guatemala. Official Nicaraguan reconstruction efforts have been plagued with political difficulties, with the government focusing on large-scale infrastructure projects designed to support tourism and conventional agricultural exports rather than sustainable agriculture. Efforts by NGO networks to influence national policy have not met with much success, with or without the study.

Public pressure needed

The Mitch study has uncovered a conspicuous 'policy ceiling' in sustainable agricultural development. While NGOs and the Campesino a Campesino Movement have been instrumental in developing the technical and methodological aspects of sustainable agriculture in Central America, they are limited in their ability to influence the *policy context*. Lack of a favourable policy context, and the lack of political will on the part of national governments to create one, appears to be holding back grassroots efforts at scaling up sustainable agriculture. The next task confronting sustainable agricultural development may be to translate farmer-to-farmer successes on the ground into the broad-based, public pressure needed to influence national policy-makers.

Far from all oil palm turmoil

Gabriela Uran, Dina Hartono and Rik Thijssen

Oil palm has been one of the most vigorous agricultural sub-sectors of independent **Indonesia**. Since the 1970s, its acreage expanded from 100,000 ha to 3 million ha in 2000. This profuse growth has provided important economic benefits, but has also become a source of concern! Oil palm's high yields of edible oil correspond to application of high quantities of chemical fertiliser and pesticides. Much of the expansion of oil palm monoculture has been at the expense of Indonesia's tropical forest cover, and has displaced local communities without proper compensation (Hakim Bayar, 1999). It has also been held partly responsible for the forest and land fires during the 1997/98 El Niño phenomenon.

Unsustainable oil palm industry

During Indonesia's current period of economic crisis and political change the many weak points of this sub-sector were unveiled. In 1998, crude palm oil production declined for the first time since 1969. This decline was attributed to several factors, including increased production costs, difficulties to access credit, a 50% drop in the world market price of palm oil, as well as environmental effects, jointly exposing the rather unsustainable nature of the oil palm industry (Casson, 2000). Large financial losses were recorded and, technically, the main palm oil companies went bankrupt. Social unrest increased in and around oil palm estates.

Farming on Flores

Oil palm plantations in Indonesia are largely confined to the islands of Sumatra (78%) and Kalimantan (16%), where infrastructure exists for production and processing, or lowland is available in plenty. On Flores, the tenth largest island of the Indonesian archipelago, there are no oil palms. Largely 'forgotten' by the Central Administration, this island is frequently shaken up by earthquakes and volcanic eruptions. Flores is carved by deep ravines and rugged valleys; rainfall is unreliable and highly seasonal and can make water scarce. Understandably, it is not a first choice area for large-scale production of palm oil.

Instead, the dominant palm on Flores is the versatile coconut palm, found up to about 700 masl, on home compounds or in fields mixed with crops and sometimes livestock. It provides food, drink, oil, medicine, cash, fibre, timber, thatch, mats, fuel and domestic utensils. And it has proven to be one of the reliable cornerstones of the local way of life, even during periods of hardship.

When asked how the economic crisis or current political situation has affected their lives, local people often respond with a shy smile. Almost apologising for not being part of the real world, the world that has been so strongly affected by these major issues, Flores' people seem to have emerged largely unscathed. Of course, these events did not pass completely unnoticed. Many Florinese migrants returned home from Java and Malaysia because of loosing their jobs. Prices of daily necessities and services increased manifold. But so did the market price of agricultural produce. Cacao, vanilla, cloves and Robusta coffee suddenly made record gains. Besides this, rural inhabitants have, almost automatically, used their long-tested coping skills to provide enough food and other needs for all, including the returning labour migrants.

Still largely self-sufficient

Different cultures of Flores have their own systems of sharing food in times of shortages. Generally, borrowed food is paid back at a later stage in the form of food. Families never hide their food stock from others in the community. Maize is even stored in trees or open, simple bamboo structures in front of the house. Such security nets are especially appreciated by women who bear the responsibility for the family's food supply.

Women also expressed that they would feel very uncomfortable if the economic situation does not permit them in using certain 'luxury' goods such as sugar, soap and fuel for lighting. They would genuinely feel *malu* (embarrassed) when visitors arrive at their home, and they are not able to prepare coffee because sugar is not available or if friends stay away in the evening hours since there is no light in the house.

Florinese women, therefore, depend on alternatives. Buying sugar, soap and paraffin from a shop is, of course, preferred. But when cash is not available they resort to resources straight from

Farmers in the field: "there is great interest from the local communities for management of natural resources as well as for further diversification of plant species on their land". Photo: Rik Thijssen nature. Good sugar can be obtained from the sap of the arenpalm (*Arenga pinnata*), and also from the coconut palm. An alternative for soap is to use black lava stones or the small brown fruits from the local tree *Mengkudu* (*Morinda citrifolia*) for washing clothes. The latter also provides body soap or shampoo. Improvisation for lighting the house comes from a combination of two other very common trees: kapok (*Ceiba pentandra*) and kemiri or candlenut (*Aleurites moluccana*). For this purpose, kemiri nuts are crushed until the oil starts seeping out. Kapok fibres are then mixed with the kemiri paste and twisted around a stick to produce a 'candle'. Not surprisingly, coconut oil - the common vegetable oil on this island - can also be used for this purpose.

There is always something to eat

Before the 1920s, when rice was introduced on this island, the Florinese were strictly hunters of small game and swidden farmers growing mostly bananas and cassava. Their main farming method, slash and burn, caused serious erosion problems.

Assisted initially by devoted catholic missionaries and more recently by several local and a few international NGOs, people have settled and become serious farmers. The traditional staple food was short of protein and had been the reason of many health problems. Adoption of the introduced species maize and rice, as well as increased attention to some indigenous species including cocoyam (*Colocasia esculenta*) and forest turnip (*Pachyrrhizus erosus*) have not only brought the much needed diversification, but also increased food security in times of hardship. Local people can assure you now that 'there is always something to eat'. If rains are not plentiful and rice and maize yields are not enough, stocks of the other less drought-sensitive plants are utilised. Apart from these starch providers, people now plant a variety of pulses and vegetables. Perennial cash crops have become common, while families tend to keep a few small livestock. And the sea yields fish that can be salted or dried in order to be stored for more difficult times.

Recent innovations

Community based agricultural development projects, such as the ones facilitated by FADO (*see Box*), are for instance involved in soil conservation and soil fertility work. Large areas on slopes have been terraced and leguminous shrubs such as *Gliricidia sepium* and *Calliandra calothyrsus* have been grown as terrace stabilisers and green manure or fodder crop. Building erosion control structures is exhausting work, yet working together in groups always provides a stimulus for completing the job.

Many farmers have started making use of liquid manure made by fermenting leaves of leguminous species, sometimes mixed with animal manure, in barrels filled with water. Some are so enthusiastic about the results achieved in rice and vegetable production that they have invested in building concrete containers, dug in the soil, for fermentation of the organic matter.

Other spear-points in these projects are integrated pest management and planting of various perennials, cash crops as well as different fruit and timber species. Attention is also given to forms of more intensive goat production.

No interest in increasing profit

Interesting to note here is that there is great interest among the local communities for management of natural resources, as well as for further diversification of plant species on their land. However, it seems that intensification of farm enterprises is not really what they are after. People are focused on satisfying their needs rather than making efforts to increase profit from one single enterprise. Coffee, for example, is making a good price these days. But farmers with coffee have not changed their routine. Pruning of coffee is not practised while shade is provided in plenty to the coffee trees using, for instance, *Erythrina variegata*. Such a system may provide lower yields, but under relatively low standards of cultivation it also gives more even annual cropping and extends the productive life of the coffee plant.

The few goats kept by most families are used in case of festivities and special ceremonies. Economic crisis or not, the Florinese love to sing and dance while traditional and catholic ceremonies are an important aspect of life and are still proudly performed. There are, however, no farmers venturing into commercial goat rearing, although quality tree fodder (*Gliricidia*, *Calliandra*) is plentiful nowadays.

What has been learned?

Given these project experiences, the worst must be expected from a newly launched government credit and extension programme, funded by IFAD, which aims at converting 20,000 ha of community land on Flores into monoculture cashew nut plantations. *Would it really be too far away from the oil palm schemes to have learned a lesson?*

FADO

FADO (Flemish Organisation for Assistance in Development) provides support to 34 Indonesian NGOs spread over 7 Provinces in Indonesia. On Flores, FADO is involved in agricultural projects with 10 local NGOs.

The focus of FADO's programmes in Indonesia is empowerment of farmers through developing sustainable agricultural practices with low external inputs, and building strong farmer organisations. In the programmes, FADO role is mostly in backstopping to increase organisational and technical capacity of local development actors. In early 2001, FADO merged with two other Belgian NGOs: Vredeseilanden and Coopibo.

FADO was co-responsible for the translation of ILEIA's publication **Farming for the future** into the Indonesian language. **Pertanian Masa Depan** 1999. Penerbit Kanisius, Yogyakarta.

Empowerment mobilisation for effective women's development

Raju Sharma

The Women's Empowerment Program (WEP) implemented by Pact was launched in December 1997. The main goal of this project is to empower 120,000 women from 21 lowland districts in **Nepal** to increase their roles in household decision-making, increase income for family well-being, and engage in collective action for necessary changes in their communities.

Education Curriculum and Training Associates (ECTA), a Kathmandu-based local NGO, has introduced the **Appreciative Planning and Action** (APA) approach as part of the low cost empowerment package being developed and applied under WEP. APA has proven to be a very effective and powerful tool for community mobilisation and motivation and for bringing about positive changes within organisations. The APA methodology is now being used successfully within other large organisations in Nepal, including NGOs, INGOs, donor agencies, and a major 5-star Hotel.

Women gain literacy by studying together using their own resources. Photo: Raju Sharma

Women's Empowerment Program

The Women's Empowerment Program has developed three interventions:

- ***Literacy***. Women study a self-instructional manual in-groups of two to twelve, achieving literacy for all members in about three months.
- ***Economic participation***. Follow up to the literacy package with neo-literate material with an economic focus. Women learn best practices for saving, credit, and income generating activities. This component includes three self-instructional manuals which women study in their groups for about nine months (3 months per manual).
- ***Rights, responsibility and advocacy***. This component, implemented by The Asia Foundation (TAF), includes a role for an outside facilitator since the material is a bit harder to understand than the literacy and economic packages.

Pact and ECTA do not provide facilitators, black boards, lanterns, or stationary which are normally supplied by other literacy programs, under the WEP principle that '**Dependency is not Empowering**.'

The seven D's of APA

APA, as a starter methodology, does not take more than 2 hours to generate a feeling among women and their groups that they can do many things on their own and do not need to wait for outside aid or financial assistance.

First, a positive and happy tone is set among the members. For this purpose, they are asked to recall and draw: *What are the most exciting things they have done in their communities with their own efforts that make them proud even today when they remember them?* This process is called '**Discovery**'. Since most people tend to forget their successes and rather focus on their failures, they are encouraged to think about their successes, and to understand and appreciate them. Recalling their successes fills them with energy and joy.

The second step is called '**Dream**'. The question here is: *What do you want your village and your children to be like after about 10 years time?* Here, they draw their colourful dreams and enjoy them. One concept emphasised is that if they really believe in their dream of something and sincerely work to achieve it, there is nothing in the world that they cannot achieve. Since these dreams are built directly on their own real accomplishments, they enable people to dream of things that are really achievable**.**

The third APA question encourages them to plan what they need to do in order to turn their dream into reality. If many needs are mentioned, they are prioritised according to necessity whilst focusing on the first among these. This they do by adding numbers to the pictures or expanding them to outline what is needed to pursue their project. This process is known as '**Design**'.

The fourth question is for each individual: *What will you commit to do in order to start to make your dream come true, to make your own or future generations' life easier and happier?* Here, each of the group members commits at least one thing she can do towards achieving their plan. After each member stands and makes her commitment the group celebrates by giving a big applause. This part is known as '**Delivery**'.

To further enhance the progress, the fifth question is put forward: *What can you do to initiate the project or the plan within 5–10 minutes time?* Here they will try to get started by making a detailed plan or drafting a needed letter. This is just to give a push towards their plan, and is known as '**Do it Now**'.

Before the end of the session, they are made to realise what was achieved that day. This is done by asking them to reflect on the good things that happened in the short meeting: *What was the best thing about today's discussion? Why was it the best part?* This is called '**Discuss/Dialogue**'.

'**Dance and Drum!**' is the end of the session with entertainment of 'Singing, Drumming and Dancing.' Here all are encouraged to dance and sing so that they leave in a very happy mood.

It's time to celebrate the spirit of the African farmer!

Nigel Marsh

Aid agencies can do a lot to help farmers become productive again after a major crisis, but it is the spirit, ingenuity and effort of the farmers themselves that should be celebrated more. Examples from **East Africa** demonstrate how creative partnerships between humanitarian organisations and farming families can transform devastation into prosperity, and even 'drought-proof' communities.

Building on farmers' insights

The era of large-scale development interventions imposed by outsiders on a pliant rural population is, hopefully, gone forever. One does not have to travel too far to find yesterday's massive diesel-powered irrigation scheme lying redundant or a vast cash crop estate bled dry by corrupt officials. Surely everyone now accepts that it is best to build on farmers' own insights and experience, rather than 'take over' with an idea or a project that ordinary farmers can never genuinely feel they own.

Rwandan farmer Julienne Mukaremera's initiative is a good example of one that took wings because it was locally hatched. In 1996, she and her family came as returnee-refugees, from what was then Zaire to their former land in Gikongoro prefecture. Like virtually everyone else in Rwanda, Julienne's family started again from scratch. Watching her hungry children, like so many other mothers, made Julienne find reserves of energy and imagination she had not needed before. She pressed the World Vision workers, who had given her a hoe and some seeds, to help her set up a local farmer association, reviving an idea that was common before the 1994 war. Encouraging her female neighbours to join her in crop multiplication and terracing projects, she quickly took charge of not only her own association, but a whole group of associations – including some run by men. Together they established a farmer's store to sell seeds, tools and inputs to members, with profits redistributed among them at the end of the year. And in just a couple of years, they began to recreate the thriving community that they had lost during the war.

Women take the lead

A focus on women is one of the key elements in many successful agricultural interventions after crises. Be it in Burundi, northern Uganda or Somalia, it is so often women who take the responsibility, make the changes, push the local agenda. Several years ago a local leader in southern Sudan, Mary Nybol, was almost brutal in her denunciation of men who, for traditional reasons, resisted newly introduced ox-ploughing techniques.

"I am very proud to get the chance to tell our men to bring their bulls for training. Our men are too dictatorial. They think bulls should only be kept for marriages," she said, referring to the traditional practice of buying brides with oxen. *"We are going to convince them they are wrong",* she added bluntly – and who is going to argue with a woman who has given birth 19 times? *"We women are coming up, after a very hard struggle, and the men are going to accept us. We think more technically than our men do. We want to change the face of our land and the behaviour of our community".*

A year later, aid workers helped an association of elderly widows in her district of Bahr El Ghazar to start its own co-operative. By then, though, men were already queuing up alongside their womenfolk to learn how to plough with precious cattle, partly because of the leadership and example of Mary Nybol.

Communal work and private ownership

Co-operative ventures are often better than attempts to help farmers prosper as individuals. One of the encouraging examples in Kenya is a co-operative irrigation scheme at Morulem in the drought-ravaged Turkana district. Here, farmers have been shown how to dig and maintain shallow wells and use them for irrigation. The scheme, which began in 1992, benefits 1,228 farming families who own half an acre of land each on which they plant maize, sorghum, fruit trees and vegetables. They share their labour in tending their individual plots, and are jointly responsible for maintaining the irrigation scheme. The land has a plant nursery with 30,000 fruit tree seedlings.

The combination of communal activity and private ownership seems to foster the best instincts of everyone, and the current drought is demonstrating the results. While more than half of the 447,000 population of Turkana resorts to relief food, the people of Morulem are enjoying a harvest and even selling surpluses. Morulem has been so successful that other Turkana communities are now clamouring for help to establish similar schemes.

Simple projects, sound results

Generally speaking, in places prone to frequent disaster or insecurity, simpler schemes are more successful. Hand-dug wells, where they are possible, are better than bore holes which need costly maintenance. Ox-ploughing is more sustainable than importing tractors. Anything that involves tapping into the abilities of the community is going to succeed more readily than an importation of technology. ■

Underground storage of sorghum as a banking alternative

Nageeb Ibrahim Bakheit, Kees Stigter and Ahmed el-Tayeb Abdalla

In Jebel Muoya, in the Blue Nile area of **Sudan**, a survey made clear that the socio-economy of *matmuras* - underground storage pits for sorghum - should be understood as a banking alternative. This farmer oriented research supported a project on physical improvement of storage conditions. A bibliography on Sudanese agriculture published in 1994 concluded that traditional storage techniques, and traditional farming in general, had seldom been studied and had never been used as a basis for agricultural improvement. However, since 1985, the Traditional Techniques of Microclimate Improvement Project had done just this at universities in several African countries, including the University of Gezira in the Sudan. In 1992 the project started work on *matmuras*. Forced by increasing climate variability, more frequent failure of rains and hence a need for longer-term storage, farmers introduced innovations for grain storage with regard to the dimensions and linings of the pits. A formal scientific study of these farmer innovations was made to ascertain their suitability for the prevailing cracking clay (black cotton) soils under marginal, semi-arid conditions.

Local production situation

The type of agriculture concerned covers about 350,000 ha of rainfed sorghum, the staple crop of Sudan. Originally, production was organised in smallholdings around the villages, but nowadays sorghum is also produced on farms of up to 400 ha and as far as 30 to 40 km away from villages. Farmers hold land at one or more sites, which fragments crop growth. Although such fragmentation is disadvantageous due to inefficiency of resource use, the diversification of soil type and rainfall distribution that decreases risk is an advantage. Staggered planting times decrease risks further and increase the food supply period. Extension services are virtually unavailable and the production shows all the dangers of monocropping without rotations, resulting in very low productivity.

A banking and safety device

Subsistence farmers have *matmuras* as a safety device for food security. The *matmuras* can hold 2 to 10 tonnes of grain. With the introduction of more commercial and mechanised agriculture, *matmuras* have increased in size. The largest farmers store up to 70 tonnes of sorghum in one *matmura*.

With poorly developed property rights and lack of assets, farmers have no collateral and consequently no access to bank loans. Instead, they depend on the grain stored in *matmuras* to take care of the high cash needs at the beginning of the planting season. Farmers without sufficient capital in the form of stored sorghum rent part of their lands to those with *matmuras* in order to finance their farm operations. This is preferred to the *sheil* practice, an informal form of credit with extremely high interest rates, which requires produce to be sold before the forthcoming harvest or even before planting.

Innovations added

Traditionally, the pits are filled until a dome shape is formed by gravity at the angle of repose (see photo). Then a layer of chaff is spread on top of the sorghum, and a layer of soil of 25 to 50 cm extending about 30 cm from the rims of the pits completes the cap.

Both subsistence and commercial farmers are interested in innovations using shallower but wider pits and adding pit wall linings of chaff. Pits tend to become as shallow as 50 cm instead of up to 1.5 m. These innovations keep the grain drier by diminishing the ingress of moisture in two ways. First, they reduce leakage through cracks. Second, they minimise diffusion of water vapour from the wetter soil into the grain. The innovations increase grain temperatures leading to lower infestation of insects, which adds to cost-effectiveness. This also substantially improves the grain quality at the end of the storage period. As participatory and quantified experiments confirmed, this increases the safe storage period. These improvements are particularly important to subsistence farmers. Farmers with a considerable market surplus are advised to use polythene linings instead of chaff.

The research led to another innovation, particularly important for the smaller pits. The caps were increased to about 50 cm in thickness and extended to about 1 m. around the filled pits. This helped to cover cracks that would otherwise allow seepage of rainwater into the pits. When pits get larger, the filling with a dome of grain is abandoned. In this way, scientific research and farmer innovations jointly improved grain storage for food security as well as cash provision. ■

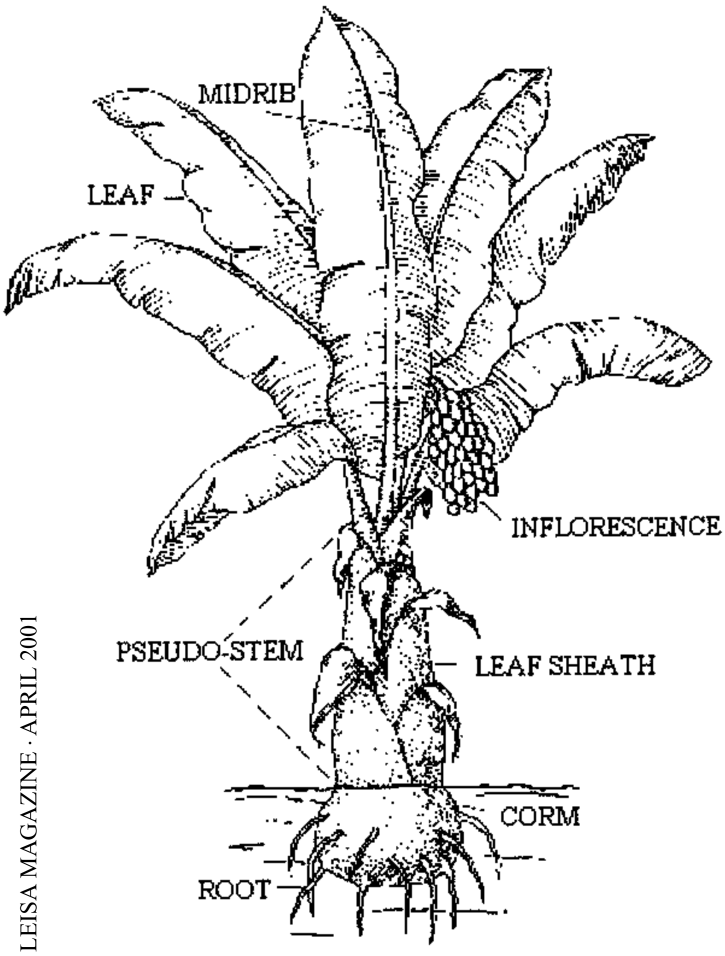
Enset - the tree against hunger

In the crisis years of the 1980s, parts of Ethiopia survived famine due to the utilisation of enset in subsistence farming. Also known as false banana, enset (*Ensete ventricosum*) helps to feed about ten million people in Ethiopia and Eritrea. Enset-based systems are among the most sustainable indigenous farming systems in Africa.

Because the development agendas of Western aid agencies still focus on cereals, enset continues to be largely ignored by development and research. Recently, the enset research team of the American Association for the Advancement of Sciences with Awassa Agricultural Research Center, Kyoto University Center for African Area Studies and the University of Florida has written a preliminary report on their research, which forms the basis of this article.

How it is grown

Enset is related to and resembles the banana plant (Plate 1) but is somewhat larger, up to 10 m tall with a pseudostem up to 1 m in diameter. Large quantities of carbohydrate-rich food come from its false stem and its underground bulb (corm). In spite of the extensive distribution of wild enset in the tropical belt, it is only in Ethiopia that the plant has been domesticated. Domesticated enset is planted at elevations ranging from 1,100 to more than 3,000 m receiving annual rainfall of about 1,100 to 1,500 mm, most of which falls between March and September. The average temperature of enset growing areas is 10 - 21°C and the relative humidity is 63 to 80 %. Enset grows well in most soil types, if they are sufficiently fertile and well drained.



Enset tree

There are 4 main sub-systems. In one sub-system enset is the staple food grown in dense plantations. Cattle are important to produce manure to fertilise enset fields. Other sub-systems combine enset, cereals and tuber crops in different combinations.

How it is used

The major foods obtained from enset are *kocho*, *bulla* and *amicho*. *Kocho* needs a lengthy period of processing and preparation, which is carried out by women. The first stage involves removing the leaf stalks and grading of the corm. Then the fibres are separated out and the pulp is crushed to extract the starch. This is put in a pit about 1.5 m deep and 1 m diameter, wrapped airtight with enset leaves before being packed down with stones. It is then allowed to ferment - a process, which may last anything from 4 months to three years. The pit is opened at intervals to allow aeration, and the enset leaves are replaced. This is repeated until the desired fermentation quality is reached or the food is needed. Finally, the fermented starch is dried and treated as flour. This can be used to prepare a pancake-like bread *ountcha*, which is eaten with milk and cabbage. *Kocho* is increasingly exported to urban markets.

Bulla is the unfermented starch of a mature plant, which can be prepared as a pancake or porridge. *Amicho* is the corm of a young plant, which is boiled and consumed as other tuber crops. Due to their low protein content these foods are eaten in combination with protein rich products like milk. The fibre is used to make sacks, bags, ropes, mats, construction material and sieves. Fresh enset leaves are used as food wrappers, serving plates and for stall feeding of cattle. There are many other uses, e.g. for medicines. A measurement on 34 farms showed an average annual yield of about 5,000 kg of *kocho* per ha. in addition to the other products.

Improving food security

Enset in the farming system contributes significantly to the stability of the food supply in several ways. Enset can: 1) be stored for long periods; 2) be harvested at any time during the year; 3) be harvested at any stage over a several year period; and 4) survive stress years that reduce other food sources.

During the 1984-85 famine, when cereal farmers from southwestern Ethiopia migrated from their villages in search of food, they learned how to cultivate and process enset. Returning home, they introduced enset agriculture, and *kocho* became an important part of their diet. In 1992, when cereal crops were severely damaged, they were able to avoid famine because of their increased dependence on enset. It is expected that enset can be introduced in many other regions to improve food security. However, this needs further study and work on trial-demonstration farms. Further research is needed on: diseases, mechanisation of processing, improvement of the livestock component, production of protein-rich food crops in enset systems, marketing of *kocho* and sustainability of enset farming under increasing population pressure and marketing.

Trees for semi-nomadic farmers: a key to resilience

Stephen Connelly and Nikky Wilson

Like many peoples of the dry lands of Africa, the farmers of the savannahs in the Western Lowlands of **Eritrea** have survived the variation and stresses of their hostile environment through developing a flexible farming system involving a mix of crops and animals, production for cash and for subsistence, and widespread dispersion of activities over hundreds of miles. The resourcefulness and resilience of such farmers is well known and well documented. They are traditionally viewed by the outside world as semi-nomadic herders and opportunistic farmers ('agro-pastoralists'). In this article, however, we show that despite such views these farmers in Western Eritrea are also dependent on a third strand of the farming system: the management, collection and processing of forest products, and in particular of the dom palm (*Hyphaene thebaica*). This third strand is always important, but never more so than when disaster strikes – in times of drought and war forests become the key to survival.

Disasters strike frequently

The Western Lowlands of Eritrea are the easternmost extension of the Sahel, lying between Eritrea's border with the Sudan and the Eritrean/Ethiopian Highlands. Principally covered in semi-desert scrub and savannah woodland their low hills and plains are interrupted by three river valleys clothed in remarkably dense woodland, some of it mixed acacia and dom palm and elsewhere almost pure stands of dom. They are home to several hundred thousand people of six ethnic groups, each of which has developed their own distinctive survival system, involving greater or lesser emphasis on animals, crops, palm fibre and other forest products. All these systems are characterised by flexibility, and all have been repeatedly disrupted by the natural and man-made upheavals of the past forty years.

A series of major droughts has struck the area (early 1970s, 1982-5, 1990-1, late 1990s), causing repeated crop failure and massive livestock losses and – in the early 1980s – a complete collapse of the farming system, many deaths and mass exodus of the population as refugees. At the same time the area has been ravaged by war: the Lowlands changed hands several times in the thirty years of liberation struggle (1961-91) and villages and crops were repeatedly bombed and destroyed by warfare on the ground. After liberation (1991) and independence (1993) farmers picked up the pieces and started farming again under more settled conditions, though facing new threats from government development policies, and then in 1998-2000 by renewed war that saw the invasion of the Lowlands by Ethiopian armies.

Dependence on dom palm

At all times, forest products play a crucial role in people's livelihoods. The traditional farming system involves growing sorghum for food, and keeping camels, cattle, goats and sheep for food and occasional sale. Amongst all the tribes a vast range of subsistence needs (e.g. housing, tools, and some food) come from the forest, and for the majority of the Lowland population (belonging to the Tigre, the Beni Amer and the Hidareb tribes) the *principal* source of cash income is dom palm fibre. Palm leaves are cut on a massive scale from the riverine forests, and either sold in their unprocessed form or woven into mats, rope and other household utensils for sale in the markets of Eritrea and Sudan.

Under 'normal' circumstances - i.e. in peacetime and when rainfall is sufficient to allow at least some cropping and herding – dependence on the forest is greatest for the poorer members of the community. Those with few or no animals, or who cannot farm land – such as the many war widows – rely on cutting, weaving and selling palm for their survival on a permanent basis, while even for most richer farmers the dom is a vital source of income, particularly during the lean months of the year. The population clearly values the forests highly. This has been a factor in its preservation: farmers that we interviewed described harvesting patterns governed by informal regulations and an understanding of the nature of dom palm regeneration and growth. These systems prevent over-cutting through restricting access and over-frequent cutting, and their overall impact appears to be a sustainable management system.

Key element of resilience

In years of bad rainfall dependence on the palm forest increases as crop and animal production falls. In serious drought years cutting and selling palm leaves becomes the main source of income for most of the population – men travel miles from villages far from the rivers in order to cut palm leaves to buy food. At the same time food collection from the forest increases: dom palm nuts are a food of last resort for the poor in the hungry season before harvests, and in drought years they become a staple food for many.

One ethnic group – the Kunama – has a distinctly different approach to the forest. They cut very little palm for income, but collect food from twenty or more tree species. These include the dom palm and others that they value as food reserves for drought years when their crops fail: for them the riverine forests are their insurance, rather than a regular income source.

Thus harvesting from the forests provides a key element of the resilience of the farming system, enabling poor farmers to survive from year to year and entire communities to weather the bad years, even to survive for a time when war makes farming impossible. Only in major droughts does the system finally collapse and people become refugees.

In the period of peace from 1991-98 the palm forests were crucial in re-establishing a normal social and economic system in the Lowlands, both for those who had remained and for those who were returning from refugee camps. Livestock numbers were low and many female headed households (war widows) and physically disabled people in the villages had limited ability to farm. Harvesting and export of palm leaves has consequently been a major source of support for the Lowland population.

Forest or irrigation?

However, this revival of the traditional system has not been actively supported by the government's agricultural extension services. This appears to be partly because they recognise neither the importance of the forest to the farming system nor its sustainable nature. The Lowland farmers are seen as 'agro-pastoralists' for whom trees are a minor aspect of the farming system, and there is a widespread – though unfounded - belief amongst officials that cutting is carried out in ways that damage the trees.

The other major factor is that the government has other priorities: the forests occupy fertile land with high water tables, which is ideal for irrigated agriculture of cash crops such as onions and bananas. Increasing production of these is a high priority, in order to feed urban populations, raise hard currency through exports, and to attract investment from wealthy (often formerly expatriate) Eritreans. Thus the traditional system and the government's preferred land use are in direct competition, and the appropriation and clearance of forest land has caused serious tensions in the Lowlands between local people and the government. Exacerbated by current and historical ethnic and religious factors, this conflict over a resource fundamental to local livelihoods contributed to unrest and the recurrence of violence in the Lowlands during the 1990s. Ironically, the recent (1998/2000) war between Eritrea and Ethiopia may have stopped the clearance of forests for commercial farming, though once again presumably forcing local people to rely on the forest as farming becomes impossible.

Sustainable forest management

With the recent peace accord the question arises again of how local communities, government and – perhaps - outside researchers and agencies can work together. Although the deeper animosities are undoubtedly still present and intractable, the more immediate resource management issues should not be impossible to solve. This would require, however, that the government recognises both the importance of the forest to the local livelihood system, and the right of local people to have continued use of and control over the forest. It would thus have to forego – or at least restrict – the issuing of licenses for agricultural production in forestland. More positively, government and local people could work together on improving sustainable management – particularly where large numbers of former refugees are being settled - and on the provision of raw material for the industrial use of palm fibre.

In **conclusion**, we can say that for many farmers in the Western Lowlands of Eritrea, the riverine forests, and in particular the dom palm, are an essential resource for their survival. They show great flexibility in switching emphasis between the components of their farming system (crops, livestock and forest) to meet changing conditions, but their ability to cope with the uncertainty of marginal farming and the stresses of war and drought is ultimately underpinned by their reliance on the forest for income and food. This dependency is even greater for poor people, and especially for those who are prevented from farming by physical disability or by social custom, as is the case with female heads of households. This dependency has been strangely neglected by both officialdom and outside agencies and researchers. We believe, however, that the sustainable exploitation of the forest under local management systems has huge potential to ensure that farmers' coping mechanisms are both preserved and enhanced.

Farmers' responses to reduce the risks of drought

Owen Shumba

Drought is a common phenomenon in the Southern region of the African continent and **Zimbabwe** is no exception. The annual average rainfall of Zimbabwe is about 600mm, but is markedly variable, particularly in drier regions. Since rainfall is the main climatic constraint to dryland agriculture, the country is divided into 5 natural regions for agro-ecological planning. Region I receives the highest rainfall while region V records the least annual precipitation. Farming systems range from intensive livestock and crop production in Region I to extensive beef production (ranching) in region V. However, some drought tolerant cash crops are grown in region IV and V. The lack of rain coupled with exceptionally high temperatures has been the cause of many droughts causing widespread disruption to many farming communities with the loss of crops and livestock.

Based in Zimbabwe, SAFIRE - The Southern Alliance for Indigenous Resources - is a collaborative initiative of several local and international NGOs, grassroots development agencies, government institutions, international organisations and individuals that assists rural communities in managing their natural resource base. Apart from its many activities, SAFIRE plays a pivotal role in the implementation of drought mitigation and preparedness initiatives in Southern Africa.

Recurrent droughts

Since 1901 Zimbabwe has suffered recurrent droughts. According to literature, the worst years with below average rainfall are 1911/12, 1923/24, 1946/47, 1972/73, 1981/82, 1982/83, 1986/87 and 1991/92. In a survey conducted by SAFIRE across nine districts in Zimbabwe, farmers recalled 6 – 16 (on average 10) drought years from 1918 to 1997 (see Table 1). Farmers' definitions of drought were diverse, including agricultural, hydrological, economic and meteorological aspects. According to the farmers, droughts seriously affected them both in the normally wet and dry seasons.

Table 1: No. of drought years remembered by farmers across nine districts of Zimbabwe 1918-1997

Rushinga	10	Mudzi	16
Nyanga	15	Chipinge	10
Mhondoro	10	Goromonzi	6
Chivi	10	Gwanda	9
Tsholotsho	10		

Impacts of drought

The 1991/92 drought had the most crippling effect in Zimbabwe and over much of the sub-region with many countries in the region having seasonal deficits of up to 80% of normal rainfall. There were unprecedented crop failures. The subcontinent, usually a food exporter, had to import 11.6 million tonnes of food worth over US$4 billion. Regional grain production fell some 60% short of expected levels. The droughts led to widespread suffering with loss of cattle and crops.

Farmers in the nine districts above summarised the major effects of these droughts as follows:

- Partial or complete crop failure (because of low soil moisture content and disease outbreaks)
- Livestock deaths
- Trees drying and dying
- Boreholes, rivers, springs and other water points drying and causing a scarcity of both livestock and human water supplies
- Shortage of basic commodities on the local markets
- Price hikes across all sectors
- High government expenditure because of food imports, especially yellow maize from Kenya
- Malnutrition, especially in children.
- Unemployment, coupled with rampant crime and robbery.

Farmers' coping strategies

Farmers' responses to the effects of drought have been varied. Below are some of the actions being undertaken to mitigate drought, especially by women in Nyanga, Chipinge, Mudzi, Chivi and Gwanda districts.

- ***Permaculture*** All the farmers interviewed stated that they were learning permaculture and practising it, both in their gardens and fields. Permaculture helps them prepare for drought through land use designs that enhance water conservation and bio-diversity.
- ***Water harvesting*** Farmers are harvesting water from rooftops and diverting water from natural springs into tanks. This ensures that they have a substantial amount of water stored up. In case of a drought the stored water will be able to sustain them for about five months depending on the volume of the tank. The water is also used for supplementary irrigation of vegetables and crops.
- ***Infiltration pits*** Some farmers are digging infiltration pits along contours. Water collects in the pits during the rainy period. When the weather becomes dry, as in the case of early stoppage of rains, the water spreads underground and is used by the plants. Crops can grow up to maturity by using this conserved moisture. The farmers in Nyanga and Chivi stated that even if there are only 5 days with rain in the whole rainy season, the crops will reach maturity using conserved and harvested water in the pits.
- ***Granaries*** A majority of the farmers interviewed store food to be used in case of a drought. They have a specific granary stocked with grain (sorghum, millets, and maize for a shorter period of time), especially those resistant to post harvest pests. This granary is kept untouched and out of bounds for children. Only the head of the household is allowed into it.
- ***Savings*** A fifth of the farmers across the nine districts save some money in order to purchase food in times of drought. These are the affluent farmers with flourishing business enterprises who can set aside enough money to buy food for a whole year if the rains fail.
- ***Drought tolerant crops*** Some farmers are slowly discarding the idea of growing maize as the main crop. They are shifting to the use of traditional crops e.g. small grains, i.e. millets, sorghums. These crops are drought resistant and therefore give a good yield even with very little rain. Farmers are also looking for indigenous maize varieties (i.e. *Kalahari*) that are short season, high yielding, drought tolerant and post-harvest pest resistant. An indigenous finger millet variety, *chiraufe*, is also planted in drought years. *Nyamunhororo,* a cucurbit, is popular as the small pumpkin ripens fast and saves people from possible starvation. It is not only drought resistant but can survive in poor soils. The early maturing cowpea variety *Vigna unguiculata* is also planted in drought seasons.

Building on farmers' initiatives

It is evident that farmers are proactively doing something for their survival in times of disasters such as drought. The array of initiatives shows that community livelihoods are dependent on a number of activities, capabilities and assets including both material and social resources. Rural community livelihoods would be sustainable when they can cope with and recover from stresses and shocks such as drought, floods or even HIV/AIDS, and maintain or enhance its capabilities and assets both now and in the future, while not undermining the natural resource base.

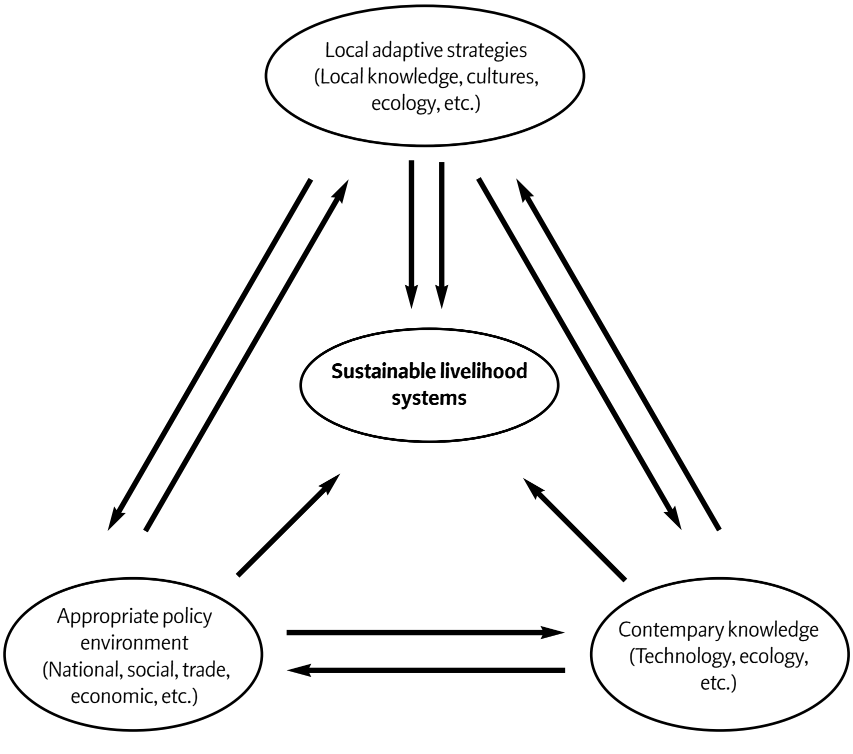
The main challenge for researchers, development practitioners and policy makers, therefore, is to facilitate this process and to build on what farmers are currently involved in. The main long term focus and goals of all drought mitigation projects implemented by SAFIRE and other partner NGOs such as ENDA - Zimbabwe, CARE Zimbabwe, Zimbabwe Freedom from Hunger Campaigns (ZFFHC) and ORAP have been to strengthen community livelihoods. The livelihood conceptual framework illustrated below has been the guiding principle in most initiatives.

Adaptive strategies

In its community drought mitigation initiatives in Zimbabwe, SAFIRE has sought to build on and promote the following community adaptive strategies:

- Multi-cropping to hedge against crop failure.
- Soil and water conservation (infiltration pits, tied ridges, water harvesting tanks and permaculture kitchen garden designs in general)
- Storage of a two year supply of indigenous maize and other drought tolerant varieties such as millet and sorghum.
- Income diversification (organic vegetable sales, organic cotton growing esp. with refugees in Zimbabwe, craft making, jam making and sales, soap making from *Jatropha curcas* oil, etc.)
- Community regulations and bylaws which control the conservation of certain trees and wooded areas.

Figure 1: Towards sustainable livelihoods and food security



This figure represents the three main systems leading to sustainable livelihoods in Africa's semi arid lands. Sustainable livelihoods draw most from the adaptive strategies that people and nature have evolved together, but they will also require an appropriate environment of social and policy conditions and will draw on contemporary knowledge systems.

Source: Rennie and Singh (1995)

Contemporary knowledge

The following new knowledge is introduced:

- Participatory ecological resource assessments conducted together with the communities in project areas.
- Oil extraction technologies either developed or sourced for the communities.
- Simple irrigation techniques such as bottle watering and low cost drip irrigation promoted in project areas.

Policy issues

The main responsibility of the government is to create an enabling policy environment, which will ultimately enhance the livelihoods of at-risk communities. Examples within the Zimbabwean context are:

- Land use/tenure: state vs community; agricultural modernisation: monocultures and cash at the expense of food security i.e. maize vs sorghum/millet.
- Marketing policies per se
- Livestock production and sale
- Promotion and legitimisation of indigenous knowledge by both government and researchers, especially in climate forecasting.

ENDA-Zimbabwe and the International Institute for Sustainable Development (IISD) have been in the forefront of analysing policies that impact livelihoods of rural people at-risk.

Achieving food security

Apart from effective networking, NGOs and governments need to work together towards fulfilling the concept of sustainable livelihoods systems, as elaborated above. This way, food security and community resilience to drought can be achieved in Zimbabwe and in Africa as a whole.

Out of balance?
Resilience in farm level food security

Astrid Björnsen and Prem Gurung

Resilience can be defined as the capacity of a household to maintain basic sustenance in food and health. Farmers have developed manifold strategies to cope with frequently occurring minor stress factors resulting in fluctuating yields. Major disasters such as earthquakes or landslides, which occur periodically, are more difficult to prepare for. This article focuses on food securing strategies at farm and community level that contribute to a resilience capacity, and compares the disturbance factors and the resilience capacity of Nepalese farmers, then and now.

Farming in Nepal

Subsistence farming and on-farm storage remain cornerstones in the livelihood of the majority of people living in remote and marginal areas of **Nepal**. Exposed to annual monsoon rainfalls in summer followed by a dry winter, farmers are highly dependent on seasonal production and storage of cereals. Production, moreover, is threatened by storms, periodic droughts, erratic rainfall, and unprecedented floods.

Efforts to modernise agriculture in Nepal were first initiated in 1956. As a result of the population growth after the 1950s, peasants encroached marginal farming environments and agricultural production per capita stagnated. Urged to cultivate risk-prone areas, farmers became extremely vulnerable to food shortages. Since then the moderate level of household food security has turned to chronic food deficits in many areas (Seddon 1987 and Adhikari and Bohle 2000).

Resilience in the past

In response to seasonality and fluctuating yields, Nepalese farmers developed several strategies -technical, economical, social, and spiritual - to secure food. Interestingly, the majority of them aim at prolonging food availability rather than increasing yield.

The most important ***technical method*** is storage. Depending on the availability of resources, the locality and climate, a variety of storage structures such as cribs, woven baskets, pots, mud bins, trunks, chambers, and ground pits are used, none completely insect-proof. Farmers generally tolerate insect damage and grain spoilage. Moulded grain is consumed even though the adverse health effects are known. Infested grain is used for brewing alcoholic beverages, while severely spoilt grain is used as livestock feed, allowing for optimal resource use.

Feeding livestock with grain is an important ***economic solution*** to enhance resilience. It could be argued that farmers would do better using it for human consumption. However, farmers reason otherwise. Livestock is a hidden storage system. Surplus and inferior quality grain is converted to protein and other products. In times of need, livestock can be sold with added value and used for buying grain, if necessary.

Apart from human consumption and livestock feed, grain is allocated for seed, barter, payment and communal events.

Surpluses are also sold and invested in gold ornaments, the common 'insurance' against food shortage.

Supplementary food such as wild yam, taro, mushrooms, fern, nettles and asparagus was collected in the forests that were abundant in old days.

Social aspects in food security are often neglected. Women control and safeguard the stored commodity, determine the rate of consumption, and take pest control measures to prevent food losses. In times of food scarcity, women adjust the household and individual food consumption. Apart from reducing the number of meals, women, children and elders cut down their calorie intake. In food deficit years, families postpone marriages that involve high costs in feeding the wedding party. To prevent high expenditure on life-cycle rituals, mourning households refrain from other celebrations for one year. Costs involved in death rituals can take years to recover.

In the past, social arrangements secured food at the community level for the needy. In Kathmandu, for instance, common property and giving of alms was common in former times. Until the 1950s, there was a system called *hundi,* under which needy persons were given everyday food items. In rural areas, two food securing systems were effective: the patron-client relationship and *dharma bhakari*, a grain store catering to the poor for religious merit.

Spiritual means of storage protection and food security have remained largely unnoticed. Grain is commonly stored inside the house to protect it from weather, theft and evil spirits. However, the storeroom is not an ordinary place; the presence of deities and spirits gives it a sacred character. For many Nepalese, children in particular, this room is an eerie location arousing fear and unease, and is entered only for storing and fetching grain.

Apart from the sanctity of the storeroom, the commodity contains supernatural qualities called *saha,* meaning 'an essence or life-force' or simply 'help' or 'plenty' - a phenomenon economising the grain use, therefore, prolonging food sufficiency. Adequate *saha* prevents food shortage and famine, and acts as a multiplying, replenishing force in the storeroom. In the past the preservation of *saha* was extremely important, as the

'Dehri-making': Tharu woman of Gobardiha, Deukhuri, building a mud bin for storage of food grain. Photo: Astrid Björnsen

'Kutli-finishing': Tharu woman plastering new mud bins with a layer of clay that is believed to have insecticidal properties. Photo: Astrid Björnsen

procurement of alternative food grain was hardly possible. Hence, various rituals, traditions, ceremonies were developed for the conservation of *saha*. Lavish handling and unnecessary spoiling of grain, for instance, was considered to have a decreasing effect on *saha*, triggering the anger of the Goddess of Prosperity resulting in dwindling stocks.

Resilience at present

Perturbing natural disasters still occur today, but are accompanied by new man-made hazards. These hazards are created in the process of population growth and land encroachment, leading to deforestation and land degradation. Resilience capacity is being seriously threatened by modernisation in agriculture. Farmers encounter unexpected difficulties with field and storage pests, as the introduced improved varieties are more susceptible than the local landraces. Traditional knowledge, old practices, and proven technologies are turning obsolete in the wake of modern agriculture.

Similarly, formal schooling prevents younger generations from traditional sources of education, preparing them for non-farming professions, and finally withdrawing them from farming. Forced by these changing conditions, opportunities and needs, farmers are adapting their coping strategies.

On-farm storage ***technology*** is changing due to increased storage pest pressure. The use of low-cost dusts and fumigants for grain protection is becoming increasingly common. Fumigation is of special concern as the use of phosphine gas in traditional non-hermetic storage structures triggers pest resistance and poses health hazards to the farmers.

The new ***economic*** food securing ***strategies*** differ from the past. Livestock is loosing importance in the face of labour shortage caused by the education system. Wild foods have become scarce and are consumed in insignificant amounts. Instead, more land is being allocated for staple crops to meet the household food demands. Cash crops are becoming important sources of income in regions having access to road and market. Farmers mortgage their lands and raise cash to purchase grain during food shortages.

Moreover, a higher incidence of storage pests is altering the pattern of food allocation. More and more households sell their grain soon after harvest to avoid storage pest losses even though the prices are unfavourable at that time. In addition, high-quality grain is sold in order to buy a larger quantity of low-quality grain.

The search for food security leads more and more to options outside the household. Patron-client relationships, i.e. labour service for wealthier households, are becoming a common risk-avoiding strategy, as annual wages are independent of yield fluctuations. Children are given away as servants to reduce the number of mouths to feed. There is also an increasing trend of male migration for temporary and permanent off-farm occupation. All this leads to increasing household fragmentation and individualisation with severe impacts on social structures and safety nets. Male out-migration particularly overburdens women, who have to take up increased control of farming and family welfare.

Social arrangements such as the *dharma bhakari* have disappeared due to growing food insecurity, the general breakdown of social structures, the growing influence of individualization and the cash-based system, and the erosion of belief systems.

Spiritual means of stabilising food security and farmers' resilience capacity have been neither changed nor replaced by new strategies, but have simply lost their importance. Rituals concerning food security are still performed, yet the belief in the super-natural is declining. Rituals, however, form important links between farmers' past and present. They include ideological concerns such as the balance between human and nature, important for social stability and mental well being. Especially in times when formal schooling devalues agricultural work and local knowledge, these rituals allow the farmers to place themselves in the universe, and to attribute importance to their lives. If this feeling of identity is lost, then the farmers' capacity to maintain mental resilience will be seriously affected.

Conclusion

The fact that more and more rural households face food deficit indicates that the Nepali farmers have partially lost their resilience capacity in terms of food security. The loss of resilience is closely linked to the loss of options rendering the farming system vulnerable and sensitive to disturbance.

Farming in Nepal is clearly out of balance and the multidimensional approach of farmers to deal with environmental fluctuations, instability and food deficits requires continuous adjustment. The primary responsibility of development professionals is to enable farmers to generate diverse options enhancing their resilience capacity. Suitable options, however, need to be generated in close collaboration with farmers considering all dimensions of their livelihood. Research as a means to widen farmers' options, therefore, needs to be highly participatory, action oriented, and responsive to local needs and priorities.

Resilience to disaster

Editorial

Besides more normal fluctuations in production conditions, many farmers have to cope with high impact hazards like droughts, floods, storms, earthquakes, epidemic diseases, war or economic crisis. These hazards make farming a risky activity and can become disasters resulting in loss of housing, stored food, crops, animals and even personal injury or death. There are also hazards that build up more gradually leading, eventually, to disasters with no less serious impacts. Examples of slow impact hazards are Global Warming, ecological degradation, HIV/AIDS, Green Revolution – Industrial Agriculture and economic globalisation.

Ecologists use the term 'resilience' to describe the process through which an ecosystem returns to its former state after it has been disturbed. We use 'resilience' in a broader sense, as the capacity of farmers (and other members of a community or society) to deal with disturbances and hazards by preventing and minimising losses and mitigating disaster to ensure food availability and sustain the agricultural production system. Farmers have developed many strategies to anticipate, cope with, resist, and recover from the impact of minor disturbances and hazards. When farmers begin to loose their resilience, their vulnerability increases, and so does the possibility of hazards turning to disasters. In rural areas, it is marginal people on marginal land – those with the least opportunity to build resilience in their livelihood systems – who are most affected by disaster.

Disasters, an increasing problem

Disasters are becoming a major global problem, increasing in number as well as in impact on people. In the past decade humanitarian assistance for disaster mitigation has risen sharply. For example, from 1990 – 1996, global overseas development assistance (ODA) for humanitarian assistance rose from USD 500 million to USD 6 billion – a twelve-fold increase and some 12 percent of all development aid. The interventions were in natural disasters and, increasingly, in emergencies of a complex political nature, often caused by serious deficits in governance and resulting in violent conflicts within and between states. Environmental degradation and socio-economic marginalisation are also important factors in the increase in incidence and impact of disasters. As disasters can have an enormous impact on rural livelihoods and their development, the challenge is to reduce the impact of hazards by strengthening the resilience of rural communities in pre as well as post disaster situations, the theme of this issue of LEISA Magazine.

Resilience in traditional agriculture

In traditional agriculture, high levels of resilience were achieved by complex combinations of economic, ecological, social and spiritual strategies. Björnsen and Gurung (p.6) show the wide variety of strategies used in traditional subsistence agriculture in the rugged Himalayan regions of Nepal where production is threatened by storms, droughts and floods. The available local resources and waste products are used optimally for a wide range of complementary products and services. Social arrangements and solidarity are fostered and emergency strategies are strictly followed for maintaining food security. The goddess of prosperity is worshipped i.e. for protection of stored grains against bad weather, theft and evil spirits. Uran et al. (p.16) point to the importance of biodiversity, the social and cultural relations and subsistence perspective of local society for the resilience of farming in Flores, Indonesia. This is in strong contrast to the low resilience of the large-scale plantations propagated by the government.

Animals and forests make an essential contribution to the resilience of many traditional systems. Connelly and Wilson (p.10) document the role of forest products, in particular of the dom palm, in the survival strategies of the people living in the savannahs of the Western Lowlands of Eritrea affected by drought and war. The flexibility of the farming system appears to be crucial, so that households can easily shift between different economic activities: crop production, herding, collection of forest products, craft, trade or migration labour. In the post-war period the palm forests were crucial in re-establishing a normal social and economic system. However, the government has not recognised the importance of the forests for the local people and intends to transform them into irrigated agricultural lands for export production. This has caused serious tensions between the local population and the government.

Coping with drought and floods

Shumba (p.8) reports on the research by SAFIRE in Zimbabwe on farmers' responses to drought. It shows that farmers are not passive victims. They have developed their own, indigenous preparedness and mitigation strategies based on longstanding experiences of living with drought. Examples are: water harvesting and conservation, enhancing biodiversity, storage of food, saving of money and drought tolerant varieties of indigenous crops. These indigenous strategies are often overlooked and undervalued by disaster specialists from outside. Such local adaptive strategies can sometimes be improved by combining them with contemporary scientific knowledge and an appropriate policy environment. Shumba states that the work of SAFIRE and other NGOs in Zimbabwe is showing that this can lead to more sustainable rural livelihoods.

Food storage plays an important role in traditional resilience strategies as the articles by Björnsen and Gurung (p.6), Brandt et al. (p.12) and Bakheit et al (p.13) show. Not only hardy traditional grain crops but also traditional famine food like Enset (false banana) can be stored for long periods, thus ensuring food availability during drought periods. Underground storage as used in Ethiopia for processed Enset and in Sudan for sorghum has been often overlooked by food aid programmes. Improvement of such farm level food storage systems is important to further decrease losses and to adapt these technologies to changing needs (Bakheit et al. p.13).

With the increasing impact of **Global Warming** destabilising the global climate, resilience to drought, but also to floods and hurricanes, is becoming increasingly important to farmers. Agriculture in industrial as well as developing countries is responsible for an estimated one third of Global Warming (FAO:AG21:Magazine). But, it is increasingly being recognised that sustainable agricultural practices can strongly contribute to mitigating Global Warming (Pretty and Ball p.31).

Farmers adapting to change

Society and agriculture are changing fast. Although the perturbing natural factors of the past are still active, many traditional strategies seem to have lost their significance. Population growth, modernisation of agriculture and education are mentioned by Björnsen and Gurung (p.6) as processes that seriously impair the resilience capacity of Nepalese farmers. But also other processes such as climate change, labour migration, economic crisis, ecological degradation and HIV/AIDS are forcing farmers to adapt their strategies.

Often driven by stress, adaptation and innovation has become a normal part of farming as demonstrated in the articles by Björnsen and Gurung (p.6), Uran et al. (p.16) and Holt-Gimenez (p.18). This can also be the case in post disaster situations. Sharland (p.26) and Vermaak (p.27) present interesting examples of post disaster innovation processes building on local conditions, knowledge and gender roles. Marsh (p.14) stresses that ***'It is time to celebrate the spirit of the African farmer!'*** With this he means that we should have more trust in the innovative capacity of farmers of which he gives some convincing examples. Women often take the lead in innovating and rebuilding rural livelihoods! To empower women to do so, ECTA in Nepal has developed an effective low cost methodology (Sharma p.15). Farmers' initiative and innovative capacity are crucial elements of resilience and therefore should be enhanced and strengthened.

Emergency agriculture

Provision of relief assistance to disaster victims over a number of decades has in many places resulted in the development of a dependency syndrome and a decline in self-help efforts. Relief must be provided to support agricultural recovery, but should not generate food aid dependency. This means that humanitarian assistance agencies must link with development agencies to promote rural recovery and development. This is not as simple as it sounds. The tensions in approach and conditions between food and development aid make agricultural rehabilitation the forgotten child of humanitarian assistance. Emergency agriculture is needed to end the relief phase, to encourage restoration of the management of agricultural resources, to restore the market systems, to reduce vulnerability and to build up resilience again (O'Keefe et al p.27).

Disasters can also create opportunities to capitalise on the sudden inflow of resources to promote rehabilitation and longer-term development. Often, however, this is translated in terms of market agriculture and 'improved' technologies (especially improved seeds, chemical fertilisers and implements), which are not always adapted to the specific needs and conditions of farmers. Instead, emergency agriculture should build on local capacities to manage available resources and mitigate disaster. For example, instead of only providing improved seeds, farmers can be supported to recover a number of 'cherished' varieties adapted to the local conditions. Thus is being done by the 'Rescue from the Pot' project in post-war Sierra Leone by recreating the local capacity to multiply and exchange seeds (Kent p.22). Or, instead of providing 'improved' hoes from outside the region, it is better to distribute quality steel plates, from which the blacksmiths can make the tools to the specifications of the local farmers (Sharland p.24).

Ecological agriculture

In a participatory study on the impact of hurricane Mitch in Central America on 1804 farms, conventional and alternative farmers concluded that sustainable agriculture applied by the farmers of the Campesino a Campesino movement is more resilient to hurricanes than conventional agriculture (Holt-Gimenez p.18) - a conclusion fully affirmed by FAO (p.20)! In fact, Green Revolution agriculture, also in permanent large-scale plantations, e.g. of oil palms (Uran et al. p.16), contributes strongly to the increase in ecological vulnerability of agriculture, just as large scale deforestation and over-grazing and soil mining by low external input farmers. Supporting development of LEISA therefore is an important strategy to increase the ecological and economic resilience of agriculture, mitigate disaster and guarantee food security. In Zimbabwe, organic agriculture and Farmer Field Schools appear to be effective in improving the situation of rural women-headed households affected by the HIV/AIDS disaster (Page p.28).

Public pressure needed

The Mitch study has also uncovered a conspicuous "policy ceiling" in sustainable agricultural development. Farmers concluded that the prevalent national credit, market, agrarian and research policies favour Green Revolution agriculture, deforestation and marginalisation of small farmers, rather than more resilient, ecologically sound land use. The lack of a favourable policy context, and the lack of political will on the part of national governments to create one, appears to block development of resilient and sustainable land use. Existing natural resource policies are therefore responsible for enhancing disaster or at least making it more serious. How can we improve this situation?

In Europe, the crisis around the Mad Cow Disease, and the epidemics of the animal diseases 'Swine Fever' and 'Foot and Mouth Disease' are symptomatic of the increasing unsustainability and vulnerability of industrialising and globalising agriculture. As a result, some political leaders, especially in Germany, have finally accepted that drastic policy changes are needed to prevent further disaster (Reijntjes p.36). Apparently such changes are only possible once people start to experience the impact of disaster and public pressure forces politicians to take responsibility for the agricultural production systems and the quality of food they produce.

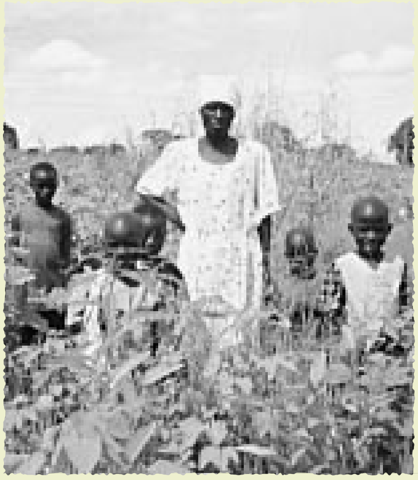
CONTENTS



ILEIA is the Centre for Information on Low External Input and Sustainable Agriculture (LEISA) in the tropics. ILEIA seeks to promote the adoption of LEISA through the LEISA Magazine and other publications. It also maintains a specialised information database and an informative and interactive website on LEISA (http://www.ileia.org). The website provides access to many other sources of information on the development of sustainable agriculture.

LEISA is about Low-External-Input and Sustainable Agriculture. It is about the technical and social options open to farmers who seek to improve productivity and income in an ecologically sound way. LEISA is about the optimal use of local resources and natural processes and, if necessary, the safe and efficient use of external inputs. It is about the empowerment of male and female farmers and the communities who seek to build their future on the basis of their own knowledge, skills, values, culture and institutions. LEISA is also about participatory methodologies to strengthen the capacity of farmers and other actors to improve agriculture and adapt it to changing needs and conditions. LEISA seeks to combine indigenous and scientific knowledge, and to influence policy formulation in creating an environment conducive for its further development. LEISA is a concept, an approach and a political message.

18 Measuring farmers agroecological resistance to hurricane Mitch

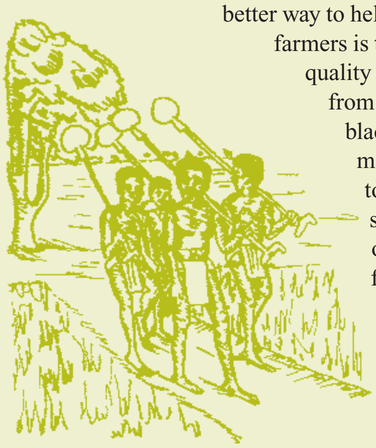
Eric Holt-Gimenez

The methodology and findings of an action research effort to measure and compare the impact of hurricane Mitch on conventionally and agroecologically farmed lands in Honduras, Nicaragua and Guatemala are presented. The study clearly shows the advantages of sustainable agriculture and farmer-led approaches. It also uncovers a policy ceiling to development of sustainable agriculture. The author states that it is due time to translate farmer-to-farmer successes on the ground into broad-based public pressure to influence national policy-makers.

24 Understanding local adaptation of tools in a relief situation

Roger W. Sharland

As people in civil war ravaged Southern Sudan have had to leave their homes in the face of fighting and famine, seeds have often become scarce and tools have been lost. In response, many mass produced East African hoes have been distributed by relief agencies. These 'improved' hoes, however, are not adapted to the specific conditions and needs of the local farmers who have a strong preference for their indigenous tools turned out by local blacksmiths. Roger Sharland discovered that a better way to help these farmers is to distribute quality steel plates, from which the blacksmiths can make the tools to the specifications of the local farmers.



DEAR READERS

By now you may have realised that we have changed the design of the newsletter and also revised its name; we now call it the LEISA Magazine on Low External Input and Sustainable Agriculture. How do you like it?

With the new team at ILEIA, presented to you in the last issue, ambitions are high and we hope to improve and expand the exchange of information on development of LEISA - agroecological approaches.

The theme of this issue is 'Coping with disaster'. We focus on the threats to production that regularly occur in the South such as drought, floods, hurricanes, war, HIV/AIDS, etc. and the possible responses to them. The articles show the importance of traditional resilience strategies, site-specific agroecological practices and farmer-led approaches to enhance the resilience of farming, leading to disaster prevention in risk-prone regions. No less important in recreating agricultural production after disaster is that relief and development agencies build on the knowledge, skill, spirit, ingenuity and efforts of the farmers themselves.

In Europe, we are witnessing how the highly industrialised agricultural system has lost its resilience. Swine Fever, dioxin polluted feed and Mad Cow Disease are now being followed by outbreaks of Foot and Mouth Disease, showing clearly how agricultural development can lead to disaster. All of a sudden the sustainability of agriculture is a hot topic of discussion and features prominently in the daily newspapers. There is a lot of consumer pressure for safe food and in some European countries, such as Germany, the politicians have now actively taken a stand for ecological agriculture – at the expense of the hitherto strongly promoted and subsidised industrialised agriculture. In which direction should agriculture develop in your country?

The editors.

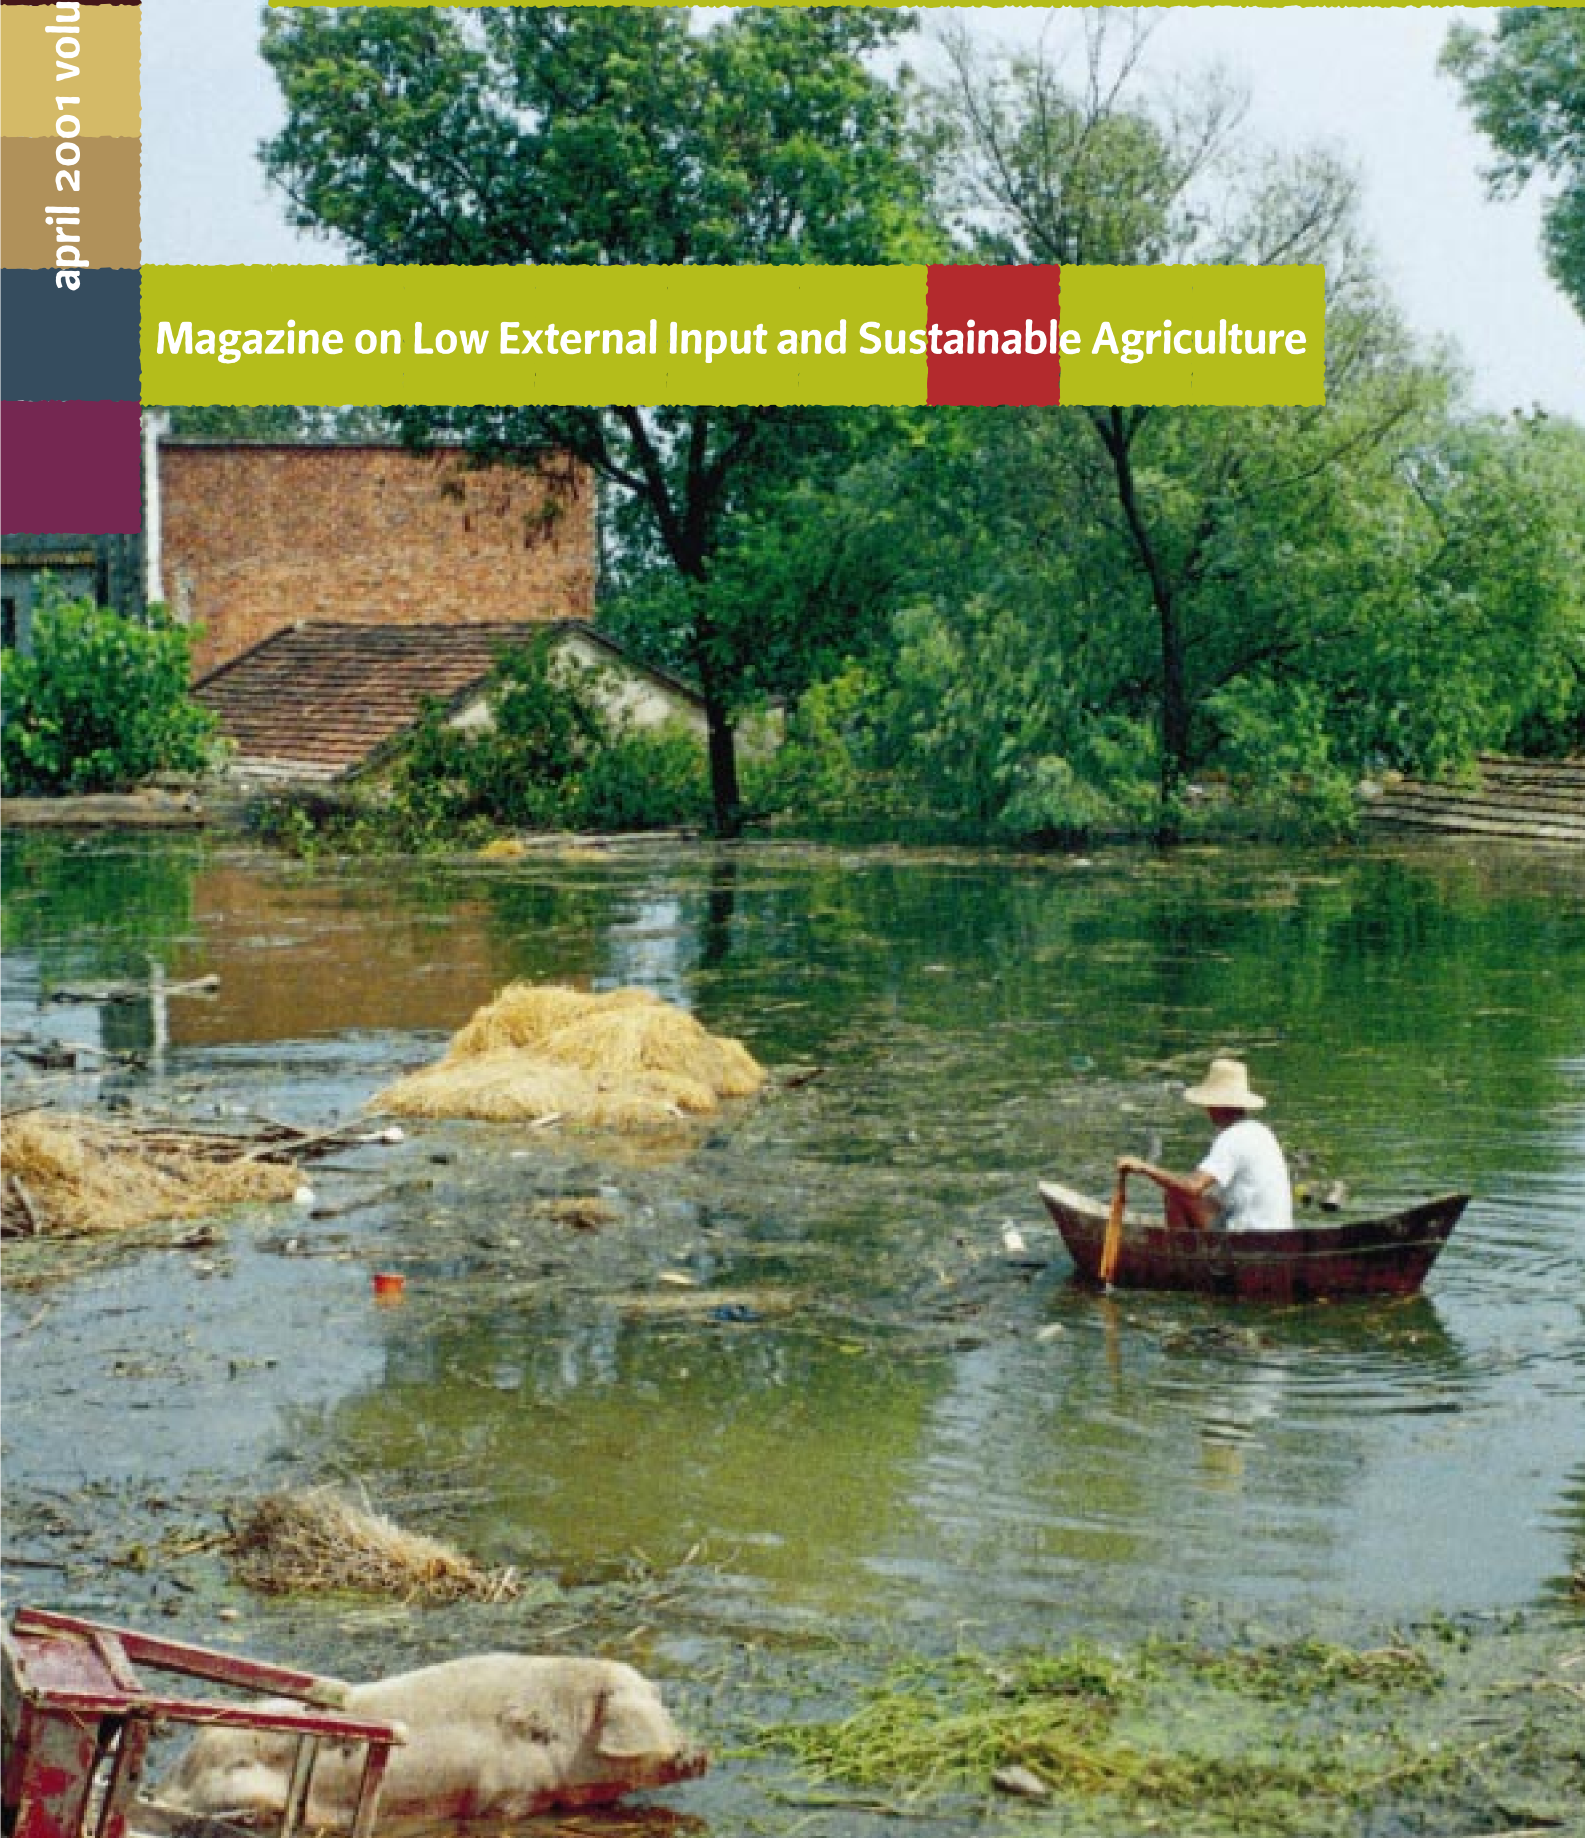
Magazine on Low External Input and Sustainable Agriculture

april 2001 volume 17 no.1



Coping with disaster

Poor information makes poor solutions

Degraded soils and low soil productivity are major constraints on the food security and income levels of small-holder farmers. Effective solutions require an integrated approach that takes biological, chemical, physical, social and cultural factors into account. It is, therefore, essential that stakeholders - international and local - know what information is available on the subject and have the capacity to use it to meet the specific needs of small-holder farmers. This was the subject of a recent *Centre for Technical Development and Agriculture (CTA ACP-EU)* seminar, where researchers, policy makers, communication specialists and representatives of NGOs and farmers discussed how information on soil fertility management could be more effectively used.

While much is known about soil and the technologies that can increase its productivity, little has been done to consolidate and make this information more accessible. There are many reasons for this:

- The results of research often remain within the scientific community and the experiences of farmer innovators remain within the local community;
- Information is lost as a result of policy shifts, re-organisations and staff changes;
- Skills and facilities to ensure systematic record keeping and documentation are inadequate;
- Responsibilities for land, agriculture and environmental issues are distributed between many different agencies and ministries making it difficult to obtain an overview of work done.

The seminar concluded that policy needs to be developed to support good documentation and communication practices. It is a matter of urgency to re-establish and strengthen the position of extension agencies and agricultural informati on services, which in many places have been undermined by structural adjustment and liberalisation programmes. This process has given international fertiliser companies a disproportionate influence over farming practices in many countries.

One speaker pointed out that *"poor people make poor soils and poor soils make poor people"*. But poor mechanisms for delivering and mediating information also mean that the poor are excluded from access to information that might provide effective and acceptable ways to increase soil productivity. The reduced capacity of extension and agricultural information services not only means that that small-holders' needs are less likely to be identified and researched but also that the media, which has the ability to reach farmers in their own language, has increasing difficulty in accessing information on agricultural and environmental issues.

CTA and other information management agencies and networks such as *AFNET* (African Network for Soil Biology and Fertility), *ILEIA* (regional and global magazines), and *WOCAT/SOTER* (an on-line biophysical information database) are all involved in collating, analysing and exchanging information on soil fertility and related issues. The conclusions and recommendations of other seminar participants suggested that priority should be given to improving the communication skills of all stakeholders, especially at the national level. More use should be also be made of local communication professionals to stimulate the flow of information in ways that will help farmers better understand local soil fertility problems and the opportunities for adopting technologies that offer appropriate solutions.

■

A full report of this seminar is available for CTA (ACP-EU), P.O.Box 380, 6700 AJ Wageningen, The Netherlands. www.cta.nl

Issue 20.2, June 2004

The next generation farmers?

Today rural communities are increasingly affected by external influence and rapid change. These processes affect the economic situation, change traditional cultures and particularly influence the younger generation. Are the communities still able to transmit the knowledge and values needed to build a livelihood in agriculture? Or is agriculture and rural life under such pressure that the older generation, perhaps even unconsciously, encourages their children to look outside farming for a future - even though this will deprive the community of one of its most valuable resources, its young people.

This issue of the LEISA Magazine will look at the situation and experiences of children and young people growing up in small-scale farming communities in the South. What livelihood opportunities are available to the younger generation? Are they prepared to make the best use of the natural and cultural resources available to them? To what extend does society at large, or formal institutions such as schools and community organisations, help young people to develop the skills they need to tackle the problems of living in, often resource poor and marginalised, rural areas? Do farmer training schemes and other development projects aimed at increasing the resilience and productivity of small- scale agriculture address the needs of the younger generation? Do boys and girls have different opportunities and needs and are these differences addressed?

Young people have always played an important role in rural life: they are strong, energetic and innovative. In the past they learned about their environment and farming from working side by side with the older members of the community. What are the options today? What are the visions of young people themselves ? What role do they play within their communities and what effect do their initiatives have on the natural resources, productivity and sustainability of the agricultural communities to which they belong?

We are interested in receiving contributions that describe initiatives and interventions that encourage and support rural children who wish to stay in the rural areas and build their future in these surroundings.

We would like to have your contributions by March 1, 2004.

You are invited to contribute to these issues with articles (about 800, 1600 or 2400 words + 2-3 illustrations and references), suggest possible authors, and send us information about publications, training courses, meetings and websites. Editorial support is provided. ILEIA offers to pay on request Euro 75.00 per article published in LEISA Magazine.

WOCAT World Overview of Conservation Approaches and Technologies

http://www.wocat.net/

WOCAT was established as a global network of SWC (Soil and Water Conservation) specialists. It facilitates more efficient use of existing know-how and, consequently, of development funds. It thus helps to optimise the implementation of appropriate SWC and to avoid duplication of effort. WOCAT's mission is to provide tools for SWC specialists to share their knowledge in soil and water management. Tools that assist them in their search for appropriate technologies and approaches, and that support them in making decisions in the field and at the planning level. WOCAT facilitates information sharing.

Saline lands

Searching expertise in bio-saline technologies? Check the website of the **Bio-Saline Project:** **http://www.undp-ausaid-biosaline.org/**
This community development project in Pakistan, coordinated by **IWASRI** (International Waterlogging and Salinity Research Institute), focuses on the utilisation of saline and waterlogged land through growing salt and waterlogging tolerant crops, trees, grasses and salt bushes. Establishing a vegetative soil cover is the first stage of soil reclamation. This vegetation (1) provides a protective cover of the soil against the harsh climatic conditions (2) allows the process of organic matter build up to occur (3) permits a more open soil structure development, and (4) encourages increased water infiltration that aids the removal of salts over time. Another option to find bio-saline experts is the databank of **Global BioSaline Network** managed by the International Centre for BioSaline Agriculture (ICBA) **http://www.biosaline.org/About.htm**

TRIOPS – Tropical Scientific Books Distribution

http://www.net-triops.de

If you are having difficulty in ordering books and publications on development issues and want to be sure your order is safely and efficiently dealt with, you may like to try TRIOPS. A family firm, established in Germany in 1789, it emerged as a publisher and supplier of tropical and sub-tropical scientific books before expanding its activities into development-orientated literature. Today, it offers comprehensive access to those seeking information on all aspects of development, including the technical, economic and social aspects of agriculture, the environment, natural resource management, trade and markets, as well as information and communications technologies. Its main customers are development agencies, scientists, librarians, research worker, development projects and booksellers. TRIOPS is a wholesaler and a book store in one so it can provide books at low wholesaler prices and give you the individual service of a book store. Its delivery service is cost effective and fast and it uses latest technologies in answering requests for bibliographies and other publication service information. In addition to its core activities it works to bring development orientated publishers together to discuss problems of associated with identifying and meeting publication needs in the South.

Wageningen International Studies Papers (Wisp'r)

http://www.gcw.nl/wispr/new/w2003_26_05.htm

The increasing salinity of the soils in the Sahel has long been acknowledged as a catastrophe for agriculture in the region. The cause of the problem is often attributed to the relatively new irrigation systems, which are believed to increase the amount of salt reaching the soil. Recent PhD graduate Piet van Asten concludes that this is not the case. Salt accumulation has more to do with the underlying bedrock, and decreased yields are more linked to a shortage of nutrients in the soil.

Seeds of promise for farmers

http://www.iaea.or.at/worldatom/Press/Focus/Chernobyl-15/farm.shtml

Farming communities in Belarus and Ukraine suffered heavily from the Chernobyl accident. Radioactive contamination of farm lands was widespread, making it hard to sell crops and foodstuffs from the region. Belarus scientists have found that some rapeseed varieties take up and store radio-nuclides from the soil in their stalks and seed coats, but not in the seeds. Growing this crop can improve the soil conditions and also yield marketable rape oil.

ACT: African Conservation Tillage Network

http://ies.uz.ac.zw/act-network/index.html

The African Conservation Tillage Network (ACT) facilitates sharing of information and experiences across sectors, disciplines and geographical boundaries among players and stakeholders involved in promoting adaptation and adoption of conservation farming principles and practices in Africa. Information is available through subscribing to their Newsletter; downloading leaflets; or through access to databases on conservation agriculture technology and cover crops. The cover crop database runs on a computer programme called **LEXSYS** (Legume Expert SYStem). This is a downloadable, searchable, database of herbaceous legumes developed by researchers in Africa, who are interested in integrating legumes into farming systems. It contains 91 data fields for each variety and the database can be searched using 47 different selection criteria.

Cover crops

Information about cover crops is widely available on the Internet. A good place to start is **Worldwide Portal to Information on Soil Health** **http://mulch.mannlib.cornell.edu/TSHomepage.html** A portal developed and co-ordinated by MOIST, and hosted by Cornell University (Ithaca, USA). This portal offers, amongst other things, links to databases on plant species including cover crops and to published information, including journals, extension material, and on-line newsletters and bulletins. It also gives a list of organisations working with cover crops: **http://mulch.mannlib.cornell.edu/TSOrganizations.html**.

CIDICCO

http://cidicco.hn/newcidiccoenglish/

CIDICCO is a NGO which has the objective of identifying, documenting, disseminating, researching and/or promoting research in the use of green manures and cover crops for small-scale farmers. Their web site contains several publications, including the bulletin "Cover Crops News". CIDICCO also manages the **Cover Crops Network** **http://cidicco.hn/newcidiccoenglish/information_network.htm**.
This is an informal network for the exchange of information on green manures/cover crops.

CIEPCA

The Center for Cover Crops Information and Seed Exchange in Africa
http://ppathw3.cals.cornell.edu/mba_project/CIEPCA/home.html
From 1998 to 2001, CIEPCA assisted researchers and development specialists to develop, target, and test appropriate cover cropping systems in Africa.

Beginning in 2002, CIEPCA was reconfigured as a web-based information centre on cover crops. It continues to provide access to on-line newsletters, Africa-based extension material and the French language cover crops electronic discussion group (EVECS-L). Extension materials on cover crops and green manures for small scale farming in the tropics can to be found on: **http://ppathw3.cals.cornell.edu/mba_project/CIEPCA/exmats/exmat.html**

Legume Research Network Project NEWSLETTERS

http://ppathw3.cals.cornell.edu/mba_project/ciepca/lrnpnews.html. The LRNP Newsletter is published twice a year by KARI (Kenya Agricultural Research Institute). In addition to reporting on network activities and coming events, the Newsletter publishes short articles on legume research, with a focus on research aimed at integrating legumes into smallholder agriculture.

IDRC

Cover crops for sustainable agriculture

http://www.idrc.ca/cover_crop/index_e.html.

This site contains research highlights on cover crops for sustainable agriculture. It also provides access to books on cover crops which can be downloaded free of charge.

A Communication and Natural Resource Management: Experience/Theory

http://www.comminit.com/stfaocommnrm/sld-8149.html

This new resource is published by the FAO's Communication for Development Group in the Extension, Education and Communication Service and was prepared as part of the Communication Initiative. It is designed to serve as a learning tool and takes the reader through a series of exercises that explore various theoretical approaches and field experiences in communication applied to different development interventions and Natural Resource Management (NRM) issues. The full text of the manual can be downloaded from this site.

Land Degradation and Development

http://www3.interscience.wiley.com/cgi-bin/jhome/6175

Land Degradation and Development is an international research journal that seeks to promote rational study of the recognition, monitoring, control and rehabilitation of degradation in terrestrial environments. The journal focuses on the causes and effects of land degradation; the avoidance, mitigation and control of land degradation and remedial actions designed to rehabilitate or restore degraded land.

Vetiver Network

http://www.vetiver.org/

The Vetiver Network is a non-profit Foundation with a mission to develop and disseminate information on the use of Vetiver grass for on-farm soil and water conservation, land rehabilitation, embankment stabilisation, disaster mitigation and pollution control.

Environmental Impact Assessment (EIA) training for sustainable agriculture and rural development: lessons and experience from Cambodia by Duffy P. The EIA training, which is the subject of this article, is meant to illustrate the importance of developing human resources through non-formal education and extension training, particularly in the protection of natural resources important to agriculture, fisheries and forestry. Environmental training is a high priority in Cambodia at present because it provides the knowledge, attitudes, and skills needed by professionals, officials and policy-makers to understand the complexities of the environment and to avoid further degradation.

GORA

http://www.aginternetwork.org/

AGORA is a portal developed by FAO to give access to agricultural scientific articles. It is aimed at users in Less Developed Countries.

IFDC

http://www.ifdc.org

IFDC is an international organisation, which aims to increase agricultural productivity in a sustainable manner through the development and transfer of effective, environmentally sound plant nutrient technology and agricultural marketing expertise. The Centre's facilities include libraries, pilot plant, laboratories, greenhouses and training facilities.

Issue 20.3, September 2004

Post-harvest management

Traditionally, researchers, extensionists and policy makers have given much emphasis to increasing crop and livestock production in the field, in order to improve farm incomes and food availability. Post-harvest handling and storage arrangements have often been neglected and not received the same level of attention. An astonishing amount of produce is lost post harvest, due to deficient transport, processing and storage techniques. It is estimated that worldwide post-harvest losses of agricultural produce are around 30%.

Taking better care and making better use of produce can enhance both farm incomes and food availability in a cost-effective way. It can also improve the quality and safety of the products because it may limit the growth of fungi or damage by insects, rats and the like. Good practices related to transport, processing and storage form the basis for improved post harvest management. Improved harvesting and packing techniques, and alternative means of transport may limit losses during transport from the field to the farm or to the market. Better and innovative methods of processing give the product a longer shelf life, making it possible to consume it over an extended period. Proper storage is very important if people have to keep products for their own consumption or if they have to keep seeds for the next crop cycle. In addition, post-harvest storage may add value to produce when it is sold, as market prices may be higher in certain periods.

Readers are invited to contribute their practical experiences on how proper post-harvest management of cereal grains, fruits, vegetables, livestock products and other rural produce have led to increased benefits for farmers. Experiences related to efficient and low-cost ways of storage, processing and transport are welcome.

Deadline for contributions is the 1st of June 2004.

You are invited to contribute to these issues with articles (about 800, 1600 or 2400 words + 2-3 illustrations and references), suggest possible authors, and send us information about publications, training courses, meetings and websites. Editorial support is provided. ILEIA offers to pay on request Euro 75.00 per article published in LEISA Magazine.

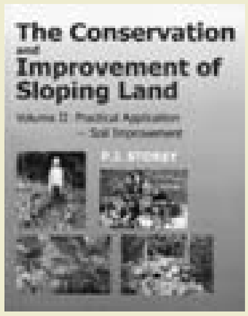
Biological management of soil ecosystems for sustainable agriculture: report of the International Technical Workshop organized by EMBRAPA-Soybean and FAO, Londrina, Brazil, 24-27 June 2002. 2003. 102 p. ISBN 92 5 104966 1 US$ 27.00. Food and Agriculture Organisation of the United Nations (FAO), Land and Water Development Division, Viale delle Terme di Caracalla, 00100 Rome, Italy / Publications-Sales@fao.org. (World Soil Resources Reports 101, ISSN 0532-0488).
This workshop was organised as a contribution to the joint programme of the Convention on Biological Diversity (CBD) and FAO. Scientists and practitioners from several regions joined efforts to review and discuss the concept and practices of integrated soil management, shared successful experiences and identified priorities for action. The workshop set out maximise the benefits (e.g. enhanced productivity and sustainability) of biological management of soil ecosystems. Based on working-group discussions, plenary sessions and existing knowledge and experiences, this report lays the foundations for the development of practical guidelines to promote on-farm research and technology development in integrated soil biological management. (WR)

Overestimating land degradation, underestimating farmers in the Sahel by Mazzucato V., Niemeijer D. 2001. 22 p. International Institute for Environment and Development (IIED), Drylands Programme, 3 Endsleigh Street, London WC1H 0DD, UK / drylands@iied.org (IIED issue paper no.101, ISSN 1357 9312).
This issue paper explores the evidence of land degradation in Burkina Faso and questions whether local farming practices are as unsustainable and environmentally destructive as many reports suggest. The paper discusses and analyses the reasons for land degradation in the region. This is followed by a discussion of local land management practices and social networks, and how they may contribute to sustainability and productivity. The conclusion is that land degradation is often overestimated because the abilities of local farmers are underestimated. Farmers have developed flexible, efficient, and effective land management strategies to deal with the limited availability of labour and external inputs, as well as the harsh environment in which they work. The challenge for future assessments of degradation is to incorporate the effect of farm management practices, including their social and institutional dimensions on soil loss, yields and nutrient budgets.(WR)

Farmers' initiatives in land husbandry: promising technologies for the drier areas of East Africa by Mutunga K., Critchley W. 2001. 108 p. ISBN 9966 896 63 5. Regional Land Management Unit, (RELMA), PO Box 63403, Nairobi, Kenya / relma@cgiar.org SIDA. (RELMA Technical Report Series no. 27).
This book is a follow-up to the 1999 publication 'Promoting Farmer Innovation' which looked at the methodology of working with farmer innovators. 'Farmers' initiatives in land husbandry' lays out case studies of 18 of the most interesting technical systems uncovered during three years of working with such innovators in East Africa. There is an abundance of illustrations and photographs. This is not just a technical manual, but also describes the people behind the initiatives. The methodology used to generate the data for the case studies was developed by WOCAT. This document is the product of collaboration between PFI, WOCAT and RELMA, which has proved to be a fruitful partnership. The book is aimed principally at field technicians and project managers in East Africa, but it is hoped that it will prove relevant to a much wider audience.

Response to land degradation by Bridges E.M., Hannam I.D., Oldeman L.R. [et al.] (eds.). 2001. 507 p. ISBN 1 57808 152 1 US$ 32.-. Soil and Water Conservation Society of Thailand (SWCTS), Bangkok, Thailand. Science Publishers, PO Box 699, Enfield, New Hampshire 03748, USA / www.scipub.net
This book provides a wide-ranging study of human responses to the causes and effects of land degradation. The background to the problem of land degradation is examined and the reasons for it described, giving the reader a comprehensive picture of the contemporary state of land resources. The driving forces that cause land degradation and impacts they have upon the environment are illustrated by case studies. Linking the two parts of the book is a section concerned with the methods for assessment and monitoring land degradation. The concluding part of the book emphasises that technological solutions are often not successful without appropriate economic, social, legal and financial conditions.

The conservation and improvement of sloping land: a manual of soil and water conservation and soil improvement on sloping land. Vol. 2 practical application-soil improvement by Storey P.J. 2003. 262 p. ISBN 1 57808 250 1 US$ 56.-. Science Publishers Inc, PO Box 699, Enfield, New Hampshire 03748, USA / www.scipub.net ; sales@scipub.net.
The author of these books is a practitioner who has realised that most of his audience cannot afford a whole library of books and written a comprehensive manual covering virtually every aspect of this subject. It consists of three volumes and this, the second volume, deals with practical aspects of soil improvement. The wide practical experiences of the author, together with his intention to write expressly for field workers make this manual to an invaluable guide for rural development workers faced with the basic problems of farmers in the developing world. The book looks at the soil, how it develops, what makes fertile soil and what spoils soil. Topics covered in the book include soil chemistry and plant nutrition, ways of recognising and treating mineral deficiencies, identifying when fertiliser use is appropriate and improving soil texture. All the well-known LEISA technologies, such as zero tillage, the use of mulch and green manure, cover crops, crop rotation and inter-cropping are described and explained. Recommended. (WR)



Optimizing soil moisture for plant production: The significance of soil porosity 2003. 124 p + CD-ROM. ISBN 92 5 104944 0 US$ 53.-. Food and Agriculture Organisation of the United Nations (FAO), Viale delle Terme di Caracalla, 00100 Rome, Italy / www.fao.org ; Publications-Sales@fao.org. (FAO Soils Bulletin No 79; ISSN 0253-2050).
This publication discusses the processes, above, within and below the soil, that enable water to move and crops to grow. It contributes to raising awareness of possibilities for better use of rainwater and improved management of soils and provides a solid basis for sound, sustainable soil moisture management. It is intended for extension staff, other technicians, and farmers' leaders. The document is made user-friendly through the inclusion of a guide containing activities and exercises described in non-technical language, and by interspersing the text with illustrations and diagrams. The complete materials of this guide are included on the CD-ROM. (WR)

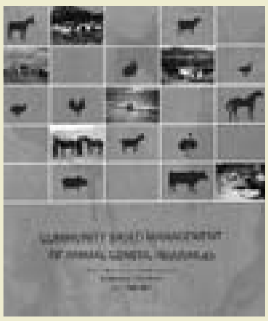
NEW IN PRINT

Land reform and peasant livelihoods: the social dynamics of rural poverty and agrarian reforms in developing countries by Ghimire KB (ed.). 2001. 112 p. ISBN 1 85339 527 7 US$ 27.50. IT Publications, 103-105 Southampton Row, London WC1B 4HH UK / orders@itpubs.org.uk ; www.itdgpublishing.org.uk.
Millions of small-scale farmers are vulnerable to hunger and poverty as a result of inadequate access to land and productive resources. This book argues that comprehensive land redistribution is key to improving rural livelihoods. A team of experts in field research, advisory work and the implementation of reform programmes, present a critical analysis of the performance of land reform efforts, and review the role of different actors in this process. The contributors scrutinise the inadequacy of the market-driven approach to land reform, which is linked to the structural adjustment policies of the World Bank. They convincingly advocate a flexible approach towards redistributive reforms as the most appropriate strategy for alleviating rural poverty. Recommended (WR).

La menace vient du nord: enquête sur le coton 2003. 69 p. Oxfam Solidarity, Vierwindenstraat 60, 1080 Bruxelles, Belgium / oxfamsol@oxfamsol.be
This folder explains the "cotton issue" in West Africa, whose poor cotton farmers will only be able to survive if the rich countries stop dumping subsidised cotton onto world markets. This case study also explores the more generalised problems of developing countries in increasingly globalised agricultural markets. (WR)

Good times and bad times in rural Java: case study of socio-economic dynamics in two villages towards the end of the twentieth century by Breman J, Wiradi G. 2002. 330 p. ISBN 90 6718 187 0 EURO 33.-. KITLV Press, PO Box 9515, 2300 RA Leiden, The Netherlands kitlvpress@kitlv.nl.
This micro-study on socio-economic dynamics in two villages along the coast of West Java, argues that since the onset of the Asian economic crisis, more than half of all households now live below the poverty level- a figure which official records have failed to identify. In contrast to the received wisdom that the villages still function as communities, the crisis has widened the gap between the rural rich and poor. This book discusses the repercussions for work and welfare in this rural area. (WR)

Community-based management of animal genetic resources: proceedings of the workshop held in Mbabane, Swaziland, 7-11 May 2001. 2003. 190 p. Food and Agriculture Organisation of the United Nations (FAO), Viale delle Terme di Caracalla, 00100 Rome, Italy / www.fao.org ; Publications-Sales@fao.org. GTZ.
This workshop was organised to develop a conceptual framework for community-based management of animal genetic resources. In the Southern Africa region about 75 percent of farm animals are kept by communal/smallholder stockowners. Animal husbandry therefore plays a key role in sustaining livelihoods of many such farmers. The sustainability of farming systems and food security is currently threatened by losses of animal genetic diversity. This workshop starts from the assumption that farmers are the custodians of farm animal genetic resources and are therefore best placed to manage these resources. (WR)



Pathways of change in Africa: crops, livestock and livelihoods in Mali, Ethiopia and Zimbabwe by Scoones I, Wolmer W (eds). 2003. 320 p. ISBN 0 85255 422 2 GBP 16.95. James Currey Publishers, 73 Botley Road, Oxford OX2 0BS, UK / sales@jamescurrey.co.uk
This book looks at the diverse ways in which cropping and livestock patterns are changing in three contrasting settings (in Ethiopia, Mali and Zimbabwe). The authors of this series of empirical case studies argue that mixed farming is not the only option for sustainable development. The book provides an analysis of the cases from this point of view. (WR)

Evaluating capacity development: experiences from research and development organisations around the world by Horton D. [et al.] 2003. 170 p. ISBN 92 9081 274 5. International Service for National Agricultural Research (ISNAR), PO Box 93375, 2509 AJ The Hague, The Netherlands / isnar@cgiar.org ; www.cgiar.org/isnar
This book is the result of a collaborative effort involving many individuals in research and development organisations from around the world. It draws together the experience and insights from six evaluation studies carried out under the umbrella of the 'Evaluating Capacity Development"(ECD) Project, co-ordinated by ISNAR.
Capacity development currently attracts a great deal of attention and considerable sums of money are spent promoting it. Yet there have been only limited systematic evaluations of such efforts, hampering attempts to draw lessons that could improve future programmes. This book is written for managers and evaluators in research and development organisations. The authors used examples and lessons drawn from the evaluation studies as a basis for identifying how capacity development efforts and evaluation can help organisations to achieve their missions.(WR)

Agroforestry by Verheij E. 2003. 85 p. ISBN 90 72746 92 9. AGROMISA, PO Box 41, 6700 AA Wageningen, The Netherlands / agromisa@agromisa.org CTA / cta@cta.nl. (Agrodok ; 16).
This completely revised Agrodok focuses on tropical agroforestry, which straddles the disciplines of tropical forestry, plantation tree crops and tropical fruit and nut crops. However, forest trees and tree crops are at the fringe of agro forestry's concern. Its main focus is on so-called "auxiliary woody plants" which do not yield a marketable product, but are multi-functional and play a supporting role in cropping systems. As well as supplying fodder and/or fuel wood these functions include providing shade or shelter, serving as support (e.g. live stakes for climbers) or protection (a hedge to keep out cattle, or – on a slope – stemming erosion. This useful manual is available once again. (WR)

Moving in sand and time

Sushila Ojha

"There is a serpent on your chest
Oh land of dunes rise and awake
Open your eyes to reality
Leave the false illusions"

The great Thar desert covers much of Rajasthan. Receiving less than 160 mm rain annually, it is perhaps the driest region of India. It is a vast, arid, unfriendly and tough terrain with shifting sand dunes, sparse population, extreme temperatures, stunted vegetation and very little arable land. Faced with deep brackish ground water, erratic rainfall and recurring droughts local communities have developed a tradition of seasonal migration and livestock rearing. Every raindrop is valued and water harvesting has always been important. Despite these tough conditions, the desert has 12.8 million inhabitants.

Today the region is cross-cut by canals, all part of the vast Indira Gandhi Irrigation Scheme, IGNP, that bring in water from the Punjab. A vision to create prosperity in this desolate region was born in the early 1900s and became reality when, in 1948, work started on one of the world's largest irrigation schemes. Financed by the World Bank and using water from the Sutlej and Beas rivers, the scheme is still being developed. The IGNP uses 90% of the ten billion cubic metres of water diverted from the Punjab to feed its 7000 km of canals and to irrigate some 1,500,000 ha of agricultural land. The IGNP accounts for 8% of the total agricultural area of Rajasthan and has turned the state into a net exporter of food grains, cotton and groundnuts. The scheme has also brought sweet drinking water to the settlers in the command areas and to those living in the many urban centres and rural villages.

The introduction of large-scale, centralised irrigation has radically affected the area. Initially water from the canal was used for intensive flood irrigation of groundnut and cotton. Intensive mechanised agriculture using chemical fertilisers and pesticides was introduced and tenancies and share-cropping practices became common. Farmers' attitudes to the use and management of land and water changed. Traditional respect for these resources was eroded by the attractions of the cash economy and as a result the customs of water harvesting, fundamental for survival in this desert environment, have been forgotten.

1987 saw one of the worst droughts of the century and the irrigation system was unable to deliver enough water. URMUL, a NGO working in arid Rajasthan for the integrated development of the cattle rearers, realized the need to reconsider their approach.

URMUL was deeply concerned about the increase in salinity and water logging in Stage-1 and emerging dangers in Stage-2. Irrigation practices and intensive agriculture in Stage-1 area were harming the soil. Irrigation and seepage from the canals was causing water logging because the local gypsum hardpan prevented water percolating deep into the ground. Instead, excess water evaporated from the surface of the soil, leaving its salt content behind. Almost 13,000 ha of land was permanently under water in Stage-1 and 1200 ha had developed into marshy land in Stage-2. The land was ruined and farmers had to leave. Water logging, salinisation and siltation had become major problems for farmers in the command area. URMUL was also concerned about the speed with which the pastoral economy and lifestyle were changing.

In 1991, URMUL organised a workshop to assess the technical, economic and social impacts of the cash economy stimulated by the irrigation scheme. For the first time the voices of farmers, new settlers, agro-businessmen and marginalized farmers affected by the canal system were heard. After the workshop participants undertook a journey along the entire course of the main canal, from the head-works to the tail-end, to put observations made during the workshop into perspective.

Several new issues were identified:
- Social and economic disintegration
- Break up of family and traditional support systems

- Loss of village identity. Settlements were now known by the numbers of the distributaries or water channels e.g. 1 LKD means first settlement at Lunkarsar Distributory
- Obstructed or dry water courses or no supply at all in the areas at the ends of the distribution channels
- Resurgence of malaria
- Inappropriate policies for afforestation and sand stabilisation (large-scale Eucalyptus plantations)
- Inadequate health and education facilities in new settlements
- Market forces cause farmers double losses - harvest bought at low prices and agricultural inputs sold expensively
- Water disputes leading to violence and crime
- Women face new problems of social insecurity and isolation
- Malnutrition because crops grown are not part of traditional diet
- Values like social justice and equity eroded in this new context

The experiences during this journey lead URMUL to change its strategy - to one based on faith in local traditions, knowledge and skills. URMUL decided to begin work in the new Stage-2 settlements. Here, farmers were organised in *Chak samities* – a *Chak* being a group of fields irrigated by a common water outlet – to work in a participative way to find solutions to these problems.

Ensuring water

Because distribution channels followed the contours of sand dunes drifting sand could easily fill them obstructing the flow of water to the fields. After a communal problem resolution exercise it was decided to adopt the low-cost technique of covering critical parts of the open channels with locally available stone-slabs and mud mortar. Pits for trapping sediments were constructed before the covered part to prevent these tiny soil particles from settling in the covered water channels and clogging them. This cost effective, simple community managed project was very successful. It ensured water flow and enabled the farmers to grow two crops a year. With the support of the World Food Programme, the IGNP command area development authorities later took up this idea and scaled it up.

Most of the settlers had not considered it necessary to construct water harvesting structures when they settled in the irrigation scheme because they were surrounded by canal water. This meant that the first drought caused a water crisis. With little water in the dam the canals dried up and farmers realised their vulnerability. They started to reconsider traditional systems of water harvesting and began to construct *Kunds,* rainwater collection tanks, again.

Improve production

Excessive use of chemical fertilisers and pesticides in the command area had made the land infertile and yields were declining. As an alternative and to ensure rehabilitation, URMUL introduced organic vermi-compost and training in its production and use is an on-going activity. Today, it is an eco-friendly, safe and low cost option readily available to small-scale farmers. The Rajasthan Agricultural University in Bikaner has taken up the idea and is promoting it in other areas.

"*Rathi*" is an indigenous breed of cattle adapted to desert conditions. The breed has been ignored for a long time in favour of cows cross-bred with Jersey and Holsteins. However, these breeds turned out to be unsuited to arid conditions whereas *Rathi* herds had survived for centuries in the Thar desert needing little water and fodder yet providing high milk yields. URMUL is now trying to improve the *Rathi* breed with the support of National Dairy Development Board. The project has started with ten thousand milk producing families in Suratgarh and Lunkaransar in Stage-1, an area where land has been devastated by water logging.
The scarcity of fodder, especially during droughts, has always been a challenge for cattle rearers. Traditionally, fodder was harvested and stored in fodder banks. The stacking was done in a way that kept the fodder safe and edible for at least four to five years. However, with the development of the canal, this crisis management practice was ignored. The severity of the drought in 1987 encouraged URMUL to revive the fodder banks and they have now been reintroduced.

Social services

Another set of problems also needed attention. The tremendous resurgence of malaria caused an epidemic in the Western districts of Rajasthan, an area normally malaria free. This resurgence is the result of the environmental changes caused by the IGNP canal. The canal has changed the ecology and the waterlogged areas flanking the canal course have become breeding grounds for mosquitoes. In addition, 60-70% of the total malaria cases in the 1994 epidemic were caused by the deadly *Plasmodium falciparum*. Primary health care services are not available because of the scattered nature of the settlements. Therefore, URMUL trained 300 local women to be primary health workers. Most of them, although illiterate, have become experts in primary health care and they now provide reproductive and child health care which includes anti-natal and post-natal care while ensuring safe deliveries, the treatment of all primary health problems, immunization and health education. An indication of the success of this initiative is that the communities are subscribing to these health care services. Village health workers have also organized women's self-help groups (SHG). These micro-finance groups are running micro-enterprises such as community shops, fodder-banks, grain-banks and also provide for other community requirements. The SHG movement have made a tremendous contribution to empowering women socially and currently almost ten thousand women are members of SHG movement.

In order to provide some education for girls, education camps were developed and these have become popular throughout the canal area representing an alternative education and life-skills development programme. On average, one hundred girls stay together in one of these camps for six months. Away from their homes they remain in the care and supervision of specially trained teachers. The girls, who are between 12 to 18 years of age, have never been to school before coming to these camps and during their six-months stay they acquire competencies equivalent to primary level of education. In addition, they are introduced to the issues such as collective living, human values, gender-equity, health and hygiene as well as other life skills. Environmental awareness, water management, land use as well as cropping patterns suitable to local conditions are also included in their training. The success of these camps can be measured by the demand for more camps and the willingness of parents, especially from poor classes, to send their daughters to them. This activity is a long-term investment in human resource development and empowerment of women.

It is true that much of the change brought by the canal have helped raise living standards of the people in the command area. But over time it has become clear that total dependence on canal system is not sustainable. The farmers – disillusioned after their bitter experience – are again turning to the knowledge contained in their traditional customs and practices for solutions to the problems they now face.

Selective wood harvesting from shelterbelt trees by the government, not by the farmers. Photo: Lambert Onyewotu

Shelterbelts and farmers' needs

Lambert Onyewotu, Kees Stigter, Yusuf Abdullahi and Jo Ariyo

Nigeria, with more than 100 million inhabitants, is situated in West Africa and shares borders with Niger, Benin, Chad and Cameroon. Climatic conditions vary considerably from south to north. The south has a wet, equatorial climate whereas on the northern border with Niger it is hot and (semi-) arid. Agriculture in the northern region is characterised by millet monoculture. In areas with a little more rainfall, millet and sorghum are intercropped with cash crops such as groundnut and cowpea. The use of fertilisers, pesticides, improved varieties and machinery is generally limited. The Hausa, Kanuri and Fulani are the main ethnic groups who inhabit the area. A small number of nomads, mainly Fulani, visit the region with large herds of livestock.

Deterioration

Over the last 40 years serious desertification has occurred in northern Nigeria as a result of both natural causes and human activity. In recent years, there has been a gradual decline in rainfall. During the 1960s, the average annual rainfall in the city of Kano in Northern Nigeria was 825 mm. By the 1970s it had fallen to 700 mm and in the 1980s annual averages of about 650 mm were being recorded. Although rainfall remained fairly stable during the 1990s, farming under such conditions became increasingly difficult. In addition, population pressure has increased as labour migrants returned to the area after the oil boom in the South ended. As a result holdings have become smaller and fallow periods shortened. Vegetation cover has been eliminated as trees in natural parklands have been cut down, bush burning has intensified and overgrazing has continued uncontrolled. Over-used, unprotected and exposed to sun and wind, the soils in the area have degraded rapidly.

Trying to cope with desertification

In the 1970s, and especially during the great drought of 1972-1973, the scale of human suffering was so great that passionate appeals were made for official intervention to halt desertification. As a result the Kano State Forestry Department devised a programme of land rehabilitation using shelterbelts. They established more than 20 km of rainfed multiple shelterbelts - eleven in total - of *Eucalyptus camaldulensis* at Yambawa, 75 km north east of Kano and not far from the border with Niger. The area was a strategic one. It was near an important road used by caravans and traders and many returning migrants had started to resettle there.

The shelterbelts settled drifting sand and undulations and encouraged the return of soil protecting grasses. Farmers tried to make use of the improved microclimatic and soil conditions between the belts by growing millet.

Design errors

Unfortunately the Forestry Department made its decisions alone and they did not involve any other stakeholders in the planning process. There were no contacts between Department officials and outside engineers and scientists who could have supplied useful information about how to construct shelterbelts. In addition, the Department had very poor access to the literature about previous research and experience with windbreaks.

As a result there were several design problems with the shelterbelts. In order to deal with the problem of seasonal changes in wind direction, shelterbelts were established at an angle to the prevailing winds. This diminished their wind protective functions in both the wet and the dry seasons. As a compromise, and in order not to occupy too much farmland, the belts had also been established too far apart. The usual distance between belts is about 10 times the final height of the trees. The Forestry Department, however, spaced its belts irregularly from between 15 to 25 times the estimated final height of the trees. Because the belts were so far apart, they were unable to protect all the land between the shelterbelts and much of the soil was, therefore, left unprotected against hot winds and solar radiation.

The width of the shelterbelts themselves was arbitrarily chosen as 30 m, which meant they still occupied about 20% of farmland. Better results would have been achieved if the width of the shelterbelts and the space between them had both been halved.

No participation, no benefits

The farmers disliked the shelterbelts which took up much of their agricultural land. Our early research confirmed that the shelterbelts competed with their crops for water, light and nutrients, while offering limited protection to the fields they were designed to shield. Instead of Eucalyptus trees, the farmers would have preferred indigenous tree species that could have offered food, fruits, fodder or medical products. They disliked their farmland being occupied without compensation and the fact that they were not allowed to do any maintenance on the belts, such as pruning the front branches to stop the trees shading the front rows of crops, or coppicing (cutting back) which would have provided them with fuel wood.

The heavy demand for wood for fuel and for building provides an important reason for establishing a shared management system for shelterbelts and woodlots. However, at the moment management is in the hands of the Forestry Department and farmers are still not involved. Fuel wood from the shelterbelts can be obtained through official channels, but a survey indicated that only 40% of farmers get wood through these channels.

In 1993, it was estimated that some 3000 people were affected by these shelterbelts. Labour migrants continued to return home and the Forestry Department was convinced that these ex-farmers were returning because of the shelterbelts. This however, was a serious misconception.

Repeating errors in the future?

In the late 1980s, the authors started doing research – partly farmer-managed – on the shelterbelts to find out how the situation could be improved. The results of this research enabled the development of a number of concrete recommendations. It showed, for example, that root pruning and branch pruning were necessary precautions to reduce competition between millet and trees. The farmers took to root pruning without any difficulty because they could see its benefits. However, the Forest Department did not allow them to prune the branches because fuel wood collection and sale is the exclusive right of the authorities.

Research also indicated that better crop yields could be achieved by using higher inputs of organic fertilisers in combination with either of the following:

- The better design of multiple shelterbelts,
- Planting farmer- friendly scattered trees at appropriate densities in the wide spaces between the shelterbelts;
- Replacing shelterbelts by a system of scattered trees – the so-called parkland agroforestry traditionally used in the area – but with considerably improved densities.

Shelterbelts were established too far apart. Photo: Lambert Onyewotu

The *Forestry Research Institute of Nigeria (FRIN)* has presented these recommendations and the outcome of the participatory experiments at several seminars that have been attended by government extensionists and forestry staff.

At the moment the Forestry Department does not seem to have any plans for improving the efficiency of the shelterbelts. Present policy, financial restrictions and the lack of a tradition, at the official level, of participatory approaches to these types of issues are important constraints. At present, no workable solutions to the problems associated with existing shelterbelts are being developed, and alternative options, such as parkland agroforestry to rehabilitate soil and stop desertification, are not being considered.

During the day, nomads and sedentary farmers like to use shelterbelts for shading their cattle and themselves. Photo: Lambert Onyewotu

Real change requires participation, planning, coherence and resolve

The experience of Northern Nigeria confirms that soil management and rehabilitation policies must be set in the context of wider development objectives and a well-defined direction of social change. Federal and state authorities in Nigeria have an important responsibility in this respect. In developing a policy of soil rehabilitation, farmers' input not only provides important insights but is also necessary for establishing effective and communal management systems. These systems should have enabled the involvement of returning landowners and farmers, and must now also be capable of evolving to meet the agro-ecological and demographic challenges of the region.

In addition to securing farmers' participation, special extension intermediaries should be trained and equipped to improve the flow of information between researchers, farmers and government authorities.

Farmer Field School on nutrient management

Davies Onduru, Fredrick Muchena, Louis Gachimbi and André de Jager

The decline of soil fertility on smallholder farms is probably the main bio-physical cause of falling food production in Sub-Saharan Africa. One approach to halting this decline is Integrated Nutrient Management (INM). In Kenya, INM is being used to make the best use of local resources and to optimise the effects of external inputs. The project "*Integrated Nutrient Management to attain Sustainable Productivity increases in East Africa farming systems* (*INMASP*)" uses the Farmer Field School (FFS) approach in working with farmers to develop technologies that can contribute to ensuring reasonable levels of soil fertility and improve food security in the major farming systems in Kenya, Uganda and Ethiopia.

Agro-Ecosystem Analysis session in Mbeere District in Eastern Kenya. Photo: Davies Onduru

The INMASP approach is inter-disciplinary and involves socio-economic as well as agro-technical and environmental issues. INMASP projects seek to involve stakeholders at all institutional levels and its strength lies in stimulating an active and participatory approach to identifying farmers' needs and their experiences with soil fertility management. Farmer Field Schools (FFS) have become a key activity in working with farmers to develop and integrate INM technologies into small-scale and communal agriculture (see *LEISA Magazine* Vol 18 No 3).

Although there are over 1000 FFS in operation in Kenya, not many focus on INM or on the integration of livestock into mixed cropping systems in order to enrich nutrient cycles. Munyaka FFS is one of the schools created under the INMASP project. This FFS is situated in Mbeere, a district that lies in the dryland area of Eastern Kenya. It has been in operation for just one season and work is being done to integrate INM into local farming practices. The FFS is developing, testing and evaluating technologies based on the use of local organic resources (farmyard manure and *Tithonia* sp.) and mineral fertilisers (diammonium phosphate, DAP). The Munyaka FFS has 31 farmer members, 77% of whom are women.

Soils in the area are well drained and range from shallow to quite deep and include loamy sand and sandy clay loams, although some places are rocky and stony. Everywhere, however, there is evidence of depleted fertility with low levels of nitrogen, phosphorus, and organic matter due to erosion, limited use of inputs and poor management practices. Rainfall averages between 150-450 mm per year, with about two-thirds falling between October and November.

Smallholder farmers at the FFS site practise mixed farming. Their crops include maize, beans, cowpeas and sorghum and a number of other subsistence crops. There is some livestock - mostly indigenous breeds - including cattle, goats, and poultry.

Developing and testing interventions

During the FFS, activities to arrest soil degradation were developed through the following steps: literature review on soil fertility constraints in the FFS site; participatory identification of production resources, farming system constraints and priorities; experimental design workshop; regular FFS learning sessions on INM (special topics); Agro-Ecosystem Analysis (AESA) framework in the central learning plot; end-of-season participatory evaluation of experiments; and further data analysis for sharing with wider scientific community.

A survey was carried out to identify production resources. This included collecting details of farmers' socio-economic circumstances including the ownership of productive assets, farming practices, broader livelihood strategies, current opportunities, challenges of soil fertility management and farmers' indicators of soil fertility management. The findings of this diagnostic exercise were used to develop a FFS curriculum with farmers and to identify possible INM technologies for trials.

Soil fertility constraints were further diagnosed through soil sampling and analysis. During the FFS, the results of the analysis were presented to farmers in a clear, visual way and this stimulated a great deal of discussion. Farmers gained a better understanding of the current fertility status of their soil and in particular that levels of soil nitrogen, phosphorus and organic matter were low. Technologies jointly proposed by farmers and FFS facilitators as options for improving soil fertility included manure, mineral fertilisers, mulches, terracing, incorporation of crop residues into the soil, using leaves as fodder, agroforestry, slurry, *Tithonia* sp., composting, rock phosphate, green manuring and zero-tillage (conservation agriculture).

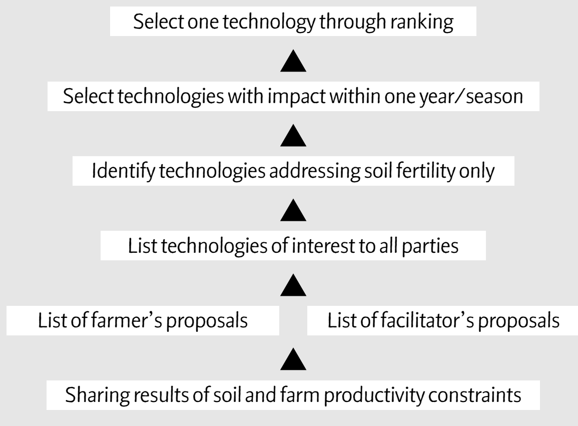

Figure 1: Process adopted for choosing technologies for experimentation

Results of surveys and assessments were discussed with farmers and used to select the technologies that would be tested in FFS central learning plot (Figure 1). The monitoring indicators to be used during the FFS were also selected. Table 1 shows the treatments that were selected through this participatory process.

Table 1: Treatments agreed upon in a PTD process in Eastern Kenya (Munyaka FFS)

Treatment	Description
T1	Farmyard manure (FYM), one handful per planting hole (16t/ha)
T2	DAP, one teaspoon per planting hole (216 kg/ha)
T3	$T_1 + T_2$
T4	$T_1 + T_2$ + Tithonia; Tithonia applied at 3.6 t/ha fresh weight

Results on the central learning plot

The FFS experience in Munyaka showed that INM-FFS not only improved farmers' analytical skills but also provided qualitative and quantitative data that could be used to evaluating the performance and impacts of INM technologies. Besides the farmers' analysis that takes place during each FFS meeting, further agro-economic analyses were done and shared with farmers in later FFS sessions.

At the end of the season, farmers' evaluation of the treatments in the central learning plot showed differences with regard to pest incidences, maize leaf colour, plant health, soil moisture retention, weed incidences and grain yields.

Treatments with combined organic and inorganic nutrient sources gave higher yields than single applications of organic or inorganic nutrient sources. The grain yields also increased with increased nitrogen and phosphorus applications. This suggests that low levels of nitrogen and phosphorus hinder maize production in Munyaka.

An analysis of the results achieved in the farmers' fields showed positive returns to labour for all studied technologies. These returns were higher than the opportunity costs (i.e. what could have been earned elsewhere). The combined application of Farmyard Manure and DAP, and Farmyard Manure, DAP and *Tithonia* sp. proved to be the most profitable practices. Although *Tithonia* grows wild in the area many farmers had not been aware of its potential in soil fertility management.

Farmers rated the combined application of farmyard manure, DAP and *Tithonia* as the best combination. They recognised that widespread adoption of this method would be limited by lack of money to buy DAP. However, a number of farmers have started collecting *Tithonia* cuttings (*Tithonia diversifolia*) from the roadside and nearby bushes to plant them within their farm boundaries.

Farmers also identified and monitored the presence of pests and beneficial insects. They found that treatments that included farmyard manure attracted a relatively high diversity of pests but also beneficial insects.

Impacts of tested INM technologies

Analysis of soil nutrients (the soil nutrient budget) showed that the amount of nitrogen removed from the soil under normal cropping practices was greater than the amount returned to the soil. In other words there was a negative balance in the soil nutrient budget. The combined application of farmyard manure, DAP and *Tithonia* resulted in a less serious loss of nitrogen than the current practice of using a single application of farmyard manure or DAP. This showed a clear benefit in using organic and inorganic inputs in combination. The synergy created had a positive effect on the nutrient depleted soils in the study site.

Communication and information

The INM-FFS have shown that they can provide a forum for strengthening linkages between farmers and other consortium partners with experience, skills and information on soil fertility management. The experience of joint learning and the effective exchange of information in the Munyaka FFS created a sense of ownership amongst farmers which is an important factor in encouraging them to put their newly acquired INM skills into practice.

Joint problem diagnosis during the FFS platforms brought Government and non-governmental organisations together to define priority problems and opportunities for research and extension. It has also provided a strong foundation for on-going cooperation and information flows and exchange. The FFS platforms have also contributed to bridging the gap between agricultural extensionists, researchers and farmers, providing a forum through which these stakeholders come into regular close contact with farmers.

Although FFS on INM is appreciated by both sexes, women in particular seem to value the approach, due to the practical, field based, learning focus as well as the social value of FFS groups.

Conclusion

No single institution can meet all the challenges involved in improving soil fertility management, which can only be overcome by building partnerships between farmers, extension agents, private sector, researchers and policy makers and, more importantly, by enhancing information exchange. Experiences from FFS in the Mbeere district has shown that INM-FFS can be used to stimulate information exchange, design and test INM technologies and increase the pace of technology adoption. The documentation and analysis of quantitative and qualitative data generated during FFS process has created room for wider sharing of FFS outputs both at the farm level, and amongst the scientific and policy communities. Furthermore, the study has shown that there is need to adapt the methodology to maximise the use of local resources (for example, *Tithonia*) and optimise application of external inputs, where available. The challenge is to bring indigenous and scientific knowledge together under one umbrella, which is usually easier said than done.

Agroecological restoration in Guangdong

Peter Riggs

In 1980, Guangdong Province became one of China's new Special Economic Zones, encouraging foreign investment in manufacturing and light industry. Today, the province's capital is a major banking and financial centre but agriculture continues to contribute heavily to Guangdong's GDP.

The developments of the last 20 years have, however, had a serious impact on the environmental health of the countryside and as a result on the welfare of many farming communities. Several food safety scares over the past few years have also underscored the importance of developing 'new thinking' for this vital sector.

In response, provincial leaders in partnership with Guangdong's agricultural university and its network of extension agents and consumer health specialists, have risen to the challenge.

Guangdong is now dramatically re-orienting its food production and agricultural research systems, putting long-term environmental sustainability, farmers' welfare, and the promotion of chemical-free and/or organic agriculture at the centre of provincial rural development efforts. Guangdong is skilfully positioning itself to take advantage of rising Chinese consumer awareness of food safety and quality concerns. At the same time it is also securing the position of the province's agricultural export sector under the new international rules that China must now follow as a result of its accession to the World Trade Organisation.

Guangdong has never been a "rice bowl" in the sense of committing vast acreage to growing staple grains. Rather, Guangdong has long enjoyed comparative advantage in the production of sub-tropical fruits, sugar cane, as well as farmed fish and horticulture products. The flat and well-watered Pearl River Delta region in southern Guangdong was famous for the "dike-pond" agriculture system, in which farmers devote the major share of their acreage to ponds for raising fish, particularly carp, and recycle pond wastes onto the bunds and dikes fringing the ponds to grow citrus fruits, sugar cane, pineapples, and mulberry trees for feeding silkworms. But 80% of Guangdong's land is hilly, and in this sub-tropical climate zone the soils are generally poor and easily eroded. The "Great Leap Forward," the Cultural Revolution and insecurity over land tenure in the late 1970s and early 1980s, all accelerated deforestation in Guangdong Province leading to alarming levels of soil erosion. Indeed, control of soil erosion has been a major concern of the Guangdong government for the last twenty years.

Today, Guangdong is one of China's wealthiest provinces and has the resources to deal with the alarming legacy of environmental damage caused by the policy instability of earlier periods. Increased wealth has also meant that the priorities of local consumers have shifted and they are increasingly concerned about food quality and safety.

The major agricultural policy challenge facing the province in the early 1990s can be summarised as follows: How can Guangdong meet the food production and food quality demands of international markets and a growing number of concerned Chinese consumers, whilst at the same time halting the degradation of the rural land base and reducing reliance on dangerous pesticides and chemical fertilisers?

Research and development

Two institutions have played a key role in Guangdong's agricultural transformation: the province's agricultural university, South China Agricultural University (SCAU) and the Provincial Committee For Science And Technology. Together, they have organised agricultural research and development as well as complementary research on large-scale land restoration.

By the 1980s, soil erosion had reached such alarming levels that in many cases the province opted for, or had no choice but to implement, "engineering" solutions that sought only to stabilise hillsides and watercourses. Bracken fern and pine trees were adopted as "green cover", useful for quickly reducing erosion rates, but not useful as economic crops for farmers. Gradually, the provincial institutes for geography and botany, and the university extension services, sought to integrate farming communities into land rehabilitation efforts. In the 1990s, Beijing authorised local governments in China to auction off degraded hilly lands to the highest bidders. In Guangdong, the bidders included individual farm families, local production co-operatives, or private companies. These "wasteland auctions," as they were called, again focused attention on the productivity-enhancing technologies that could be used to bring these lands into production while keeping soil erosion to a minimum. The wasteland auctions were also an innovation with respect to the rights of landholders. Now, families and enterprises could count on long-term tenure security, which made the construction of terraces both possible and profitable. Consequently, in the last ten years we have seen an immense input of labour and capital into terracing, primarily for the production of fruit trees. First amongst these fruit trees is the lychee, which has brought much prosperity to rural Guangdong.

Orchards

Guangdong accounts for a high proportion of the *global* production of lychee, a much-coveted fruit in China and amongst overseas Chinese. At a number of research stations in lychee-growing areas of hilly Guangdong, SCAU has been involved in developing organic and "high-quality" production lines. Pest management has been a particular concern and research has focused on biological control, promotion of organic fertilisers through on-farm composting, and the inter-cropping in fruit orchards of species that provide a habitat for those "natural enemy" species that keep pest numbers in check. The diversity of production settings resulting from the "wasteland auctions" has been a complicating factor in the design of appropriate extension services; yet at the same time, has helped ensure a wide range of experimental settings.

As more of Guangdong's farmers and agribusinesses become interested in integrated pest management to reduce production costs and to enhance product quality, farmers and farm managers are paying greater attention to the environment in which "natural enemies" of pests can thrive. In the past the practice of clearing all the brush and grass from orchards was widespread, even though farmers had no other explanation than that the bare soil "looked better" than an unruly ground cover. Now, farmers increasingly realise that this under-story provides a good environment for insects what can dramatically decrease the need for spraying pesticides. The new frontier for research now is whether it is possible, and whether it makes economic sense, to pursue inter-cropping of annuals (like peanuts or maize) or Chinese medicinal plants to add another source of income from orchard lands. Already, one can see areas in which trees are planted farther apart to enable this kind of agroforestry approach.

Cutting the legume Stylosanthes guianensis for decomposition on the farm. Photo: Jianwu Wang

The drive to increase soil organic content has led to two further technical improvements. The first is an increased integration of animal production into these farming systems. The excellent price that farmers obtain for lychees has allowed many of them to set up piggeries, or chicken houses, with pig and chicken wastes recycled back to the orchards. Some parts of Guangdong also have a very high adoption of household-level biogas systems, with pig wastes making the major contribution to these systems. Farmers have also found that having "free range" chickens in the orchards has helped reduce pest problems and increase nutrient cycling.

Some municipalities in Guangdong have also experimented, with some success, in recycling municipal wastes back to farms. In the worst cases, municipalities see this as a "low-cost option" for dumping garbage in areas where farmers are desperate for *any* contribution to soil organic matter. Now several large-scale municipal composting facilities are being set up. Odour control, product quality, investment, and urban-rural linkage schemes remain major challenges for these ventures. The question of how to transform urban China's growing solid waste problem, through better waste separation and composting, into a stream of benefits for farm communities is a new frontier for research and development activities.

Sustainable agriculture

Guangdong has developed the technical capacity to reorient its rural sector toward "sustainable agriculture." With South China Agricultural University as the focal point, Guangdong hopes to build the service infrastructure for organic production. There is political will at the provincial, county, and township levels to implement changes in orientation, but in most cases there is still a generally weak understanding of what is required to meet international organic production standards. In addition, there are still a number of issues that urgently need to be addressed.
One of these is water pollution. The continued over-reliance on chemical fertilisers and the increase in concentrated animal feeding operations are wreaking havoc with surface water quality. There is an urgent need to develop organic fertilisers, improve municipal solid waste management (including through composting of the organic fraction of urban wastes) and prioritise the safe handling of livestock wastes. Much of SCAU's research also focuses on the development of botanical pesticides and on the chemical interactions between insect predators and preys.

Another critical issue is the re-tooling of extension services. The move from a centrally-planned economy to a market economy has completely changed the conditions under which the agricultural extension services have to operate. In Guangdong, many extension services have been privatised. A variety of public-private partnerships might be explored, but it is crucial that the worst abuses of the "contract farming" approach found elsewhere in Asia be avoided.

Conclusion

While the immediate driving force behind Guangdong's rural-sector reorientation is a concern for the competitiveness of its agricultural products in markets increasingly concerned with food quality and safety, the goals of the reorientation are much broader than this. They include restoring a degraded land base; maintaining rural communities and reconnecting them with local cultural traditions; and combating severe surface- and ground-water quality problems. To achieve these goals, scientists and planners in Guangdong have become practitioners of *agroecological restoration*, the attempt to "reconnect food systems with ecosystems." Of course, one can see such efforts in other parts of China; but it is in this wealthy southern province where the farm-to-table market opportunities, the "knowledge infrastructure," and the political willingness to innovate have come together most dramatically. Guangdong's changing countryside may hold important answers not just for the future of agriculture in China, but also for rural livelihoods generally, in response to the challenges posed by globalisation.

Indigenous fodder trees for rehabilitation

Blesilda M. Calub

In the hilly communities of Western Batangas, South Western Luzon in the Philippines, farm households depend largely on the sale of livestock as a source of income, and are farmers therefore highly concerned about the available fodder supply. In this area, the main farming system can be characterised as slash-and-burn or swidden agriculture. Patches of land (0.5-1.0 ha) are cleared from tropical rainforests and then planted with food crops such as corn, rice and beans. After growing crops for two to three years, the area is left fallow for four to ten years. These fallow lands are used as grazing areas and consequently do not get the chance to recover. Instead, grazing animals cause land degradation through overgrazing and trampling the land. Manure and urine return only a limited amount of nutrients to the soil. Furthermore, the fallow lands usually only provide poor quality forage. The livestock carrying capacity of these grasslands is low because of the predominance of poor quality pasture grasses such as *Imperata cylindrica*, *Themeda triandra* and *Chrysopogon aciculatus*.

Cattle and goat raisers have traditionally relied on indigenous fodder trees and shrubs as animal feed. They shifted to *Leucaena leucocephala* (ipil-ipil) when this multipurpose tree was heavily promoted in the 1970s. However, after a psyllid (an insect) attack destroyed *Leucaena* stands in 1985, farmers showed a renewed interest in the use of indigenous fodder trees and shrubs, although the remaining *Leucaena* stands continue to be utilised.

Farmers carrying fodder over long distances. Photo: Blesilda Calub

Farmers appreciate fodder trees and shrubs as they play an important role in bridging the gap in fodder supply during the critical dry months. Being perennials, trees are more able to withstand prolonged periods of moisture stress than grasses. In addition, fodder from trees and shrubs have a high nutrient value that supplements the, often poor, quality of crop residues, the normal feed during these dry months. However, harvesting of fodder trees and shrubs has often been so heavy that the trees cannot regenerate as it prevents trees from producing the seeds required for natural regeneration. Despite these problems, farmers were not inclined to plant fodder trees. They believed that, being indigenous, these trees would grow by themselves. At the same time farmers also pointed out that fodder trees and shrubs that used to grow around their homes have now receded farther into the mountain forests. They now need to travel further and spend more time gathering tree fodder.

Domestication of fodder trees and shrubs

From 1997 to 2002, a project on the domestication of indigenous fodder trees and shrubs was undertaken to address these problems. The project had an action research/participatory technology development approach. On-farm trials were conducted with farmers to help refine technologies that would fit into existing farming circumstances. Farmers participate in the programme because they liked to experiment and try out new technologies. They were also attracted to the idea of having an assured supply of fodder.

A Participatory Rural Appraisal (PRA) was conducted to understand the existing silvipastoral systems, identify the different fodder trees and shrubs and rank them according to characteristics identified by farmers and project staff. We then continued to study the “highly preferred” species, looking into propagation and nursery techniques, herbage production, cutting management and persistence studies as well as feeding value and nutrient composition.

Farmers’ preferences for tree species

The species included in the research were identified in collaboration with farmers. Farmers’ preferences for certain fodder species were based on feeding values (palatability and ability to fatten), tree growth characteristics (fast regrowth, ease of propagation and establishment) and tree management issues. For farmers it is important that the trees are tolerant of frequent cutting and the cut herbage is easy to handle.

Farmers like to plant various different species as they say that animals do not like to eat the same fodder all the time, but prefer to consume mixtures of several species. Other farmers pointed out that they prefer fodder species that serve other purposes as well. For example, they prefer to plant fodder trees that can also serve as fence or border markers or can hold soil in very steep portions of their fields.

Many farmers still want to plant *Leucaena* despite the psyllid infestation. According to them, *Leucaena* is fast growing, it can fatten animals quickly and the animals like it a lot. However, some farmers only plant *Leucaena* because they believe that it is not necessary to plant indigenous species.

Preferred planting sites

Farmers have started planting fodder trees and shrubs along farm boundaries and in backyards. Many farmers are limited to these planting sites as their farmland areas are small or because they do not own their land. But they also prefer fodder species to be near their homes to save time gathering fodder. Women in particular indicated that they prefer planting near the house so they do not have to go far for fodder or leave their homes for a long time. In addition, planting near home reduces the risk of fodder being surreptitiously collected from their trees by others. Planting along boundaries is also done to mark the borders and to ward off stray animals.

Farmers with relatively larger holdings (2-4 hectares) can plant fodder trees as hedgerows integrated with crops. Those with larger fields in steeply sloping areas have established several hedgerows of *Leucaena* or *Gliricidia*. They were pleased to see that soil gets trapped on the upper slope of the hedgerows. These farmers may also plant trees in blocks as fodder banks in areas where crop farming is difficult. This is often on steep slopes or near waterways. However, farmers will prioritise planting food crops wherever possible. In general, they only consider planting fodder trees, or some fruit trees, where the land is not suitable for food crops.

Fodder production

Some trees, such as *Leucaena, Gliricidia, Muntingia calabura, Erythrina orientali* can start producing fodder as soon as six months after planting. Other species like *Trema*, need at least nine months, or in the case of *Macaranga* and *Pipturus* 10-12 months, before they can be cut for fodder. *Streblus asper* and *Albizia saman* are very slow growing in the first three years, which makes them difficult to recommend to farmers, although they have a high nutrient content and are relished by animals. Instead of planting, farmers were advised to allow the natural stands of this species more time to regrow, so they would not die.

Depending on the tree species and soil conditions, average edible herbage yields from 90-120 day old regrowing trees is 1.5 kg dry matter per tree. At this rate, 400 trees will yield 600 kg fodder. If a 300 kg cow consumes 7.5 kg dry matter per day, it will be assured of good quality feed for 80 days. In practice, however, farmers try to extend the availability of green fodder throughout the dry season. Usually, they will give their cattle tree fodder once a day (about half of what is required) and for the rest of the day, the animal feeds on crop residues or grazes the remaining grasses in the fields. If the farmer has some spare cash, he may mix some rice bran and salt to the water. In most cases however, his animals will be mainly dependent on tree fodder to survive this critical period.

The frequency of cutting fodder or harvesting from these trees depends not only on the species but also on the season. *Leucaena* and G*liricidia* can be cut every 60 days during the rainy season but every 90 days during the dry season. *Trema orientalis, Muntingia calabura* and *Macaranga tanarius* can be cut every 90 days during the rainy season and every 120 days during the dry season. *Streblus asper* can only be cut every 4-6 months.

Farmers' management of planted trees

Trees planted on or near crop fields need to be cut regularly to keep them from shading the crops. This may cause a problem, as the trees need cutting at the beginning of the cropping season when labour is in short supply. In this area, however, overharvesting is the more pressing problem. Trees tend to be cut too frequently, when there is little regrowth and this can threaten their survival.

About 30-40 farmers in various villages continue to plant indigenous fodder trees and shrubs using seeds (for *Leucaena, Trema orientalis* and *Macaranga tanarius*), stem cuttings (for *Gliricidia* and *Pipturus arborescens*) and wildlings (for *Muntingia calabura* and also *Trema orientalis*). Some also plant *Flemingia rostrata* and *Desmodium rensonii.*

Challenges

Promoting tree planting for the purpose of rehabilitating degraded lands is not, in general, appealing to farmers. But they can be easily motivated to plant certain species such as fodder trees and shrubs that directly address their needs. Promoting fodder tree planting in degraded grazing lands is like hitting two birds with one stone. On the one hand, it helps meet livestock raisers' needs for fodder, and on the other hand, trees help alleviate degradation.

Successful adoption by farmers, however, does not happen overnight. It involves working hand in hand with farmers in analysing the root causes of their problems, identifying possible solutions, and testing these together. In addition to involving the farmers in research activities, it is useful to conduct complementary activities such as training seminars. These should not only focus on the technical aspects of growing and managing the trees but also on enhancing farmers' appreciation of sustainable resource management. On-going monitoring and evaluation with the active participation of farmers is also important.

Capparis micracantha	4	5	4	11th

Farmers' criteria range from 3 (lowest possible score) to 9 (highest possible score)
Overall rank ranges from most preferred (1st) to least preferred (11th)

Using weed to fight weed

Paul B. Okon and Uche C. Amalu

The most devastating weeds are usually found on farmlands degraded of fertility and they can make or break a farm and lead to a total loss of yield. Two types of grasses have wreaked havoc on farms in Nigeria: Spear grass (*Imperata cylindrica* (L) Beauv.) and Running Carpet grass *(Axonopus compresus)*. The former is most common on degraded farms in the savannah areas, while the latter is mainly found in Nigeria's rainforest zone. Currently, these grasses infest thousands of hectares, and their elimination is required in order to rehabilitate the agricultural productivity of these areas.

Weeds as allies

Local farmers in southern Nigeria know that a number of broad-leaf (dicotyledon) weeds are capable of suppressing and, in time, replacing other weeds. They have found that a plant, known locally as "*Awolowo*" or "independence weed", is able to eliminate Carpet grass on degraded farms. However, Awolowo (*Chromolaena odorata*) can also become quite a menace itself (see Box 2). The capacity to suppress grassy weeds is not unique to Awolowo. It is known that a number of cover crops like *Centrosema pubescens* and *Mucuna pruriens* are also able to do this. As broad-leaf plants they compete vigorously with the grassy weeds for light, shading these grasses with their dense canopy and eventually containing their growth.

Box 1: The burden of weeds

Weed control may be one of the most labour intensive practices in crop production. In traditional Nigerian agriculture weeding is usually done by hand. In the tropical rainforest zone, three rounds of weeding are required before the crop is sufficiently well established to smother their growth. It has been estimated that in small-scale production systems weeding consumes between 30 to 54% of the total amount of labour, depending on the crop and the level of other available resources. It takes about 280 hours of labour to weed one hectare twice. Weeds are among the most serious pests farmers have to contend with, and fields are often abandoned when weed pressure become unmanageable.

- Source: Chikoye, D. 2000. **Weed Management in small-scale production systems in Nigeria.** In: Agronomy in Nigeria by M.O. Akoroda, Dept. of Agronomy, Univ. of Ibadan, Ibadan, Nigeria. pp. 153-156.

In order to get rid of Running Carpet grass farmers collect Awolowo seeds available in the vicinity of their farms and spread them in their fields at the beginning of the rainy season. After it has become established it is occasionally cut back (a process known as *slashing*) to encourage vigorous and timely re-growth. The slashed material itself is used as a mulch to further suppress the grass. The operation is considered successful if it suppresses the grass from maturing to the seed bearing stage. Awolowo is cut back up to three times, usually during the rainy season. This practice means that farmers have to leave their land fallow for a year or more, but they consider it a small price to pay as it is preferable to shifting cultivation sites every three or four years, just to get some relief from Carpet grass. Other options such as expensive herbicide are beyond the farmer's means.

We think that Spear grass can be dealt with in a similar way. This weed is already being suppressed using cover crops in Benin, where over 14,000 farmers are using *Mucuna* species to increase maize production and suppress Spear grass. However, using Awolowo or other cover crops to get rid of Spear grass is a more difficult business. This is because Spear grass does not reproduce through seeds but through stolons or shoots at, or just below, ground level, which take root and develop into new plants. These stolons must be dried out before Awolowo or cover crops are introduced. Fields infested with Spear grass need to be ploughed twice a year in the middle of the dry season, before the seeds of broad leaf plants like Awolowo, *Centrosema*, and *Mucuna* are spread at the beginning of rains. The exposed stolons dry out and the Spear grass plant cannot effectively reproduce. Ploughing also has to be repeated the following year to ensure that no stolons survive.

Box 2: Awolowo, a "bad weed" revisited

Awolowo, also called "Siam weed" or "Independence weed", is a shrub native to South and Central America and can grow to more than three metres in height. In recent decades it has become a serious pest in the humid tropics of South East Asia, Africa and the Pacific Islands. However, some researchers and farmers have found it a useful ground cover under certain conditions. Farmers in South Cameroon have adopted Chromolaena odorata fallows in groundnut based cropping systems because of its accretion of organic carbon and plant nutrients. Its use as a natural weed suppressor is now under investigation.

However, the plant should only be used in areas where it is already common. It should not be introduced into new areas!

Kick-starting legumes

Ken Giller

Leguminous plants must rate among the most bountiful and perfect gifts of nature. Legumes provide a large number of products, and at the same time they enhance soil fertility. The products range from beans and pulses that are the principal source of protein for the majority of the world's poor, to vegetable oil, animal fodder, poles and fuel wood. Legumes are also capable of improving soil fertility through their ability to fix nitrogen from the air making use of rhizobia bacteria in their root nodules.

Legumes add nitrogen to the soil mainly through falling leaf litter, and to a lesser extent by decaying roots and root nodules below-ground, and thus they have great potential for restoring degraded soils. The organic matter produced by legumes is generally rich in nitrogen and of good quality, meaning that it decomposes quickly and is a good source of nitrogen for other plants. The legumes best for enhancing soil fertility are those specifically grown for that purpose, namely the herbaceous green manure legumes and fast-growing legume trees. Herbaceous green manure legumes are often referred to as cover crops, as they provide a dense soil cover that can prevent soil erosion and suppresses weeds. In the case of food and fodder legumes, much of the nitrogen fixed is removed from the land with the produce.

Getting legumes going

Although legumes have a high potential to rehabilitate degraded soils, they also need good conditions to grow. Degraded soils are, by definition, inhospitable environments for plants, including legumes. Therefore, some soil improvements may be needed before the benefits from nitrogen fixation can be realised. Maximal rates of nitrogen fixation are mainly achieved under very good conditions: with irrigation under cloudless skies, and with abundant supply of other nutrients than nitrogen.

Phosphorus

When trying to establish legumes, the most common problem is shortage of phosphorus. In highly acid soils liming or adding animal manure can raise the pH and increase the availability of phosphorus. In most soils, however, the only option is adding phosphorus. Adding plant residues or animal manures will help provide some phosphorus, but mineral fertilisers are by far the most effective means. When sowing grain legumes or green manures, adding small amounts of phosphorus (20 to 30 kg per hectare) will usually be enough.

All over the uplands of South-East Asia, the invasion of *Imperata cylindrica* is a huge land degradation problem. These grasslands, covering millions of hectares of land, are man-made savannas as Imperata mono-cultures do not occur naturally. Imperata poses major difficulties for restoring the land for productive agriculture, as it is very difficult to get rid off. One option to deal with this problem is planting velvet beans. Velvet bean (*Mucuna* spp.) is a universal green manure in the tropics which can adapt easily to many different conditions. After slashing back the grass, velvet beans should be sown with abundant phosphorus so that a cover will develop rapidly and suppress aggressive weeds. One highly successful approach is to add one ton of rock phosphate per hectare, but this is only possible with external investment. Reclamation of these grasslands can also be achieved by sowing other crops such as groundnuts, but these require considerably more labour. A similar approach has been used in Western Kenya, where either phosphate fertiliser or rock phosphate have been used to establish 'improved' fallows of fast-growing trees and shrubs such as *Sesbania, Tephrosia* and *Crotalaria* species.

Despite the many claims as to the usefulness of phosphate rocks, one should be aware that the vast majority of rock phosphates cannot be applied directly to the soil. The way rock phosphates can be used will depend partly on their chemical composition. As most rock phosphate sources have been researched extensively, information should be available about the usefulness of different rock sources.

Other nutrients

Other nutrient shortages may also limit the establishment and growth of legumes. Depleted soils commonly lack potassium and sulphur. Shortages of calcium and magnesium are often associated with soil acidity, which is a widespread problem in the tropics. The toxicity of aluminium can be overcome with small amounts of lime. For example in the Mekong delta, drainage of land previously flooded with brackish water led to the formation of 'acid-sulphate' soils, where extreme acidity prevented growing legumes such as soyabean (*Glycine max*). A very elegant and simple method of dealing with this problem is using mulches of rice straw and small amounts of ash to create a favourable environment in the planting holes. This allows rhizobia bacteria inoculated with the seed to form nodules and fix nitrogen from the air. The results were spectacular, with yields increasing ten-fold from 0.3 to 3 ton per hectare.

Tailoring and targeting technologies

The extensive literature on the rehabilitation of degraded soils by using legumes, suggests the existence of 'off-the-shelf' methods with universal acceptability. However, such research has often been done under favourable conditions and with the assumption that 'We have shown that it works so now farmers will use it!' Despite more than a century of research on green manures in the tropics, examples of smallholder farmers using such methods to regenerate their soils are remarkably rare. Extensive reviews of past experiences indicate that rapid uptake by farmers occurs only when green manures have other advantages, beyond simply improving soil fertility. Cover crops and green manures appear to spread rapidly among farmers only when they bring additional benefits such as the suppression of aggressive weeds. This

Researchers standing in a field with Mucuna. In the background a 2 m high stand of sunn hemp. Photo: Ken Giller

suggests that simply improving soil fertility does not justify the investment of labour and land in green manures. Farmers appear to be more interested in legumes that provide food or fodder as well as improve soil fertility, such as cowpea (*Vigna unguiculata*) and soyabean. These 'multi-purpose legumes' have the advantage of providing some immediate benefit in the form of products with direct economic value while also helping to improve soil fertility for subsequent crops.

In many smallholder farming systems, soil fertility may vary considerably within individual farms even on the same soil types. This generally results from concentrating available animal manure, compost and other organic inputs to fields close to the homestead. Few, if any, inputs are added to soils that are further away. Farmers understand and manage this variability: they have insufficient manure to effectively fertilise all of their land and choose to concentrate resources where they can be reasonably sure of good crop yields. A major challenge remains to experiment together with farmers to explore ways that they can release some of the manure to use as a means of kick-starting the growth of nitrogen fixing legumes in their degraded outfields, and so to bring this land back into productive agriculture. ■

Bioremediation: decontaminating polluted soils

Peter Doelman

Healthy, fertile soil supports plant growth and crop production. One look at the quality of surface vegetation is usually enough to get a rough impression of soil health. Plants establish their roots in the top layer of the soil. Closer study of this layer shows that every gram of earth contains over one billion organisms of over 10,000 different species. These little creatures are known as microorganisms. They are soil-friendly, beneficial microbes that eat organic material and excrete minerals such as nitrates and phosphates in a continuous re-cycling process that has a direct effect on plant quality and productivity.

Microbes are responsible for 90% of biological recycling. Amongst the things they need to do their work are oxygen, water and the right soil temperature. All natural organic compounds in the soil can be recycled providing the soil has sufficient microbe-carrying capacity to encourage biodegradation.

Creating healthy soil with an active soil life ensures that geo-physical processes continue undisturbed and also that it is capable to deal with human interventions that could lead to long-term degradation. One aspect of degradation that is receiving increasing attention is the way in which soil contamination can be reversed by supporting the activity of soil organisms.

There are thousands of elements that can contaminate soil. However, only organic contaminants can be broken down by microorganisms. For this process to be effective, however, the soil must have some degree of natural fertility. If this is not the case contaminated land must be "farmed" back to health so that the microorganisms can begin their work of biodegradation.

A closer look into the soil shows the presence of millions of beneficial friendly microbes. Illustration: Loek de Moll, 2003

Adoption of green manure and cover crops

Roland Bunch

Worldwide, green manure and cover crops (gm/cc's) have proven to be a successful technology for maintaining soil fertility and controlling weeds. The numerous advantages of gm/cc's have led to their widespread adoption in many parts of the world. In other areas, however, farmers have been reluctant to adopt these crops. Moreover, farmers are also known to have abandoned traditional systems. The question is why the introduction of gm/cc's has been a success in one area, while similar programmes have failed in others? Under what conditions can we expect small-scale farmers to be interested in growing cover crops?

Farmers clearing a field with Mucuna in Veracruz, Mexico in preparation for planting maize. Photo: IDRC

After 20 years of experience with gm/cc systems around the world, I would like to discuss the main conditions for adopting green manure and cover crop systems. The following conclusions are based on experiences with 140 different systems, involving 41 species. Sixty percent of these systems have basically been developed by farmers themselves, which shows how appropriate these systems are for farmers and how interested farmers are in them. This article summarises some of the lessons learned from my experiences with programmes and organisations that have been successful in introducing sustainable gm/cc systems.

Opportunity costs

Green manures or cover crops should be grown on land that offers farmers few other opportunities such as income, food, fodder, etc. Generally, farmers are not interested in planting something that only fertilises the soil when the same land could be used for either subsistence or cash crops.

This may seem to impose many restrictions for growing gm/cc's, but in fact we are finding more and more places and times when they can be used:

- If the gm/cc does produce a valued food, it can be grown in any way that fits into the system like any other crop.
- The gm/cc can be grown intercropped with another food for example jackbean with maize or cassava, or perennial peanut with coffee. This is presently the most popular niche for introduced gm/cc systems.
- The gm/cc can be grown on wasteland or on fields under fallow. Suitable species for these areas are gm/cc's that can survive on very poor soils, such as jackbeans, tephrosia, or particularly hardy trees. Farmers in Vietnam, for example, seed *Tephrosia candida* into their first year fallow, thereby reducing the normal five-year fallow to just one or two years.
- The gm/cc can be grown during the dry season, planted after the normal crops like the ricebean/rice system in Vietnam, or intercropped with the normal crop and then allowed to grow through the dry season such as the sweet clover/maize system in Mexico. It can also be planted as a relay crop amongst rainy season crops at the end of the wet season to take advantage of the moisture still in the soil, such as the cowpea/maize and lablab/maize systems in Thailand.
- The gm/cc can be grown under fruit trees, forest trees or almost any perennial crops. In this case, particularly shade-tolerant species, like jackbeans or *Centrosema pubescens* are chosen.
- Other small, occasional niches can be found, such as during periods of frost (lupines, such as tarwi, often do well), in extremely acid soils (velvet bean or buckwheat), or during very short periods of time (*Sesbania rostrata*).

Jackbean (*Canavalia ensiformis*) is probably the second most widely used introduced green manure and cover crop. It is resistant to drought, poor soils, insects and diseases and is capable of surviving and growing well in the worst conditions. The jackbean can be used during the dry season and in very marginal environments where crops will not grow. It has an ability to fix large amounts of nutrients and is also capable of helping wastelands to regenerate.

Cash costs

Growing green manure and cover crops should involve minimal, or no cash costs. This implies that farmers should be able to produce their own seed year after year, and that these crops should be resilient to disease or insect problems. Preferably gm/cc's should save farmers money. They can reduce the amount of money farmers spend on chemical fertilisers. In addition, they can lead to a reduction in or even a total elimination of herbicides. Some species can also be substituted for certain chemicals: the velvet bean is a wide-spectrum nematicide, and sunnhemp (*Crotalaria ochroleuca*) can be used to control grain storage pests.

Labour demand

The gm/cc selected should not lead to an increase in the amount of work farmers have to do. In fact, when intercropped, gm/cc's can save on labour because they can shade out weeds. This reduction in labour required for controlling weeds can in many cases counterbalance the labour needed for planting and cutting the cover crop. Furthermore, farmers can often be partially motivated to plant gm/cc's by the prospect of never having to plough or hoe their fields again: the technology offers the possibility of moving to a zero till system.

Other benefits

The gm/cc's chosen should provide at least one major benefit other than improving the soil. Farmers seldom choose gm/cc's because of their effects on the soil fertility. Usually, farmers are motivated by the potential of gm/cc's to support food production (which usually has a high priority) or to control weeds. The most commonly used gm/cc's, such as pigeon peas, common beans, soybeans and scarlet runner beans are grown for human food. Velvet beans (*Mucuna* spp.), usually not eaten by humans, are also popular cover crops, probably because of their ability to smother aggressive weeds and effectively control nematodes and several plant diseases.

Experiences with projects introducing gm/cc's show that systems that produce benefits other than soil improvement tend to last longer and continue after the "project" has come to an end. This can partly be explained by the fact that soil improvement is a long-term process, which is not immediately noticeable to farmers. The long time that it takes for positive results to emerge is an obstacle to the more widespread adoption of gm/cc's. Therefore, it is often preferable to promote gm/cc's for reasons other than soil fertility. Thus, whenever possible, we should choose gm/cc species that can be eaten, fed to animals or provide some other benefit which farmers need. For example, farmers grow scarlet runner bean (*Phaseolus coccineus),* intercropped mostly with maize, for the edible bean, even though they also realise its importance for conserving soil fertility.

Finally when considering the introduction of gm/cc's, the demand for the products of green manures and cover crop should also be considered. The demand may not be very great if people do not like to eat beans or sprouts, when farmers only have few animals to feed, or when they have already sufficient fodder for the animals.

Existing farming systems

Green manure and cover crops must fit into the existing farming systems. At least for the first few years these crops will be seen as much less important than food or cash crops. They will have to be adjusted to fit into the existing farming system, not the other way around.

Furthermore it is important to understand when, and to what extent farmers would prefer slow maturing tree species and when farmers would prefer fast maturing, less woody and shorter statured plants in their fields. Planting trees as improved fallow is only an option if farmers already have fields under fallow: otherwise it will be too expensive. Whether farmers would prefer a gm/cc system above a tree based system will depend on the relatively demand of the products of both systems. If farmers have rights or gain rights to land by planting trees, they will probably prefer tree-based improved fallow technologies above gm/cc's. Furthermore, many tropical crops do better with a light shade (say 20 to 30%) than with either a heavy shade or no shade at all. Thus, "dispersed tree" systems can very often be ideal for crop growth. And, of course, a dispersed tree system provides a better environment for gm/cc's than total sunlight.

In Brazil, gm/cc's are widely used by farmers with landholdings up to 100,000 hectares. On the other hand, gm/cc's are useful for resource-poor farmers as well, provided that they have sufficient land to allow the incorporation of gm/cc's without affecting the regular cropping system. If farmers have sufficient land to practise shifting cultivation with long fallow periods, farmers may not be interested in gm/cc's.

At farms with little land, the use of the land is often so intensive that there is virtually no time or place when the opportunity cost is very low. In these cases, farmers may be better off using compost or buying soil amendments.

Specific characteristics

Green manure and cover crop species should fit the available niche(s). In general, good gm/cc species should have the following characteristics: easy establishment; vigorous growth under local conditions; ability to cover weeds quickly; and the ability to either fix plenty of nitrogen or concentrate plenty of phosphorus. They should be resistant to insects, diseases,

The role of gm/cc's in rehabilitating degraded land

Green manure and cover crops can contribute to the rehabilitation of degraded lands and the restoration of wastelands in various ways. The most important impacts and effects of gm/cc's are listed below.

Increased organic matter and nutrient cycling. The organic matter from gm/cc's has, in turn, a whole series of positive effects on the soil, including making soil nutrients more accessible to crops. For example, in acid soils phosphorus may be four to five times more available to plants when surrounded by organic matter.
Nitrogen fixation. Organic matter often adds significant quantities of nitrogen to the farming systems. Many, if not most, of the widely used legumes are capable of fixing more than 75 kg/ha of N, while a few species fix a good deal more: the velvet bean can fix 140 kg/ha/crop, the jackbean up to 240 kg/ha, and Sesbania rostrata is capable of fixing 400 kg/ha.
Weed control. Intercropped with food or cash crops, green manure/cover crops are important for controlling weeds and consequently they reduce farmers' labour requirements and costs. Additionally, gm/cc's are also known to be able to control very aggressive weeds. In West Africa, for example, velvet beans (Mucuna spp.) are largely grown to control Imperata grass.
Soil conservation. The soil cover provided by the green manure/ cover crop protects the soil from erosion.
Improved soil moisture. The soil cover plus the increased infiltration and water holding capacity brought about by the organic matter, often increases the crops' resistance to drought.
Zero tillage. After a few years of heavy applications of organic matter from gm/cc's farmers can move to zero tillage systems that retain very high levels of productivity.
Control plant diseases and nematodes. Gm/cc's can reduce, and in many cases totally eliminate, the use of pesticides.

Green manure and cover crops can play an important role in the restoration of wastelands. Their use can result in such a significant increase in soil fertility that it is possible to speak not just of soil conservation, but of soil restoration and soil recuperation.

Extremely low or irregular rainfall, extremes in soil pH, severe drainage problems, or combinations of these problems, which are all too common on the farms of resource-poor farmers, will reduce the growth of gm/cc's, thereby reducing or destroying their impact. Through the years, we have learned how to overcome an increasing number of such problems, often using gm/cc's species that are particularly resistant to specific problems. However, such solutions are often achieved at the cost of reduced biomass production, reduced nitrogen fixation, and reduced additional benefits.

Nodules on the roots of Mucuna pruriens formed by Rhizobium soil bacteria. Photo: IDRC

grazing animals, bush fires, droughts, or any other problem they may have to face within the desired system. They should also have multiple uses, and should produce viable seeds in sufficient quantities for future plantings. If they are to be used for intercropping, they should tolerate shade and fit in with the cycle of the main crop(s).

Some species that have been introduced may establish themselves so successfully that they become pests. Great care should be taken not to introduce potential pests. Known candidates are common kudzu (*Pueraria lobata*), tropical kudzu (*Pueraria phaseoloides*), and even perennial peanut (*Arachis pintoi*) and perennial soybean.

The more ecological deterioration that has taken place, especially as far as soil quality and rainfall regularity are concerned, the more limited will be the selection of gm/cc species that grow well. Nevertheless, in a year or two, when these gm/cc's have improved the soil somewhat, farmers can often graduate to less hardy varieties that produce more subsidiary benefits.

Jicama (Pachyrhizus erosus) is a food crop that can also be used as a cover crop. Photo: CIDICCO

Conclusions

We have learned, while trying to apply these rules in many different situations around the world, that finding acceptable, widely adopted systems for (or preferably, with) farmers requires a great deal of flexibility and creativity. No textbook is able to tell us exactly what technology could or should be used in any particular case. We have to be open, listen to and learn from the local farmers, and then work together with them to find out which species and which systems will best fit their particular situation.

Generally, the most successful way of doing this is to first observe the local farming systems, and look for an appropriate niche: traditional crops among which gm/cc's could be intercropped, times during the growing season when lands are left idle, or perennial crops around which gm/cc's can be grown. In the absence of these possibilities, one can try growing the gm/cc during the drier seasons or as improved fallow. After identifying the best niches, one should select for experiments those species that are known to function best in those niches that will provide the benefits most desired by the farmers with the least amount of labour.

In order to introduce green manure and cover crop systems successfully, we need a much better understanding of existing systems. We need to understand the geographical extent of present systems, the rates of adoption or abandonment, and the reasons why gm/cc's have been accepted or rejected. At the moment research into finding ways that the most common gm/cc's can be used to feed different animals is a high priority. Innovative associations of gm/cc's need to be investigated as well as the associations between these and common crops. We also need to know a good deal more about the theory of inter-cropping and the mechanisms by which gm/cc can lead to zero tillage. What are the minimum requirements to move to zero tillage, and how can these be easily achieved under different conditions? New gm/cc species need to be found which can respond to farmers' needs. Virtually all of this research can and should be done in the field through participatory processes. ■

Table 1: Characteristics of some important GM/CC species

Common name	Scientific name	Resistance to shade	Resistance to poor soil	Resistance to drought	Controls weeds	Other uses
Velvetbean	Mucuna spp.	3	3	3	4	Medicine, animal feed, human consumption (when processed)
Jackbean	Canavalia ensiformis	4	4	4	3	Human consumption (tender pods)
Cowpea	Vigna unguiculata	3	3	Some vars. 4	3	Human consumption
Pigeon pea	Cajanus cajan	3	3	4	2	Animal feed, human consumption
Tephrosia	Tephrosia vogelii or T. candida	2	4	4	2	Insecticide

4 = extremely good   3 = good   2 = fair   1 = poor

Understanding traditional terracing

William Critchley and Marit Brommer

Terracing land for rainfed agriculture has long been the basic response of farmers to the problems of cropping in hilly and erosion-prone conditions. A comparative study of conservation strategies amongst traditional, small-scale terrace farmers in Uganda, South Africa, the Indian Himalayas and upland Java has demonstrated striking similarities in their approach and techniques. The main objective of the survey was to understand how different groups of farmers perceived erosion and countered its negative effects. The reasons given by farmers for their conservation practices did not always coincide with conventional "scientific" thinking on hillside conservation, but their local practices were based on a keen understanding of land degradation processes and the need to protect soil fertility.

The survey involved farmers from areas with strong terracing traditions. It was carried out over a number of years as the opportunity arose in areas with terracing traditions in four different countries.

Four terracing systems

The most ancient terraces in the survey – well over a thousand years old – are in the foothills of the Himalayas in the State of Uttaranchal in India. Here, all cultivated land is terraced. True bench terraces, with flat beds to encourage rainwater infiltration, make it possible to use oxen to cultivate the steep slopes. Average annual precipitation is around 1750 mm, although this is erratic and highly seasonal. The terrace walls or "risers" are sometimes stone faced – when stone is available - but more often they are earth structures. The most common crops in the area are finger millet, sorghum and soya bean. On the valley floors there are irrigated terraces, but rainfed agriculture dominates the landscape and the economy.

Kabale District, in south-west Uganda has a gentle hilly landscape checkered with small plots at various stages of cultivation and divided by terrace bunds that cover every hillside. These are not old terraces, but a local 'interpretation' of a compulsory colonial ordinance passed in the 1940s requiring farmers to plant strips of napier grass (*Pennisetum purpureum)* across the slope at intervals of 15 metres to control soil erosion. What has evolved since are a series of forward sloping terraces. In 1949, an official Ugandan publication boasted that the area had reached 'a standard of soil conservation perhaps unsurpassed anywhere in Africa'. These terraces tend to have a highly fertile strip of deep soil held back by the grass barrier. This is a result not only of water erosion (rainfall is between 1000 and 1500 mm per annum), but also of the practice of hand hoeing while facing upslope, which drags the soil progressively down the slope through 'tillage erosion'.

During the cropping season the healthy crop in the rich soil behind the barriers stands out in stark contrast to the poor crop growth in the shallow soil at the top of the fields. The variation in fertility – the so-called 'fertility gradient' – is obvious. Declining soil fertility and landslides continue to be problems in Kabale.

By contrast, upland Java has relatively fertile volcanic soils. In the region around the city of Yogyakarta in south-central Java, for example, agriculture has steadily climbed up the hillsides, using terraces like stepping-stones. During the nineteenth century, under the pressure of rapid population growth, farmers began to encroach rapidly onto previously forested hillsides. As in India, farmers have traditionally terraced their rainfed holdings. In some areas government programmes have transformed what were forward-sloping terraces into benches, but in most places farmers have completed this transition themselves. The result is a landscape of bench terraces that have a slight backslope, allowing excess runoff to drain away. The rainfall is about 2000 mm per year. A wide variety of annual upland (*palawija*) crops are grown and all livestock is stall-fed, with the manure being returned to the land.

Venda is part of Limpopo province and is home to one of the very few examples of traditional small-scale terracing in South Africa. Visually it is dramatic. Most of the terraces have stone-faced walls (*mitsheto*) that have been constructed with pride and considerable masonry skill. During apartheid, Venda was designated as one of the "homelands" into which the country's black population was crowded by the government. Because these areas were generally isolated and resource poor, agriculture was marginal and land quickly became severely degraded. However, this was less noticeable in Venda, where a tradition of building houses and terrace walls with stone has existed for generations. Local farmers continue to invest enormous amounts of voluntary labour in building stonewall terraces for their main crop – maize and it is not uncommon for farmers to spend as much as 500 days per hectare creating terraces on the steeper slopes.

These four terracing systems are thousands of kilometres apart and involve different peoples, origins and problems. Over a period of eight years, the same basic questions – with some location-specific additions – were asked to farmers in these areas. Table 1 shows the responses that these four groups gave to five key questions.

The first four sets of questions were answered with remarkable consistency. Practically all farmers interviewed recognised that erosion processes were happening in their own fields, despite the terraces, and the majority in each country sample believed the problem was becoming less serious. Perhaps the most significant finding of the survey was the consistent ranking of 'soil fertility decrease' as the most important negative effect of erosion. Not the loss of kilograms of soil, but the consistent decline of its productive potential was what mattered to farmers. There was also, not surprisingly, a clear appreciation of the need to maintain terraces and to build up the terrace 'lips' (the bund or ridge directly above the riser) each season. Human activities, including overgrazing and lack of maintenance, as well as natural causes (heavy rainfall) were given as the main causes of erosion.
The main differences between the farmers in the four areas emerged in their answers to the question "What are the main sources of erosion in the landscape?" and to some of the other questions not included in the summary provided in Table 1. In Java the farmers agreed with an on-going scientific investigation in which one of the authors was involved that indicated that terrace risers were the main source of sediment in the agricultural landscape. In Venda, local people noticed and suffered from the fact that the roads had been badly designed and poor drainage was causing gully erosion. The Venda also provided an example of how local spiritual and ritual practices can influence approaches to soil conservation. The local lake – *Fundudzi* – is considered sacred. During the 1960s it 'turned red', apparently as a result of increasing sedimentation. This led the elders to intervene and mount a campaign to get people to conserve their soil better in order to maintain the integrity of the lake.

Table 1: Perceptions of erosion and conservation strategies: Surveys of small-scale upland terrace farmers in four countries

	Indonesia Gunung Kidul, S-Central Java	**South Africa** Thohoyandou District, Limpopo Province	**Uganda** Kabale District, S-W Uganda	**India** Pauri & Almora Districts, Uttaranchal
Date of survey	1994	1997	1999	2002
Number of farmers interviewed	24	20	24	15
Is erosion taking place in your (terraced) fields? If so is it a little, moderate, a lot; increasing, the same or decreasing?	Yes: 100% A little: 65% Decreasing: 70%	Yes: 100% Moderate: 55% Decreasing: 80%	Yes: 95% A little: 60% (of the 95%) Decreasing: 60% (of the 95%)	Yes: 100% Moderate: 60% Decreasing: 70%
Main negative impacts?	1 Soil fertility decrease 2 Terrace collapse 3 Loss of soil	1 Soil fertility decrease 2 Terrace collapse 2 Gullying	1 Soil fertility decrease 2 Destroys crops	1 Soil fertility decrease 2 Gullying
Conservation strategies?	1 Terraces 2 Toe-drain upkeep 3 Riser 'lip' upkeep 3 Tree planting	1 Terraces 2 Grass strips 2 Various (including. Controlling grazing/ gully checks)	1 Trash lines 2 Tree planting 3 Terraces	1 Terrace upkeep (building up riser 'lip')
Perceived causes of erosion?	1 Heavy rainfall 2 Sloping land 2 Soil type	1 Heavy rainfall 2 Ploughing up/down 2 Overgrazing 2 Burning grassland	1 Overgrazing 2 Overcultivation and no fallowing	1 Heavy rainfall 2 Some people unconcerned
Main source of erosion in landscape?	1 Terrace risers 2 Terrace beds	1 Roads 1 Hillside grazing land	1 Crop fields 2 Grazing land	1 Degraded forest 2 Barren land / roads 3 Gullies

In Uganda, crop fields were considered to be the main source of erosion. Indeed a characteristic of the area is that terrace bunds tend to collapse when the soil becomes saturated, leading to a 'domino effect' as a whole series of terraces gradually slip down the hillside. Ugandan farmers pointed out the importance of terrace bunds as boundary markers. Field-end bunds are those that are most keenly protected: if these collapse, then the down-slope neighbour receives a free gift of rich soil. In Uttaranchal, India, the farmers look after their terraces following centuries old traditions and clearly understand their purpose and value. More interestingly they perceived that degraded forest land was the cause of the dry season 'low flow' problem because it leads to reduced rainfall infiltration opportunities. They also voiced their concern about the invasion of thirsty pine trees (*Pinus roxbughii*) which had replaced the original 'moisture conserving' oak (*Quercus leucotrichopora*).

Conclusions

Despite the difficulties of making comparisons across very different cultures, using a basically common questionnaire, it is possible to draw some conclusions. For example, in these areas which all have traditions of rainfed terracing, there is a remarkable degree of consistency in indigenous knowledge and local practice. However, there are clear differences that inevitably arise from variations in production systems, landscapes, and socio-cultural traditions. Various lessons emerged from comparing the results from the four groups who took part in this survey.
First, traditions of terracing are strong in each of the locations. People are aware of the importance of their terraces for agricultural production. They appreciate the problems associated with terraces and the need for continuous maintenance. Second, while their environmental knowledge systems do not exactly match 'scientific knowledge' they generally do not clash. In fact, they can add value to the observations and measurements of outsiders, as some of the results here show. Third, there are clearly possibilities for 'cross learning' through sharing indigenous knowledge, whether this comes from long established traditions or recent innovations.

This survey was not done in a structured, pre-determined pattern. However, by taking the opportunity – when it arose over the years – and by looking at the same factors in different places, it was possible to document people's approaches to more or less common problems using similar criteria. The results show that these farmers have a clear understanding of their problems and their own ideas of how to deal with them. Such information and experiences can further encourage changes in the way soil conservation technologies are perceived and promoted by 'specialists' in different parts of the world. It is not the prevention of soil loss as such that should be the focus of soil conservation efforts – but rather the optimisation of the agricultural production on the land available to the farmer. Production and conservation go hand in hand.

Healing the earth: an Ethiopian story

Million Belay and Sue Edwards

A farmer holding a faba bean plant grown with compost. Photo: Solomon Hailemariam

Land degradation is one of the most serious problems facing Ethiopia today. Population pressure and low yields are forcing farmers into abandoning fallowing and crop rotations - the system they have used for millennia to maintain their livelihoods. In Tigray, the most northern region of Ethiopia, over 85% of the population are farmers who struggle to feed their families from soils in poor condition that only produce low yields of staple crops.

In order to improve crop yield in the region, the Bureau of Agriculture and Natural Resources in Tigray (BoANR) adopted the Sasakawa Global (SG) 2000 package, which is based on high input demanding varieties and chemical fertilisers. However, the cost of these inputs is beyond the purchasing power of most farmers in the region and some of those who have used these inputs have fallen into the dept trap. In addition, prolonged use of chemical fertilisers has a number of negative side effects on the environment.

A pilot experiment

The challenge is to find mechanisms that help poor rural communities to improve the environment and their capacity to produce crops without becoming dependent on external inputs. In 1996, the Institute for Sustainable Development (ISD) in collaboration with BoANR started a project in four selected rural farming communities in Tigray. The overall aim of the project was to help establish productive agricultural systems based on ecological principles that effectively managed and used local natural resources. The main components of the project included soil and water conservation practices, compost making, and the re-establishment of vegetation.

The four communities selected for the project were Zeban Sas and Gu'emse in the Eastern Zone of Tigray, Adibo Mossa in the Southern Zone and Adi Nefas in the Central Zone. Each area has its own specific characteristics. Depending on the specific needs of each of the communities, different practices were employed. These included the construction of trench bunds, check dams and ponds; the making and use of compost; the use of manure; the planting of trees, forage and grass species; use of genetically diverse seed material and natural pest and disease management.

The performance of the organic production system developed in each of the four communities was compared with the performance of a production system based on the Sasakawa Global (SG) 2000 package in a neighbouring village. This was done in order to compare the two strategies for sustainability.

Benefits from compost

Because compost making is a new practice in Ethiopia, some efforts were required to convince the farmers try it. At the start of the project only a small number of farmers made compost. But after observing how production increased when compost was used, many farmers started to prepare and use it. Farmers also observed that the straw from crops grown with compost was more palatable to livestock and that composting had a dramatic effect on weeds.

In 1996/97 the project started in Adibo Mossa with 45 farmers making and using compost. However, by 1998 this figure had more than doubled. In Adi Nefas, farmers not included in the project started making compost on their own personal initiative without any encouragement from the project personnel.

In every project location, farmer-managed trials were established in the fields. Yields obtained from composted fields were compared with those obtained with Diammonium Phosphate (DAP) + Urea at 100 kg/ha and 50 kg/ha, respectively. The amount of compost applied was different in each site (according to availability) and varied between 5000 kg/ha in Zeban Sas and

The four communities

Zeban Sas (Eastern Zone) is located at an altitude of between 2000 and 2400 metres above sea level. Rainfall is less than 900 mm per year and temperature averages between 16° and 20°C throughout the year. The soil is sandy silt, which tends to be extremely thin, 4–10 cm deep, with little moisture holding capacity and poor fertility. Vegetation cover is sparse. Soil degradation is a pressing problem. The main crops grown by the farmers when the project started were barley with some wheat and a little tef. Approximately two-thirds of the land is used for crops and the rest as grazing land.

Gu'emse (Eastern Zone). Climatic conditions are the same as those of Zeban Sas. The farms are on a flat alluvial plain. The soil is very deep and more fertile than in Zeban Sas. The whole plain is threatened by rapidly advancing gully caused by the seasonal stream that once formed the plain. This problem probably arises from changes in the vegetation cover of the surrounding hills.

Adi Nefas (Central Zone). The site is at the foot of a steep but low basaltic mountain range. The average rainfall is around 600 mm per year. The farmers live on the flat land that consists of vertisol soils which are prone to gullying. The lower slopes of the mountain, which have better drained reddish soils but which are easily eroded because of the sloping landscape are also cultivated. These slopes have been completely deforested and their vegetation replaced by shrubs - mostly Euclea shimperi – which have a low productivity.

Adibo Mossa (Southern Zone). Located in the plain at the shores of Lake Hashenge, the only lake in Tigray. The site was chosen because of its high human and livestock population densities. The lake is in a closed basin with no outlet and needs careful protection from pollution from inorganic inputs.

15,000 kg/ha in Adibo Mossa. The yields of finger millet, barley and wheat on composted fields were comparable with those where chemical fertilisers had been applied. Tef, however, gave higher yields when grown on composted plots. The effect of compost on maize yields was variable when compared to the results achieved with chemical fertiliser. There were much higher straw yields from the composted plots in comparison to the chemically fertilised ones. The farmers welcomed this because their animals often have to subsist on crop residues during the dry season. The increased straw yields also enable the farmers to prepare more compost because there was more animal manure and increased plant material.

Soil and water conservation

Impressive results in soil and water conservation have been observed in three of the four project sites since 1997. The spread of gullies had been halted and soil has been retained that would otherwise have been washed away. Water retention and infiltration has also been improved.

Adi Nefas had been losing fertile land through a gully that started at the base of the neighbouring hillside. The farmers built a series of check dams up the gully, and in one year enough soil was captured to allow for the planting of grass and trees. The construction of check dams has been effective in Zeban Sas as well, although soil accumulation has been slower. Unfortunately, Gu'emse has not been successful in its attempts to halt a very wide gully that is caused by the run-off from a large catchment area of virtually bare hillside. An effort that involves several other communities upstream is required. Gullying has not been a problem in the Adibo Mossa site.

Water is very scarce during the dry season in Adi Nefas, Zeban Sas and Gu'emse and the farmers, with financial support from ISD, have now constructed ponds to collect water so that it is available in the dry season. The programme was expanded to 21 villages in 1999 and construction of trench bunds on farmlands and check dams in gullies was carried out in 14 out of the 21 new sites.

Planting of grass and trees

Various indigenous and some selected exotic forage grasses and legumes, as well as other trees and shrubs for construction and fuel, have been planted in and around farms and houses, on hillsides, around the newly constructed and maintained gullies and along trench bunds. This planting has been carried out in the four original sites as well as in 14 of the new sites. This has resulted in the farmers using forage trees for feeding their cattle, planting and protecting grasses and legumes for stabilising trench bunds and check dams, enrichment planting on degraded lands, and increasing the amount of biomass available for compost making and for feeding their animals.

In Zeban Sas, the success of the project showed first in the rehabilitation of approximately 30 hectares of abandoned, rocky grazing land. Having seen their grazing land restored, the farmers started working on other components so the area as a whole has now been almost rehabilitated and is green, with farmers getting their income from fattening and selling cattle.

Embedding sustainability in society

All four communities have now drawn up their own statutes to control the use of their land and renewable natural resources. These statutes set out rules and regulations that community members agree to and penalties for anyone who infringes them. The communities themselves developed the statutes, and the respective local governments have recognised these statutes and uphold them.

The regional government of Tigray has also adopted this project. This means that, if the ISD has to pull out, the programme will still continue. The regional government has spread the project to more than 2000 households in more than 83 villages. A very recent development is even more significant: the project has been taken up by the Environmental Protection Authority (EPA) of Ethiopia with support from UNDP and will now be upscaled to the national level.

Conclusion

The secret of the success of this project lies in the involvement at the planning stage of almost all of the stakeholders. Ensuring the active involvement of farmers requires providing a range of choices and alternatives for them to consider, rather than making prescriptions for improving one part of the farming system.

The project offers a range of choices and farmers adopt those that suit their ecological and social setting. Experience has shown that each village has a preference for one or two of the different components of the project. At Zeban Sas, the emphasis has been on soil and water conservation, because the area was badly affected by soil degradation. At Gu'emse and Adibo Mossa farmers adopted composting rapidly, because there was already sufficient plant material and animal manure for making this natural fertiliser.

A woman working in her compost pit in Zeban Sas. Photo: Solomon Hailemariam

At Gu'emse, check dams were not very effective in halting gullying and halting the spread of gullies is now the community's top priority.

The farmers at Adi Nefas are actively participating in all components of the project, much more noticeably than at the other sites. This is probably because of the rapid positive outcomes of making check dams and preparing and using compost. These early successes, coupled with the high population density, have given farmers a strong motivation for intensifying the use of their land in a sustainable way. ■

From soil erosion to soil quality

Farmers' priorities may have nothing to do with agriculture. Lempira, Honduras. Photo: Jon Hellin

Jon Hellin

Throughout the tropics, smallholder farmers are increasingly forced to colonise marginal areas such as steep-lands. The consequence has been increased land degradation, loss of soil quality and accelerated soil erosion. This threat to sustainable agricultural productivity has led to considerable interest in soil conservation technologies that control run-off and erosion. Cross-slope technologies such as live barriers, rock walls, infiltration ditches, terraces, and earth bunds have been widely promoted all over the world.

Farming communities have been encouraged to adopt these technologies, but the response has been poor. Many development organisations have reverted to using direct incentives such as cash payments and food-for-work to encourage farmers to adopt soil conservation technologies. The problem with this approach is that farmers often abandon the technologies when projects end or funds dry up.

Based largely on field experiences from Honduras, this article discusses the case for a different approach to improved land management. Rather than focusing on controlling soil erosion it seeks to improve soil quality. In doing so, it not only takes farmers' concerns about productivity into account but also addresses the growing problem of land degradation.

Controlling soil erosion

The scene is all too familiar. The valley below is criss-crossed with neat green lines of honey melons destined for export to Europe and the United States. Standing on a hillside above the melon farm in Southern Honduras, I am surrounded by a mosaic of maize plots and the remains of the dry forest that used to stretch, unbroken, along the Pacific coast from Mexico to Panama. Inequality in land distribution in countries such as Honduras has meant that resource-poor farmers have few alternatives and have to work on what land is available. This is often in marginal agricultural areas such as hillsides.
Heavy rainfall and steep slopes mean that large parts of Central America are particularly prone to high rates of soil erosion. As land degrades, production falls and farmers are forced either to clear more patches of forest or migrate to the cities in search of work.

In Central America and many parts of the tropics and sub-tropics there is a danger that land degradation caused by farmers' own activities will undermine efforts to increase sustainable agricultural production. One response is investment in soil conservation technologies. In the last 30 years, soil conservation programmes have become commonplace in the developing world. Development practitioners provide farmers with technical advice, assistance and technologies designed to restrict soil loss and actively promote cross-slope technologies such as live barriers (contour hedgerows), rock walls, terraces and earth bunds.

Farmers, however, are often reluctant to adopt these technologies. Sometimes soil conservation programmes use incentives such as cash payments to encourage adoption. The problem, as shown in Figure 1, is that farmers often abandon the technology once the incentive is removed.

When farmers do not adopt recommended technologies, it is often said that this is because they are under-educated, conservative and unwilling to change. Recently, however, there has been a greater appreciation of the farmers' own situation. This has led some to question whether farmers are unwilling to follow recommendations because many of the technologies being promoted do not address their needs and real priorities.

Farmers' perceptions

Those concerned about the severity of soil erosion and the effects it can have on agricultural production are often surprised to learn that smallholder farmers often do not share the same concerns. This lack of concern about soil loss is partly explained by the fact that many farmers do not recognise that soil erosion is taking place. In Honduras it is not uncommon to hear farmers talk about 'rocks growing out of the hillside'. Soil loss rates as high as 20 to 40 tonnes per hectare per year result in an annual lowering of the soil surface by less than 0.3 mm. As farmers cannot see this erosion occurring, the explanation of rocks growing is a logical explanation for rocks becoming exposed.

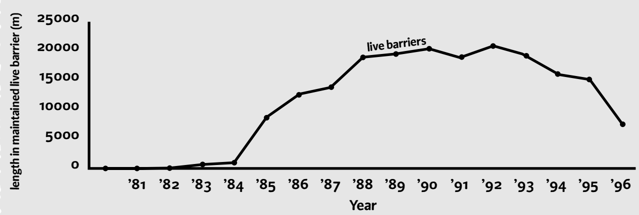

Figure 1: Adoption and abandonment of live barriers on 147 farms in La Paz, Honduras. The project lasted from 1980 to 1991 and direct incentives were provided from 1984 to 1991.

The major worry of farmers in Honduras seems to be the damage caused by pests and diseases, drought and irregular rains (see Table 1). Soil erosion is seldom seen as a threat to their livelihoods.

Deeper questioning reveals that farmers are not worried about pests and diseases or reduced rainfall as such. Their real concern is what these problems will mean to them in terms of reduced productivity. When asked about the effects of the problems identified, reduced productivity (360 responses) and hunger (46 responses) accounted for 91% of the responses.

Soil erosion and productivity

The reason why erosion control has received so much attention is the assumption that there is a direct relationship between soil loss and crop productivity. Conventional soil conservation technologies, focusing on controlling soil loss, tackle what outsiders consider the main threat to (and from) farming on sloping lands rather than the problems and priorities identified by the farmers themselves.

Yields are actually determined by a complex interaction of factors including soil quality, crop and land management systems, and climate. In countries such as Honduras, the amount and distribution of rainfall has a much more profound impact on yield than the amount of soil eroded. Given such variation in yields, farmers' 'failure' to identify soil erosion as a threat to their livelihoods seems reasonable.

By placing too much emphasis on erosion, we are potentially doing a disservice to farmers because any relationship between productivity and the soil depends more on the quality of the soil remaining on the land rather than the amount of soil removed through erosion.

A soil in good condition is well structured, allows roots to penetrate, exchanges gases and absorb rain easily. The more rainfall that is absorbed, the less erosion takes place. Erosion occurs once the soil is degraded. A degraded soil is less able to absorb rainfall and the result is greater run-off and erosion. Cross-slope technologies, such as live barriers, do little to improve the quality of the soil between the barriers. As a result, farmers seldom witness an improvement in production as a result of such soil conservation efforts. Clearly, there is a need for a new approach to soil conservation. The farmers' concerns – agricultural productivity and its sustainability through the preservation and improvement of soil quality – provides the starting point for this approach and should be given priority.

Improving soil quality

A more effective approach than focusing on cross-slope soil conservation technologies is the use of agronomic, biological and mechanical measures to improve soil quality via soil protection, the incorporation of organic matter and the use of soil organisms. These procedures directly address factors such as surface cover and soil structure, that are within the control of the land user and that can be used to rebuild the soil into a dynamic and living system. Soils that favour root growth also favour better water retention and the conservation of soil and water on the farm itself.

Improving soil structure and infiltration capacity can result in improvements in both production and soil conservation. Improvements in crop management, such as early planting, optimum density, leaving crop residues on the surface and the use of green manures (see LEISA Magazine Vol 13 No 3, p 12-14), reduce erosion, encourage water infiltration and, through improving soil quality, lead to improved crop production. A practical example of this approach is the *Quesungual* system in Western Honduras (see Box and also LEISA Magazine Vol 18 No 3, p 10-11).

Table 1: Farmers' perceptions of threats to agricultural production. Based on a questionnaire administered to 213 smallholder farmers in Honduras.

Threat	Responses	Percentage of responses
Pests and diseases	172	38
Drought and/or irregular rain	136	30
Low productivity	60	13
Quality of land (eroded, waterlogged etc.)	40	9
Availability of land	29	7
Few economic resources	7	2
Others	4	1

The Quesungual System in Honduras

The Quesungual system is an agroforestry system that is characterised by three layers of vegetation: mulch, crops and dispersed shrubs and trees. Farmers in Western Honduras used to practise a slash-and-burn agriculture. Different development organisations encouraged them to stop burning their fields prior to planting their maize crop and instead to cut the weeds, leave them on the soil surface and sow their maize seed through the mat of vegetation.

The three-tiered vegetation canopy affords ample protection to the surface of the soil and as soon as the farmers stopped burning they noticed there was hardly any erosion: the rivers were 'clean' as opposed to 'dirty' when it rained. Soil erosion control is not, however, the reason that farmers are increasingly adopting this system. The issue at stake is improved soil quality.

Having abandoned the practice of burning their fields, there are more beneficial insects and increasing levels of organic matter in the soil. The attraction for farmers is that the soil can now hold moisture much better. The result is improved production. The reduction in soil loss is a 'secondary' benefit of the system. Farmers do not see the Quesungual System as a soil conservation practice. On the contrary, it is viewed as a productivity-enhancing practice that also happens to be effective for soil conservation. This approach to land management is more attuned to the farmers' priority needs and is more readily adopted by them.

The Honduras experience shows that, although there is still a role for cross-slope conservation technologies, these should be combined with technologies and agronomic practices that lead to an improvement of soil quality. If used on their own, they are unlikely to result in improved productivity, which is the farmers main concern.

Recent positive experiences with the rapidly expanding zero tillage systems of Latin America show that when soil quality is improved, agricultural production increases and soil erosion is reduced. Fundamental policy changes are, of course, still needed to alleviate the pressure on the steep lands of Central American. These changes include more equitable land distribution and greater access to markets. However, despite numerous social, economic and agro-ecological constraints to better land management, farmers can improve soil quality through the use of technologies that enhance both productivity and soil conservation. Through such approaches Central America's hillsides can support more smallholder farmers on a more sustainable basis.

Nitrogen fixation on a national scale

Adriana Montañez, Carlos Labandera and Luis Solari

Intensive grazing of vast areas combined with continuous cultivation of wheat, barley, maize, sorghum and sunflower under conventional tillage practices, without proper fertilisation or erosion control, have been degrading land in Uruguay ever since the first European emigrants arrived in the country in 1910. Farmers and producers abandoned the land once it became infertile and degraded and moved on to areas where soils were still productive. As a result the problem of soil depletion grew. In 1959 the government, technicians, NGOs and farmers unions started to discuss the problem. A plan for the development of agriculture - the *Plan de Desarrollo Agropecuario* – was developed. This "Agricultural Development Plan" was set up to improve productivity in the short and long terms and included all agricultural land. Special emphasis was given to the development of pasture-crop rotations.

Bacteria to the rescue

In 1960, using positive experiences with legume inoculation in Australia and New Zealand, researchers of the former Laboratory of Soil Microbiology and Inoculants (now the Department of Soil Microbiology of the Department of Agriculture) started to work on biological nitrogen fixation (BNF) involving the soil bacteria Rhizobium. These organisms live in association with specific plants, forming small nodules (swellings) on the roots. They fix nitrogen from the air into the soil and in doing so provide crops with one of the elements essential for good growth and yields.

The research group worked in close collaboration with rhizobiologists, plant breeders, agronomists, farmers and extensionists to identify, select and test native Rhizobium strains that were well adapted to specific soils and host plants. In addition, native and introduced pasture varieties that responded well to the presence of Rhizobium were selected. In collaboration with farmers, field and on-station trials were established across the whole of Uruguay to study the efficiency of established pasture-crop rotation practices, such as the use of a mix of legume and non-legume pastures in rotation with winter crops like wheat and barley, and summer crops such as sunflowers, maize and sorghum.

Improved pasture-crop rotations were established. Farmers were given technical support and benefited from a credit plan that covered 80% of any investments they made. Adoption of the BNF technology was further facilitated by the fact that it is easily applied in the field. Rhizobium bacteria, mixed with sterile soil, are fixed to the seeds by using a special type of glue, after which sowing takes place.

The livestock sector has greatly benefited from BNF technology. Photo: Federación Uruguaya de Grupos CREA (FUCREA)

A gene-bank of N-fixing and other microorganisms was established at the Ministry of Agriculture's Department of Microbiology to serve as a source of high-quality germplasm for researchers, extensionists and commercial producers. The private sector was closely involved in the development of the BNF technology investing in both the production and multiplication of the required Rhizobium strains. Today, three enterprises produce high-quality Rhizobium for Uruguay and other South American countries.

Good for the farmers, good for the country

BNF in Uruguay continues to be developed and improved and, over the last 40 years, the technology has brought considerable economic, ecological and social benefits to those who have used it. The country has saved millions of dollars through reducing imports of nitrogen fertiliser. Individual farmers have greatly benefited because Rhizobium is cheaper to buy than urea-based fertilizers. Currently one application of Rhizobium costs one US$/ha whereas one application of urea fertiliser costs US$50 per hectare. BNF technology has the capacity to fix and incorporate 250 kg per hectare of nitrogen in the soil in a very efficient way. Farmers are well aware of the benefits and as a result rotation with legumes and inoculation with Rhizobium is now being used by nearly all arable farmers.

BNF's contribution in Uruguay

- Soybean yields have increased 800-1000 kg/ha/year (a 40% increase) on land where they have not previous been cultivated and where Rhizobium is used.
- Pea producers using BNF have recorded yield increases of up to 240%.
- Each year savings in the order of 90 million dollars have been made because of farmers using Rhizobium rather than buying in fertiliser for forage legume production.

Explaining the success of BNF

This initiative is a good example of the planning and implementation of a national, government supported strategy with an ecological and multi-disciplinary approach. There was a strong functional relationship between the government, industry and farmers. The spontaneous integration of these stakeholders made it easy to define limiting factors, find solutions and apply these in short term. An aspect worth mentioning is that BNF was not an objective in itself but a valuable tool that could be used to meet the goal of improved productivity in the short and long term. While farmer pressure and government support was essential in the process, the key for success was the excellent performance of BNF technology in the field, leading to its successful adoption and the improved production systems currently in place.

Little bugs, big problems

Tim Hart, Roberta Burgess and Hans Hugo

In 1999, small-scale farmers, organised in the Friemersheim Kleinboer Vereniging (FKV), purchased an under-utilised 100 hectare commercial farm near their village in the South-Western Cape (South Africa). This arrangement had been made possible through the South African Government's Land Reform Programme (see LEISA Magazine 19.3 pp 27-29). The newly acquired land had been left fallow for many years and in several places there were heavy concentrations of weeds such as Australian Black Wattle (*Acacia* sp.), Hakea trees (*Hakea* sp.) and Night Shade (S*olanum nigrum*).

Early harvests

After the purchase, the old farm was divided into two-hectare plots and distributed to the members of the FKV. Their first planting season was in 2000 when most of them cultivated a mixture of vegetables, maize and legumes. Deformities began to be noticed in some root vegetable crops by mid-2001. However, farmers observed that although crop growth was stunted in some parts of their smallholdings, the same crops did well in other areas. They immediately suspected that the condition of the soil was responsible for these irregularities. They knew they had cultivated all parts of their plot in the same way and had used the same inputs and practices. They did not know what the problem was and neither did local commercial farmers in the area.

Galls on the roots of a Honeybush plant. Photo: Tim Hart

Land with problems

During 2000, some of the farmers involved in the FKV began to work with researchers from the Agricultural Research Council Infruitec-Nietvoorbij (ARC) to establish a new economic crop, Honeybush (*Cyclopia* spp.), used as a herbal infusion and a potentially valuable export commodity.

During the sessions when researchers were training farmers and providing them with information on various aspects of Honeybush cultivation, the farmers began to talk about their crop problems especially the deformities and stunted crop growth in root and tuber vegetables. The researchers recognised that these signs suggested that there might be a high level of root-knot nematode infection in the soil of some of the smallholdings.

Soil problems explained

When the growth of some of the Honeybush plants at the trial site also appeared stunted, the researchers started to look more closely at the problem. An examination of the trial plantings revealed galls or knot-like growths on the plants' roots. Laboratory tests proved these galls were caused by root-knot nematodes. Root-knot nematodes are microscopic organisms that live parasitically in plant roots. They cause root knots or galls, which make it difficult for the plant roots to take up water and other nutrients. As a result plant growth is stunted and root vegetables such as carrots and beetroot become deformed. In this case the root-knot nematode involved was identified as *Meloidogyne javanica*. This organism can live in more than 700 species of plants, including most vegetables and a large number of weeds. The weeds that were present on the farmers' land – Australian Black Wattle, Hakea trees and Night Shade – and crops such as tomato and potato were known to be good hosts to the nematode. Many brassica species such as cabbage and cauliflower, however, are not and can be grown without problem. Working the plant material of these varieties into the soil after harvest bio-fumigates the soil and can help control the nematode population. In the absence of host plants, root-knot nematodes cannot survive for more than a year or two.

A meeting was held with interested farmers and the research team explained the effects of the root-knot nematode and suggested that crops should be planted that would not host these organisms. These crops could be planted and seasonally rotated with other crops to reduce the number of nematodes in the soil. Local commercial farmers used to rotate crops and this, together with other farming practices, may have been the reason why they had not experienced a problem with nematodes.

The farmers wanted to know how much of their land was infested with nematodes and asked the researchers to carry out a survey. Working together, farmers and researchers surveyed about 40 hectares of land over a two day period in September 2002 during which samples were taken from farmers smallholdings. Farmers were also asked about the history of their piece of land and to explain their crop planting and crop rotation practices.

When soil samples were analysed, researchers found there was a high level of infestation of root-knot nematodes on most of the smallholdings. Samples taken from land that had not yet been cultivated also showed a high presence of root-knot nematodes. Samples taken from plots where farmers had planted vegetable crops indicated even higher concentration of the pest. This suggested that their cropping practices might be making the problem worse.

This suspicion was confirmed when researchers analysed the survey data further and compared it to the data they had collected on the various cropping practices farmers had followed in the period 2000-2002. Most farmers had planted Irish potatoes – a favourite root-knot nematode host – season after season, without observing any resting period or crop rotation.

Mr Hans Hugo carrying out soil sampling. Photo: Tim Hart

Options

After the samples and the cropping practises had been analysed, three members of the research team met with each farmer on their smallholding and explained the extent of the nematode problem to them, advising them on possible strategies to reduce the numbers of root-knot nematodes in the soil. Researchers agreed that, once the farmers had selected the option that best suited their individual circumstances, they would help them draw up a proposal to obtain support and funds to tackle not only nematode infestation but also other soil health problems. In the FKV area these problems included poor soil fertility, soil borne diseases and inappropriate crop rotation systems.

Identifying locally appropriate solutions

The researchers suggested four options that could be used to restore soil health under present circumstances. Farmers could:

- Fumigate the soil with chemical soil fumigants;
- Plant marigolds and plough the plant matter into the soil before it began to form seeds;
- Plant oats on the affected soil for a few seasons to control and possibly arrest the root- knot nematode levels;
- Plant broccoli, cauliflower or cabbage and plough the plant material into the soil after harvest.

The options selected by individual farmers depended on their social and economic situation and the resources they had available. Some of farmers, for example, had access to alternative employment and income, which made them less reliant on agricultural production and better able to try out more costly and long-term measures than farmers who had no alternative source of income.

All the farmers immediately ruled out the fumigation option because of the cost and the long-term damage it could do to soil biology. They did not consider planting and ploughing in marigolds to be an appropriate strategy because whilst marigolds might control nematodes, they could not be eaten and they did not generate income. Farmers did not want options that involved spending money on external inputs or ones that would involve taking land out of production and a subsequent loss of income.

Some farmers decided to plant oats on their land because the crop could be used to feed livestock. Others were more interested in planting cabbages and other brassicas. All farmers wanted more information on the type of crop rotation systems that would reduce the nematode numbers.

While the researchers and farmers were developing a concept project proposal to address the soil health problem in an organic

Discussing cropping patterns with farmers. Photo: Tim Hart and sustainable way, four farmers started using local resources to try and develop ways to control and reduce the presence of root-knot nematode. They did not use any external inputs but relied on low-external-input suited appropriate to their specific farming needs and providing immediate benefits.

Working together

Two farmers, for example, decided to combine their resources in order to tackle the root-knot nematode problem. In 2002, they agreed to plant oats on one of their smallholdings and food and cash crops on the other. In 2003, they intend to repeat this process. In 2004, they will plant oats where the food and cash crops had been and food and cash crops on the land where oats had been planted. These two farmers are considering the possibility of getting a third farmer involved in the process. Not only is this a good strategy as far as soil health is concerned, it also encourages the conservation of soil nutrients in general.

Honeybush field with low plant density probably due to root-knot nematodes. Photo: Tim Hart

Single plot rotation

In 2002, another farmer planted oats on three-quarters of his land and used the remainder of his plot for food and cash crops. In 2003, he ploughed in some of the oats and started planting cabbages at periodic intervals. He intends to rotate his vegetable crops each season. Like his colleagues who are also using the oats rotation, he intends to practise crop rotation on a regular basis and on a larger scale once the nematode population has been reduced on the land currently under oats.

A recent soil analysis showed that where oats had been planted for two consecutive years, root-knot nematode numbers remained low, while the number of free-living nematodes, which are non-parasitic and whose presence is desirable, had increased. This strengthened the theory that oats can have a role in reducing root-knot nematode population levels.

Increasing scale

In 2001, another FKV farmer who had a four hectares plot decided to plant cabbage and broccoli on one part of his smallholding. When the results of the nematode survey showed that he had the lowest number of root-knot nematodes he made plans to continue planting these crops. At the moment he is looking at ways of improving his crop rotation strategy because he wants to scale-up his crop rotational practices and completely rehabilitate his smallholding.

Future steps

Seeing the work being done by innovative farmers, two other smallholders made parts of their farm available for experimentation. At the moment this land is being planted with cabbages and these will later be rotated with other suitable vegetable crops.

Not all farmers are interested in taking part in experiments, however. Some have said they are going to wait to see whether the project proposal is successful in generating funds and further support, while others do not see the root-knot nematode problem as hindering their particular type of farming activity. There are also farmers who, for financial reasons, cannot change their cropping pattern even though they recognise that such a step might help them rehabilitate their land.

Conclusion

It is still too early to say whether the measures that farmers are trying to develop in Friemersheim will be effective in arresting or reducing the level of root-knot nematode infestation. At this stage we are unsure what other changes might have taken place. We also need to be able to account for the changes we have observed. Structured and regular soil monitoring is needed in all the areas where farmers are trying to develop new nematode management and soil health strategies in order to assess whether soil composition and nematode levels have changed as a result of their interventions.

Structured surveys of the soil where farmers have not introduced innovative practices are also necessary. The results from these surveys must be analysed and compared to those obtained in areas where measures are being undertaken to restore soil health. This type of data will give farmers the information they need on the effects their different interventions have had on soil content and nematode numbers over time and can be used as a basis for providing advice on soil management.

The experiences of those involved in experimenting with the options available to counter root-knot nematodes is also important given the proposals to introduce Honeybush into the area as a commercial crop. The recent soil survey showed, for example, that in areas planted with Honeybush there appeared to be a doubling of the root-knot nematode population, strengthening the suspicion that the pest was attracted to these plants.

Appropriate crop management systems, based on crop selection and rotation of locally important crops might be a viable low-input solution for containing or resolving the root-knot nematode problem. As the FKV experience shows the continuation of cooperation amongst farmers and between farmers and researchers is important to achieve this goal.

Reversing degradation

Fertility gradient on terrace in Uganda. Photo: William Critchley

Land degradation is a broad term and refers to the way in which the quality and productive capacity of the soil can be temporally or permanently undermined. It includes such processes of physical, chemical and biological deterioration as the loss of organic matter, the reduction of vegetative cover and biodiversity as well as a general decline in soil life and fertility. Degradation also results in soil compaction and erosion, a reduction in its water holding capacity and increased salinization in areas where irrigation has been poorly managed or where there is toxic chemical pollution.

Land degradation is something that most small farmers in the South are familiar with, although they may not use that term. They report that the soil is getting thinner, that there are more stones on the surface and that their soil is "tired" and "worn out". In some places production has fallen dramatically, it is difficult to find firewood and water sources have dried up. Changes in land use practices or pressure on land that make traditional farming methods unsuitable are the main reasons for land degradation in many parts of the world. Restricted access to more productive agricultural lands also force farmers to cultivate more marginal areas such as forested slopes that have low farming potential and are vulnerable to soil erosion once forest cover has been removed.

Land degradation is closely linked to farming practice and it is often suggested that small farmers and the circumstances in which they farm lead to accelerated soil erosion and the rapid deterioration of the landscape. However, most farmers depend on the land for their survival and are deeply attached to it. They do not degrade it by choice. Their main concern is to maintain its productivity and use it to support their families and provide a future for their children. Though the direct reason for land degradation may be farming practices, underlying socio-economic and political factors form the context in which this takes place. These factors include unequal access to land and resources, including income, needed to keep it in good condition.

But small-scale farmers are not the only ones who face soil degradation problems. Large-scale and intensive agriculture can often have a crippling effect on even the best agricultural soils. In this type of agriculture, the over-use of fertilisers and pesticides, heavy machinery and monocultures all contribute to land degradation. Often it is market pressures and the need to maintain a competitive position in export markets that force farmers to adopt practices that lead to soil degradation.

Although land degradation is a worldwide phenomena countries in the South tend to suffer more severely from its consequences than countries in the North. This is partly a result of geological and climatic conditions, but also because many millions of people in the South are directly dependent on farming for most of their livelihoods and income. The link between agricultural production and livelihoods is much less direct in the North, but ultimately we all need good food produced on healthy soil. Present agricultural practices threaten the resource base on which we all depend.

At present, all land suitable for agricultural production is in use. There are no reserves of good land into which agriculture can expand as it tries to meet the needs of the growing global population. The world's demand for food will have to be met by intensifying agriculture on land already in cultivation. The logical conclusion is therefore that we must take good care of the agricultural land we have, ensure that it is kept in productive condition and improve when necessary. Regrettably, this is not the case at the moment. Although it is difficult to quantify the impact of soil degradation, the estimates available are alarming.

The Global Assessment of Soil Degradation (GLASOD) has estimated that nearly 2 billion hectares worldwide or 22 % of all cropland, pasture, forest and woodland have been degraded since 1945. Of the 1.5 billion hectares cropland worldwide, an estimated 38% has been affected to some degree by human-induced soil degradation and more than 6% has been degraded to such an extent that rehabilitation is only possible with large capital investments. Recent global studies indicate that one quarter of the world's agricultural land has been degraded at a rate that has consistently accelerated over the last 50 years. Various sources suggest that between 5-10 million hectares of arable land are lost annually to severe degradation. For an overview of the regional extent of degradation, see Table 1.

Although we know that soil degradation threatens agricultural productivity in the long term, it is difficult to determine exactly how and to what extent soil degradation affects productivity or what this means in terms of declining farm production. This is because of the complexity of factors involved and the way in which they interact with each other.

Although some types of degradation are irreversible, most can be prevented and some can also be reversed. Nutrients can be added to nutrient-depleted soil, for example, or top soil can be rebuilt by incorporating organic matter or by introducing physical erosion control measures. However, rehabilitating degraded land requires much more effort and investment than introducing measures to prevent degradation in the first place.

Nevertheless, much is being done to rehabilitate degraded land and efforts by researchers, policy makers, extensionists and farmers are taking place at international, national, regional and local levels. Results at field level vary considerably and often do not bear much relation to the efforts involved. Examples here include the large-scale soil conservation activities undertaken in recent decades. Heroic efforts have gone into building erosion controlling structures such as bunds, shelterbelts and vegetative barriers with the help of incentives, only to realise that these structures were not maintained (Hellin, p. 10). While techniques may be technically relevant and effective, they may not be appropriate for the particular situation of the farmer. Farmers will, therefore, have quite clear preferences for certain measures (Belay, p. 12; Hart, p. 6). This can be taken into account if farmers are involved from the beginning and this is exactly why a number of experiences described in this edition of the *LEISA Magazine* have been successful. A very useful method of actively involving farmers at all stages of the process is the Farmer Field School methodology (Onduru, p. 26).

A good plant cover is very important for preventing soil degradation and achieving soil rehabilitation. A vegetative cover has a number of beneficial effects on soil aeration, soil moisture and organic matter content, physical characteristics and biological activity in the soil. In addition, a plant cover protects against erosion by wind and water. This makes them one of our most versatile allies in our efforts to protect the land and the reason why a number of articles in this edition deal with vegetative covers. Okon (p. 21) shows that even some weed species can be useful by describing how “Awolowo” – a well-known weed – is used in Nigeria as a cover crop in order to get rid of more aggressive weeds such as Running Carpet grass.

Although a good plant cover is necessary to protect the soil the plants used should ideally serve other purposes that clearly benefit farmers and which they appreciate. The introduction of trees and shrubs to rehabilitate degraded grazing lands in the Philippines were successful because the species selected were useful sources of fodder (Calub, p. 22).

The successful introduction of cover crops, for example, depends to a large extent on the advantages these plants offer to farmers (Bunch, p. 16). Cover crops can be quite aggressive creepers and may compete with the main crop. On the other hand, if leguminous plants are used as cover crops they add nutrients because they fix air-borne nitrogen and make it available for the crop. If soil is very badly degraded, however, even leguminous plants that will help restore the soil will have trouble growing. In such situations a number of additional measures will be required to restore soil quality (Giller, p. 19).

Soil life is very important to the health and functioning of the soil. The soil harbours a great variety of microscopic and macroscopic life. These creatures digest organic material and make minerals available to the plants, thereby contributing to plant growth. Legumes are able to fix nitrogen from the air with the assistance of Rhizobium bacteria if the right kind is present in the soil (Giller, p. 19). The presence of effective strains of these bacteria in the soil can be enhanced by reproducing them in a laboratory and mixing them with seed before sowing. This can lead to significant yield increases (Montañez, p. 9). However, some microorganisms may be noxious for crops and the presence of high populations of these organisms will affect plant growth and crop yields. The root-knot nematode in South Africa is an example (Hart, p. 6).

Farmers are not the only ones who should be involved in soil rehabilitation activities. Such efforts usually require a multi-disciplinary approach and strong collaboration between different stakeholders. This was an important factor in achieving a nation-wide adoption of Rhizobium inoculation in Uruguay (Montañez, p. 9).

Finally, efforts related to the rehabilitation of soil and land should be an integral part of regional and national (agricultural) policies. The Biological Nitrogen Fixation Programme in Uruguay was part of the national *Agricultural Development Plan* (Montañez, p. 9) and as the article by Riggs shows agroecological restoration in Guandong, China was facilitated by the formal policy developed by Guandong Province (Riggs, p. 24).

ILEIA is the Centre for Information on Low External Input and Sustainable Agriculture (LEISA). ILEIA seeks to promote the adoption of LEISA through the LEISA magazines and other publications. It also maintains a specialised information database and an informative and interactive website on LEISA (**http://www.ileia.org**). The web site provides access to many other sources of information on the development of sustainable agriculture.

LEISA is about Low-External-Input and Sustainable Agriculture. It is about the technical and social options open to farmers who seek to improve productivity and income in an ecologically sound way. LEISA is about the optimal use of local resources and natural processes and, if necessary, the safe and efficient use of external inputs. It is about the empowerment of male and female farmers and the communities who seek to build their future on the basis of their own knowledge, skills, values, culture and institutions. LEISA is also about participatory methodologies to strengthen the capacity of farmers and other actors to improve agriculture and adapt it to changing needs and conditions. LEISA seeks to combine indigenous and scientific knowledge, and to influence policy formulation in creating an environment conducive for its further development. LEISA is a concept, an approach and a political message.

Readers are welcome to photocopy and circulate articles.

24 Agroecological restoration in Guangdong

Peter Riggs

Since the early 1990s, China's wealthy Guangdong Province has been trying to increase the sustainability of its rural sector. Its principal motivation was the need to keep its agricultural products competitive in both the domestic and export markets. However, other issues have also been taken into consideration including land rehabilitation, the quality of local water supply and the stabilization of rural livelihoods and cultures. This article explores the factors that have contributed to the success of these initiatives.

28 Shelterbelts and farmers' needs

Lambert Onyewotu, Kees Stigter, Yusuf Abdullahi and Jo Ariyo

As a response to desertification and long periods of drought in Northern Nigeria in the 1970s, the Kano State Forestry Department designed a programme of land rehabilitation using shelterbelts. It soon became clear, however, that the shelterbelts had design errors and had many disadvantages. Farmers had not been consulted when they had been established and this added to their sense of dissatisfaction with the measures implemented. In this article the authors use the Nigerian experience to stress the importance of actively involving farmers as well as researchers and policy makers in soil management and rehabilitation programmes.

DEAR READERS

As ILEIA approaches its Twentieth Anniversary (1984 – 2004), a number of interesting new institutional developments are taking place. First, we are delighted to welcome four new members to the ILEIA Board:

- Dr. Guido Gryseels, Director, Royal Museum for Central Africa, Belgium;
- Dr. Jan Pronk, Professor in Theory and Practice of International Development, Institute of Social Studies, The Netherlands;
- Dr. Paul Engel, Director, European Centre for Development Policy Management, The Netherlands;
- Dr. Teresa Fogelberg, Special Adviser, Netherlands Ministry of Spatial Planning, Housing and the Environment, The Netherlands.

We are certain they will make valuable contributions to the development of ILEIA's activities. Second, we have strengthened the ILEIA team in the Netherlands with two new editors: Mrs. Erika van Duijl and Mr. John Hollands. Both will work on the production of the *LEISA Magazine*. With the team complete once again we can increase our efforts to strengthen our collaboration with our partner organisations and work towards establishing new regional editions of the *LEISA Magazine*.

In February 2004 the editors of the five regional editions of *LEISA Magazine* will meet with their colleagues in the Netherlands during the annual International Editors Meeting of the LEISA Magazines. During the meeting ideas for increasing the flow of information between the regional editions of the LEISA Magazines, strategies for extending their outreach, and plans for the further development of the global LEISA network will be discussed. Our aim, as always, will be to make as much information on LEISA available to as many people as possible. This is a huge task and requires not only the full commitment of the ILEIA team and its regional partners, but also the active support of all our readers. You can help us by spreading information on LEISA to friends and colleagues – and by making sure they subscribe and get their (free) *LEISA Magazine*!

The Editors

With this edition of the LEISA Magazine we send all our readers our best wishes for the New Year and we hope that 2004 will bring you happiness and good fortune.

Reversing degradation

Diversity on display at the first agricultural biodiversity fair in Guangxi, China. Photos: Authors

Celebrating diversity in China

Ronnie Vernooy and Yiching Song

It is market day in Guzhai township, Guangxi province, and there is excitement on the streets because the fair has come to town. No ordinary fair this, it is an agricultural biodiversity fair, the first such event ever to be seen in the province - or very likely anywhere else in China for that matter.

Many hundreds of local farmers crowd the section of the main street where the fair has been set up to view the diversity of crops and seeds on display. Others are there too - township officials, merchants, curious children, important visitors from Beijing, even a local television crew filming the action. What they see is a rich diversity - 38 crops and 107 varieties. There are 31 varieties of maize, 17 of beans, 16 of vegetables, 14 of cereals and eight root crops. Some are rare and unique to the area, such as black wax maize and mountain lily. There are also traditional herbs, spices, and medicinal plants - almost all of them landraces.

This rich array of diversity is displayed in booths just like produce at a regular market, and at each booth there is a neatly printed card giving details of the type and origin of the items laid out. Proud farmers and some researchers and extension agents attend the booths, happy to talk about their produce with anyone who asks - and many do.

The fair-goers are impressed. "I didn't know it was possible to grow so many varieties of crops here," says one. An older farmer examines the maize on display and shakes her head in wonder. "I haven't seen these seeds since the 1960s," she says. "There are seven maize varieties here that I've never seen before," responds her companion.

Throughout the day the participants - farmers, researchers, and officials - exchange many opinions, ideas, experiences, and of course seeds. In the afternoon a committee that has been assessing the wealth of diversity at the fair awards prizes to the most outstanding displays. The first agricultural biodiversity fair in Guangxi province is attended by more than 2000 people. It is a huge success - and it will not be the last such event.

Multiple functions

The fair was the culmination of a year of planning and preparation by local farmers and a team of researchers who have been working in the province since 1999 to improve the livelihoods of resource-poor farmers through participatory plant breeding (PPB) techniques. It provided an animated demonstration of the results of a project, now in a second phase, that is a joint effort by the Center for Chinese Agricultural Policy (CCAP) and the Guangxi Maize Research Institute (GMRI). This project is built on a study carried out in the 1990s by the International Centre for Maize and Wheat Improvement (CIMMYT) and is supported by Canada's International Development Research Centre (IDRC) and the Ford Foundation.

This may have been the first agricultural biodiversity fair in China, but the concept has been tried successfully elsewhere, from neighbouring Nepal to the Andean highlands of South America. The fair in Guzhai adapted the experiences of similar fairs held in other countries to the Chinese context. Its purpose was primarily to bring together farmers, plant breeders, extension agents, seed merchants, and policy makers, and to demonstrate to them the diversity of genetic resources, knowledge and ways to strengthen resource management, as well as plant breeding and seed supply. The fair also provided opportunities for the exchange of both seeds and knowledge, and a chance to explore the market demand for PPB improved varieties. Last but not least, the success of the fair gives farmers the confidence to continue to strengthen local seed development systems.

Other experiences with seed fairs have been described in previous LEISA Magazines. See for example the Zimbabwean experience described by Neuendorf, page 24 of issue15.3/4, Seeds for agrobiodiversity.

Land rights in Africa
http://www.oxfam.org.uk/landrights/

Access to land, which remains for many people in Africa the ultimate form of social security, is being severely threatened. The threat comes from a combination of local and international factors, which include excessive liberalisation, the search for foreign investment, and an often-blind faith in market solutions. This online "resource bank" of documents and references contains papers and reports from Oxfam GB and its partner organisations, its allies, and land rights specialists. The aim of the resource bank is to spread greater awareness of land rights issues, to make current information widely available, and to provide a point of contact for key actors in Africa and elsewhere. The resource bank is available for people without Internet by sending an email to www.4mail@web.bellanet.org.

Land Tenure Center
http://www.wisc.edu/ltc

The Land Tenure Center serves as a global resource institution on issues relating to land ownership, land rights, land access, and land use. The Center conducts research programs throughout the world on issues such as land tenure, land use, agrarian reform, land markets, legislative drafting, registration and titling, institutional dimensions of rural development, and natural resource management. LTC's research activities emphasise collaboration with host country institutions and individuals.

MYRADA
http://www.myrada.org/index.html

MYRADA is a NGO managing rural development programmes in three States of South India and providing on-going support including deputations of staff to programmes in six other States. It also promotes the Self Help Affinity strategy in Cambodia, Myanmar and Bangladesh. Their mission is to encourage a process of ongoing change in favour of the rural poor, by enabling them to build and manage appropriate and innovative local level institutions rooted in values of justice, equity and mutual support. The core strategy is based on the belief that enabling people to build up experience in governance - through managing their own institutions - is a major factor contributing to their empowerment.

The United Nations Research Institute for Social Development (UNRISD)
http://www.unrisd.org

Poverty eradication, the promotion of democracy and human rights, gender equity, environmental sustainability and the effects of globalisation are overarching concerns in UNRISD's work. These concerns are reflected in research carried out. An overview, together with details of the projects is available on this website. UNRISD also pursues an active and varied publications programme, which includes in-house and commercially published books, special reports, programme and occasional papers, as well as newsletters on specific events and the Institute's work in general. This website provides a catalogue of their publications, and free online access to many of them.

ODI Forest Policy and Environment Group
http://www.odifpeg.org.uk/publications/

The RDFN papers, outputs from the ODI Rural Development Forestry Network, are available from this website.

MEAD-ESA (Media for Environment, Agriculture and Development in East and Southern Africa)

MEAD-ESA is a new network for journalists, editors, radio and television staff, web masters and information officers concerned with the agricultural and environmental aspects of development. At a recent meeting of national representatives in Nairobi, strategies were discussed to increase journalists' capacity to report on agro-ecological problems and ensure that articles and features dealing with these issues appear more regularly in the local media. In this way, MEAD-ESA hopes to increase awareness of the many experiences, initiatives and results of research that already exists in the public domain but which is little known to agricultural policy makers and farm practitioners. MEAD-ESA was established in Lusaka in October 2002. It has national branches in Zambia, Malawi, Zimbabwe, and Kenya. It is also associated with journalists concerned with these issues in West Africa, Ethiopia, Mozambique and South Africa. The network is open to all those interested in this area of reporting and information sharing. Contact: Parkie Mbozi, pmbozi05@yahoo.com, Aghan Daniel, bta@swiftkenya.com or chimarcel@hotmail.com

CBNRM Net, Community-Based Natural Resource Management Network
http://www.cbnrm.net

Worldwide, people working on Community-Based Natural Resource Management (CBNRM), as practitioners, managers and researchers, are talking about an urgent need for greater communication capabilities. Capabilities for networking on CBNRM would make it possible for people to exchange experiences, manage relevant knowledge, and support learning across countries, sectors, cultures, and languages; and in this way achieve better results. *CBNRM Net* is a response to this call. *CBNRM Net*'s web site provides a powerful set of broad, robust and useful networking tools aimed at linking stakeholders. As a complete, integrated, and adaptable knowledge management tool, *CBNRM Net* is presented as a service to the global CBNRM community of practise.

The Centre for Alternative Agricultural Media (CAAM)
http://www.farmedia.org

CAAM is an Indian network for alternative agricultural journalism. One of their objectives is to facilitate the media to focus on the positive efforts carried out in the rural areas. As an example of their work, the first event contributing to this objective is Harogerige Hogona Banni (Come, let us visit Harogeri). This programme will unfold the different stages of sustainable

Call for contributions to a sourcebook on participatory research and development

Contributions are being solicited for a proposed Sourcebook on Participatory Research and Development, featuring field-tested concepts and methods for enhancing local people's participation in research. The focus will be on developing-country experiences associated with managing natural resources to support agriculture and rural livelihoods. Copyright-free and highly illustrated, the sourcebook is primarily intended for fieldworkers seeking to learn and apply participatory approaches in their research activities. Development of the sourcebook is a collaborative effort by the Users' Perspectives With Agricultural Research and Development (UPWARD) Network and partners around the world (see www.eseap.cipotato.org/upward). For more details about the sourcebook and guidelines for contributions, please contact Ms. Hydee de Chavez, CIP-UPWARD, c/o IRRI DAPO 7777, Metro Manila, Philippines (email hydee@laguna.net).

development in Harogeri to the media. BAIF Institute for Rural Development in Dharwad (India) has been working effectively in 22 villages including Harogeri, in Dharwad district for six years. Through its participatory activities, BAIF has reached the poorest of the poor. The programme has helped people improve their lives, by enhancing the natural resources in their villages and adopting many other developmental practises.

The Association of Agricultural Research Institutions in the Near East and North Africa (AARINENA)
http://www.aarinena.org/
AARINENA's mission is to contribute to the enhancement of agricultural and rural development in the Region. By fostering agricultural research and technology development and by strengthening collaboration within and outside the region, the website provides a list of regional and international organisations with details.

Network, smallholder irrigation market initiative (SIMI)
http://www.siminet.org
Access to irrigation is a limiting factor to the productivity and profitability of small farms in many parts of the world. Low-cost micro-irrigation and a series of other low-cost technologies related to small-scale irrigation like treadle, rope and similar pumps, small-scale water storage technologies etc. have a good potential to allow a large number of small farm households to escape the most severe poverty by producing high value cash crops for local and more distant markets, or food during the dry season, and thus to increase household incomes and improve livelihood security. Information, resources and links related to smallholder irrigation technologies, as well as market creation for their large scale dissemination are now available on the new website of the SIMI network.

Bees for Development
http://www.beesfordevelopment.org/
This new website of Bees *for* Development is an information service at the centre of an international network of people and organisations involved with apiculture in developing countries. Beekeeping is an effective way for poor people to strengthen their livelihoods, and Bees *for* Development works to provide information to assist them.

Policy Discourses On Women's Land Rights In Sub-Saharan Africa: The Implications Of The Re-Turn To The Customary by Whitehead, A and Tsikata, D.
This article examines some contemporary policy discourses on land tenure reform in sub-Saharan Africa and their implications for women's interests in land. It demonstrates an emerging consensus among a range of influential policy institutions, lawyers and academics about the potential of so-called customary systems of land tenure to meet the needs of all land users and claimants. This article which was published in the *Journal of Agrarian Change*, vol. 3, nos.1 and 2, January and April, 2003 is available as a pdf file from the "Land rights in Africa" resource bank at:
http://www.oxfam.org.uk/landrights/Re-turn.doc

PLAAS NETWORKS:

- **Co-Govern, promoting common property in Africa**
  http://www.uwc.ac.za/plaas/co-govern/
  The website of Co-Govern: Networks for Influencing Policy and Governance of Natural Resources. This project works to strengthen networks of African researchers and land professionals, to promote exchange of experience, dialogue and analysis, and identify ways of ensuring that local practise better informs legal reforms and policies regarding CPRs.
- **Pan-African Programme on Land and Resource Rights (PAPLRR)**
  http://www.cbnrm.uwc.ac.za/paplrr
  The PAPLRR network aims to develop and articulate a pan-African voice on land and resource rights, policies and advocacy, and engage with other stakeholders at regional and international research and policy-making events.

Both of these Networks are coordinated by the Programme for Land and Agrarian Studies (**PLAAS**), School of Government, University of the Western Cape, South Africa.

Water policy briefing
http://www.iwmi.org/waterpolicybriefing
Challenges of Integrated River Basin Management in India, issue 3 of the Water Policy Briefing series. This paper, available online, is about tailoring water management solutions to South Asia.

LEISA issue March 2004

Underutilised plant species

It has been estimated that humans have, at one time or another, cultivated or collected more than 7000 edible plant species. Today, however, only about 30 crops form the basis of world's agriculture. Over 50% of our energy requirements are now met by just three crops: rice, wheat and maize. The continuously narrowing base for global food security limits the options available to farmers, and reduces the agricultural biodiversity necessary to provide security in resource-poor environments.

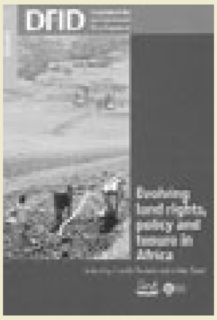
Many underutilised species are particularly useful in marginal lands where they have evolved through selection over generations to increase productivity and withstand stress conditions. These crops contribute to sustainable production and usually require less external inputs than high yielding varieties of major crops. Often they contain essential micronutrients not present in staple foods. These crops are also part of a great cultural heritage and diversity that enriches our lives. Many rural people and development organisations have recognised the importance of these underutilised and neglected species and have successfully increased their production and utilisation, thereby improving livelihoods, providing more options to small farmers and increasing diversity within the agricultural system. This issue of LEISA will present some of these successful cases. We invite articles on experiences with revival, conservation, cultivation, utilisation and marketing of underutilised plant species that are interesting to field practitioners and will make it possible to promote the use of these species.

Deadline for contributions is the 1st of December, 2003.

You are invited to contribute with articles (about 800, 1600 or 2400 words + 2-3 illustrations and references), suggest possible authors, and send us information about publications, training courses, meetings and websites. Editorial support is provided by ILEIA. Authors of published articles are entitled to a standard fee of US$ 75,–.

The common property resource digest International Association for the Study of Common Property (IASCP), PO Box 2355, Gary IN 46409 USA. Email: iascp@indiana.edu.
This quarterly publication of the International Association for the Study of Common Property (IASCP) addresses common property issues from all over the world. Besides a forum discussion on what makes institutions for the management of common-pool resources emerge and function successfully, the March issue presents a series of short articles dealing with the role of the commons in Eastern Europe's transition away from communist property systems. A digital library of the commons is available from the website: http://dlc/dlib/indiana.edu (WR)

ODI natural resource perspectives Overseas Development Institute (ODI), 111 Westminster Bridge Road, London SE1 7JD, UK. Manage, India. Email: nrp@odi.org.uk; www.odi.org.uk/nrp/
This Indian edition of the Natural Resource Perspective series is co-published by National Institute of Agricultural Extension Management (Manage) and Overseas Development Institute (ODI). The series presents accessible information on current development issues from a policy point of view. It is available in print and from the website www.odi.org.uk/nrp/ as a pdf file.



Evolving land rights, policy and tenure in Africa by Toulmin C, Quan J (eds). 2000. 336 p. ISBN 1 899825 51 7 GBP 12.50. Drylands Programme, IIED, 3 Endsleigh street, London WC1H ODD, UK. Department for International Development (DFID). (DFID issues). Email: drylands@iied.org; www.iied.org/drylands
The material in this book draws on a 1999 workshop on Land Rights and Sustainable development in Sub Saharan Africa, at which DFID brought together policy makers, researchers and civil society representatives from across the African continent. The book follows the overall thematic structure of the workshop. It examines the linkages between land reform, economic growth, and poverty reduction. It discusses the legislative and practical challenges of tenure reform and the harmonisation of customary and formal land rights in both anglophone and francophone Africa; the management of Africa's commons; opportunities for and constraints on women's land rights; institutional arrangements for securing and managing land rights; the challenges of decentralisation; and policy and implementation processes that are currently underway. The appendix provides network addresses. (WR)

Land policies for growth and poverty reduction: a World Bank policy research report by Deininger K. 2003. 208 p. ISBN 0 8213 5071 4. The International Bank for Reconstruction and Development/The World Bank, 1818 H Street, NW Washington DC 20433, USA. Email: feedback@worldbank.org; www.worldbank.org
This report aims to strengthen the effectiveness of land policy in support of development and poverty reduction, by setting out the results of recent research in a way that is accessible to a wide audience of policymakers, NGOs, donor agency officials, and the broader development community. Its main message rests on three principles: First, that providing secure tenure to land can improve the welfare of the poor, by enhancing the asset base of those whose land rights are often neglected. Second, that facilitating the exchange and distribution of land, at low cost, through markets as well as through non-market channels, is central to expediting land access by productive but land-poor producers. Third, that governments have a clear role to play in promoting and contributing to socially desirable land allocation and utilisation. This report can make an important contribution in the policy debate on land. It can provide the basis for integrating land into broader strategies and implementing specific land policies that will help increase growth in a way that benefits poor people. The full report is available online at http://econ.worldbank.org/prr/land_policy/text-27809/ (WR)

The economic role of women in agricultural and rural development: revisiting the legal environment: summary report of a seminar Kampala, Uganda 19-23 February 2001
2002. 72 p. ISBN 92 9081 2621. Technical Centre for Agricultural and Rural Co-operation (CTA), PO Box 380, 6700 AJ Wageningen, The Netherlands. Email: cta@cta.nl; www.cta.int/pubs/women/index.htm
Recognising the importance of the role women play in agricultural and rural development is fundamental to any attempt to strengthen their economic situation through improved legal rights. The legal environment provides the framework determining women's access to productive resources. The objective of this regional seminar was to raise two important issues regarding women's legal status. First, the state of current legislation and the way it treats women, an issue of lobbying for change on the part of women and raising awareness on the part of the legislators. Secondly, it addressed women's awareness of their legal rights and their ability to claim these rights, an issue of information, legal literacy and legal counselling. The seminar addressed these issues through papers focusing on the legal environment in Eastern and Southern Africa, women's entitlement to productive resources and their access to legal rights. It concluded with recommendations for policies and strategies to strengthen the legal status in rural areas in the region. With this report, CTA provides a valuable document for everyone involved in gender and rural development. The report also provides an annex with a list of website resources on the topic. (WR)

Going home: land & property issues 2000. 47 p. The Refugee Studies Centre (RSC) in association with the Norwegian Refugee Council, Queen Elizabeth House, 21 St Giles, Oxford, OX1 3LA, UK. Email: fmr@qeh.ox.ac.uk. (Forced Migration Review no 7: ISSN 1460-9819).
Housing and property restitution has emerged as one of the most important components of post-conflict reconciliation and rehabilitation. This special issue of Forced Migration Review deals with many of the difficult issues arising from schemes to restore property to returning refugees. Contributions about situations in Asia (Bhutan), Lebanon, Central Africa, Latin America (Guatemala, Colombia) and Europe (former Yugoslavian countries) make this issue to a valuable source of information on the topic. It also describes an innovative self-help project seeking to promote eventual restitution and return. (WR)

Stakeholder incentives in participatory forest management: a manual for economic analysis
by Richards M, Davies J, Yaron, G. 2003. 238 p. ISBN 1 85339 559 5. Overseas Development Institute (ODI), ITDG Publishing, 103-105 Southampton Row, London WC1B 4HL, UK. Email: itpubs@itpubs.org.uk; www.itdgpublishing.org.uk.
This manual aims to help the economic analyst assess the incentives of local forest users in a context of multi-purpose forestry. The main users will be those with a formal training in agricultural or natural resource economics, but with limited experience in applying economics in participatory forest management. What makes the manual innovative is its approach to enabling small farmers and foresters to participate in using economic tools to analyse their situation and identify solutions to their problems. Using concrete examples from Bolivia, Ghana, Mexico, Nepal and Zimbabwe, the authors give practical

advice on how to conduct farmer workshops, rapid rural appraisals, key informant interviews and household surveys that incorporate simple economic tools in ways that allow greater discussion, feedback and debate with local farmers. (WR)

Lake Mweru is our bank: a documentary on resource management of a Zambian fishery 1995. EURO 25.– STUG Video productions, P.O.Box 3011, 6802 DA Arnhem, The Netherlands. www.stug.nl

This video is a documentary on resource management, created to inform policymakers, politicians and fishery managers in Zambia about the complexity and dynamics of the Mweru-Luapula Fishery and its significance for the livelihoods of so many people. It highlights the importance of considering economic, social, political and historical aspects of fisheries management next to ecological dynamics. It provides insight into the conflicting interests of various stakeholders. The formulation of new policies for community-based management of inland fisheries could be much improved if these policies are based on the area specific problems and potentials. Such policies can only be put in practise if local ideas and initiatives for managing the fishery are taken into consideration.

Borders, rules and governance: mapping to catalyse changes in policy and management by Alcorn JB. 2000. 24 p. International Institute for Environment and Development (IIED), 3 Endsleigh Street, London WC1H 0DD, UK. Email: sustag@iied.org (Gatekeeper Series no. 91 ISSN 1357-9258)

This issue of Gatekeeper is about the role that mapping techniques and satellite imagery can play in improving local decision-making and enabling local analyses to be shared with outsiders in order to improve national level policies. Maps reveal information about conflicts, overlaps and trends in areas where rights and responsibilities are cloudy. Mapping programmes can empower civil society efforts to bring accountability and transparency to local and national governments. This paper uses numerous examples to highlight the power of maps in bringing about local change. (WR)

The future of community lands: human resources by Ndione E, Leener Ph (de), Ndiay M, Jacolin P, Perier JP. 1995. 236 p. ISBN 1 85339 248 0 (pbk): USD 28.50. GTZ Supraregional Project 'Natural Resource Management by Self-Help Promotion (NRMSH)', Wachsbleiche 1, D-53111 Bonn, Germany. Intermediate Technology Publications (ITP), 103-105 Southampton Row, London WC1B 4HH, UK.

This detailed account of the experiences of the Research-Action-Learning Group (GRAF) of ENDA (Environment and Development Activities in the Third World) in Senegal traces the history of relationships between local people and external agents, both governmental and NGO. The cases refer to tree planting on community land in the Thiès area and dam building in the Kaolack area. Differences in perception of natural resource management become obvious when tree planting in Africa is seen in the context of deforestation and afforestation in Europe: in the eyes of the Africans, trees were instruments of colonial domination. The fascinating history of development in the Thiès area, related by local farmers themselves, points to numerous indigenous projects, experiments and innovations without external assistance. The history is told from only one viewpoint; other ethnic groups in the area, such as the Fulani herders, might have enriched (and confused!) it. ENDA-GRAF makes a very honest and revealing analysis of the convoluted path of interaction between them and the various local interest groups, and uncovers the very diverse interests and power issues within each "community". Some very useful ideas for analysis of actors and motivations are given. Creative management of uncertainty and reflective analysis of failure and confrontation were important keys in the learning process by both villagers and fieldworkers. The book gives much food for thought. This publication originally appeared in French, but, strangely, the original is not mentioned. (AWB)

Water rights and empowerment by Boelens R, Hoogendam P (eds). 2002. 256 p. ISBN 90 232 3764 1: EURO 25.00. Van Gorcum, PO Box 43, 9400 AA Assen, The Netherlands. Email: assen@vangorcum.nl

In the Andean region, local users, organised into peasant or indigenous communities, have built most irrigation systems. Commonly, they also manage their own systems collectively. This book emphasises the issues of internal water rights, within irrigation systems, but since collective rights between irrigation systems or between these systems and other types of water users are becoming increasingly important, it also includes a chapter on collective rights within the context of water management in watershed or catchment areas. Further chapters reach beyond the system level: discussing the issue of local collective rights regarding other normative frameworks, other groups of local, regional or national interest, and from the perspective of national legislation. With this book, the authors seek to contribute to the development of methodological proposals that strengthen local water control and empower peasant and indigenous communities. (WR)

Land, trees, and women: evolution of land tenure institutions in Western Ghana and Sumatra by Quisumbing AR, Otsuka K [et al]. 2001. 90 p. ISBN 0 89629 122 7. International Food Policy Research Institute (IFPRI), 2033 K Street, N.W., Washington, D.C. 20006, USA. (Research Report 121). Email: ifpri@cgiar.org; www.ifpri.org/pubs/pubs.htm

How do women's land rights change as customary tenure systems give way to individualised land tenure? While the individualisation of land rights creates incentives for poor farmers in marginal areas to adopt agroforestry, not much is known about its impact on women's land rights. This research report examines the evolution of customary land tenure institutions in areas of Western Ghana and Western Sumatra where traditional matrilineal inheritance systems have been changing. In these two areas, the authors find that individualisation of land tenure has contributed to both increased gender equity and to greater efficiency in agroforestry management. While property rights institutions are moving toward providing proper incentives for efficient natural resource management, the authors conclude that any program or legal framework that assigns rights to resources must be evaluated for barriers to women's participation. This book is recommended for professionals involved in natural resource management, agroforestry, gender and development, food policy, rural development, and property law/property rights. (WR)

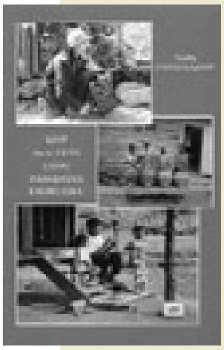
Best practices using indigenous knowledge
by Boven K, Morohashi J (eds). 2002. 280 p.
ISBN 90 5464 032 4. Nuffic-CIRAN (Centre for International Research and Advisory Networks), P.O.Box 29777, 2502 LT The Hague, The Netherlands; UNESCO-MOST (Management of Social Transformation Programme). Email: ik@nuffic.nl; www.nuffic.nl/ik-pages; www.unesco.org/most/bpindi.htm
Indigenous or local knowledge refers to a body of knowledge, know-how and practises maintained and developed by peoples, generally in rural areas, who have extended histories of interaction with the natural environment. This publication, the result of cooperation between Nuffic and UNESCO/Most, aims to encourage researchers and policy makers to take indigenous knowledge and practises into account in all activities affecting local communities. It presents 22 best practises illustrating the use of indigenous knowledge in the development of cost-effective and sustainable strategies for poverty alleviation and income generation in Africa, Asia and the Americas. The publication includes the guidelines used to document the cases, the cases themselves and indexes to facilitate searching the information. The practises presented in this publication have also been added to the Indigenous Knowledge database, available at www.unesco.org/most/bpindi.htm (WR)

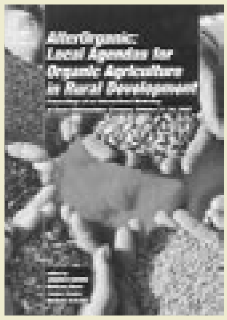


Agriculture and HIV/AIDS by Guerny J du. 2002. 16 p. ISBN 974 680 204 6. United Nations Development Programme (UNDP), South East Asia HIV and Development Project. www.hiv-development.org/publications/ewrs.asp
The impact of HIV/AIDS on the farm-household level is impressive, ranging from abandoning the cultivation of remote fields or cash crops to the sale of assets to cover medical and funeral expenses. In such a context, agricultural policies and programmes have a crucial responsibility in reducing the conditions that create vulnerability in rural populations, leading to higher risks of HIV infection. This paper argues that the agricultural sector should not attempt to carry out health work for which it is ill equipped, but concentrate on activities in agriculture. Agriculture can be developed in such a way as to increase the resilience of rural populations and thereby contribute significantly to HIV prevention. (WR)

INASP rural development directory 2003/2004 2003. 455 p. ISBN 1 902928 15 6 GBP 25-. International Network for the Availability of Scientific Publications (INASP), 27 Park End St., Oxford OX1 1HU, UK. Email: pwr@inasp.info; www.inasp.info/pubs/rd
The aim of this Directory is to provide access to a wide range of information on rural development, and particularly to promote South-South information dissemination and interchange. It contains profiles of more than 430 international, regional and national networks and organisations around the globe. Each entry provides contact details and a brief description of the organisation, highlighting its objectives, activities, subject areas of interest and geographical coverage. In addition there is often further information provided by the organisations, including newsletters, journals or online documents. The directory is also available on the INASP website at www.inasp.info/pubs/rd or www.inasp.info/south/index.html where the contents will be updated on a regular basis. CTA will make copies of the CD Rom available free of charge to its ACP subscribers. INASP also has a limited number of copies of the print version at available for organisations in developing countries which do not have access to computers with CD ROM drives.

People-oriented approaches in global conservation: is the leopard changing its spots? by Jeanrenaud S. 2002. 68 p. ISBN 1 84369 036 5. International Institute for Environment and Development (IIED), 3 Endsleigh Street, London WC1H 0DD, UK. Email: INFO@IIED.ORG . Institute for Development Studies (IDS), Sussex, UK. Email: IDS@IDS.AC.UK (Institutionalising participation series).
Local people were once considered a threat to nature and were often removed from protected areas. Today, global conservation organisations like WWF and IUCN are promoting a wide range of people-oriented conservation approaches. This publication includes the main findings of a collaborative research programme coordinated by IIED and IDS. The programme was designed to examine the dynamics of institutionalising people-centred processes and participatory approaches for natural resource management, and includes case studies in West Africa, India, Indonesia and Mexico. The authors of this publication suggest that it is important to exercise caution in claiming that 'participation' has been mainstreamed in global conservation programmes. An analysis of people-conservation narratives identifies contrasting ways in which 'nature', 'problems' and 'solutions' are framed. Beyond possible lessons for conservation agencies, this study highlights several questions and issues of wider interest to organisations involved in participatory natural resource management. (WR)

Alterorganic: local agendas for organic agriculture in rural development: Proceedings of an international workshop at Bonn-Königswinter, Germany, October 21-24, 2002 by Kotschi J, Bayer W, Becker T, Schrimpf B (eds.). 2003. 186 p. ISBN 3 8236 1403 7 EURO 10. AGRECOL, Johannes Acker 6, D-35041 Marburg, Germany. Email: info@agrecol.de; kotschi@agrecol.de; www.agrecol.de



This workshop was prepared by the AGRECOL working group on Organic Agriculture in Rural Development. The group has taken care to identify key problem areas faced by developing countries in the promotion of their organic sector, as well as important experiences from developing countries, as stimulants for focused and result-oriented discussions. Much of the discussion and many of the activities concerned with promoting organic farming in the South have been focused on marketing organic products in the North. This workshop aimed to broaden the discussion. Producing for overseas markets is only one of many reasons for promoting ecologically sound or organic agriculture in the South. This volume presents the papers contributed to the workshop and the main outcomes of the working groups and the plenary discussions, including the Bonn Declaration prepared by the participants. (WR)

Economic change, governance and natural resource wealth: the political economy of change in Southern Africa by Reed D (ed.). 2001. 168 p. ISBN 1 85383 872 1: USD 25-. Macroeconomics for Sustainable Development Programme, WWF-International. Earthscan Publications, 120 Pentonville Road, London N1 9JN, UK. Email: orders@lbsltd.co.uk; www.earthscan.co.uk
As the debate regarding the benefits and costs of globalisation evolves, this book confronts the stark realities of how economic and political reforms in southern Africa have affected the poor and the environment. It further examines the crucial role of international development and business communities in creating effective institutions for long-term, sustainable prosperity and social vitality.

Food production and HIV/AIDS

In Zimbabwe, where two-thirds of the population live in the rural areas, poverty and underdevelopment have facilitated the spread of HIV/AIDS. Throughout Southern Africa, governments have tended to see HIV/AIDS as a health problem. However, experience shows that HIV/AIDS is much more than this. Not only has the epidemic caused social and emotional devastation but it has crippled the capacity of many village communities to produce the food they need for an adequate and nutritionally balanced diet. Without reliable and varied food the population becomes more susceptible to disease and the sick deteriorate quickly. The remaining households do not have the strength and energy to meet the increasing demands made on them by the HIV/AIDS epidemic including caring for the sick and orphans at the same time as they have to take increasing responsibility for providing good food.

Poor diet leads to deteriorating health and effects both physical and mental development. In both the short and long term this can only lead to an intensification of poverty and the persistence of conditions that break people's resistance to disease. For those already infected with the HIV virus good nutrition can help delay the onset of AIDS. The sustainable production of good quality food is, therefore, basic to breaking the cycle of poverty related disease. However, food production depends on secure access to natural resources, and in many parts of Southern Africa large numbers of rural households do not have access to sufficient agricultural land or the agricultural inputs they need to grow food.

Impacts

HIV/AIDS has caused a particularly heavy death rate amongst able-bodied men and women. This is clearly reflected in the demography of rural Zimbabwe. More than 52 percent of the country's population are women and 86 percent of them live and depend on land for their livelihood. Women account for 70 percent of the agricultural population but many have no land, few resources, are illiterate and excluded from information and decision-making processes because of their weak social status. HIV/AIDS has had a dramatic effect on the lives of many of these women. In communities devastated by HIV/AIDS it is becoming increasingly difficult for them to meet their responsibilities and provide food and care.

Two systems

Zimbabwean women have no constitutional rights under customary law. This is a legacy of British colonialism which maintained the system of traditional law alongside the statutory law they introduced to support their colonial administration. For the British, both at home and in the colonies farmers were by definition men. They had little interest in the complexities and inequalities of women's land rights under customary law, even in those areas hardest hit by labour migration.

Since the early 1900s, land tenure arrangements in Zimbabwe, as in neighbouring Botswana, Zambia, Malawi, the Republic of South Africa and Swaziland have been based on British, Roman Dutch and customary law. These systems apply to different categories of women and define rights of ownership and access according to their own specific principals.

Under statutory law women can buy land on the open market but not many rural women are able to get control of land in this way. In pre-colonial times, customary land tenure arrangements offered relative security to all members of the community. Women were given pieces of land to manage in their own right either by their fathers or by their brothers and husbands. The political and economic changes of the twentieth century, however, have destabilised customary practises and gradually eroded the effectiveness as far as women's rights to land are concerned. Today, in Southern Africa where customary law puts the inheritance rights of a man's paternal relatives above those of his wife, the traditional system is often unable (or unwilling) to meet its responsibilities to his widow.

The provisions of statutory and customary law as these were developed in the colonial period were taken up in the constitution many of independent African states. Zimbabwe is an example. Whilst the Zimbabwean constitution states that every citizen has an equal right to the ownership of property, women do not have the right to land under customary law. More recent legislation passed by the Zimbabwean government has strengthened customary law and further weakened the position of women living in communal areas. Today women have no secure access to land and can never be certain that they will be able to benefit in the long term from the labour and capital they invest in land that they hold through rights that belong to their husbands or other male relatives.

Agricultural productivity suffers not only because implements and other assets often have to be sold to pay for medicine, but also because women, although they play a major role in agricultural production, may not always have the agricultural knowledge they need to carry out tasks traditionally done by men. A hidden effect of HIV/AIDS is that the transfer of agricultural knowledge between generations and from one member of the rural community to another is rapidly deteriorating. The impact this has on women's capacity to deal with agricultural problems is intensified by the fact that women generally have less access to agricultural extension services than men. While access to land is fundamental to food production, it must be combined with the knowledge and capacity to use it effectively.

Recording land rights at Ekuthuleni

Donna Hornby

Ekuthuleni, a former mission station farm owned by the Department of Agriculture and Land Affairs (DLA), lies in Melmoth on South Africa's north coast. Long-term tenants at Ekuthuleni asked the DLA to upgrade their informal tenants rights into community ownership so that land rights issues would no longer delay the development of their area. The DLA agreed, and aims to complete the process of transferring the land to a Communal Property Association (CPA) in 2003. 240 households are involved in this process.

Members of the Ekuthuleni Communal Property Association viewing a boundary map. Photo: AFRA

Some residents at Ekuthuleni wanted individual land ownership while retaining links to the Ntembeni tribe that administers them. However, this option raises problems:

- People with incomes below the poverty line cannot afford the costs of surveying and transferring property;
- Government property administration agencies (specifically Deeds and Surveys) are far away from poor, rural people and their rules and requirements difficult to understand;
- Exclusive nature of ownership can undermine household access to essential firewood, grazing, thatching, water, herbs and mud;
- Simplification of ownership rights can erode the complex rights that extend to family members in practise.

In 1998, the DLA contracted the Association for Rural Advancement (AFRA), a leading South Africaland NGO, to assess the tenure rights of people at Ekuthuleni and recommend how it should proceed with the application to upgrade them. AFRA advised the DLA to transfer the land to a communal entity, which would allow the community to develop its own constitution on how land would be held and managed. This would be less expensive to arrange as individual rights, and would ensure links were retained with the tribal authority.

AFRA offered to help the community to develop legal, affordable and accessible records of household land rights in order to strengthen the communal system and give households more security over their holdings. Records or "individual ownership documents" would provide households with evidence of their land rights and enable them to settle disputes and access credit. More importantly, they would protect holders from arbitrary eviction or loss of land rights, and give them the right to decide how to manage and use the land.

Registration

The first step in the registration process was a detailed tenure revue to establish how land was currently being allocated, subdivided and transferred. Research showed a widespread experience of insecure tenure resulting from changing practises and rules. It also showed there was local capacity to administer land allocation and rights. The next step was to find cheap ways of providing land records to households.

A stakeholder meeting including participants from government departments, academics and tenure experts met to discuss this problem. Systems and procedures for producing and maintaining records were discussed at a community workshop late in 2000. Much progress has been made on producing and presenting these records and deciding on who would be responsible for maintaining them locally. Everyone is aware that managing the process of formalising tenure requires great care because changes can threaten existing arrangements.

In Ekuthuleni AFRA is still working on ways to provide affordable and accessible records of household land rights. An advisory committee of key stakeholders that includes NGOs, CBO, and government departments directs and guides the process. A major objective is to develop and support local structures and establish links to external institutions that can help issue records, mediate disputes and assist in the evaluation of records when credit application are being assessed or disputes resolved. Project experiences are shared with other NGOs and government departments, as well as with national and international tenure experts in order to influence tenure reform in South Africa.

Recording rights in informal tenure, to ensure security and at the same time creating links to formal institutions is a complex process. In a system like South Africa, where an extremely accurate and secure formal land tenure system exists side by side with an informal tenure system that depends on an individual's ability to negotiate rights through local institutions, it is a major challenge. ■

Community consultation and national lobbying in South Africa

Ben Cousins

South Africa's new democratic government is working on a large and ambitious land reform programme. During apartheid, access to land was determined by race. Black South Africans were removed from their lands and resettled in so-called homelands. These areas included some of the poorest and most degraded soils in the country and they became islands of rural poverty whose main function was to provide industrial labour for South Africa's farms, mines and urban areas.

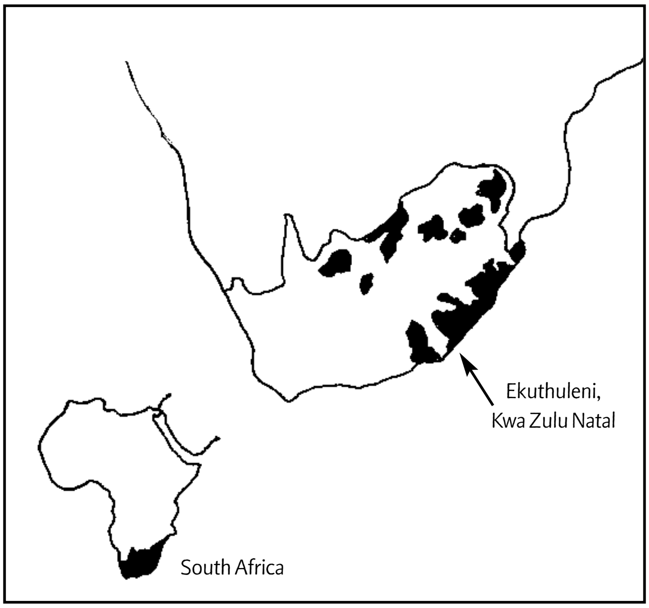

Figure 1: Communal lands in South Africa

The Republic's current land policy has three main aims: to redistribute land, to give back land taken away under racist and discriminatory practises, and to develop a system of land tenure that will give the rural population living in the homelands a greater degree of land security as well as protecting farm workers and labour tenants from arbitrary evictions.

Insecurity

Communal land has a second-class status in South Africa. Those living under these types of tenure arrangements are dependent on the local authorities – the traditional leaders – for access to land and the right to use it. Rights of occupation are not recognised and this increases insecurity. The near-collapse of land administration has further aggravated the situation and women are in a particularly difficult position.

In many places development projects have been held up because the status of land is unclear. This has had a particularly deep impact in community areas where houses, roads and other infrastructure are urgently needed. These problems have increased the tensions that already exist between traditional authorities and local administration and make it more difficult to determine how land should be allocated for development and how access to common resources such as grazing, firewood and water should be guaranteed.

A draft Bill

In August 2002, a draft Communal Land Rights Bill (CLRB) was published and the public was asked to discuss its contents. The aim of the Bill was to transfer title or ownership of land in the former homelands from the state to local communities. Before this could be done, however, communities would have to make an inquiry into lands rights in the area, organise community meetings to inform people of the proposed changes, and reach agreements on what constituted the boundaries of the community. Before transfer of ownership can be completed, the community also has to work out a set of rules that describe the land tenure rights of all individuals, households and families in the community. The community's legal right to own land can only be recognised when this has been registered. After this has been done a Land Administration Committee (LAC) must be elected to manage the property.

Under the proposed CLRB, traditional leaders can become members of the LACs, but only as advisors and they must not make up more than 25 percent of the LAC. Such groups as the *Congress of Traditional Leaders of South Africa* have protested strongly against this regulation and have demanded that the traditional role of tribal authorities in administrating land be reinstated.

LACs

In the Communal Land Rights Bill, the LACs have great power. These bodies are responsible for the land administration system at the local level. Within the community they are responsible for defining land rights and making sure they are recorded and registered. However, the draft CLRB does not make any provision for supporting the LACs either financially or institutionally. Officials will be made available if inquiries are necessary or communities need help to implement the law but this is very inadequate given the enormous and difficult task facing the LACs if the Bill is passed.

What the Bill means

The publication of the draft CLRB in 2002 has stimulated widespread public debate on communal tenure reform in South Africa. Although the government said it wanted to encourage discussion on the issues proposed in the new legislation, it has done little to facilitate this process. Instead it has been left to civil society organisations and others involved in community land reform to get discussions going on the CLRB. In recent months many activities have be organised in the communal areas to encourage the exchange of experiences and views on existing land tenure arrangements and the new legislative proposals. The National Land Committee and the Programme for Land and Agrarian Studies of the University of the Western Cape has been involved in this process through a project designed to increase people's understanding of the effect the Bill will have on their rights to access and control of land. Amongst project activities was a symposium to discuss experiences of tenure reform in other parts of Africa, the provision of capacity building support to NGOs working on land tenure issues, and advocacy and lobbying activities such as holding workshops on the Bill with a range of civil society stakeholders.

A series of seven consultative meetings were also held between November 2002 and April 2003. These meetings were attended by 700 participants from 75 rural communities in 5 provinces and representatives were chosen from the meetings to report their recommendations to the Parliamentary Portfolio Committee on Agriculture and Land Affairs.

Community views

The field experiences of NGOs and views expressed by community members in the consultative meetings suggest that the CLRB has many weaknesses. These conclusions have been confirmed by those attending the consultative meetings. Many were concerned about the negative effect the collapse of the present system of land administration has had on land security in the communal areas, and were disappointed that the draft CLRB did not go far enough in dealing with the chaotic and complex situation in which land rights would have to be administered. There was no attempt in the Bill to define the relationship between the LACs and local authorities, for example, and although the draft CLRB gave LACs far-reaching powers, it made no attempt to create a link between their work and the function of local government. Where tensions already existed between traditional leaders and local authorities it was felt that the provisions of the CLRB would only makes them worse. There was an urgent need to resolve this standoff and it should be taken into consideration in redrafting the CLRB.

Common property

The fact that the draft CLRB made no provision for managing access to and control of common resources such as grazing, mud, thatch, wood and water was seen as a very serious omission. If the new Bill does not protect these rights, the rural poor can be denied access by more powerful members of the community or by interventions from outside.

Those attending the consultative meetings also raised the complex and sensitive issue of boundaries. A major criticism of the Bill was that the boundary issue was not well covered by the proposed legislation. Under the terms of the draft CLRB, title would be transferred to the communities as a first step towards tenure reform and it would be the job of the LACs to define community boundaries. It was pointed out that serious problems could arise in situations of conflicting claims, especially if these were tribally based. Representatives from areas with experience of boundary conflicts such as Elim in Limpopo Province, where communal land borders on the three former 'homelands' of Gazankulu, Venda and Lebowa, warned that the CLRB seemed to be "returning to apartheid thinking" in basing its proposals to formalise boundaries along traditional (ethnic) lines.

Whilst defining tenure rights and granting title to land would remove one of obstacles to development, confirming old boundaries in communal areas where there was already overcrowding and land shortage would only make the situation worse. Legislation such as the CLRB could not deal with this type of problem and there was a need for more comprehensive land policy.

The consultative meetings also provided women with the opportunity to discuss the implication of the proposed legislation for their right to access and control land. It was agreed that the CLRB did little to improve women's land security. They could still be evicted from their land when their husbands died or they divorced, and no provisions had been made to include them in communal decision-making processes on land issues. The biggest weakness of the CLBR as far as women were concerned was that it did not state that land rights must be given to men AND women and that land should be allocated to women on the same terms as men.

Local action to national lobby

Concerns about the implications and possible effects of putting the CLRB into practise were widespread amongst NGOs and other organisations working with local communities on land tenure issues.

The need to discuss the implications of the CLRB provided a focus for a wider discussion on land tenure reform. It gave those who had discovered the limits of local action the chance to link up with a wider national lobby. In this way they would be better able to put pressure on government for a national policy framework and new legislation on communal land rights that was strong enough to guide the highly sensitive and complex process of land tenure reform. The consultative meetings described here give an indication of how local experiences, views and strategies can be brought to together and taken forward into a process of national lobbying and advocacy.

Alternative proposals

Discussions on the CLRB during the consultative meetings indicated that the new Bill should:

- Recognise existing occupation and use rights and give them the status of secure property rights, without waiting for a time-consuming and expensive process of transfer of title which government is unwilling to devote sufficient funds to or create capacity for;
- Ensure that measures to secure individual rights were complemented by mechanisms to support the management of common property and other resources held in common;
- Make sure people can participate in community processes as stakeholders with guaranteed rights;
- Explicitly define and secure the rights of women;
- Provide rights holders and local land administration bodies with government support as part of a wider, clearer programme of rural development.

A revised version of the CLRB is scheduled to go before parliament in August 2003. It remains to be seen whether community and civil society views will be taken into account. What has been made clear from civil society action is that consultations not only yield powerful insights into the nature of land tenure problems but can also lead to the development of potential solutions. The conclusions of meetings such as those mentioned above have shown that there is a limit to the progress that can be made on land tenure issues through local actions alone and that it is necessary to establish links with other community groups in a co-ordinated process of lobbying and advocacy at the national level.

Traditional water management in Bali

The Subak system makes water available for irrigation in the hills. Photo: Rik Thijssen

I.G. Suarja and Rik Thijssen

The Indonesian island of Bali is famous for its unique system of irrigation. Guided and informed by religious values, it combines impressive feats of engineering with complex and elaborate social structures.

Most of the 162 large streams and rivers that flow from Bali's mountainous interior have cut deep channels into its soft volcanic rock. This has made it impossible for farmers to dam and channel water for irrigation in the usual way. Instead, they have taken to cutting tunnels through the rock, and constructing elaborate aqueducts and bamboo piping systems to carry water to the top of a series of terraced rice fields. From here it can flow, with gravity, from *sawah* (field) to *sawah*.

Community organisations called *Subak* control the water irrigation system to ensure reliable, fair and equitable distribution. Besides its technical functions, the *Subak* also provides social benefits including strengthening the possibilities of its members to maintain social contacts. This is reflected in the various communal activities undertaken in the form of task-oriented self-help groups (*seka*).

Community groups and group activities are traditionally very important in Balinese society. They reflect the significance attached in Hindu philosophy to the relationships an individual has with others members of society. This is a highly valued principal particularly in rural society.

Bali's famous *Subak* system is one of the most vital components of Balinese society. Built over the course of several centuries, it remains an integral part of Balinese life and is a product of the island's history and culture.

Subak

Irrigation is essential to Balinese agriculture because of the long dry season that extends from April to October. The elaborate system of channelling water from lakes, rivers and springs across countless *sawahs* is controlled by fully autonomous *Subaks*. Their engineering knowledge is sophisticated and the tunnels they build and maintain through the hills can be up to 3km long and 40m deep.

The distribution of irrigation water among *Subak* members is based on the principle of *ayahan.* This is the right of the *Subak* members to make use of available water resources in exchange for *ngayah* or free communal work on *Subak* activities. All *Subak* members have the same right to irrigation water. The amount of water is computed by dividing the total amount of water available by the number of *Subak* members.

A *Subak* consists of all the landowners – or their representatives - in a particular rice production area. The *Subak* is not only responsible for the construction and maintenance of canals, tunnels, aqueducts and dams, and for the distribution of water, but also coordinates the planting and organisation of ritual offerings and festivals.

Registered *Subak* members are mostly men because they are regarded as the representatives of their family. However, women are also involved in meetings as they play a major role in the various religious ceremonies.

There are about 1500 *Subaks* on Bali (1999) each with about 200 members and they cover a total irrigated area of more than 90 000 ha. The organisation of the *Subak* includes the *Paruman Subak* (General Assembly), the *Prajuru Subak* (Board), and the *Kerama Subak* (Members). The general assembly is the highest forum, and allows for open and democratic discussion among the *Subak* members, in order to create consensus on issues of general interest. The *Subak* Board is elected through the General Assembly.

Participatory management is typical in *Subak* organisations. A *Subak* head can call for meetings to discuss and decide upon issues such as maintenance work, cropping plans and the

Collective burning of rice straw to control pests. Photo: Rik Thijssen

allotment of water to members. Responsibilities and duties for *Subak* activities are equally distributed among the members, regardless of family status or social position. Obligations are in direct proportion to the amount of water *Subak* members receive for irrigating their rice fields. For example, farmers who receive one *tektek* - the amount of water necessary for one-season irrigation of rice fields with an area up to about 1 ha - are asked either to take full part in manual activities, or to provide financial compensation as specified in *Subak* regulations.

Subak organisation

- **Sedahan Agung**: the highest Subak institution, located at the office of regional income at district level. A Sedahan Agung is a regional government position with a regular government salary.
- **Sedahan Yeh**: similar to Sedahan Agung, but located at a lower hierarchy of a watershed of a river (yeh) in a district.
- **Subak Gede**: Subak organisation at a watershed ecosystem, socially organised, led by a sedahan or pekaseh gede, at sub-district level.
- **Subak**: water user organisation at a part of a watershed area, headed by a pekaseh and socially organised.
- **Tempek**: the lowest hierarchy of water user organisation at a planting area, led by a kelian. A tempek is usually an area with natural boundaries such as a creek, tall trees, rock outcrops, etc.
- **Kerama**: individual member of a Subak

Participation

Subaks are not societies for Balinese Hindu's alone. Farmers of other religious beliefs living in the *Subak* areas may also participate in the system and those farming other people's land are also included in the *Subak* system. Their 'share-cropping' contracts state who is responsible for paying *Subak* fees and this is usually the landowner.

It is possible to distinguish three types of *Subak* members. Apart from the special members, such as Hindu priests, there are 'active' members, who carry out the essential work of maintaining the irrigation systems and 'passive' members who prefer to pay for maintenance. There are also two types of meetings: the more regular, short meetings where work is divided between the 'active' members and, only if necessary, general meetings to discuss more serious issues. All members are expected to attend these.

Why cooperation?

What is the basis for this widespread cooperation? It might be thought that upstream participants in this cooperative network would be less inclined to cooperate because cooperation means they would have to leave some water for the farmers downstream and therefore would not be able to use it all themselves. However, in the particular ecology of Balinese rice paddies the flow of irrigation water affects the population dynamics of rice pests. If fields are planted randomly, rice pests can easily move from one field to the next after harvest, allowing pest populations to escalate. By coordinating planting over a wide enough area, farmers can create large fallow spaces that prevent pests from migrating between food patches. In this way pest populations are kept small. The rather low incidence of pests and diseases in the rice might, however, also be attributed to other specific agricultural practises, such as the collective burning of rice straw, maintaining water layers on fields after harvest and herding ducks in harvested fields. Even ceremonial offerings have been identified as possible reasons for pests being lured or scared away.

In short, both upstream and downstream participants gain advantages from cooperating with each other. Pest damage is reduced upstream, while downstream farmers experience less water stress.

Collaboration

Officially there is no link between the *Subaks* and government institutions and the autonomy of *Subaks* is guaranteed by their legal status defined in local Balinese regulations. However, government agencies have sometimes tried to 'use' the existing *Subak* cooperatives for their own purposes. These have included agricultural extension, introduction of new rice varieties, as well as the provision of credit for chemical fertilisers. At one stage taxes were also collected through the *Subak* heads. Most of these government 'intrusions' have back-fired and the *Subaks* have proved their resilience by surviving these attempts to hijack the community groups for reasons other than their main objective: fair and equal provision of irrigation water to farmers.

Farmers see the *Subak* as their one and only agricultural organisation. Such aspects of their agriculture as planning the time when a new crop should be planted or the use of fertiliser, for example – can be dealt with through the *Subak* if there is a clear relation with the provision or use of irrigation water. A *Subak*, for instance, decides on the type of rice to be grown, depending on the amount of water that is expected to be available. In some cases, when there are signs of water shortages, a *Subak* can also decide, as a group, not to grow rice but to plant alternative crops (*palawija*) that are less water demanding.

Resilience

Irrigation water management by community organisations on Bali has proven to be effective, efficient and durable. The *Subak* system has adapted itself time and again over the last 1000 years. Any minor conflicts that have arisen have generally been effectively solved. This capacity to resolve problems is only one of the strengths of this system that is deeply rooted in Balinese traditions.

Mahender Rautela: water volunteer

William Critchley, Marit Brommer and Girish Negi

Five years ago, at the age of 35, Mahender Rautela resigned from his private sector job in Delhi to come back to his home hamlet of Chhabisa, in the poor mountain state of Uttaranchal in northern India. He took up farming for an income - and dedicated himself to helping others in his spare time. Rautela joined a small group of existing part-time water volunteers. He wanted to help his community to cope with the increasing problem of water shortage. While other volunteers - elderly men - were already doing something towards the problem, Rautela felt that someone younger and more dynamic was needed to take charge of managing the water, and particularly to '*do justice to the shy ones*'.

Rautela in an irrigated kitchen garden. Photo: William Critchley

Why the streams and springs have been drying up over the last 20 years or so in the region is another story: rainfall hasn't decreased, but water levels have gone down dramatically. Some observers point to the invasion of thirsty *Chir* pine trees in place of the original oak forest, some blame increased extraction of water by pipelines upstream for urban use, and yet others criticise poor land use practises. Whatever the reason, the stream in Chhabisa where children used to swim in summer is now a trickle. The irrigated area has fallen to less than 10 percent of what it was. In the driest months –when the *naulas* (step wells) have dried up, the villagers are solely dependent on the unreliable and limited supply from the government pipelines. In areas of water scarcity, no drop of water should be wasted - but dripping taps and broken pipelines are common features in Chhabisa and other neighbouring villages. Many families in the area have to do with less than 100 litres of household water per day - a recipe for disease and poverty.

Water volunteers are a phenomenon of the last 20 years, a response of society to the growing water shortage problem. Water volunteers are now characteristic of all villages in the region and there may be between three and five part-time volunteers in a typical settlement. Rautela has become the lead water volunteer in Chhabisa. Dedicated individuals step forward informally and spontaneously, and society then accepts them on the basis of their integrity and hard work. The role of water volunteer is not limited to a particular caste, they mediate for everyone. However, volunteers do tend to come from the better educated, better off groups. Rautela, of course, has worked in Delhi, and has a comfortable home overlooking the village fields. He speaks English, which is a rarity in Chhabisa.

But what precisely is the role of these water volunteers, and how are they accepted by the community? These are questions we put to Rautela on the veranda of his cottage during the height of last summer. Vital of course is protection of water sources and outlets - step wells *(naulas),* springs *(dhara)* and pipelines. Yet what also became clear to us is that fair distribution and prudent use of limited water can make a big difference locally. So a water volunteer needs to keep his eye both 'upstream' - where the water comes from, and 'downstream' - where it is shared and used.

Rautela explains that in Chhabisa two water pipelines have been installed by the Government. The first of the two pipelines is now an ageing 40 year-old, and it is becoming increasingly unreliable. But the irony is that villagers are not permitted to 'interfere' with these, even when they break down. They are therefore continuously dependent on the slow reactions of government officials for help, which is often needed urgently. Rautela, with his fellow volunteers, now patrols the pipelines regularly for cracks in joints and dripping taps - walking, so to speak, where the shadow falls between the law and people's urgent needs. Not surprisingly, leaks are repaired quickly in Chhabisa. Rautela makes sure that this happens, even though he often needs to collect money from the villagers for tools and equipment. Officially this tends to go 'unnoticed'. The community appreciates it.

This begins to give us a clue to the character of a water volunteer. He (it is rarely a 'she' we discovered: it's basically considered to be a man's job) needs to tread with caution and sensitivity, bridging the gap between local society and government, while also helping to settle internal disputes. Conflict resolution between resource users, where common property resources are dwindling and populations are growing, is a concern worldwide. Such mediation is one key role of a water volunteer - but without the protection of an official position or the comfort of the salary that goes with it. The volunteer receives no tangible benefits. Strangely, this lack of 'officialdom' helps. That is probably because it's hard to turn away a well-intentioned, and good-natured, volunteer. Personal integrity establishes their authority within the community. Significantly, water volunteers often tend to be elected to the village *Panchayat* (village council) on the basis of their selfless deeds.

The day before we talked to him, Rautela had mediated between two families: one had allowed irrigation water to flood the ground floor of another's house. This was wastewater from the main storage tank in Chhabisa. After women wash cooking utensils in rationed amounts of water (washing clothes is not permitted here in summer), the waste is collected in an adjacent

Two of the authors interviewing Mahender Rautela in front of his house in Chhabisa. Photo: Girish Negi

storage pond with a capacity of 2 000 litres. Rautela oversees the use of that water - for irrigation of people's kitchen gardens where chillies, tomatoes, potatoes and fruits are nurtured. The area irrigated is between a quarter and one hectare , depending on the season. He supervises a rotational system: each of 14 nearby families receives the flow on a given day. These days can be 'traded' through negotiation. The flooding incident was resolved through such bargaining, arbitrated by Rautela.

Of course the key is how to attract and keep volunteers who are as effective and popular as Rautela: such volunteers are, we were told by one villager, *'as scarce as the water in this area'*. Nevertheless Rautela carries out his work with evident satisfaction, and there is no question that he, and his like, are appreciated in their communities and become trusted leaders. He has a gentle demeanour, but a firm commitment to seek for equitable access to water. Where water is limited and communities are affected it is not just scientists, or digital information highways to which we should turn, but local 'social hydrologists' as well. Their skills of applied common sense and tact can make their impact both potent and immediate. Villagers recognise this, and in return grant informal authority to such community members, to help control - and make better use of - their common resources.

Arvari Sansad: the River Parliament

Ambuj Kishore

The Arvari is a small river in the drought prone Alwar District of Rajasthan, India. For decades, the Arvari ran dry apart from a brief flow of runoff from the monsoon rains. Now, thanks to water-harvesting efforts in the region, the river holds water all year round.

The change began in 1987, when the NGO *Tarun Bharat Sangh* (TBS) started helping villagers in Gopalpura village to construct and rejuvenate traditional earthen dams called johads (see *LEISA Magazine* 16.1, p 14-15). More than 350 johads have been built in the Arvari catchment, and the active participation of villagers in the planning, design, implementation and monitoring of water resources has led to strong feelings of community ownership. Johads are small-scale structures but they have made a large–scale impact on water conservation. The improved availability of the water in this drought prone area has greatly improved the quality of life of those living in the area. In addition, the water harvested and stored in the johads caused the water table in the entire catchment area to rise. From 1996, the Arvari river began to flow strongly again and became perennial.

The question of ownership of these improved water resources, however, has been a source of recurring conflict. The first *johads* in the village of Gopalpura were declared illegal because formally as water resources belong to the state. When the villagers planted trees in the watershed catchment they were warned they would be fined because the land belonged legally to the state revenue department. Finally, after continued resistance by the villagers, an unwritten understanding was reached with the state agencies to let the villagers manage their environment.

The next challenge came as the Arvari River began to flow and the fish came back. In 1996, villagers received notice that the state had granted a contractor a license to fish in the river. Although the villagers are all vegetarians and do not eat fish, they realised that this might set an important precedent about control over the water resources. The villagers insisted that the river was theirs, it had begun to flow again as a result of their efforts, and they were entitled to a say in its management. The result has been a drawn-out battle between them and the fisheries department.

The *Arvari Sansad,* or *Arvari parliament,* was formed on 26 January 1999 as a way of managing the river and its waters fairly and to create a united front against outside intrusion. The river parliament represents 72 villages and meets four times a year to discuss problems and to decide on the best strategies for land and water use. It has 142 members who are nominated by their respective village institutions. The parliament has framed rules for the use and protection of the river and the surrounding land that relate to water use, the type of crops grown (excluding crops with high water needs), tree felling and illegal hunting. Another issue addressed by the parliament is the increasing value of land in the area - farmers and herders are coming under pressure to sell their land to businesses that depend on water extraction. A coordination committee comprising members selected by the parliament handles the operations and ensures that the rules are observed.

Villager's efforts have resulted in the departure of the fish contractor and they also succeeded in turning away a beer company that had hoped to set up a brewery using local barley and fresh water. The members of the river parliament and their communities have gained increasing confidence in their ability to take collective action, but this has not always been an easy process. Suspicions and conflict between different castes and factions need to be managed, and the village councils maintain many traditional limitations: they still rarely include women and the landless poor.

Forest access: policy and reality in Kafa, Ethiopia

Yihenew Zewdie

Kafa is a predominantly highland region in southwest Ethiopia. About one third of Kafa and the surrounding area is covered by tropical rain forest comprising a rich mixture of species arranged in three or more stories. The forest ecosystem makes an important contribution to the livelihoods of people in the area in a variety of ways. Tree species with several high horizontal branches, for example, are ideal for hanging cylindrical log beehives - a widespread local bee-keeping practise. The forest provides shade for coffee and a variety of commercially valuable spices that thrive when protected from frost and direct sunlight. The forests also supply rural communities with fuelwood and timber, which they use both for household consumption and for sale. There is urban demand for both wood and non-wood forest products such as honey, coffee, and spices.

This article draws on research and case studies from six forest villages in Gimbo *Woreda* (district) of Kafa Zone (Figure 1). In the case study areas, the level of income from non-wood forest products varies from household to household but averages at least a third of the annual cash income of the rural households. This income may not be sustainable due to heavy deforestation as timber production is sometimes excessive. However, it is worth noting that the considerable effort local people make to secure access to forest resources is a direct consequence of the importance of these resources to their household economy.

Land reform and access to forests

During the late nineteenth century, Ethiopia's central government expanded to control the Kafa region, replacing the Kafa kings as the dominant authority. Land and forests were allocated to local notables and wealthy and powerful outsiders. The latter were interested in extracting some of the more commercially valuable forest goods, such as coffee. The majority of the local population became tenants, who could only access forest resources through a variety of tenancy arrangements.

In March 1975, the new military government of Ethiopia (known as the *Derg*) that ruled the country between 1974 and 1991, issued a land reform proclamation that brought all land resources in Ethiopia – including farmland, grazing areas, and forest land – under the direct administration of the State. As part of the reform, grassroots level Peasant Associations (PAs) were established.

One of the tasks of the PAs was to implement the land reform and to solve land conflicts. As the land reform proclamation was decreed without adequate preparations, it came to be implemented in a hasty and haphazard way, leaving considerable space for local interpretation. In most areas, the land reform proclamation was, therefore, implemented in ways compatible with local notions of fairness and entitlement.

The involvement of the PAs in controlling access to forest resources varied. In some of the case study areas, the PA authorities saw the land reform as a means of redistributing agricultural land only. The absence of specific directives on the utilisation of forests reinforced this view - the law dealing with forest resources came into being only five years after the land reform proclamation. The villagers in these communities continued to claim forest access through locally recognised customary channels. The principles informing customary forest access included geographical proximity to the resource, proven track record of use, and ancestral claim of ownership.

In other communities, where conflicts over local forest user rights threatened the smooth implementation of the land reform, the PA authorities intervened and distributed patches of forest to needy households as their respective bee-keeping and/or coffee collection domains, although this intervention was never included in the land reform.

Neither the PA-sanctioned forest access nor the forest utilisation through customary principles were formally recognised. In "official" government thinking, forest resources were basically expected to be preserved and passed on to future generations.

In March 1990, about a year before the *Derg* fell and the government changed, the *Derg* proclaimed a halt in land re-allocation. This was also taken as an order to the PA's to disengage from allocation of forest rights.

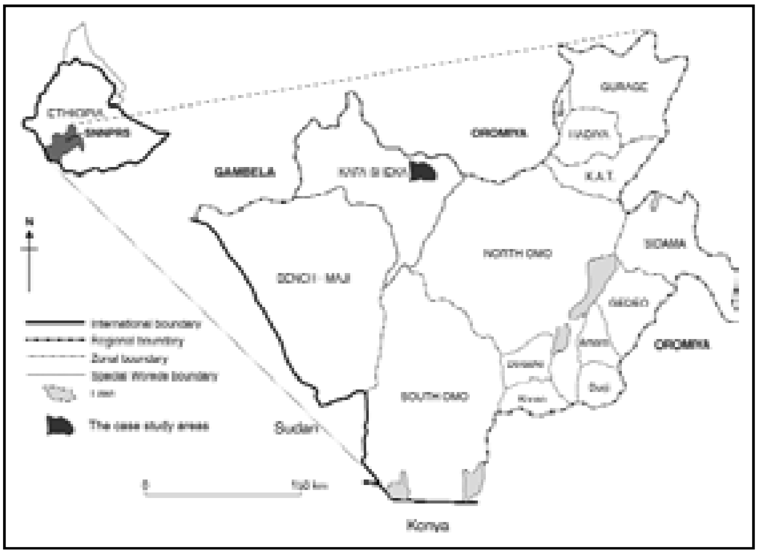

Figure 1: Map of the study areas in southwest Ethiopia

The current forest legislation

The post-*Derg* Ethiopian government (1991 – present) continued to support the state control of land resources. The current land law encourages the participation of private investment in agriculture and recognises the "holding right" of farmers to farmland. It is, however, silent regarding the natural forest from which most of the marketable forest goods are produced. The country's present forest proclamation has a strong element of forest protection, but does not spell out the villagers' rights to use the forest clearly. The proclamation makes timber processing by villagers an illegal undertaking, and introduces an element of uncertain legality to forest gathering operations such as bee-keeping and collection of wild coffee and spices. This is in direct conflict with traditional forest use practises.

The forest proclamation entrusts the Ministry of Agriculture with the tasks of controlling, protecting, and managing forest resources. The proclamation puts great faith in the role of 'forest guards', who are employees of the Ministry of Agriculture, to protect forests from fire hazards and forest use violations. In spite of these efforts, encroachment into natural forest areas is widely reported. Forest guards have neither the incentives nor the organisational backing to hinder this trend. Not surprisingly, forest resources in highland Kafa continue to be seen and utilised as village commons. This complex situation is a consequence of a mismatch between government policy, implementation capacity and grassroots realities and the informal forest access mechanisms described below should be seen as instruments developed to secure forest livelihoods within the restrictions of the local socio-cultural environment.

Wejoo and Gogoo

In the present post-*Derg* period an increasing proportion of younger households have no *direct* forest access rights. Although traditional rights can be inherited, the prevailing population dynamics make it difficult for younger families to benefit from this arrangement. All the same, local people employ a number of informal mechanisms that enable the younger generation and other sections of the population to participate directly in the local forest economy.

One of these mechanisms is *Wejoo*. Under this system, parents grant their sons trees when they come of age so that they can gather forest products for themselves and their families, and also in anticipation of their continued support in forest and food farming activities. The other informal forest access mechanism is *Gogoo* (which literally means "equal share"), a sharecropping arrangement for forest goods. Both *Wejoo* and *Gogoo* are originally traditional practises; however, they rose to prominence in recent years as mechanisms of coping with a lack of institutionally recognised forest access mechanisms.

Gogoo is a much more widespread means of forest access than *Wejoo.* Its importance as a means of forest access can be explained in terms of three main factors:

Distribution of skills

The uneven distribution of skills in bee-keeping and lumber production means that some holders of tree rights need a share partner to realise the economic value of their forest resources. In honey production, for example, those who have direct access to tree resources seek the services of skilled partners in preparing and mounting beehives on the high branches of forest trees. Harvesting is a joint undertaking and the produce is divided equally. In wood processing, the processor takes two-thirds of the income from the planks produced, while the tree 'owner' receives the remaining one-third. Wood processing is an illegal activity, although the individuals involved are well known locally. Weak enforcement of forest laws combined with uncertainties concerning villagers' continued use of natural forests has encouraged wood processing for short-term benefits, although it is an unsustainable practise.

Timing

The need for timely coffee collection among larger scale coffee growers also necessitates involvement in sharecropping. During the main harvest period (October – November) share tenants (the collectors) receive a third of the total quantity they pick. At the second coffee harvest, which mainly involves the collection of fallen coffee beans, share tenants receive half of the amount collected. Collection of fallen coffee beans is a time-consuming and a socially despised activity, which may be why the amount given to the share tenant is higher.

Stigma

There is a cultural stigma associated with the marketing of buckthorn and spices, but the increased commercialisation of these products has prompted right holders to opt for share cropping arrangements. For buckthorn, which is used as a condiment in the preparation of local alcoholic drinks, share tenants are made responsible for selling the produce that the tree right holder has gathered, and the sale proceeds are divided equally. For spices (notably, Ethiopian cardamom – *Aframomum korarima*) the share tenant is responsible for both collection and marketing, as the tree right holder usually desires to dissociate completely from the sale of spices, a low status activity. The share tenant retains half of the sales proceeds and gives the other half to the right holder.

Gogoo has been identified in particular as an important means of securing access to forest resources for younger households who have no PA-allocated or customarily recognised bee-keeping domains. Moreover, the *Gogoo* arrangement has helped resource poor farmers, including women, to generate cash income that would otherwise have been difficult to come by.

The way forward

The forest access situation in highland Kafa shows a complex combination of state tenure and *de facto* private rights of use similar to the overlapping systems of tenure that exist in much of Sub-Saharan Africa. Local people have developed forest access arrangements that have reflected the changing realities. However, lack of official recognition of locally tailored forest access rights has contributed to tenure instability and encouraged a short-term mentality in the use of forest resources, for example through illicit timber production and wood processing. Reconciling the state's position as an overall resource owner and the villagers' concern for security of forest use rights is therefore an important issue.

Policy makers need to formally recognise the forest use rights of rural households, in a manner similar to the recognition of farmland. This might facilitate the development of village-level institutional norms that would challenge destructive forest uses. Sustainable forest management demands that 'rights' to use forest resources are accompanied by corresponding farmer 'obligations' in forest conservation. The forest law should, therefore, be re-oriented to support local organisational development and forest management, rather than a blanket policy of forest protection through the use of forest guards, as has hitherto been the case. These steps should be taken as preliminary measures aimed at stabilising local forest use at a sustainable level. At the same time, it is also important to address the inequalities in direct forest access between generations, through local-level consultative processes.

The interest that even non-tree right holders such as *Wejoo* beneficiaries and share tenants in NWFP activities - have in the local forest economy is an asset that has to be seized upon for enlisting the co-operation of villagers in bringing about sustainable forest management. Extension agents and other grassroots level field workers entrusted with the responsibility of advising farmers with improved agricultural practises and natural resource conservation should recognise the multiple tenure under which forest resources are utilised. In practise this includes recognising and consulting with beneficiaries and rights holders under informal access systems like *Wejoo* and *Gogoo*.

Resolving resource conflicts around Sherkolle Refugee Camp

Alemayehu Abebe, Solomon Hussien, Assegid Tesemma and Jan Gerrit van Uffelen

At the present time population movements have taken on unprecedented proportions. The total number of refugees alone has reached over 20 million. The majority of refugees tend to find themselves in places that are environmentally fragile, and where resources are limited. Displaced populations, like other marginalised groups, are forced to rely directly on local natural resources to sustain themselves in the short term. Poverty, the struggle to build sustainable livelihoods and lack of control over resources characterise their experience. Their daily struggle to make ends meet does not promote sustainable management. This situation often brings refugees into conflict with local populations over essential resources.

A major problem for the many refugee women living in camps all over the world is access to fuelwood. Options to ease this burden seem very limited, yet fuel is a primary household need and lack of access directly affects a household's poverty status and food security.

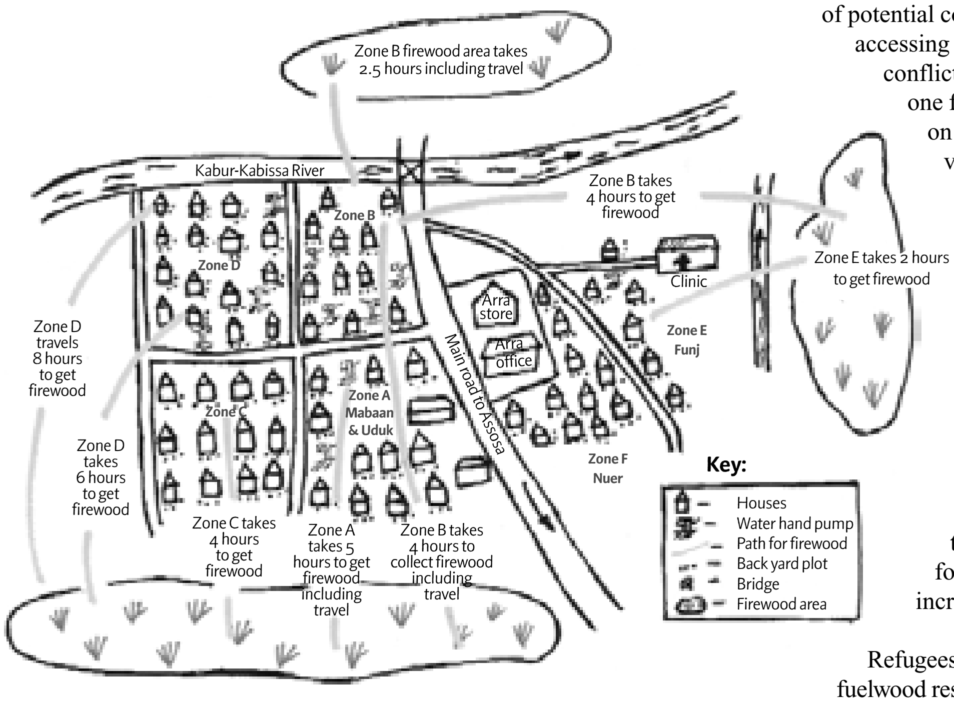

Figure 1: Resource map drafted by refugees in February 2001

So far, the United Nations High Commissioner for Refugees (UNHCR) and its government counterparts have paid little attention to the issue of access to and control over resources when locating refugee camps. Some NGOs however, are tackling these issues. In Sudanese refugee camps in Western Ethiopia, for example, ZOA Refugee Care, a Dutch international NGO working worldwide with refugees, internally displaced and disaster victims, has been working together with refugees and locals to jointly manage the natural resources on which they both depend. One of these camps is Sherkolle.

Sherkolle

Sherkolle is a relatively small refugee camp, established in 1997, which hosts around 16 000 Sudanese refugees from different ethnic tribes such as Mabaan, Funj, and Uduk who have fled fighting and insecurity in the Blue Nile province of the Sudan. The camp is located in a sparsely populated area in western Ethiopia around 50 km from the Ethiopian-Sudanese border. The area is hilly and covered with patches of deciduous and bamboo forests. The local inhabitants are the Berta communities who depend mainly on agriculture and a little trade. Berta cattle have been decimated by the tsetse fly and as a result they can no longer rely on animal traction, which has a serious impact on their agriculture.

The Sherkolle camp operates under the concept of partial self-sufficiency, meaning that 75 percent of the food needs of the refugees are covered by the World Food Programme. The refugees are expected to make up the remaining 25 percent by engaging in backyard farming on small 20 by 20 metre plots within the camp boundaries, and by engaging in a variety of income generating activities.

In 2001, ZOA Refugee Care undertook an assessment into access and control over natural resources and found high levels of potential conflict between refugees and locals in accessing fuelwood. Actual and potential levels of conflict between refugees and hosts differed from one fuelwood collection area to another, depending on the distance from the area to the nearest Berta village. High levels of conflicting interest were found in the area directly bordering the refugee camp, as the camp is set amidst local villages and the Berta did not like to see the refugees collecting fuelwood in the forests around their villages.

Sherkolle camp is organised in six zones with a different ethnic group living in each zone. A resource map drawn by the refugees in February 2001 indicated that each zone in the camp had its own fuelwood collection area. The study showed that it took the different tribes between four to eight hours for a round trip to collect fuelwood, a four-fold increase since the camp was established in 1997.

Refugees, especially older women, negotiated access to fuelwood resources in the direct vicinity of the camp by working for locals or by collecting fuelwood for them. Collecting fuelwood in areas further away from Berta villages met with lower resistance from the Berta. As travel times to these areas were much longer and the trips more demanding, they were mainly undertaken by younger refugee women. Forest guards, local Berta men employed by the local government and funded by the UNHCR to control the fuelwood collection, imposed major restrictions in these areas. Refugees were not allowed to use axes and were to collect dry wood only. If axe marks were found on the wood it would be confiscated. Paying small amounts of money to the guards or, in some instances, giving in to their demands for sexual favours would allow the women to return to the camp with their fuelwood.

The problems of unequal access to and control over fuelwood resources, as reflected in the statements made by refugee and local women, is presented in Table 1.

Table 1: Complaints of refugee and local fuel wood collectors

	Refugee (%) (n=80)	Host (%) (n=91)
It's demanding		
'It makes us very tired, it's heavy work, we suffer from the hot sun'	8.8	76.9
'Getting weak, makes me sick, body ache'	1.3	38.5
'Getting thirsty/hungry'	11.3	3.3
'It's far'	67.5	58.2
'It's difficult to penetrate the forest'	2.5	0
'We face a fuel wood shortage'	0	23.1
It's dangerous		
'I am hurting myself'	13.8	54.9
'Since we are forbidden to use an axe we have to use our hands, stones or sticks'	13.8	0
'We are afraid of the wild/dangerous animals in the forest like lions and snakes'	61.3	29.7
The system works against us		
'My axe is or will be confiscated by forest guards or the local people'	51.3	0
'I am forbidden to collect fresh fuel wood'	2.5	0
'We are caught up by the fire set by the locals'	3.8	0
'We are being checked, or send away, by the forest guards – wood at times is confiscated'	25.0	0
'I risk getting punished by the forest guards or locals, put in prison or being beaten'	2.5	0
'Fight with the locals or guards, chased out, threatened by guns'	42.5	0
'Locals ask us why we don't return to our homeland, they insult us, quarrel with us'	28.8	0
'We are being asked for money, work for locals, share our wood, being used as slaves'	27.5	0
'Being raped, asked to be their wife, have sex with men in the forest'	5.0	0

Fuelwood collection is seen as a very demanding activity by both refugee and local women. In 2001, refugee women spent an average of 28 hours a week gathering fuelwood and local women a surprising 27 hours a week, though the latter group combined it with some agricultural activities. Since the arrival of the refugees, Berta women say they find it harder to collect fuelwood. A quarter of them said they were experiencing a fuelwood shortage. Refugees consider fuelwood collection to be a dangerous business. They have to use their hands, stones and sticks to break off and split wood. Berta women complained they found it difficult to use their axes. Many of these had been acquired recently after being confiscated from refugees. Refugee women collect in far-away areas and face wild animals more often than the local women. They feel very strongly that 'the system' is against them. Restrictions are imposed by forest guards, local people (mainly men) or both.

The findings of the assessment highlighted that the system of access to and control over resources has resulted in increasing frustration and tension. The local Berta were becoming increasingly concerned about the loss of forest cover in their area. Not only was fuelwood collection becoming more difficult but their livelihoods were becoming less secure. Normally their grain supplies are sufficient to cover a six to nine month period only. After these supplies are used up they depend heavily on the wild foods they find in the forests.

The refugees for their part were frustrated and agitated by what they saw as an unfair system of resource control. It seemed just a matter of time before serious conflict would erupt. The refugees knew that this might threaten their stay at the camp and they did not look forward to returning to insecurity at home. The UNHCR and the Ethiopian government agency responsible for managing the camp only discussed issues related to the camp and its inhabitants at a regional level. Access to and control over resources was not very high on their agenda.

Only a comprehensive, community-based approach involving host and refugee community representatives, including women, could ease the tension. Fundamental for the success of such an approach would be the creation of a forum that offered a non-threatening environment, where refugees and local leaders and representatives could share and discuss their problems and start thinking about ways to encourage positive change.

A programme for change

In consultation with the local and refugee communities, ZOA Refugee Care designed the Agri-Environmental Education and Protection programme. Assessments taking into account the perspectives of the refugees and the Berta, the local and regional government as well as the perspective of UNHCR and its government counterpart have created the basis for change.
The programme is made up of the following four interrelated components:

Awareness

First, the programme makes refugees aware that the agroecology of the Sherkolle camp is different to that of their home areas. The fact that the camp is located amongst Berta villages creates an extra challenge as far as maintaining the natural resource base is concerned. Local people are made aware that indigenous and context-specific knowledge and expertise in managing natural resources is being permanently lost. For example, the Berta use fire to clear their lands. A generation ago the use of fire was subject to a complex set of rules, regulations and sanctions. Now fires often burn out of control for weeks during the dry season. Not only do these fires expose hillsides to erosion because fragile vegetation is burned, they also result in a gradual loss of biodiversity reducing both the variety and availability of wild food plants. The Berta have noticed this because wild foods form an important part of their livelihood security.

The programme provides context-specific agri-environmental education, developed in consultation with the communities. It does so via a number of avenues, including community meetings and seminars, group discussions, field 'studies', cultural awareness programmes, environmental education at primary and secondary schools and setting up school and debating clubs. Well-respected Berta and refugees are trained as facilitators to guide the dialogue on environmental and livelihood issues within their communities. Refugee and local facilitators meet once a week and they receive a one-week refresher course every three months. They do not usually work together although sometimes they go together on visits to familiarise themselves with each other's situation.

Establishing structures

A key element of the project has been the establishment of Environmental Working Groups (EWGs). The aim of the EWGs is to enable refugee and host communities to develop rules and regulations for access to natural resources, to work out natural resource management plans, and to empower community members who have the skills and interest to further develop the resources available in the area. Harmonising their different perspectives has resulted in a set of regulations that are, generally speaking, well observed by both the local Berta and the different refugee groups. Part of the work of the EWG is to make sure that people adhere to these rules and that the sanctions agreed upon are applied. The EWGs are also responsible for the progress of the natural resource management plan in their area.

Demonstrating appropriate practises

Small farmer field schools have been established and leading farmers selected and trained to demonstrate a range of appropriate sustainable resource management practises. They address the demand as well as the supply side of the fuelwood including issues such as fuel-efficient stoves, stove and fire management, mud block construction, community-managed nurseries, multi-purpose live fences, and small-scale fuel and construction wood plantations. A joint irrigation scheme has also been set-up and refugee and host farmers learn to work together to produce vegetables year round. The farmer field schools and the irrigation scheme are the responsibility of the EWGs, while ZOA provides technical expertise and some inputs.

Indigenous resource management systems

Between 1975-1991, the former Ethiopian government disengaged and replaced local leadership and management structures by a highly bureaucratic, top-down and sectorised government system. The changes were so dramatic that indigenous forest resource management systems suffered greatly. At present, the project advocates that government policies recognise and accommodate the most important elements of these indigenous resource management systems. A positive development is that the present Ethiopian government has acknowledged the potential role of community-based organisations. The EWGs fit well within that category.

Environmental Working Groups

The EWGs form the heart of the programme. They are community-based organisations that develop natural resource management plans with limited outside facilitation and assistance. Awareness-raising about resource base degradation and the demonstration of sustainable resource management practises are central to the EWGs. The older refugees in particular supported the set-up of EWGs because they recognised the approach from their own traditional resource management practises and were well aware of the need for improved management in their present environment. They were also strongly motivated by the fact that the EWGs provided a way of improving relationships with their hosts and they knew from past experience that poor relationships could compromise their stay. The younger refugees showed keen interest in more appropriate practises because they regarded them as 'modern' and representing 'a way forward'. The Berta saw the EWGs as a vehicle through which they could make their complaints and concerns about the collection of fuelwood by refugees heard. They also saw that the EWG could help them regain control over their resources, which they had lost under the former Ethiopian government.

Communities were asked to suggest candidates for the EWGs who were well respected and trusted. Those in leadership positions, such as sheiks, chiefs and church elders either took part in the EWGs themselves or publicly expressed support for candidates. ZOA's request to have at least two women selected for the EWGs met with surprise and lively discussion. In the end it proved much more difficult for the Berta than for the Sudanese refugees to have women selected for the EWGs.

Environmental Working Groups were established at three different levels. Each higher level has more decision-making, monitoring and sanctioning powers. EWGs at zonal level (in case of the refugees) or village level (the local Berta) consist of six members. They meet each week to discuss on-going issues and the progress of activities on agreed natural resource management plans. The refugee and Berta EWGs meet together twice a month to inform and discuss issues and activities. The EWGs at this level delegate individuals to represent them in the EWG at camp level. At this level the UNHCR, its government counterpart and aid agencies are also represented and overriding issues at the camp and its surroundings are discussed. The EWG at the third and highest level brings together representatives of the EWG at camp level, Berta EWGs established in villages further away from the camp and provincial authorities.

The way forward

So far the experience with Environmental Working Groups in and around Sherkolle refugee camp has been very encouraging. Awareness raising and the demonstration of appropriate practises and techniques have become more and more under the control and responsibility of the EWGs themselves.

New technologies that save fuelwood or develop fuelwood resources are being adopted. Concerns of women related to the collection of fuelwood are now taken seriously and are being addressed, for example by agreeing on safe access paths to fuel collection areas for refugee women. Rules and regulations have been agreed upon to prevent tree cutting and to access fuelwood, grazing lands and water sources. A situation that had the potential to escalate into serious conflict has been defused. The EWGs are maturing and are increasingly seen by the communities as important instruments in sustainable natural resource management. As a sign of their increasing confidence, the EWGs themselves have raised issues related to indigenous wild food plants, natural medicines and the fires that destroy many herbs and plants with medicinal properties, and the question of who can collect which non-wood forest products and when.

EWGs, nevertheless, still depend on outside assistance for facilitation and inputs. In order to be more sustainable, they need to concentrate on low external inputs and find ways of generating some income to finance their activities. However, the biggest challenge is now for the Berta EWGs to be recognised by the regional government as community based organisations that can play an important role in managing and developing natural resources. In trying to re-create indigenous resource management systems based on local reality they are taking into account environmental conditions as well as the social and political context. When it comes to the refugees, the challenge is not only to address current issues through the EWG, but to build up the interest and capacity that will enable refugees to set up EWGs when they return to their own areas to facilitate their rehabilitation and reintegration.

More than access to land: MST in Brazil

Ciro Eduardo Corrêa

Brazil is a continent in itself and has abundant natural resources. The potential that lies in its water, soil, biodiversity, coastline, diverse climate and mineral wealth is to be envied. It has one of the world's largest river basins and its people come from many different ethnic and cultural backgrounds. It is a rich and fertile country.

Yet Brazilians live in conditions that compare to the most needy in the world. Incomes are heavily concentrated. The richest 10 percent take 48 percent of annual income leaving the poorest 20 percent to share just 2 percent between them. Today, 23 million Brazilians live below the poverty line, and 52 million cannot get enough food for a balanced diet.

Analysis

The social and environmental degradation prevalent throughout Brazil is rooted in the way agriculture has developed in the country. Agriculture has always been subordinate to the logic of foreign trade, its profits generated by exploiting natural resources and the labour of the Brazilian poor. Since the time of European colonisation, extraction and later the extensive productions of export agriculture for the European market have been the main priorities.

This pattern has been sustained in recent years by advanced technological interventions. The "modernisation of agriculture" has enabled Brazil to maintain its present agricultural export strategy, which is based on extensive *latifundio* (estate) land-holding patterns, export-oriented commodity production and sub-human labour relations. In Brazil today one percent of rural household own 47 percent of the country farmland while more than 12 million people live in landless destitution. At the same time 166 million hectares of arable land lies unused in large estates. Small farmers make up 80 percent of the countries rural population yet they own less than 18 percent of the available farming land.

A drastic reduction in the demand for farm labour has intensified poverty. In the last ten years more that five million jobs have been eliminated by mechanisation in the sugar plantations alone. In 1984, hundreds of thousands of hectares of agricultural land was lost through the creation of the Itaipu dam, the largest dam in the world. In the cotton and coffee plantations 65 percent of the labour force have no formal working papers and work 14-16 hours for US$2.00 a day. As a result there is a constant exodus from the countryside to the already overcrowded cities. In the last 30 years 20 million people have left the rural areas for the towns. In 1903, when Brazil's total population numbered some 17.4 million 80 percent of its population lived in the rural areas. A hundred years later Brazil has a population of 175 million people and 80 percent live in the overcrowded urban areas. Staple food is scarce and although agribusiness ensures that Brazil has a favourable export surplus, it still imports such basic items as beans, rice, and wheat. In 1990, Brazil imported US$1 billion worth of basic foodstuffs. Today, it imports US$10 billion.

Agrarian reform is fundamental to the social, economic and political transformation of Brazil and there is an urgent need for an extensive and large-scale re-distribution of land. The political and economic geography of the country needs to be changed and land given a real social function.

Organising the landless

The struggle for land has dominated Brazil's history. The *Canudos* resistance movement and the *Contestado* war in the late 1800s and the Peasant Leagues and MASTER movement of landless farmers from in the 1950s and 1960s are typical of actions taken by rural workers to access land and improve their working and living conditions. *Movimento dos Trabalhadores Rurais sem Terra (*MST) is part of this tradition.

MST is one of 35 people's organisations fighting to get agrarian reform onto the political agenda. Established in 1984, it is active in 23 of Brazil's 27 States. More than 1.5 million people are involved in the MST, and it has managed to provide access to land for some 300 000 families who now live in 1600 settlements. Another 80 000 claimants are still living in camps while negotiating the legality of their claims. The process of land occupation and the struggle to secure tenure rights is a complex, hazardous and sometimes violent process. MST supports groups in occupying land and in their efforts to negotiate and formalise legal ownership. When claims are recognised, MST works with the new settlers to establish communities in which agroecological and social reform guide development.

The wider activities of MST touch all aspects of community life including education, health, cultural identity, environmental education, leisure, sports and jobs. As an organisation MST tries to introduce men and women to a fairer, more fraternal and egalitarian way of life. Over the years it has developed it own methods and ways to help people organise their struggle and while winning land is important, its wider objectives are to initiate a process of agrarian reform that will not only re-organise the land tenure but also contribute to deeper transformations in the society as a whole.

Taking care of nature

MST's struggle for agrarian reform is, in fact, a struggle to preserve life and nature. MST has always tried to increase the awareness of landless workers of the important role they play in preserving nature. In general, the areas chosen for agrarian reform tend to be areas that have been devastated and degraded by inappropriate and exploitative estate management. In MST settlements, the major challenge has, therefore, been to regenerate the environment and ensure that there is enough environmental education to encourage sustainable practises. Considerable effort is invested in elaborating ways to sensitise and educate families to the need to promote reforestation, build seed beds and nurseries for native and exotic trees, preserve the river banks and springs, build ecological corridors, work towards the collective management of forests and develop settlement patterns that encourage soil and water conservation.

With a growing awareness of the importance of agroecology, MST has also introduced new production and consumption patterns into its settlements. Healthy, pesticide- and chemical-free food is cultivated, a wide diversity of plant life is encouraged, and animal varieties that are best adapted to local conditions are reared and bred. In addition MST is involved in strengthening the local economy, ensuring that settlers do not become dependent on any single product and trying to establish links to wider regional markets where there are other potential sources of income.

Activities

Since 1997, MST has accumulated much experience in agroecology and forestry. Many settlements produce and market organic rice, soybeans, peanuts, cassava, corn, cashews, coffee, bananas, peaches, chickens and pigs.

Together with other social movements in the *International Via Campesina*, the MST is involved in the *Campaign for Seeds as the Heritage of Peoples in the Service of Humankind*. The objective of this campaign is to confront the global process of privatising biodiversity in which a few major trans-nationals are taking over life on the planet and turning nature into a commodity. MST has undertaken activities to recover local seed varieties focusing on corn, rice and beans, crops that are basic to the food security and animal husbandry of its settlements. In the municipality of *São Miguel do Oeste*, in the southern State of Santa Catarina, for example, 48 varieties of corn have been recovered and an additional 18 corn varieties and five bean varieties are being bred. During the last harvest, 80 metric tons of seed was collected. This was enough to secure supplies for local families and provided a surplus for further distribution.

For several years, MST has been building up the agroecological production of horticultural seeds through BIONATUR and today they are the only suppliers in Brazil producing and distributing such seeds. BIONATUR grew out of the need to confront the monopoly that multinationals have established over the seed market. It was first established in Rio Grande do Sul, a state in the far south of the country and subsequently expanded to other regions of Brazil. BIONATUR works exclusively with horticultural varieties. There are no hybrids. The result of these activities has been to enhanced the regional distribution of seed and today these are being cultivated as near as possible to the regions in which they were obtained. In 2002, BIONATUR produced and marketed seven tons of seeds from 32 different varieties. By 2008, it expects to be marketing 15 tons of seed from 56 different varieties.

Another important activity has been the biodiversity management project in the settlements of *Pontal do Paranapanema* in the south-eastern State of São Paulo. Here MST enabled gene flow between three areas of native forests classified as Interior Atlantic Forest. These forests cover 33 000 hectares, 400 hectares and 300 hectares respectively and are home to many small farmers. The project consisted of planting exotic and native species in the areas belonging to farming settlements in order to enhance gene exchanges amongst the various species of animals and plants in the three forest areas. Over time a migratory corridor for animal species (in particular birds and insects) has been created and the transmission of genetic material from the native trees that make up these ecosystems has been greatly facilitated. From a social perspective, these islands of biodiversity – which also contain multiple-use agroforestry groves – will support the improvement and diversification of farming activities in rural allotments located between the forest fragments.

In the same region, Ribeirão Bonito, some 123 families are involved in a project known as *Abraço Verde* – the Green Embrace. The main aim of this project is to plant a belt of native and exotic trees between the forest and the areas used by farmers for crop and cattle production in order to halt degradation. From an economic and social point of view, the sustained exploitation of the Green Embrace has provided a new source of income for these rural communities, and has helped to reduce conflicts over access to fauna and flora.

Challenges

The MST faces many challenges. One major difficulty is that agrarian reform is still seen as a way to compensate the landless and to relieve social tensions, rather than as policy to restructure land tenure. Therefore, MST has adopted a broad agenda in which it commits itself to lobbying for public policies that reflect not only a concern for the value of rural spaces and the preservation of the landscape but also guarantees the well-being and rights to land of those who live in the countryside.

Access denied: the Brazilian land issue

Luc Vankrunkelsven

From the time the Portuguese established themselves in Brazil in the sixteenth century, the country has been ruled by an economic elite whose power lies in land. A major piece of legislation enacted in 1850 - the *Lei da Terra* - recognises two forms of land use in Brazil: *propriedade* (possession) and *posse* (right of use or usufruct).

Lei da Terra defined land in capitalistic terms as a commodity to be bought and sold, making it possible for a small minority to establish control over the countryside. As a result, when slavery was abolished and impoverished immigrants started to enter the country in the late nineteenth century, most of them could only claim users' rights to land. Known as *posseiros* or "farmers without papers" their heirs still depend on usufructory rights granted by private and company landlords.

Green counter revolution

Demand for fair land redistribution has increased steadily in Brazil in recent decades. However, the military dictatorship (1964-1985) and the United States wanted no "communist-type" land reform. Instead they encouraged the Green Revolution - a counter revolutionary answer to the cry for justice. Super seeds, pesticides and large subsidies were made available and resulted in a new gold – soya. But family farms drawn into soya monoculture were unable to compete with the large estates. *Posseiros,* without papers and rights were driven from their farms and joined the hundreds of thousands of farm labourers who, having lost their jobs because of mechanisation, joined the massive exodus to the cities.

Churches and resistance

During the military dictatorship the churches were the only places where people could organise and many civil society movements emerged from the grassroots of the Christian community. Amongst these was the trade union CUT (*Central Unica dos trabalhadores)* and the PT (*Partido dos trabalhadores)* - both established by the present socialist President of Brazil Luiz Inácio Lula da Silva – as well as the *Comissao Pastrol da Terra* (CPT), *Movimento dos Trabalhadores Rurais sem Terra* (MST), women's organisations and human rights groups. The CPT, CUT and MST were particularly important actors in agricultural politics.

The organisations involved in land issues such as the CPT, CUT and MST support each others efforts. CPT is a service of the Catholic Church. It helps farmers and farm labourers as well as the urban poor and their organisations in their struggle to hold on to or acquire land. In some of the provinces where the MST is less strong CPT organises land occupations.

The trade union CUT works with farmers, farm labourers and urban labourers. Since 2002, several alliances such as *Federação dos Trabalhadores da Agricultura Familiar da Região Sul* (*Fetraf-sul/CUT)* have been formed. CUT has established a number of cooperatives on *assentamentos* (redivided land), particularly in *Mato Grosso do Sol,* the north and the north-east.

One of the organisations most specialised in the fight against unfair concentrations of land is the MST. MST has a strong international reputation and this status is reflected in its website which is available in six languages. Since the late 1990s, MST has broadened its perspective to include agroecological issues.

Land reform through the market

In 1998, then-president Fernando Henrique Cardoso launched "land reform through the market". With financial support from the World Bank, local banks provided money to farmers so they could buy land from estate owners. Farmers, in fact, were paying for the land reform which was their right and richly compensating estate owners at the same time. The effect of Cardoso's programme on small farmers was disastrous: land prices rose and many went bankrupt, unable to pay back their loans. Even so, in this way, 80 000 farmers gained access to land. Cardoso's approach raised considerable discussion in Brazil and within the landless movement. Lack of credit eventually put an end to this neo-liberal approach to the land problem.

Lula and land reform

Since January 2003, when President Lula came to power, there has been more hope of a strong land redistribution policy. Lula is closely associated with the fight for land reforms. One of the priorities of his government is the *Zero Hunger Programme* in which the family agricultural model has been given a central place. The question for all those concerned with the politics of land reform in Brazil is whether "Lula" will be able to stay out of the landowners "clutches".

For its part the landless movement currently follows a double strategy: it puts government under pressure by encouraging land occupation yet it is also ready to engage in dialogue. On 2 July 2003, the President met several representatives of MST. These amicable discussions were not greeted with enthusiasm by the country's estate owners.

Future direction

The land issue continues to be a life or death struggle. In the first 6 months of 2003 alone, 31 farmers have been murdered. Whilst the landless movement demands that a national plan for land reform be drawn up which would ensure one million farm families will receive land rights by 2006 and an immediate solution is found to the problem of the 120 000 farm families living in camps, landowners are organising themselves to hold on to their (il)legal possessions. In this highly volatile situation it is difficult to predict the direction land reform will take in Brazil.

Accessing livelihoods through shared farming

Seema Tripathi and Shiraz Wajih

In eastern Uttar Pradesh, more than 90 percent of the economy is based on primary production. The area has a high population density with some 1200 persons per square km. Land is divided each generation between the sons of the family and this has lead to very high land fragmentation. The average land holding is now extremely small and around 70 percent of the families have access to less than 0.4 ha. This includes the 10-15 percent of families who are landless and work as agricultural labourers, cattle rearers, or as wage labourers in nearby towns.

This article is based on a study conducted in some villages in Gorakhpur district where the Gorakhpur Environmental Action Group (GEAG) is active. However, it reflects the general situation in eastern Uttar Pradesh. In the villages studied 60 percent of the land holdings are smaller than 1ha and farmers with larger holdings are considered to be better off. Only about 5 percent of farmers own more than 2 ha of land and this, in combination with other sources of income through employment or running small businesses, makes them relatively wealthy.

Land reforms have not helped much in this area. Laws such as the *Land Ceiling Act* that limits the amount of land that can be held by one individual, have only benefited small farmers in those areas where there are land holdings of more than 10-15 ha available for redistribution.

Livelihoods in the area are largely dependent on land-based activities, and opportunities continue to shrink as population and land fragmentation increases. The adoption of high input agriculture, including the use of hybrid seeds and agrochemicals, has lead to increased costs and a reduction in crop diversity. This means that the economic margins in farming are becoming very small.

Markets and government purchase centres give priority to larger quantities of produce, which also disadvantages small producers both in terms of sale and price. As a result many small farmers often have no option but to migrate to the city.

Increasing labour costs and decreasing gains have also created problems for larger farmers. Absentee landlords who live and work outside the region, large landowners and families with older or physically less able members are not able to manage their own farms. Nevertheless, they want their land to be used and if possible to receive some income or products - food, fodder or fuel - from their fields. At the same time, there are a large number of smaller and landless farmers who have agricultural skills, but no way of earning a livelihood.

These two groups of people have developed a tradition of sharing their resources for mutual benefit. Where the resource base is shrinking this is a considerable help to resource-poor farmers. Share cropping has become a viable and acceptable mechanism for generating income for deprived communities.

Sharing resources

The history of present share cropping arrangements can be traced to the Zamindari abolition days in the 1950s. During this time, land titles and the right to transfer land was handed over to farmers. This changed the nature of negotiations as far as land use and payment of revenue was concerned. Previously, farmers ("*asami*") paid the revenue to collectors ("*zamindari*") for the use of land. Today, share cropping arrangements are agreed between farmers themselves. There has been no significant change in land ownership in the area since then, although hierarchical divisions (land being split between sons) and land consolidation (small plots belonging to one holder being brought together to create larger areas) have continued.

Currently, approximately 30 percent of the agricultural land in the villages studied was being worked under share cropping agreements. Some 45 percent of the smaller and resource poor farmers depend on share cropping for their livelihoods (see Figure 1).

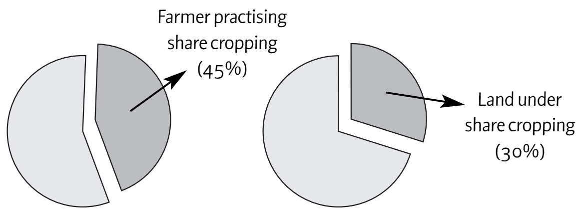

Figure 1: Percentage of farmers practising share cropping and land under share cropping in the study villages

There are three main kinds of share cropping systems:

Adhiya

Land is cultivated by resource-poor farmers who share inputs and outputs with the landowner on a 50-50 basis. In this system, the landowner provides land and one or more of inputs (oxen, labour, fertiliser, and seed). The produce is shared equally. This is the most common practise in the area and causes very little conflict. This arrangement is also common amongst farmers with equal status.

Honda

In this system, the land is hired on fixed terms by a resource-poor farmer. The fixed terms include the type of crop to be grown and how much of the harvest should be used to pay for the land. The landowner only supplies the land. All other inputs are provided by the share cropper. In some cases, the land owner provides a loan in kind (fertilisers and seed) or cash. This loan has to be repaid in addition to the share of the harvest agreed upon. At present, as share cropping becomes more common, landless people have started to compete for these arrangements. Under *Honda* , the element of exploitation is stronger, as the share cropper is responsible for any loss or damage caused by rainfall or other natural disasters. More conflicts occur under these arrangements.

Share croppers harvesting a field, Gorakhpur district. Photo: Ramesh Sharma

Rehan

In this arrangement, land is leased at an agreed price for an average period of one to three years by a resource-poor farmer or group of farmers. The amount of cash involved in this system is relatively high and normally cash crops are grown on this type of land.

Other arrangements

In addition to crop-based sharing arrangements, resource poor farmers rear cattle - but more often pigs and goats - on a shared basis. The farmer cares for the animal(s) and also provides them with fodder. Offspring from these animals is shared on a 50-50 basis. Similar sharing arrangement also exists for fruit trees, where the resource poor farmer takes the tree at an agreed price, looks after it and harvests and sells the fruit. The income generated is shared between the owner and the farmer in accordance with the agreement between them.

Access and control

Share cropping mechanisms have evolved around the principal of mutual interest. The involvement of both partners can be seen in different farm activities. Table 1 provides an overview of the power relationship between farmers and landlords in share cropping situations. The column "Influence" shows who has a say in decision making, and the column "Control" indicates who has the final word. For example, when decisions about the choice of variety have to be made farmers and landowners discuss this together. However, if there is a difference of opinion it is the landowner who decides.

The preferred crops for share cropping are paddy, wheat, sugar cane, maize, groundnuts and vegetables. The landowner and the farmer usually have different preferences about which crop to grow. Labour intensive cash crops are generally preferred by the landowner, whereas farmers usually prefer crops that provide safer returns and require less labour. Share cropping arrangements are mostly agreed between a male farmer and the landowner. This means that women involved in working these fields have even less influence on decision making than is normally the case in family farming. For them, share cropping usually means more work.

The agreement between landowner and share cropper is bilateral and in a conflict situation, decisions are controlled by the land owner. However, as the system of share cropping has become more prevalent and socially accepted, generally agreed and uniform rules have emerged. The land owner is morally bound to adhere to these rules. However, there is nothing that can stop landowners from taking other decisions. If a conflict of interests arises, resource poor farmers are at a disadvantage. However, in the absence of other viable livelihood options, the system of share cropping provides large numbers of resource poor farmers with access to a livelihood.

Effects on farming systems

The crops grown on shared land and farmers' own land do not differ very much. However, on closer inspection it becomes clear that farmers give priority to their own land when implementing LEISA techniques. GEAG has been dealing with both types of land and has found that it is on farmers' own land that effective LEISA models have been developed. Farmers incorporate organic compost and bio-fertilisers and practise principals of diversification on their own land because these practises ensure long-term benefits from the extra labour and precious organic inputs invested.

Conclusion

In the prevailing situation of landlessness and a complete lack of alternative livelihood options in the villages, the shared farming system has brought land controlled by comparatively better-off farmers who are unable to farm it fully back into agricultural production. More importantly, although such arrangements can be exploitative, they provide a source of livelihood to significant numbers of people.

Lake Mweru is our bank

Nettie Aarnink and Paul van Zwieten

Lake Mweru lies in the Luapula valley on the borders of Northern Zambia and the Democratic Republic of Congo. Its fishery provides food, employment and income to about 400 000 local people and supplies 40 percent of the fish sold on the Zambian market. Families in the area have a long history of combining fishing with cassava farming. However, since the early 1900s there has been a steady growth in fish trading between the lake and the towns and copper mines of Zambia and the neighbouring Congo. This has lead to a heavy exploitation of the lake's fish resources and a strong inter-regional trade that increasingly overshadows the traditional local economy.

In contrast to the early 1970s when most of the fish caught were consumed locally, 70 percent of today's catch is either salted, dried or marketed fresh outside the region. Rapid population growth especially in the towns has created a big demand for fish and the recent liberalisation of the Zambian economy has made it easier for commercial interests to enter the Mweru fish market. This has resulted in considerable new investment in large vessels, fishing gear, and the development of freezing plants.

Government

Officially the Mweru-Luapula fishery is State property but in practise, it is a common resource open to everyone. The local Department of Fisheries (DoF) at Nchengele is responsible for "promoting sustained fish production and increasing food availability and employment opportunities based on the sound exploitation, management and conservation of fish stocks". However, it is difficult for the DoF to carry out its tasks because it does not receive the funds and manpower it needs from central government. The weakness of the DoF and its inability to enforce conservation regulations has increased the problems of local fishermen who are finding it more and more difficult to adapt to the ecological and economic changes that have taken place in the fishery as a result of the heavy, unregulated exploitation of fish resources.

Local economy

The local farmer-fisher communities are made up of members of the Lunda, Bwila and Shila tribes but there are also many migrants who have been attracted to the area by its fish. Today, there are three categories of fishermen working on Mweru-Luapula. First, the owners of powerful large vessels that have the capacity to fish the lake for long periods of time, salt fish on board and act as a floating market for smaller fishing boats. Second, there are those who have earned enough money to invest in a plank boat equipped with several types of nets and a small crew, and there are the local, subsistence fishermen who set their traps along the shores of the lake and in the swamps and tributaries of the Luapula River. It is this last group of fishermen who are most at risk from the heavy and largely uncontrolled commercial exploitation of Mweru-Luapula.

Livelihood fears

Local people depend on fish for their livelihood. It is their main source of protein and fishermen usually reserve part of their catch for their families. Fish is their major 'cash crop' and is shared, bartered, and given in tribute. It 'pays' wages and settles bills. It also ensures the social and political security of the local fishing communities.

Those whose day-to-day survival depends on fish are becoming increasingly anxious about the future. Fish catches have been in

steady decline. In the late 1950s, fishers caught between 11 and 12kg of fish per 100 meters of net per night. Today, this has fallen to less than 3kg. Older people remember the huge catches of the past when young fish were thrown back into the lake to mature. Now undersized fish (*mponde nshima)* are routinely marketed.

To some extent the cassava gardens managed by the women of the household shield local families from the uncertainties of fishing. Once matured, cassava can be harvested when needed. It is, therefore, an important source of food and income and can be bartered for fish and other necessities when catches are low, nets are stolen, or when the families are in difficulties because a fisherman is sick or dies. However cassava is only one part of a fish-dependent livelihood system in an area where there are very few other sources of income.

Stakeholders

Local shopkeepers also depend on the lake. If their customers are unable to catch or sell fish there is no money to spend. Most of the shopkeepers in Mweru-Luapula started their businesses with capital they earned from fishing, trading in fish, or working on the boats. Apart from providing essential commodities, shopkeepers are important sources of credit to the local fishing communities.

Traditional authorities have also an interest in the lake. Tribute and other customary dues are paid in fish or with earning from the fish trade. Tribute is an important part of local life and is seen as a token of respect. It ensures good relations between fishers and the traditional authorities who still have considerable power. Although the official mandate to manage the fishery is in the hands of the DoF, fishermen and traders know that chiefs have the power to ‘punish’ fishers who break traditional law by confiscating their fish or gear, that they can refuse to grant traders permission to enter their areas, and that they have the right to discourage inappropriate fishing practises.

Everyone has a stake in fish. Photo: Nettie Aarnink

Stakeholder action

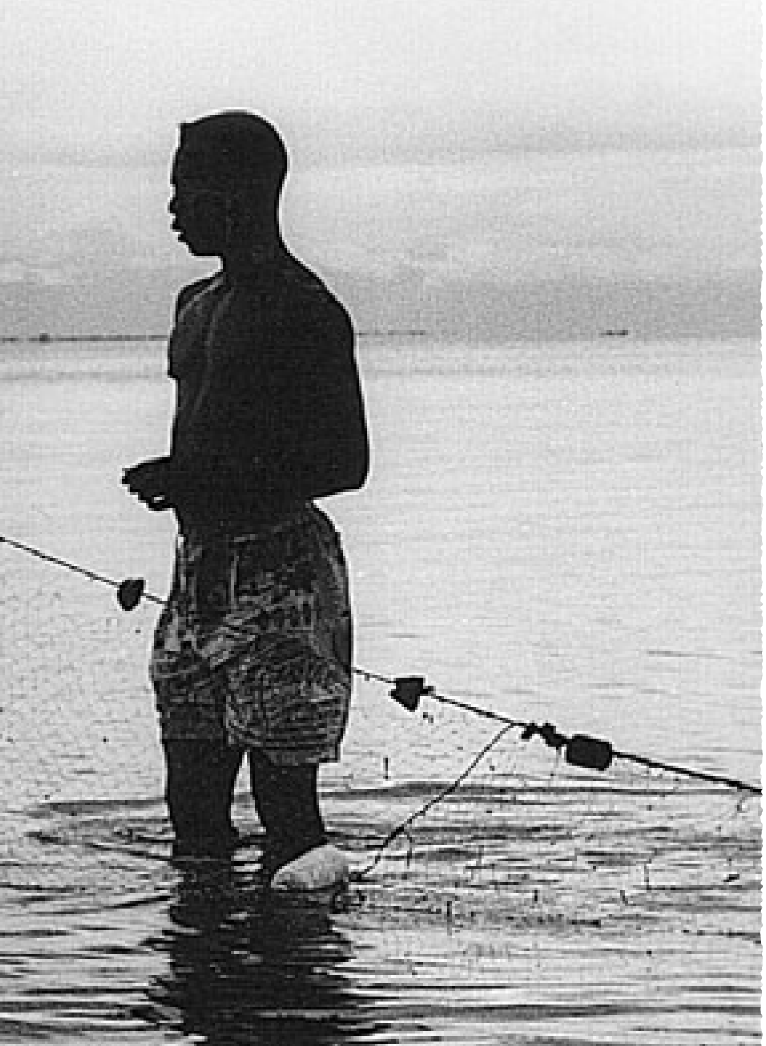
Those with a stake in the fishery have not accepted the growing threats to their access and control of resources passively. Some local fishermen have set up fishers associations to combat net theft, destructive fishing practises and lack of support from local authorities. The first associations started in the north of Lake Mweru in the 1980s and followed the constitutions developed by Congolese fishermen. Gear registration systems were set up to protect nets and other equipment and in some places monitoring systems were established to track down stolen nets. Association members complained openly to government about their declining catch. They demanded better local management and enforcement of conservation measures by the DoF. They also wanted local councils to use some of the money collected by taxing the fish trade to provide better services and infrastructure. At the same time some associations took the initiative to educate their members about the value of conservation and the importance of obeying DoF regulations.

Other stakeholders, such as local business people and traders, also demanded better control of the fishery and action against competition - especially the freezing companies who they say “milk our fish”. While shopkeepers pressed government to make funds available to enforce existing regulations and stop industrial fishing practises, consumers turned to their chiefs with complaints about the scarcity and high price of fish on the local markets, and women traders demonstrated against the closed season because it deprived them of their only source of income.

Conservation dialogue

In the early 1990s, in an effort to increase its effectiveness, the DoF changed its approach from trying to enforce government rules and regulations, to looking for more participative ways of involving stakeholders in the management of the fishery. This was a difficult and complex process for, although most of those fishing on Lake Mweru realised the consequences of heavy and unregulated fishing and respected the DoF as the “father” of the fishery, this did not encourage them to follow conservation measures. In the struggle for survival and the race for fish and a share in fishery-related profits the most common course of action was to ignore traditional and statutory regulations.

The DoF attempt to get local support for a more community-based management began with activities that aimed at helping stakeholders understand the background and objectives of the conservation process. This involved meetings and discussions

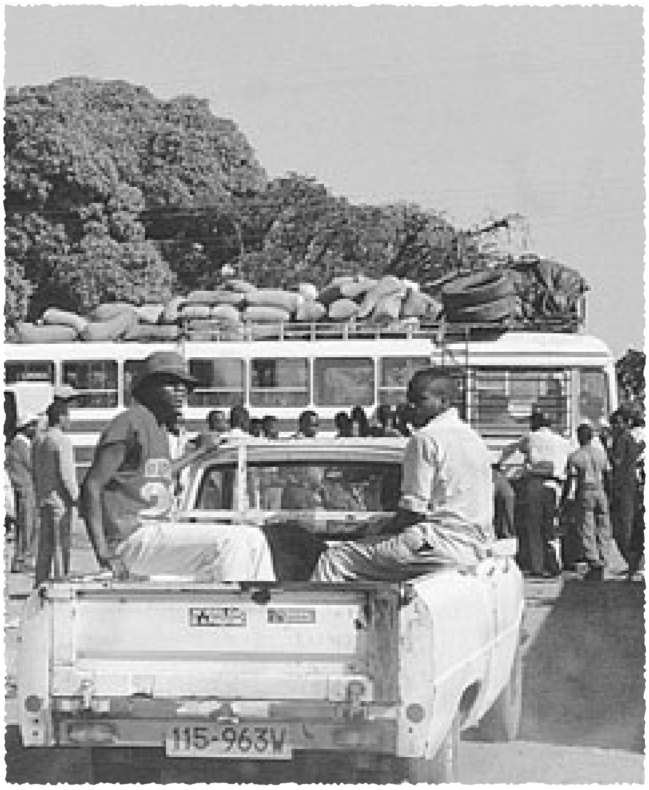


Fishermen on the shores of Lake Mweru. Photo: Nettie Aarnink

with fishers and their loosely organised and scattered fishing associations, and with traders, local business people and traditional leaders.

In 1992, as part of this conservation dialogue, the DoF organised a meeting for fishers and chiefs at which the management of the Mweru-Luapula fishery was discussed in an open and critical way. It became clear that past efforts at conservation, particularly dissatisfaction with the way in which the closed fishing season had been arranged, played an important role in people's attitude to rules and regulations. In pre-colonial times the opening and closing of the fishing season had been clearly accompanied by rituals and ceremonies. However, during the colonial period and later the country's fishery policy, including regulations relating to conservation, had often been applied in harsh and discriminatory ways or manipulated for political and economic ends.

Meetings and discussions, as well as joint field visits by staff and fishers and educative activities such as theatre, documentaries and pamphlets helped the DoF to get a clearer picture of the perceptions and concerns of different stakeholders. During participatory training and learning sessions, fishers made it clear that if stakeholders were to be involved in managing the fishery and in working out acceptable rules that were fair to everyone, the DoF should make sure they were enforced.



Fish continue to stimulate a thriving transport business. Photo: Nettie Aarnink

Towards co-management

The experience and information exchanged during these meetings showed the DoF that there were initiatives being taken at the local level that could be developed further in a process of community-based management. Better and more frequent communication would lead to more information about social practises, strategies and resource users and how they control, exploit, monitor or protect the fishery. As a result of the conservation dialogue process some DoF staff began to change their attitude to stakeholders and became more prepared to involve them in the conservation effort. The Nchelenge Fisheries Coordinating Committee, a management platform that included the district council secretary, the manager of one of the freezing companies, DoF staff, fishers, traders, marketers and chiefs was set up with these co-management objectives in mind.

To some extent stakeholders in Mweru-Luapula agree that the fishery should be state-regulated, provided rules are fair, applied to all, and are enforced strictly and transparently. But they also have to meet their daily needs for food and cash. Customary and social obligations have to be honoured. For many fishing families the need for short-term security may outweigh any sense of obligation to keep to externally imposed regulation that promise to protect future fishery resources but which clearly cannot be enforced.

Rethinking the balance

In Mweru-Luapula a weak DoF, a mixture of customary and statutory regulations and many, often conflicting stakeholder interests, encouraged stakeholders to ignore conservation measures. However, as the stakeholders meetings showed, there was a basis for developing a dialogue between the DoF and key stakeholders. The experience of the Nchelenge DoF has shown that in order to develop acceptable management strategies that balance the interests of local communities, commercial actors, and traditional and local authorities the DoF should:

- negotiate with all stakeholders to strike a balance between economic, social and ecological concerns
- increase its understanding of local perceptions and initiatives in management and monitoring.
- explore and monitor local ideas, strategies and initiatives. and understand how people at various levels cope with uncertainties or respond to new (external) developments.
- inform the Zambian government about initiatives for new policy, legislation and fishery management based on current trends.
- advocate an international, harmonised management framework with the Democratic Republic of the Congo, an issue strongly advocated by fisheries officers, fishers and local leaders in Zambia and the Congo.

If the DoF can maintain a fully participative approach to managing the Mweru-Lualpula fishery, keep the confidence and trust of key stakeholders and receive adequate support from central government, it may be able to succeed in developing conservation measures that provide security for local fishermen and, at the same time, create opportunities for a well-regulated exploitation of the fishery potential of the lake.

Securing access to water in Ngurunit

Laura Lemunyete

Ngurunit location lies in the foothills of the Ndoto mountains in the semi-arid environment of Northern Kenya. The local Samburu and Rendille pastoralists live in scattered villages and depend on their livestock for milk, meat and other products. Water is a problem for both humans and livestock. Though many riverbeds cut through the foothills, most have no surface flow except during the twice-yearly heavy rains. The main river, which is also fed by some mountain springs, can sometimes flow for three to four months at a time but then becomes progressively drier further and further up the mountain like the other riverbeds.

These dry riverbeds provide most of the water for livestock and people when wells are dug at strategic points. During and after the rains water can be drawn from shallow holes dug in the riverbed. After the rainy season, when the area dries up, more extensive wells are dug deeper and deeper as the water level in the riverbed drops. These can reach up to 30 or 40 feet deep.

Traditional wells

In the past, wells were dug in the riverbed or in areas where water accumulated. During the rains, these were usually destroyed and re-dug in the dry season. Traditionally, those who dig and maintain the wells are considered the owners. As this is laborious work, only the men are involved and they are recognised as the sole owners of the wells. Those who have not dug their own wells and women in general have access to wells under traditional rules.

The owner of the well has first priority, first for his livestock and then for his family's needs. Afterwards, if there is water, others can use it for their livestock. Women and children are the last to get water. As the dry season progresses, traditional rules start coming into play and people must respect the owners of the wells and the complex schedules regulating water access. Directly after the rains when there is plenty of water, women can get it from anywhere along the riverbeds by digging shallow holes and do not have to rely on the deeper livestock watering wells.

Problems

During the rains and immediately afterwards, everyone has easy access to water. However, when it starts to dry up problems arise. These include women and children having to walk long distances to existing wells and then waiting for the livestock to be watered. During times of drought when there is very little water, this can mean waiting into the night for the well to recharge because it has been emptied by a large herd. Sometimes they get no water at all.

Common problems associated with the traditional system of well construction and use, especially when water is scarce are:
• School children having to wait to get the water they need to take to school for cooking and cleaning, thus missing classes.
• Women having to wait for hours for household water, sometimes even into the night.
• In dual purpose wells (livestock and human) water is easily contaminated making it unhealthy for human consumption.
• Households that are not able to dig their own wells, especially women-headed households, become dependant on the good will of well owners.
• Digging and maintaining traditional unprotected wells requires much labour because they collapse when it rains.
• During times of severe drought people resort to stealing water at night and well owners must guard their wells to ensure their livestock get enough.

Solutions

From April 1996 to April 1997, there was severe drought in Ngurunit and wells up to 30 or 40 feet were dug in the main river bed because all other sources were dry. Women and children were hard hit. When the rains came and water became easily available again, the community, especially the women, decided to deal with the problem of water access.

One group, Salato Women's Group, started looking for ways to build their own wells. They used funds from various sources including their profits from craft sales, a grant from a development organisation and some assistance from a church group in America. In 1998, they started to build two wells next to their group plot. The well for their group livestock was finished in mid-1999. The other well was covered and fitted with a hand pump donated by a German aid programme in 2000. Once dug, both wells were protected with cement to prevent them collapsing.

These wells were the first in the area to be owned by Samburu/ Rendille women rather than by individual men. Having separate wells for livestock and humans and especially the covered household well also set an example for hygiene. Although owned by the women's group, all households in the surrounding area could access the covered well.

The Salato Women's group was successful in building the wells because they had funds to hire labour. Women generally do not have their own property. Since coming together as a group, they had been able to get funds they could not have accessed as individuals. Over the years, the group's activities earned the respect of the men. As the group started to earn an income and build connections to outside assistance, men's attitudes started to change. They were willing to help them dig their wells and appreciated being paid.

The Salato women's decision to build wells fitted into the general pastoralist perception of the importance of water resources. Men in the area were able to support this choice because they also benefited from the wells, even if they did not own them. In Ngurunit, water scarcity is relative. There is water in many of the dry riverbeds if wells are dug deep enough. The major constraint is the labour needed to dig the well, hence the ownership rules. When a women's group was able to get resources to dig more wells, men were prepared to welcome this development.

From mid-2000 when the Salato Women's group second well was completed, the attitude towards water and access to water began to change in Ngurunit. The community started to try and get funds to build covered, hand pump wells that women and children could use for household needs. One well was built for the primary school so children would no longer have to wait for long hours at individually owned livestock wells. A second woman's group also raised funds and built their own well to provide water for their tree nursery and their families.

In 2002 there was a drought. Even so, with some rationing, the availability of hand pump wells meant that everyone was able to meet their needs with less waiting and trouble than under the traditional well system. That year Salato Women's group also raised funds for a preventive health practises project. They built three more covered hand pump wells in villages that were farther away from the main riverbed. With clean water nearer to home, the group succeeded in reducing the workload of the women and young people who no longer had to walk long distances for household water.

By March 2003, Ngurunit sub-location had eight community hand pump wells for household water, five of them owned solely by women's groups. In addition there was also the original livestock well built by the Salato group in 1999.

Plans

The success of the hand pump projects and the empowerment of the women who own some of them, has shown there are workable solutions to the problem of water scarcity in this semi-arid area. Some outlying areas that now depend on the Ngurunit wells but do not have appropriate places for hand pump construction, are working on their own solutions such as rock rainwater harvesting systems and protected water pans. In Lebendera, Meingati Women's Group is the driving force behind developing their own community water sources. After seeing the success of the Salato Women's group in accessing water, they have realised that men were not the only ones who could control water, and that to care for their households, women also need secure access. In the villages of Illaut and Arsim, women's groups are also trying to get enough resources to develop wells for community use.

Women in the Ngurunit area are becoming increasingly independent in their access to water. In addition to the important changes in water access and control, the successes of the various women's groups in securing water has affected other aspects of their lives as well. Through the support and actions within women's groups, they have been able to gain control of many assets they did not have in the traditional system. These include ownership of livestock and group plots for income-generating activities and an increased capacity to run business enterprises such as beadwork and marketing local commodities and livestock products both on a group and individual basis. Any resistance men may have shown to these changes in the traditional pastoralist system has been largely neutralised by the clear benefits that these activities have brought to the community and individual households.

Land tenure and resource access in West Africa

Most West African countries depend heavily on natural resources for income, employment, livelihood, and export earnings. The legal and administrative measures that determine the access to and control over natural resources are, therefore, very important to enable improvement of long-term productivity, stimulate investment, encourage fair access and make it possible to avoid conflict.

In recent decades there has been rapid population growth and increased urbanisation and labour migration throughout West Africa. Some areas, such as the coastal countries along the Gulf of Guinea, have experienced heavy urbanisation. In other areas, pressure on farmland as a result of migration of people and cattle from drier to wetter parts has caused problems. These patterns are expected to continue, leading to land scarcity and a reduction in the size of holdings. Urban populations are expected to triple by 2030 creating an increasing market for food produced in the agricultural hinterlands.

West Africa's agricultural and ecological zones range from moist forest in the south to arid deserts in the north. Their history and socio-economic characteristics have resulted in many different systems for managing resources. However, there are issues common to all countries.

Common issues

Throughout West Africa contradictions exist between customary tenure and government laws and regulations (statutory tenure). However, customary tenure remains the most important system through which people regulate access to land and other resources. Customary tenure is based on the values and norms of each social group and this gives legitimacy to local decision-making.

Customary systems

In most customary systems land cannot be bought and sold freely. Despite this restriction, customary practises do not seem to have hindered investment in the small-farm sector. However, customary systems do have drawbacks. Powerful groups, for example, may use their position to access key resources, or try to sell land that is traditionally considered community property. In some customary systems the rights of socially marginal groups, including women and certain castes are poorly guaranteed. Also many governments do not recognise the legal power of customary authorities to regulate and administer land. As the interests of communities and groups in West Africa change this affects customs and practises of resource management. In addition, as commercial opportunities increase many customary tenure systems are tending to evolve towards individual rights.

Statutory systems

The state controls land in statutory systems and has the power to decide rights and titles. Statutory systems are based on state authority and are enforced by government to serve state interests. Statutory and customary systems have different ways of deciding on issues of access to resources. For this reason statutory systems are not always accepted at village level. As land becomes scarce and its value increases, problems caused by the differences between customary and statutory law can lead to growing insecurity. In West Africa, other factors such as Islamic law and the impact of development projects can increase the difficulty of reaching decisions on the issues of rights to resources.

Effective and just implementation of customary and statutory laws and practises depends on clear definitions of the relationships between the two systems. One way to achieve this could be to define the areas in which statutory law applies - such as in peri-urban areas - and let the customary system apply outside these areas.

Registration

In West Africa, ensuring land tenure security is seen as a way of encouraging land users to invest in agriculture. At present less than 5 percent of land is in individual ownership under statutory law. Most of this land is in towns where its relatively high commercial value makes it worthwhile for owners to invest in registering title. However, experience shows that there are serious difficulties associated with land registration in West African conditions:

- Land registration is expensive for the state, requiring the maintenance of a centralised system for land survey and administration.
- The mapping and registering of title to many small plots and maintaining and updating registration is extremely difficult. In practise, widespread land registration is very time consuming and difficult. Legislation permitting or requiring registration is widely ignored.
- Once land is registered, informal, unregistered land transactions still continue along customary lines and registers quickly become out of date.
- Local elites and private investors generally have privileged access to formal registration systems and can exploit them to the disadvantage of customary rights holders.
- Survey and registration fees, illiteracy and bureaucratic processes discourage poorer rural people from registering land.
- Registration campaigns cannot deal with the full range of customary rights and they frequently undermine the security of women, other subsidiary rights holders, and community claims to common resources leading to increasing disputes and insecurity.

However, registration programmes may be useful in certain cases. For example, where customary systems have broken down or are very weak or where the value of resources has increased, leading to conflicts and disputes.

Other approaches

Registering individual rights is not the only way of regulating access and control to land and some other methods are being tested in West Africa. They include community land-use planning projects, such as *gestion de terroir* approaches where decisions on land and natural resource allocation are made at village level and accepted by government. Finally, farmers are also developing more informal ways of securing land tractions (rental land, sharecropping, or even sale) by involving witnesses and putting agreements into writing which are then signed by the village chief or even a local level administrator.

Conflict management
As resources become scarcer and more valuable, competition between users intensifies. It is therefore important that procedures and mechanisms are developed to resolve conflicts and disputes. Places where serious competition is likely to develop include peri-urban and wetland areas and regions that attract agricultural migrants. Relations between farmers and herders are likely to become tense as village cattle herds expand, grazing areas contract, fodder becomes scarce, and fields start blocking cattle tracks. In such situations customary systems for resolving conflict, where they exist and are still effective can be elaborated as a step towards dealing with disputes.

Common property resources
Common property resources remain important. Access to fuel wood, common grazing, the availability of non-timber forest products, fish resources and construction timber are important to most rural communities. Nationalisation measures by various governments and a lack of any recognition of villagers' rights in certain West Africa countries has meant that many common property resources are unregulated and open to all. In addition, resource use has altered because of interventions that have undermined existing management systems. Forests have been demarcated as government reserves, public boreholes have opened up grazing areas to all-comers, and traditional fishing regulations have been over-ruled by new projects and regulations. Common resources are under pressure, particularly in densely populated areas where a decline in fallow has reduced the amount of bush land available for forage and has lead to an increasing assertion of individual rights to grazing and other resources.

Will it be possible, in future, for different users to agree on ways to manage common resources in the interests of long-term productivity, and will government be able to give sufficient power to local communities to enable them to negotiate and enforce controls on access to resources? Recent pilot projects have shown that such measures as the joint management of forest areas, and local management agreements between villagers and the government have considerable potential.

Pastoral livestock sector
The pastoral sector is critically important in many parts of West Africa and continues to be an important source of income and export earnings in drier areas. It is now recognised that the continued viability of the pastoral sector in the semi-dry areas of the savannas and the Sahel depend on herds being able to move as freely as possible between grazing areas and sources of water. They must also have access to dry season grazing because rainfall and forage resources are not enough to allow herds to remain in one place for long.

Pastoralism, in contrast to farming, is not recognised by most West African states as productive land use. This complicates the issue of pastoralists' rights in statutory law. It undermines security in pastoralist communities and makes it more difficult to deal with the problem of grazing areas being converted into agricultural land. Further, if pastoralists cannot use crop residues because farmers are using them for their own herds, grazing areas are reduced through cultivation and transhumance routes are blocked, it will be impossible to maintain a productive, mobile livestock system.

Future
In West Africa policies are being discussed to tackle these problems. These include decentralisation, clarifying customary and statutory tenure systems, and encouraging debate at local, national and sub-regional levels.

Given the diversity of most West African countries, the development of national policies on land and natural resource management must take local conditions into consideration. Several West African governments follow decentralisation policies that involves central government giving more power and responsibility to regional or district administrations and elected bodies. Land tenure administration should, if possible, be carried out at the lowest level of management leaving the higher levels of government to take on issue lower levels can not handle. This is the principal of subsidiarity. The idea behind this approach is that, by electing local representatives, local interests and needs are better served and contact between local people and the administration will improve.

West African states have limited financial and administrative resources making it difficult for governments to become heavily involved in managing land at local level. However, government remains responsible for providing the principles and framework that guide decision-making on issues of tenure and access to resources and ensure that local organisations are transparent and accountable.

West African governments already support a number of initiatives related to land tenure and access to resources. National governments can draw on these to encourage local debate on the policy options available in land tenure. Public consultation is particularly important in countries preparing new land tenure legislation. Experiences such as *gestion de terroir* can provide useful insights into how community-based natural resource management works. Lessons can also be learned from initiatives to establish the co-management of forest and wildlife resources and programmes to improve the management of conflict.

Finally, the exchange of experiences between countries not only strengthens the capacity to analyse and solve land tenure problems, it also allows trans-boundary issues to be taken into account. At this level regional bodies such as CMA-AOC, CILSS and ECOWAS can provide representatives from West African countries with opportunities to discuss common problems in developing policy for land tenure and natural resources management.

Access to and control over resources

Editorial

Access and control over land and other natural resources is regulated through many different systems and arrangements. Whether these systems are formal or informal, statutory or customary, restrictive or open, they all play a major role in rural livelihood security.

History, values and beliefs are reflected in the way societies organise their systems of agricultural production and natural resource management. They determine the extent to which farmers and other rural community members have the right and power to secure the resources they need to ensure food security and income. They also have an important influence on the political climate in which resources are managed and regulated.

Security

Security in access to resource use is essential to sustained agricultural production. Without long-term security farmers find it difficult to invest in improvements that only produce returns over many years. Farmers must feel confident that they will be able to benefit from their efforts. Secure land rights provide them with the opportunity to accumulate wealth and to ensure it is transferred between generations. They often have a very strong bond with the land they farm, land they may have inherited from earlier generations and would like to hand over to the next generation in good condition. Where the future is uncertain, people may make short-term, exploitative or destructive decisions about the use of natural resources (Zewdie p 21).

Securing access to land for food production represents a particular problem for many women living under systems of customary law. In Southern Africa, for example, the effect of HIV/AIDs in the rural areas has resulted in increasing numbers of farm households headed by widows. Many of them have been dispossessed of land and agricultural assets under customary laws that invest land rights in the husband and his heirs. Without security of tenure women's capacity to produce food and care for their families is being seriously undermined (see the article on p 30).

Secondary access to land and other resources is not only a problem that confronts women. Other marginal groups such as herders, migrants and refugees often have serious problems in negotiating access to resources, as the article on the Sherkolle refugee camp clearly demonstrates (Abebe p 18).

In the rare situations where there are few limits to available resources, secure access is not a problem. As soon as land and other resources become scarce, however, either in real terms or because of restricted access, rights have to be regulated in ways that are acceptable to most of the community and give users enough security to invest efforts in sustainable management practises.

Different arrangements

There are many different ways in which access to land and other resources can be organised. These include freehold, leasehold, sharecropping and rental arrangements. There are also systems of usufruct in which the owner – whether this is the clan, traditional leaders or a landlord - grants rights to use the resource for a limited period of time. Access arrangements depend on many factors and are influenced by local conditions such as population density, the availability of land, its productivity as well as the socio-political context and history of the community concerned. In some societies, land use is egalitarian as most community members have equal access to land. Usually, however, access to land depends on social status gender and power structures, where the most influential in the society control most of the land and the poorer members work it under certain specified conditions.

All systems that do not depend on repression and the use of force to maintain themselves need the acceptance and support of the majority of their members. In addition, those responsible for enforcing them must have enough power, legitimacy and political will to do this effectively. Such systems provide a relative level of security – people know what the rules are today and what they are likely to be tomorrow. Systems that are deeply embedded in the culture and values of a community and continue to provide benefits for their members can be resilient enough to survive for centuries. An example is the *Subak* system of water management in Bali (Suarja p 25). However, some customary systems are also characterised by deeply entrenched biases against certain groups such as women and migrants.

The resilience of traditional arrangements for managing resource rights can also be seen in situations where new legislation has been imposed on local communities but can only be weakly or incompletely implemented (Aarnink p 10). In Africa it has been estimated that less than 10 percent of land is being administered under statutory law. Most of it continues to be regulated under customary provisions and in many countries these have yet to be formally recognised by the state. In West Africa, this has resulted in an ill-defined and sometimes contradictory relationship between statutory and customary law (IIED p 6). Some African countries are currently trying to give statutory status to customary practises, but this is a complex process and difficult to implement. This can be seen in the article on South Africa's efforts to introduce communal land rights legislation (Cousins p 27).

Change
Changes in access to land and other agricultural resources have, historically, often provoked violent and far-reaching reactions because not only do they affect economic security but also deeply disrupt cultural and spiritual life.

Customary systems of natural resource management that have evolved gradually over time are vulnerable to radical economic and political change. In rural communities in many parts of the world traditional rights and obligations were undermined by the imposition of colonial law and settler practises. In countries like Brazil, such interventions continue to have far reaching consequences (Vankrunkelsven p 15).

In areas of continuous population growth where pressure on agricultural resources fuels rapid economic and social change, conflicts and disputes over land and other resources are common. This is particularly so in peri-urban areas and in the agricultural hinterland of large cities, where expanding markets open up promising commercial opportunities. In such situations there is the danger that those with custodial powers and responsibilities in the traditional system may start to use them to their own advantage, ignoring the communal nature of the resources involved. In societies where the gap between rich and poor is widening an increasing number of the dispossessed are left to share a decreasing and frequently degraded resource base. The consequences of ineffective access to the political system has lead those without land to organise themselves in popular movements to force a more equitable land policy (Corrêa p 16).

Resourceful people
In situations where governments are either unwilling or unable to meet their responsibilities for the management of resources that are under their control, rural communities often look for practical solutions. The role of informal leaders can be very important in such circumstances. This can be seen, for example, in the article on the experience of Rautela, the water volunteer, who helps his community make better use of all available water resources (Critchley p 23).

In some cases, people have come together to improve the resources available, such as the pastoralist women of Ngurunit who took the initiative to collect funds and organise the digging of wells so they had a reliable and safe water supply (Lemunyete p 8). When communities improve access to resources such as water this can lead to a need to re-define rights of ownership and use. This was the case in the Arvari river where local initiatives to revive traditional small water-harvesting structures resulted in renewed river flow. The communities subsequently had to defend their rights to the water and fish production created as a result of their efforts, against outside interests (Kishore p 24).

For those who do not own or have access to their own resources, having the capacity to negotiate the right to use land and other necessities is critical. Share cropping is a strategy often used by landless and other marginal groups who find themselves without access to local resources (Tripathi p 13).

Understanding the dynamics
Access to and control over resources is about power, and there are usually winners and losers when change occurs. Many development projects that deal with agriculture and natural resource management do not pay enough attention to assessing or understanding the issues of rights and tenure before starting project activities. It is often assumed that development interventions will automatically benefit the community at large. Without proper management and channelling of resources this is unlikely to be the case. This is particularly the case with projects that considerably increase the value of resources.

Destitute nomads from Mali came to Christine Wells in Burkina Faso in search of pasture but found a wasteland. Photo: FAO/ F. Botts

This issue of the *LEISA Magazine* focuses on rights to renewable natural resources. However, it should be remembered that other resources are also necessary for a sustainable and responsible agriculture. Today, in many communities, the effects of poverty and unregulated social change have created barriers that inhibit communities from maintaining access to local knowledge and the richness provided by their traditional cultures and beliefs. Ensuring control over the way these human resources are protected and developed remains to be explored in later editions of the *LEISA Magazines.* ■

ILEIA is the Centre for Information on Low External Input and Sustainable Agriculture (LEISA). ILEIA seeks to promote the adoption of LEISA through the LEISA magazines and other publications. It also maintains a specialised information database and an informative and interactive website on LEISA (**http://www.ileia.org**). The web site provides access to many other sources of information on the development of sustainable agriculture.

LEISA is about Low-External-Input and Sustainable Agriculture. It is about the technical and social options open to farmers who seek to improve productivity and income in an ecologically sound way. LEISA is about the optimal use of local resources and natural processes and, if necessary, the safe and efficient use of external inputs. It is about the empowerment of male and female farmers and the communities who seek to build their future on the basis of their own knowledge, skills, values, culture and institutions. LEISA is also about participatory methodologies to strengthen the capacity of farmers and other actors to improve agriculture and adapt it to changing needs and conditions. LEISA seeks to combine indigenous and scientific knowledge, and to influence policy formulation in creating an environment conducive for its further development. LEISA is a concept, an approach and a political message.

Readers are welcome to photocopy and circulate articles.

10 Lake Mweru is our bank

Nettie Aarnink and Paul van Zwieten

Since the 1970s, there has been increasing competition for the fish resources of Lake Mweru, Zambia. This has led to serious conservation problems. The Department of Fisheries found it increasingly difficult to implement the existing rules and regulations to prevent overfishing. It decided to involve local stakeholders in the process of establishing acceptable and enforceable conservation measures. One of the tools used in this process was the highly successful video *Lake Mweru is our bank.* (see page 33).

27 Community consultation and national lobbying in South Africa

Ben Cousins

A proposed Communal Land Rights Bill is being discussed in South Africa. The legislation makes provisions for formalising customary land law. This article looks at the implications of these discussions for the bill and draws the conclusion that only by establishing strong links between local action and national advocacy activities can the voices of local communities be heard.

DEAR READERS

As you read on the back cover of the last issue, the LEISA Magazine is now available in five different editions and four different languages, thanks to our partner organisations in Latin America, India, Indonesia and West Africa. This represents a major step forward for the exchange of information on LEISA and we are very excited to see the different issues develop, each with their own character. ILEIA's new website is under construction and will be launched towards the end of the year. It will carry the information and articles from the five editions, thereby making a lot of LEISA material available in one place. We hope it will become a useful resource and a platform for information exchange.

Another major step for ILEIA is that we are now setting up our own offices after almost 20 years in Leusden. From the 1st of October 2003 we will be located at Zuidsingel 16 in the centre of Amersfoort, the Netherlands. Our new postal address is:

PO Box 2067, 3800 CB Amersfoort, The Netherlands
Telephone +31 33 467 38 70, Fax +31 33 463 24 10

Our email addresses remain the same: ileia@ileia.nl and subscriptions@ileia.nl. Our old postbox address will also remain in use for the coming year, so you do not need to change our address on the subscription card.

We hope you enjoy this issue on access to and control over resources.

Rights and resources

Spherical water tanks

Gedion Shone

For resource poor smallholder farmers in water scarce areas, even small volumes of stored water for supplemental irrigation can significantly improve a household's economic position. The Regional Land Management Unit (RELMA) in Eastern Africa has been promoting spherical water tanks for harvesting rainwater from roofs and other surfaces, similar to the ones promoted by the Gansu Research Institute for Water Conservancy (GRIWAC) in China. Demonstrations and trainings on water harvesting conducted by RELMA inspired the Ethiopian Minister of Agriculture to arrange an exchange visit with GRIWAC in Gansu province.

Advantages of using spherical tanks compared to other shapes:
- The water pressure is evenly distributed within the tank and the tank therefore requires less reinforcement
- A spherical shape has a smaller surface area than square one and thus uses less building material
- The bottom part is directly supported by the ground, further reducing the need for heavy reinforcement materials
- Easy to construct
- No evaporation takes place as the tank is closed.

In order to reduce construction costs, the tanks are built with locally made clay bricks and mortar. The walls are lined with a mixture of cement and clay on chicken mesh and finished off with a *cement nil* water-proof coating. These tanks are less expensive to build than the conventional concrete structures, and experience has shown that they can be built by local masons with only basic building skills. It generally takes only one session of practical training for local masons to master the construction method.

Three types of spherical tanks - semi-circular submerged tank, underground spherical tanks and partially underground spherical tanks - have now been tried out in Ethiopia, Uganda, Kenya and more recently in Tanzania. The size and shape of the tanks can be adapted to local needs. In the Machakos district of Kenya, for example, where arable land is very scarce, the tanks are dug in such a way that the only soil surface that cannot be cultivated is the manhole opening at the top. These tanks are used to irrigate kitchen gardens, enabling farmers to diversify their sources of income. Micro-irrigation schemes are promoted together with commercially available, low-pressure drip irrigation systems. Cheap drip kits (for example, the Chapin bucket kit, see *LEISA Newsletter* Vol 14.1 p 29) save water and labour, and are increasingly being adopted by farmers.

LEISA Magazines!!

Regional editors and ILEIA staff

In May this year, the editorial teams of all five LEISA Magazines met together in the Netherlands for their international editors' meeting. When the members of the teams from Africa, India, Latin America, the Far East and Europe left, they all felt a strong sense of common identity and purpose and a determination to increase their capacity to ensure that the information, experiences and the growing number of dynamic examples of LEISA in practice will continue to be collected and published regularly.

Establishing new regional editions of the LEISA Magazine is one of the key elements in the ILEIA programme 2002-2006. In 2001, the *ILEIA Newsletter* celebrated its seventeenth anniversary and became the *LEISA Magazine*, a global quarterly already supporting two regional magazines – *LEISA India*, published by the AME Foundation in Bangalore, India, and *LEISA – Revista de Agroecologica,* produced and distributed in Latin America in the Spanish language.

In 2002, with more than 20,000 subscribers and supported by an evaluation that strongly recommended the launching of new regional editions by regional partner organisations, our donors decided to support this development. Two new regional magazines have already been launched and the ILEIA web site is being developed into an easily accessible interactive platform, where information on sustainable agriculture and LEISA approaches to rural development can be collected and retrieved.

The first of the new magazines – *SALAM* – appeared in Indonesia in December 2002. Published by VECO Indonesia, and relying upon their extensive network of collaborating partner organisations, it drew together experiences of low external input agriculture relevant to Indonesian farmers. *SALAM* was exceptional in that it set out a new strategy. Its editors scoured the ILEIA archives for articles relevant to the small-scale farmers of the Indonesian archipelago and, having translated them into Bahasa Indonesia, published them alongside articles they had collected on Indonesian experiences of LEISA.

In May 2003, the fifth LEISA magazine *AGRIDAPE* appeared in the French language. Produced by IIED, Senegal, it focuses on West and Central African French-speaking countries and is supported by the *Technical Centre for Agriculture and Rural Cooperation* (CTA). Launched at the recent meeting of the Global Forum for Agricultural Research (GFAR) meeting in Dakar, Senegal, it was seen by representatives of farmers' organisations, NGOs and agricultural research institutes as a breakthrough in the language barrier that makes exchange between those involved in LEISA in English- and French-speaking Africa difficult. Appropriately, some of the first editions of *AGRIDAPE* will deal with topics of particular concern to the dryland areas of West Africa: water harvesting, access to scarce resources and the restoration of degraded lands. It is clear that many regional experiences await publication and, if the growing number of subscriptions is anything to go by, *AGRIDAPE* is well on the way to becoming standard reading amongst those concerned with agricultural sustainability and environmental issues in the region.

Paulo Petersen of AS-PTA Brazil joined the LEISA editor's meeting to explore the possibility of establishing a Portuguese language version of the LEISA Magazine. While his contribution highlighted the political and economic specificity of the Brazilian experiences with LEISA, it also illustrated that farmers around the world have much in common when they confront the consequences of the global agricultural crises. It was the global dimension of LEISA that formed the theme of the two study days organised for the editorial teams while they were in the Netherlands and it this theme that will guide the documentation, analysis and publication of experiences with LEISA in the LEISA magazines in the coming four years.

The international editors' meeting is held twice a year. The following meeting will be held in Peru in 2004. For further information on the proceedings of this meeting, themes of forthcoming editions and other activities see www.ileia.org or contact ileia@ileia.nl.

Issue 19.4, December 2003

Rehabilitation of degraded land

Developing economies, growing populations and intensified agricultural practices have all contributed to increasing pressure on land resources. Economic growth and intensified, large scale production often leads to the most productive land being used for larger commercial plantations, pushing small farmers onto degraded lands. How can small-scale farmers go about maintaining the land they depend on for survival and increasing its productive potential? How can productive soils be conserved in the face of increasing pressures, and how can sodic, saline, eroded, or toxic soils be rehabilitated to a fertile condition? This issue of LEISA will deal with practices that contribute to maintaining productive soil and rehabilitating land that has been degraded. Please contribute your experiences, ideas and solutions!
Deadline for contributions is the 1st of September, 2003.

You are invited to contribute with articles (about 800, 1600 or 2400 words + 2-3 illustrations and references), suggest possible authors, and send us information about publications, training courses, meetings and websites. Editorial support is provided by ILEIA. Authors of published articles are entitled to a standard fee of US$ 75,–.

World Water Forum
http://worldwaterforum.idrc.ca
Participants of the eight-day Third World Water Forum made more than 100 new commitments on water. This important event was held in Kyoto, Shiga and Osaka, Japan, March 16-23, 2003.

ADB Water for All
http://www.adb.org/Water/help.asp
The Asian Development Bank *Water for All* website provides information on water policies and case studies from different countries in Asia. It also provides information on events and gives references and links.

WCA InfoNET
http://www.wca-infonet.org
The WCA infoNET information system is a growing database of information on water conservation and use in agriculture. It was launched to the public in August 2001 and is managed by the International Programme for Technology and Research in Irrigation and Drainage (IPTRID), hosted by FAO. This site includes documents, data, computer programs, discussion groups and links to other relevant websites.

CSE rainwater harvesting
http://www.rainwaterharvesting.org
This rainwater harvesting website is an effort by the Centre for Science and Environment (CSE) India to provide targeted information and contacts for researchers, planners, NGOs and journalists on water issues. It provides practical information from different parts of India on different aspects of water harvesting, including technical information and case studies.

Water Policy Briefings
http://www.iwmi.cgiar.org/waterpolicybriefing/index.asp
The *Water Policy Briefing* series presents new perspectives and solutions to water problems in developing countries. Each briefing is based on peer-reviewed research that challenges policy makers and planners to think differently about the way water is managed for agriculture. The series has grown out of research conducted by the IWMI-TATA Water Policy Program in India, which recommends solutions to India's water crisis. It is now being expanded to provide more general policy recommendations.

InterWATER the gateway to water and sanitation organizations all over the world
http://www.irc.nl/interwater/
Inter*WATER* offers information about more than 650 organisations and networks in the water supply and sanitation sector, mainly for developing countries. You can search for an organisation by name, acronym, location or description. There is also a list of key international organisations and UN organisations. Each organisation has a short description, contact details, e-mail and website address, and related sites where applicable.

UNESCO Water Portal
http://www.unesco.org/water/
The UNESCO Water Portal is a gateway to information on freshwater available on the World Wide Web. The site provides links to the current UNESCO and UNESCO-led programmes on freshwater and will serve as an interactive point for sharing, browsing and searching websites of water-related organisations, government bodies and NGOs, including a range of categories such as water links, water events, learning modules and other on-line resources.

Global Water Partnership
http://www.gwpforum.org/servlet/PSP
The Global Water Partnership is a working partnership among all those involved in water management: government agencies, public institutions, private companies, professional organisations, multilateral development agencies and others committed to the Dublin-Rio principles. Today, this comprehensive partnership actively identifies critical knowledge needs at global, regional and national levels, helps design programs for meeting these needs, and serves as a mechanism for building alliances and exchanging information on integrated water resources management. The mission of the Global Water Partnership is to "support countries in the sustainable management of their water resources."

International Institute for Land Reclamation and Improvement (ILRI)
http://www.ilri.nl
The core business of ILRI is to disseminate knowledge that will facilitate the improved and sustainable management of land and water in developing countries. ILRI undertakes applied research on the sustainable development of irrigated agriculture. The results of ILRI's research are published in the series of ILRI publications and in papers, scientific journals, and conference proceedings. ILRI has also been conducting annual post-graduate courses on irrigation and drainage for scientists and field engineers in mid-career.

World Water Council
http://www.worldwatercouncil.org/
The World Water Council is an international water policy think tank, dedicated to contribute to improved management of the world's water resources. The mission of the World Water Council is to promote awareness and build political commitment on critical water issues at all levels, including the highest decision-making level, to facilitate the efficient conservation, protection, development, planning, management and use of water in all its dimensions on an environmentally sustainable basis for the benefit of all life on earth.

International Commission on Irrigation and Drainage
http://www.icid.org/
The International Commission on Irrigation and Drainage (ICID) is a NGO based in New Delhi, India. The mission of ICID is to stimulate and promote the development of agriculture in managing water and land resources for irrigation, drainage, flood management and river training applications, including research and development and capacity building for achieving sustainable irrigated agriculture.

IRRISOFT Database on Irrigation and Hydrology Software
http://www.wiz.uni-kassel.de/kww/irrisoft/irrisoft_i.html#index
IRRISOFT is an Irrigation and Hydrology Software Database, which provides information on irrigation and hydrology software and links to servers containing the software packages and further information. Numerous irrigation programmes, written by individuals or groups, are available as public domain, shareware or commercial software. The objective of IRRISOFT is to give an overview of the irrigation and hydrology programmes available and to facilitate their retrieval and distribution by opening up download facilities or by e-mail order through the World Wide Web.

Sustainable agriculture, training of trainers: a resource book 2002, International Institute of Rural Reconstruction (IIRR), 351 p. ISBN 1 930261 055 US$ 20 (inclusive CD-Rom). Available from: IIRR, Y.C.James Yen Center, Biga, Silang, Cavite, Philippines and ETC EcoCulture, PO Box 64, 3830 AB Leusden, The Netherlands. Email: Bookstore@iirr.org; www.iirr.org

This resource book is designed for trainers in sustainable agriculture. It has been developed in response to the need to increase the capacity of sustainable agriculture training institutions to impart and share sustainable agriculture concepts, principles and experiences. It brings together IIRR's 40 years of training experience and the results of a five-year Training of Trainers project on sustainable agriculture. Produced in 2002, the resource book and accompanying interactive CD offer a complete set of materials, training session guides, handouts and illustrations useful for training on all aspects of sustainable agriculture. The materials are also useful to those either involved in or planning training programmes. The resource book is divided into two parts. The first part reflects on key considerations in sustainable agriculture training, while the second part focuses on training programme development and management.

Bringing the food economy home: local alternatives to global agribusiness
by Norberg-Hodge H, Merrifield T & Gorelick S. 2002, Zed Books and the International Society for Ecology and Culture (ISEC), Foxhole, Dartington, Devon TQ9 6EB, UK. ISBN 1 84277 233 3. Email: zed@zedbooks.demon.co.uk; www.isec.org.uk

This book shows how a shift towards local food economies would protect and rebuild agricultural diversity. It would give farmers a bigger share of the money spent on food, and provide consumers with healthier, fresher food at more affordable prices. It would reduce transport, greenhouse gas emissions, and the need for toxic agricultural chemicals. It would lessen the need for storage, packaging, refrigeration and artificial additives. It would also help revitalise rural economies and communities in both the industrialised and the developing world. Because it benefits the farmer, consumer and the economy as well as the environment, local food is a powerful solution-multiplier, one that we cannot afford to ignore.

The environment and zero tillage
by Saturnino HM, Landers JN (eds), 2002, APDC, SCLRN, 144 p. ISBN 85 865006 01 x. Available from: APDC, 712 Bloco C Loja 18, Brasilia, DF, Brasil Cep 70760-533 and FAO Viale delle Terme di Caracalla, 00100 Rome, Italy. Email: apdc-DF@terra.com.br; www.fao.org

All over the world it is recognised that erosion is responsible for the degradation of fertile soils, water resources and biodiversity and has undermined the economic viability of farms, regions and whole countries. Zero tillage provides an effective answer to these problems (see *LEISA Magazine* Vol 18.3). The evolution of zero tillage is a story of farmer persistence and empowerment, community resource management and farmer-private sector-government partnerships, which have engendered a new philosophy for truly sustainable agricultural systems at high production levels. Zero tillage is not just an alternative planting method, it represents a change in agricultural thinking, an approach that takes the whole system into consideration and focuses on integrated crop rotations, the maintenance of surface residues with cover crops, the integrated management of weeds, pests and diseases, rational fertiliser practices, watershed management and other environmentally sustainable practices. This handy well-illustrated booklet presents the experiences of more than five million large- and small-scale Brazilian farmers who have used this conservation method on more than 14 million hectares. The booklet is not a practical handbook on zero tillage, but rather presents a well-argued case for the approach. (CR)

Food and feed from Mucuna: current uses and the way forward. Proceedings of an international workshop by Flores M & Eilittä M et al (eds), 2002, International Cover Crops Clearinghouse (CIDICCO), 411 p. ISBN 99926 24 02 7, Available from: CIDICCO, PO Box 4443, Tegucigalpa, Honduras. Website: www.cidicco.hn

Mucuna, the Velvet bean, has been well researched and broadly promoted as an alternative method of restoring and maintaining soil fertility in a wide range of agro-ecological conditions in the Tropics. However, it has not been widely adopted at farm level. The objective of the workshop was to intensify efforts to encourage the introduction of Mucuna, assess the state of knowledge on how Mucuna can be used for food and feed, identify bottlenecks to its greater use as food and feed and make recommendations for research and extension efforts. The report brings together workshop contributions. It begins with an overview of Mucuna and the papers are presented according to session: Mucuna as a food, Mucuna as a feed for ruminants, and Mucuna as a feed for non-ruminants. The workshop confirmed that Mucuna could contribute to the sustainability and productivity of tropical smallholder farming. (WR)

Participatory monitoring and evaluation (PM&E) with pastoralists: a review of experiences and annotated bibliography by Bayer W, Waters-Bayer A, 2002, ETC and GTZ, 88 p. ISBN 3 8236 1309 X. GTZ, PO Box 5180, 65726 Eschborn, Germany. Website: www.gtz.de

This report reviews documented experiences on participatory monitoring and evaluation with pastoralists and other livestock-keepers. It is divided into two parts: an analytical assessment and an annotated bibliography. Key websites for further information are given in an annex. The review refers to many training reports, guides and plans for establishing participatory monitoring and evaluation. There are not many examples of the actual implementation of systems that give balanced attention to the concerns of both pastoralists and other actors, and a number of reasons for this are suggested. The report emphasises the importance of this kind of evaluation for building the capacity of local people. (WR)

Ants as friends: improving your tree crops with weaver ants
by Van Mele P, & Cuc N.T.T, 2003, CABI Bioscience, 67 p. ISBN 958 97218 2, Available from: CABI Bioscience, 6 Bakeham Lane, Egham, Surrey TW20 9TY, UK. Email: CPM@cabi.org; www.cabi-bioscience.org

This manual teaches us how weaver ants can help farmers save money. It provides practical tips for making optimal use of the beneficial weaver ant in protecting fruit and other tree crops and is based on improved insights into underlying ecological principles. In this colourful and attractive manual, the authors have brought together a rich collection of scientific and farmers' knowledge. The authors have succeeded in writing a clear and practical guide on how to make use of the weaver ant as a crop protector. The manual will be particularly valuable for NGO workers, extension staff, students and all those engaged in communicating science to farmers. (WR)

Water harvesting and soil moisture retention

by Anschuetz J et al. 1997. Agrodok Series 13, 92p. Price: Euro 8.25. Available from: Agromisa, PO Box 41, 6700 AA Wageningen, The Netherlands and the Technical Centre for Agricultural and Rural Cooperation (CTA), PO Box 380, 6700 AJ Wageningen, The Netherlands. Email: cta@cta.int

This practical booklet, part of the Agrodok series, describes how rainfall and runoff water can be used to greater effect in agriculture. Many techniques are described briefly and clearly. The water-harvesting techniques covered in this booklet are particularly relevant for arid and semi-arid areas and the section on soil moisture retention contains information valuable for sub-humid regions. (IHG)

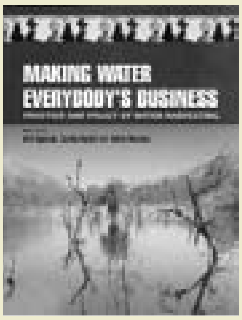
Making water management everybody's business: water harvesting and rural development in India

by Agarwal A. & Narain S. 1999. International Institute for Environment and Development (IIED), IIED Gatekeeper series, 20p. ISSN 1357 9258, SA87. Available from: IIED 3 Endsleigh Street, London WC1H 0DD, UK. Email: sustag@iied.org

This advocacy booklet about water harvesting in India provides arguments and examples of successful rainwater harvesting experiences. India only uses a small part of its water. It currently faces a water crisis, despite being one of the wettest countries in the world. Reviving rainwater-harvesting systems can restore ecosystems and contribute to rural development. The authors argue that the only way this can be done is to deepen systems of participatory democracy and expand participation at the village-level as much as possible. (WR)

Making water everybody's business: practice and policy of water harvesting

by Agarwal A, Narain S & Khurana I (eds.) 2001. Centre for Science and Environment (CSE), 456p. Available from: CSE, 41 Tughlakabad Institutional Area, New Delhi 110062, India. Email: cse@cseindia.org; www.cseindia.org



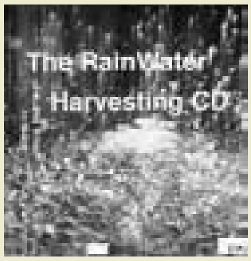
After the enormous success of "Dying wisdom: rise, fall and potential of India's traditional water harvesting system, The state of India's Environment, Fourth citizens' report" (1997), that gave a detailed account of India's traditional water harvesting systems, CSE has published this impressive new book. It continues the work begun in "Dying wisdom" and goes on to describe new examples of traditional rural water harvesting systems. It also gives many examples of communities that have undertaken water-harvesting programmes in recent years, including examples of water harvesting from outside India. Urban water harvesting programmes and new technologies for safeguarding the quantity and quality of water are also discussed. A central argument is that it is not simply low rainfall that causes water shortages, but a heavy reliance on surface and groundwater. It is here that the revival of traditional water harvesting systems becomes important. Another issue dealt with in the book is the tendency to see the government as being responsible for providing water. The authors argue that communities must take water management into their own hands and become involved in the provision and protection of water resources. (IHG)

Waterlines: International Journal of Appropriate Technologies for Water Supply and Sanitation

ITDG Publishing. Available from ITDG, 103-105 Southampton Row, London WC1B 4HL, UK. Email: itpubs@itpubs.org.uk; www.itdgpublishing.org.uk

This quarterly journal published by ITDG is the only international journal that deals with developments in low-cost sustainable water supply and sanitation in the South. It is written for professionals, project managers, policy makers, trainers and field workers.

The rainwater harvesting CD



by Hartung H 2002. The Technical Centre for Agricultural and Rural Co-operation (CTA); CD-Rom; ISBN 3 8236 1384 7. Available from: CTA, PO Box 380, 6700 AJ Wageningen, The Netherlands. Email: cta@cta.nl

Rainwater catchment systems have a long history that stretches back thousands of years in many parts of the world. Recently, increasing attention has been given to the importance of rainwater collection in rural areas. Programmes on harvesting rainwater focus on securing water for domestic use and agriculture, preventing floods, and protecting communities from the effects of drought. This CD-Rom contains reports from a selection of projects, together with many background documentation and case studies, including a CTA study visit to Kenya in 2000. The documents section contains selected articles from the magazine "Waterlines" and the proceedings of the 1999 and 2001 rainwater harvesting conferences. With this CD-Rom, CTA sets out to contribute to the growing body of literature on rainwater harvesting, which, hopefully, will help make it unnecessary for "any single village in any single part of the world to remain short of drinking water". (WR)

Water harvesting: indigenous knowledge for the future of the drier environments

by Oweis T, Prinz D, Hachum A. 2001. Available from: International Center for Agricultural Research in the Dry Areas (ICARDA), 36 p, ISBN 92 9127 116 0, US$7. Available from: ICARDA, PO Box 5466, Aleppo, Syria. Email: icarda@cgiar.org; www.icarda.cgiar.org.

This publication brings together knowledge and experience of water harvesting gained by ICARDA, national research groups, and advanced institutions over the years and presents them in non-technical language. It emphasises the techniques most suitable for the steppe areas of West Asia and North Africa and discusses some of the principals that apply to drylands everywhere.

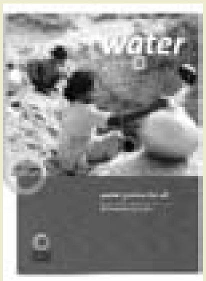
Keep it working: a field manual to support community management of water supplies

by Bolt E, Fonseca C, 2001, International Water and Sanitation Centre (IRC), IRC Technical Paper Series 36, 172 p, ISBN 90 6687 030 3, Euro 24. Available from: IRC, PO Box 2869, 2601 CW Delft, The Netherlands. Email: farmer-water-training@fao.org; publications-sales@fao.org; www.irc.nl

This useful manual is written for staff working directly with communities to help them establish or improve water supply management. Governments cannot and should not manage all rural water supply systems. Rather they should create an enabling environment in which communities can manage their own systems either alone or in partnership. Communities are the ones who are most aware of the nature of local demand, possible conflicts and the water resources available. They are also ones who are best able to judge the extent to which the various users will be able to contribute to operation and maintenance activities. The first section of this manual contains 20 fact sheets related to the different elements of sustainable water management. The 29 participatory tools described in the second part of the manual are designed to facilitate communication and community-based decision-making processes. The manual also provides 16 checklists that can be used to assess things like the way the water supply system works or cost recovery in operation and maintenance activities. There are clear links between the different parts of the manual. This makes it easy to use at community level. It also contains useful addresses, references, websites and discussion lists. "Keep it working" is one of a series of IRC publications on community water supply management and is also available in Spanish. IRC has more interesting information on its web site: www.irc.nl/manage (WR)

Water-wise rice production by Bouman BAM, Hengsdijk H, Hardy B, Bindraban PS, Tuong TP, Ladha JK(eds.) 2001. Proceedings of the International Workshop on Water-wise rice production, 8-11 April 2002, Los Banõs, Philippines. 356p. Available from: International Rice Research Institute, DAPO Box 7777, Metro Manila, Philippines. Email: irri@cgiar.org; www.irri.org

Together with Plant Research International of Wageningen University and Research Centre (WUR-PRI, the Netherlands), IRRI organised a thematic workshop on Water-wise Rice Production from 8-11 April 2002 at IRRI, Los Banõs, Phillipines. The objectives of the workshop were to present and discuss the state of the art in the development, dissemination, and adoption of water-saving technologies at spatial scales ranging from field to irrigation system. 75 participants from 12 countries came together at the workshop, which resulted in the creation of the International Platform for Saving Water in Rice (IPSWAR; www.irri.org/ipswar/about_us/ipswar.htm). The platform is intended as a mechanism to increase the efficiency and coherence of research on water savings in rice-based cropping systems in Asia.



Water justice for all: global and local resistance to the control and commodification of water 2003, Friends of the Earth International, Issue 102. Available from: Friends of the Earth, PO Box 19199, 1000 GD Amsterdam, The Netherlands. Email: info@foei.org; www.foei.org

Water justice is central to this brochure from Friends of the Earth International. The arguments and 15 case studies from all over the world criticise the commercial approach to water management of some international organisations and governments. (WR)

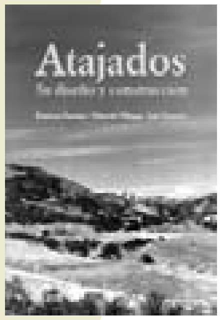
The River Senegal: flood management and the future of the valley by Adams A. 2000. International Institute for Environment and Development (IIED), Drylands Programme, IIED Issue Paper No.93, 27p, ISSN 1357 9312. Available from: IIED, 3 Endsleigh Street, London WC1H 0DD, UK.

This study by the IIED Dryland Programme describes the management of the Senegal River valley and the agricultural policy associated with it. The enormous investment made in two dams has not brought the promised development. It has in fact destroyed production systems that supported some degree of balance in subsistence crop production. The farmers, herdsmen and fishermen of the valley have had no part in the decisions affecting their future and as a result agriculture in the valley is in serious difficulties. (WR)

Participatory training and extension in farmers' water management 2001, FAO, Land and Water Digital Media Series 14; CD-Rom; ISBN 92 5 104636 0. Available from: FAO, Viale delle Terme di Caracalla 00100, Rome, Italy. Email: farmer-water-training@fao.org; publications-sales@fao.org; www.fao.org

This CD-Rom provides guidelines, procedures and relevant material for the development of a participatory training and extension programme. It is aimed at technical staff, extension workers and other stakeholders who are working with farmers to take charge of water management at field and scheme level and to help them adopt sustainable and appropriate water technologies. The programme is particularly relevant to irrigation management transfer programmes that help water users' associations to operate and maintain farmers' irrigation systems. It is also useful for smallholder irrigation programmes involved in guiding farmers in the adoption of efficient water control technologies. The interactive menus and cross-references in the documents provide quick and easy access to training guidelines, farmers' training manuals and a considerable amount of relevant training and audiovisual material and web links. (WR)

Atajados, su diseño y construcción by Tammes B, Villegas E, & Guamán L. 2002, Plural Editores, ISBN 99905 62 41 5, US$ 8. Available from: GTZ, FDC, KFW and Plural Editores, Rosendo Gutiérrez 595, Casilla 5097, La Paz, Bolivia. Email: plural@caoba.entelnet.bo

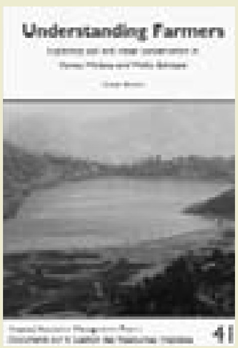


This is a manual about building an "Atajado". Atajados are small water reservoirs used in Bolivia to catch rainwater. Water collected with this technology is used for cattle, irrigation and domestic purpose. Recently Atjados have been revived in the valleys of Bolivia and this experience is the subject of the present manual. The new Atajados are slightly larger than the traditional ones and are often machine built. The manual describes how they are designed, developed and constructed. It also discusses how they can be used and problems that might arise. The book is accompanied by a diskette containing computer software to calculate soil removal for the construction. Available in Spanish only. (WR)

Understanding farmers: explaining soil and water conservation in Konso, Wolaita end Wello, Ethiopia by Tesfaye Beshah, 2003, Erosion and Soil & Water Conservation Group, Wageningen University and Research Center (WUR), 245 p. ISBN 90 6754 691 7. Available from: WUR, Nieuwe Kanaal 11, 6709 PA Wageningen, The Netherlands. Email: office@SEC.TCT.WAU.nl; www.dow.wau.nl/eswc

The study is also available in French "Documents sur la Gestion des Ressources Tropicales" (Tropical Resource Management Papers) ISSN 0926 9495 41.

This study deals with soil and water conservation behaviour among farmers in Ethiopia and was carried out at farming system, watershed, household, farm and plot levels. It provides insights into how farmers have reacted to externally introduced soil and water conservation technologies within and across farming systems. Their responses were analysed in terms of their knowledge and attitudes to soil erosion. The study pinpoints the different ways that farmers and outsiders see the problem of soil erosion, an element missing in most external interventions. Understanding farmers is seen as the entry point to promoting the sustainable management of natural resources. Suggestions for improvement are provided, based on study findings. The author hopes that his study will challenge research and development and extension professionals in Ethiopia. (WR)



Growing rice on raised beds

Donald E. Van Cooten and Andrew K. Borrell

Rice farmers in Eastern Indonesia are facing an uncertain future. The area is characterised by a monsoon rainfall pattern, but the wet season is often short and unreliable. Periods of intense rain often cause waterlogging and flooding and can be followed by periods of two weeks or more when no rain falls. Because of this, rice crops fail much too often.

Permanent raised beds are a potential alternative to present rice growing systems. By using water more efficiently, the risk of crop failure may be reduced. In addition, other crops can be grown on the same plots in rotation with the rice, creating a more diverse and secure system.

Crops other than rice can be grown on raised beds in the wet season. Photo: Author.

Permanent raised beds

The idea of growing crops on raised beds is nothing new to Indonesian farmers. In many parts of Indonesia after harvesting rice, farmers plant vegetables on raised beds so that they can be irrigated from the furrows without the risk of water logging. Each season, a lot of work is put into creating these beds after the rice has been harvested only to destroy them again in order to flood the following rice crop.

On the island of Java, farmers use a similar system, called *Surjan*, which combines upland crops and rice in one field. The system is established by moving the soil from one half of the field and placing it on the other half to form raised fields. Rice is grown on the low part and upland crops on the raised part. This system allows farmers to grow crops other than rice in the wet season. However, a lot of work is required and the soil needs to be deep enough to establish the system.

A major breakthrough came with the discovery that rice does not need to be flooded to grow well (this is also an important concept in the Systems of Rice Intensification (SRI) approach, see *LEISA Newsletter* Vol 16.4 p 12). Experiments with permanent raised beds have shown that flooded rice varieties can produce similar yields on permanent raised beds as in flooded paddies, while using much less water.

Trials in West Timor

In West Timor, upland crops are traditionally grown in swidden gardens on the hillsides in a slash-and-burn system, and flooded rice is grown in the valleys in the wet season. In recent years, however, both these systems have come under pressure and no longer provide food security.

Swidden gardens have been cultivated in the area for hundreds of years. Crops like cassava, maize, pigeon pea, and pumpkins do not need as much water as rice. They are grown on the hillsides because the more fertile lowland areas waterlog in the wet season. However, yields from these slash and burn gardens are limited by a lack of rain, poor soils, weeds and erosion. An increasing population has meant that farmers have to return to the same plot of land too soon, and the fallow period is not long enough to restore soil fertility. To reduce the risk of crop failure, farmers may cultivate three or four swidden gardens with distances of 5 to 10 km between gardens. This increases the chance that at least one field receives enough rain at the right time for a successful harvest, but it also increases the labour and time required to walk between these gardens.

Flooded rice (*Oryza sativa*) is grown in the valleys. Large amounts of water are needed and yields are very vulnerable to water shortages. If there is not enough water at the beginning of the wet season, land preparation can be delayed. If there is not enough water while the crop is growing, yields can be low or even fail completely. If the wet season ends too early and the rice plants have not yet filled the grain, the grains can be empty or only partly filled at harvest time.

During the 1998-1999 wet season an on-farm experiment was conducted in the village of Oenesu in West Timor. Five hectares were developed with a combination of small and large raised beds (see Box). Traditional upland intercrops and fodder species were planted on the large beds. Soybeans and rice (*Oryza sativa*) were planted on the small beds.

In the wet season, the rice and upland crops planted on the raised beds utilise the available rainfall. In the dry season, if irrigation water is available, it can be supplied to the furrows at a constant rate, maintaining the water level about 0.1 metre below the bed surface. An alternative to this system is to supply water at regular intervals, for example twice weekly, to rice grown on raised beds within bunded fields. If there is no water available for irrigation after harvesting the wet season crops, drought-resistant crops like sorghum, pigeon pea and cassava, or quick-maturing crops, like mung beans and millet can be planted and left to grow on the moisture stored in the soil.

Two types of raised bed

Small beds: Small beds are at least 30cm high from the bottom of the furrow to the top of the bed. They can be 60cm to 1.5m wide, depending on the soil type. These beds are suited to the cultivation of lowland rice and soybeans in the wet season. These crops do not need very much soil above the water in the furrows to grow well.

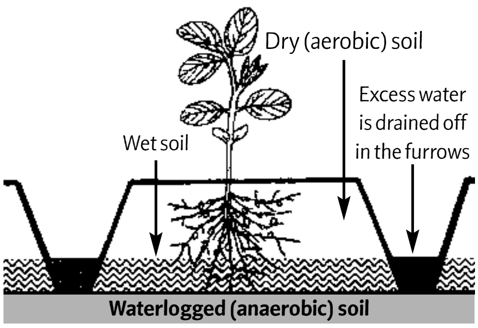
Large beds: Large beds are at least 2m wide and at least 50cm from the bottom of the furrow to the top of the bed. They are suited to the cultivation of upland crops, fodder grasses and trees, as these plants need a greater volume of soil above the waterline to grow well in the wet season. Large beds can be formed around the field boundary. They can also be formed at regular intervals in the field to prevent the small beds being washed away during heavy rain.

The rice on these beds gave a similar yield to the traditional rainfed flooded system. Grain yields were 1.5 to 2 ton/ha, including the furrows. The farmers had never seen soybeans grown in the wet season before. They thought that only rice would grow in the wet season. But the most outstanding result was that the yield of the intercrops was so great that they had to get people from the next village to help them harvest it. They had never had such a bountiful harvest. The beds are permanent so the farmers can use them each year.

Potential benefits

Earlier planting
A major constraint to wet season rice in Eastern Indonesia is delayed planting when there is not enough rain to puddle the soil before sowing. If planting is delayed at the start of the season, the crop is likely to experience drought at the end of the season. On permanent raised beds, water is not needed to puddle the soil before sowing. Rice seed is sown into the top of the beds at the beginning of the wet season in the same way as upland rice.

More efficient water use
While the rice is growing, water is stored in the furrows to reduce evaporation and seepage through the soil. Permanent raised beds also provide excellent drainage during heavy rainfall. Furrows between raised beds and on-farm dams can capture water without causing water logging. This means there is more water available to the crop during dry periods. After harvesting the rice, drought-resistant crops like sorghum, pigeon pea and cassava, or quick-maturing crops, like mung beans and millet can be planted and left to grow on the moisture stored in the soil.



Less walking
Growing rice and upland crops on raised beds enables upland swidden gardening and rice cultivation to be combined in one field. More efficient use of water on the permanent raised beds means that widely dispersed gardens are no longer necessary.

Greater flexibility
Raised beds give farmers the flexibility to choose between a variety of crops at short notice, because no pre-season or crop-specific land preparation is necessary.

Diversification
Raised beds enable farmers to grow a range of crops in the same field. Various traditional intercrops have been successfully grown on raised beds. A combination of grain, legume, tuber, fodder and fruit species can be grown in the wet season and, more importantly, the total yield and the nutritional value of this combination is far greater than that achieved with rice monoculture. Crops are harvested over a long period, so that food is available throughout the year. The eroded upland cropping areas can be reforested with a range of perennial species to provide food, fodder, firewood, building materials and medicines, since the basic food and cash crop requirements of subsistence farmers can be met from intensive lowland production on permanent raised beds.

Crop rotation
Crops can be rotated to control weeds, to reduce the build up of pests and diseases and to reduce the need for external inputs. Including legumes such as soybeans in the crop rotation can help fix nitrogen and reduces reliance on inorganic fertilisers. Incorporating the crop residues can also improve the organic matter content of the soil.

Important considerations

A major limitation to implementing a raised bed system is the initial labour required. Extra labour is needed to till the soil and form the beds during the dry season. Drains also need to be dug so that the excess water does not wash the beds away. Organisations that have expertise and access to credit need to work with farmer groups to implement the system. Although the initial inputs are high, the total yields from the system are higher than rainfed, flooded rice and farmers save labour in subsequent years. It should, therefore, be possible to repay initial inputs within a few years.

To plan a balanced, low-external input system it is important to consider environmental factors such as the species to be used, soils, and crop rotations. The on-farm trials showed that rice grown on raised beds can yield the same as rice grown in flooded conditions. However, other rice varieties, for example, traditional upland rice varieties that can withstand periods of water stress, may be better suited to the raised bed system. Permanent raised beds are suited to areas where water is limited but, because of the high clay content of the soil, crops become easily waterlogged when it rains. Soils that are rocky, shallow or do not hold their shape, are not suitable. Factors such as fertility, organic matter content and pest and disease control should be taken into careful consideration when planning crop rotations.

Growing rice on permanent raised beds is still a relatively new technology. The many different factors that contribute to its success or failure have not yet been fully defined, and many factors, such as soil type, are locally specific. Therefore, it is important to first try the raised beds in a small area. The beds can easily be introduced in stages, for example, by first building wide bunds around the rice fields that can be planted with upland crops, to reduce the risk of failure.

Flood Control in Taiwan

A typical retention pond in the upper reaches of a watershed. Photo: Author.

K.F. Andrew Lo

Taiwan is a mountainous island country, often confronted with floods and droughts. Torrential typhoons are responsible for an annual rainfall of some 2500 mm, which often leads to massive soil movement, concentrated runoff and large peak flows that cause a lot of damage downstream. Efforts to control these floods have focused on controlling the water flow at the bottom of the watershed using large and costly engineering structures. In the Wudu watershed area, however, a different approach has been tried. Small-scale water harvesting structures have been installed in the upper reaches of the watershed in order to reduce the runoff.

The case of the Wudu watershed

In the Keelung River Basin, Wudu watershed, a low impact development concept was integrated into the flood protection programme with the aim of reducing the flood hazard down stream.

Scattered small-scale runoff retarding structures such as pits, pools, farm ponds and dugouts were installed throughout the watershed to promote the infiltration of runoff water. The runoff retardation structures installed in the upper and middle reaches of the watershed proved to be very effective in reducing the flood burden downstream. With a conventional check dam constructed down stream, a flood peak reduction of 20 percent could be expected. With small-scale retarding structures installed throughout the watershed, a flood peak reduction of 30 percent was achieved at considerably lower cost.

The infiltration enhancement structures and retardation ponds will intercept large volumes of runoff, but a large amount of sediment is also delivered with the water. As the sediment will rapidly reduce the capacity of the infiltration structures, some changes in land use are necessary. For example, providing forest cover around the structures can reduce runoff volumes by up to 50 percent. Sediment reduction is even more significant and can reach as much as 95 percent. This result shows that proper land use and soil conservation measures are essential to ensure maximum runoff interception and minimum sediment load reaching the retardation structures.

The collection of runoff upstream will increase the availability of water resources for farmers downstream. This water can be used for irrigation, livestock, aquaculture, the introduction of high yielding cash crops or the reclamation of wastelands. It also provides other indirect benefits. These include depressing flood peaks, diminishing soil erosion, providing large sediment storage space, and improving the operation of reservoirs and channels.

In Taiwan, the upstream parts of a watershed are usually government owned and often forested. In heavily populated cities located in the downstream river basin areas, acquiring land for public infrastructure becomes increasingly difficult as property values rise. Upstream runoff retardation measures are the most feasible flood mitigation solution for future urban storm water management.

Lessons learnt

In rainfall-abundant watersheds with steep terrain, torrential rainstorms often result in accelerated soil erosion and runoff, causing irreversible damages downstream. Storm water collection using small infiltration enhancement structures and retention ponds has proven to be extremely effective in runoff reduction and flood control. Storm water is controlled in the upstream parts of the watershed, along with the disaster-bearing sediment load. Although small-scale runoff retardation facilities may not be able to prevent large storm runoff events, they may reduce the problem considerably. Besides flood control benefits, increased infiltration and runoff storage will increase the availability of water resources. ■

Farming where there's no water

Theib Y. Oweis and Ahmed Y. Hachum

The drier environments of the West Asia and North Africa (WANA) region, called *albadia,* are characterised by extreme water scarcity, degraded lands and declining livelihoods. These areas have a fragile natural resource base, with very low rainfall and poor vegetation cover. Without appropriate interventions, *albadia* environment will continue to deteriorate and can generate very few benefits for its already poor population. This article presents three cases of interventions that have successfully improved living conditions in this extreme environment.

Background

The climate in *albadia* is extreme, with cold winters and very hot summers. Rainfall, the main source of fresh water, ranges from 50 to 250 mm annually, and is highly variable both in time and space. It falls in sporadic and intensive storms and causes substantial runoff. As a result, a crust is usually formed on the soil surface and this limits infiltration and intensifies runoff. Runoff water generally flows to salt sinks where it is lost to evaporation. It causes soil erosion and further land degradation.

Land tenure in *albadia* is a major constraint to development and varies from one country to the other. In Syria, *albadia* are largely public lands, but other forms of land tenure also exist, such as rented and private land ownership. Most of *albadia* in Jordan is private tribal land. Due to lack of appropriate land tenure systems in these countries, communal land is used as common property, where overgrazing is a common practice and little attention is given to sustainability.

In recent years, traditional migratory pastoralist communities have gradually been transformed into more sedentary communities. The change in lifestyle has resulted in a decline in the traditional, communally managed rangeland system. It has also put pressure on adjacent lands and there is an increasing demand for water for sanitation, home gardens, and supplemental irrigation for subsistence agricultural production. Where groundwater is available, some marginal grazing lands are even used for conventional agriculture.

Albadia in Syria and Jordan have traditionally supplied most of the meat and milk products for these countries. Increasing consumer demand for sheep, meat and milk in combination with rapid population growth and inappropriate government policies have stimulated the growth of the sheep population. This means that more feed is now required than *albadia* can sustainably produce. Mismanagement has resulted in land degradation, a decline in biodiversity and increasingly insecure livelihoods. *Albadia* still has a much higher potential than its current output. Proper management of available natural resources would help improve people's livelihoods and reverse land degradation.

Indigenous practices of rainwater harvesting provide a sound basis for improved resource management. Moreover, innovative techniques of water harvesting built on traditional knowledge can reduce cost and provide people with tools for improving the rangelands as well as their income and livelihoods. Following are three examples of interventions that build on traditional technologies.

Contour bunds and ridges

Mehasseh is a very dry area in southern Syria. It has a mean annual rainfall of less than 150 mm. Vegetation cover is poor and land degradation due to overgrazing is a major problem. In 1995, a water-harvesting project based on traditional technologies of contour bunds and ridges was started, with the objective of improving land management and the livelihoods of the people living in the area.

Half a metre high *contour bunds or ridges* were constructed along the contour lines some 5 to 20 metres apart. The first metre along the upper side of the ridge is allocated for cultivation, and the remaining area between the bunds make up the catchment. Contour ridges are one of the most important techniques for supporting regeneration and new plantations of forages, grasses and hardy trees on the gentle to steep slopes in *albadia.*

The key to the success of these systems is to locate the ridge as precisely as possible along the contour line. Otherwise, water will flow along the ridge, accumulate at the lowest point, and eventually break through and destroy the whole down-slope system. Surveying instruments suitable for small-scale farmers can be used for contouring. The simplest method is a transparent, flexible tube 10 to 20 m long, fixed on two scaled poles. The tube is filled with water so that the two water levels are clear on the scale. Two people can trace the contour by adjusting the position of one of the poles so that their water levels are the same.

To avoid contouring difficulties, an alternative is to develop smaller semi-circular and trapezoidal bunds in staggered rows across the slope. Earthen bunds in the shape of a semi-circle, a crescent, or a trapezoid are formed facing directly upslope. Spacing should allow a sufficient catchment area so that each bund can collect the required runoff water. Water accumulates at the lowest spot on the upper side of the bund, where plants are grown. Cutting the soil to form the bund creates a slight depression directly above the bund. Runoff is intercepted in this depression and stored in the plant root zone. The distance between the two ends of each bund varies between 1 and 8 metres, and the bunds are between 30 and 50 cm high. These bunds are used mainly for the rehabilitation of rangeland and fodder production but they are also used for growing trees, shrubs and field crops.

In Mehasseh, a comparative trial was carried out on two adjacent areas. Both areas were planted with Atriplex (*Atriplex halimus*) shrubs. Water harvesting bunds were built on one site, and an adjacent field without water harvesting bunds was used as a control. In 1997, there was 160 mm of rain. On the site with bunds, runoff accumulated on the upper side of the bunds and was harvested. On the site without bunds, water flowed downstream to salt sinks and was lost. The bushes planted in the field with bunds had a survival rate of over 90 percent, whereas the survival rate for the untreated site was less than 10 percent. The next three years were very dry, with an annual rainfall of less than 60 mm. The few surviving shrubs on the site without bunds died during the first year of drought. The shrubs supported with water harvesting bunds survived the three consecutive years of drought and are still growing vigorously.

The project was considered a breakthrough in this fragile environment. It now forms the basis for a national project based on this low cost technology.

Small runoff basins for fruit trees in Jordan,

This technique is sometimes called *negarim.* The runoff basins consist of small diamond- or rectangular-shaped grid plots, each surrounded by low earth bunds. They are oriented along the slope so that runoff flows to the lowest corner, where the plant is placed. The usual grid size is 50 to 200 square metres. They can be constructed on any gradient. They are most suitable for growing trees but can also be used for other crops. When they are used for trees, the soil should be deep enough (over one metre) to hold sufficient water to sustain the plant for the whole dry season.

The arid land of Jordan receives about 160 mm of rainfall annually. No economic crop can be grown with this amount of rainfall, and farmers in the area depend on livestock and other forms of agriculture using a steadily decreasing amount of groundwater. In 1987, a project was launched to diversify farmer's production by introducing tree crops in combination with water harvesting. The introduction of the *negarim* system to support fruit trees was a great success. Plots of 50 to 100 m^2 were constructed on deep soils and almonds and olive trees were planted in the winter season. Polymers were added to the planting pit of the tree in order to increase the water storage capacity of the soil, so that enough water is kept for the long dry summer. All trees planted survived and grew satisfactorily over the seasons and are still growing. The production was so satisfactory that farmers started adopting the technology. Generally, they were successful, but some problems emerged. These were usually associated with the selection of land, for example if the soil was not deep enough, or the species used was sensitive to drought. It is important that the location and crops are properly selected for this technology to be successful.

Semi-circular bunds in the Syrian badia after a rainstorm. Photo: Theib Oweis.

Cisterns in north western Egypt

Cisterns are an ancient and indigenous rainwater harvesting system, used mainly for supplying human and animal water needs in water-scarce areas. They are usually subsurface reservoirs, with a capacity ranging from 10 to 500 m^3. In many areas, for example in Jordan and Syria, they are small and dug into the rock. In north western Egypt, however, farmers dig large cisterns (200–300 m^3) in the earth deposits underneath a layer of solid rock. Water is used not only for human and animal needs but also for growing cash crops in home gardens. The rock layer forms the ceiling of the cistern and the walls are sealed with plaster. Modern concrete cisterns are now being constructed in places where there is no rocky layer.

Along the north west coast of Egypt where there is an average annual rainfall of about 150 mm, there is no other source of freshwater. Runoff resulting from a few major rainstorms in winter is directed into cisterns from adjacent catchments, or through channels from remote areas. The runoff from the first rainfall event of a season is usually diverted away from the cistern to reduce the likelihood of pollution. Settling basins are usually provided at the cistern entry points to reduce the sediment inflow. In addition, farmers clean the cisterns once every year or two. A bucket and a rope are typically used to lift water. However, there are several problems associated with using the cisterns including the extent of the catchment area, the capacity of the reservoir, the cost of construction and maintenance and the low water use efficiency in agriculture. A project was started in the area to overcome these problems by providing technical and financial support to the local communities in order to improve the management of these systems. Three interventions were found to substantially improve the efficiency:

- Clearing, cleaning and smoothening the catchment area improved the collection efficiency and water quality significantly.
- The cistern's seasonal water capacity was more than tripled through efficient management, without increasing the actual size or cost. Hydrological studies showed that the cistern could be re-filled at least three times during the rainy season and before the last storm of the season, which would fill it for the summer. Farmers were encouraged to use the water from the first and second filling for agriculture and to preserve the third filling for human and animal consumption during the summer. The availability of manual pumps and low cost pipes helped to make the task easier.
- The water use efficiency was improved by providing a small kit of materials and introducing a few changes in the agricultural production system at the home garden level. For example, placing high value crops such as seedlings and vegetables in plastic houses became popular and provided additional income to the farmers without requiring much additional water.

Although the cisterns of Egypt are a very special water harvesting system, the case illustrates the importance of careful water management very clearly. With careful management, harvested water can be efficiently used and the impact of the harvested water can be substantially increased.

Implementation and management

Micro-catchment systems such as contour bunds and ridges and runoff basins are usually within the boundaries of individual farms. This is a simple and low-cost approach, although farmers may experience some difficulty with elements that require precision, such as following contour lines or determining maximum slope. The community should be involved in implementing water-harvesting systems. It is especially important that the community is involved right from the planning stages of any programme.

New systems should be inspected often, especially during the first one or two rainy seasons. Micro-catchment systems should be inspected after every runoff-producing rainstorm so that any minor break in bunds can be promptly repaired. Special attention should be paid to earthen dikes and bunds, water storage facilities and their spillway, and diversion structures. Treated catchments and water harvesting structures should be protected against damage by grazing animals. Silt and rubbish should be removed from the catchment area, from the harvested water and from storage facilities.

These experiences, and many others, show that the productivity of rainwater in the drier environments can be substantially increased when appropriate water harvesting techniques are implemented.

Holding the Rain

Ivan Yaholnitsky

In Lesotho, agriculture consists of subsistence farming and involves extensive mono-cropping with very few external inputs. Livestock graze freely over communal pastures and barren or harvested fields. As a result, much of Lesotho suffers from chronic land degradation and soil collapse. This has led to the loss of biodiversity, declining agricultural productivity, depletion of nutrient balances, falling water tables, flash flooding and an increasingly dependent and poor rural population. Despite the innovations and considerable personal efforts of individual farmers, Lesotho still imports 85 percent of its food, and large parts of the country are turning into desert.

BBCDC

Bethel Business and Community Development Centre (BBCDC) is a rural development and education institution located in the Senqu Valley in the Mohales Hoek district of Lesotho. BBCDC aims to help build up the capacity of young Lesotho men and women so they can contribute to rural and urban development in their region.

View of the Phamong Valley from Mt Moorosi, Lesotho, 2000. Photo: BBCDC.

The Centre is situated on degraded pasture land typical for this area of Lesotho. It was established in 1993 and was immediately confronted with severe weather challenges. The annual average rainfall of 500-600 mm tends to fall very irregularly and in the early years there were frequent droughts. When the rains finally came, the streams filled up quickly despite the parched earth, highlighting the low capacity of the soil to absorb water. Famine was only averted through the intervention of the World Food Programme (WFP).

When BBCDC, in partnership with WFP, began a road construction programme in 1995, it came to understand the importance of drainage and run-off mitigation. Small dams and swales (see Box) were constructed at several locations along the roadway to control water flow, but because no one assumed ownership of these structures, they quickly silted up and lost much of their impact. However, the experiences of this programme made BBCDC aware of the importance of water.

Restoring the land

Inspired by theories drawn from permaculture, BBCDC decided to use ecology to restore the environment and started a programme to systematically develop the BBCDC campus. Soils on the campus were extremely compacted and despite some grass cover, were largely sealed, cemented and anaerobic. This was obvious to anyone digging swales or involved in excavating the building foundations.

New swale construction. Photo: BBCDC.

In order to halt the flow of storm water into the campus and to collect run-off from compacted areas like roads and paths, BBCDC students and staff constructed an extensive system of swales and diversion drains. Almost all the swales were dug by hand using picks and shovels, and simple A-frames or line levels were used to survey them. In the beginning the going was tough. Each swing of the pick dislodged a lump of clay-like rock. Once the rain came, things speeded up and deepening and extension of the swales required less effort.

Restoration required very careful landscape design. Rain falls at intensities of up to 100 mm per hour during summer in Southern Africa, whereas infiltration rates are perhaps 1 to 4 mm per hour on unimproved land. In the uppermost reaches of a watershed or micro-shed, the "stacking" of water and subsequent run-off lasts only a few minutes during high intensity rainfall.

The swales worked magnificently and a dynamic process of restoration and accelerated biological activity was set in motion. Storm water not only carries away soil, but also organic debris such as leaves, grass and manure. When storm water is diverted from the roads and tracks used by animals, swales act as a nutrient pump and trap. Vigorous pioneer plants growing more than two metres high do not always impress visitors, but their root systems do a great deal of beneficial work. Besides breaking through plough pans (the layer of compacted soil below the reach of the plough blade) and opening up the soil, they also provide essential organic matter for mulching and composting.

An evolving farming system

At the same time as more fruit trees were planted and became established, the swale system grew, matured and became more resilient. As conditions improved, BBCDC started to develop the farming system into a more sophisticated system characterised

Swales

Swales (or earth bunds) are the cheapest and simplest earthworks for water harvesting and storage. Swales are dug along contour lines or in flat areas and are designed to store water in soil and sediment by intercepting overland flow and enhancing groundwater recharge. Soil can hold thousands of times more water than tanks or dams, and water which infiltrates the soil in a swale is stored three to five metres deep, where it is available to trees. A good swale system can handle 200 percent of a village's runoff. A well-designed succession of five to seven swales can actually create a spring from stored groundwater. Swales become increasing efficient as they age and tree roots develop and humus accumulates. To encourage vegetation to re-establish itself quickly and to derive the maximum benefit from tree roots and humus, it is important that swales are smooth and have the right shape.

A system of small closely spaced swales keeps water flows small, their velocity near zero and minimises their destructive force. This is one reason why swales need to be surveyed accurately. The most important principal is that they should slow, spread and sink water.

by intercropping, mixed orchards and forage production. Over the years, intercropping between the fruit trees in the orchard has altered the structure of the soil and increased its infiltration capacity.

The large fields along the west side of the campus have been subdivided into smaller fields marked out along contour lines; and various market gardens have been developed all over the campus in the corridors between the swales and tree plantings. Many of these sheltered gardens enjoy a noticeably better microclimate. They are more productive and are also more responsive to irrigation and intensive management. All the fields on campus are now being converted along these lines.

Multiple water sources

To get through stretches of drought, BBCDC steadily invested in multiple water sources and in pumping, storage and delivery systems. At present, sources of additional water supply include rainwater tanks, a hand dug well, a spring, a groundwater dam, and a small pond constructed at the highest point of the campus. In 1998, BBCDC constructed a sand dam on a stream on the eastern side of the campus. It is working as planned and has helped raise the water table and made more water available for irrigation. Plans are being made to scale-up this initiative and build three more sand dams along a 5 km stretch of the stream. These dams will be located at points that make gravity flow irrigation possible.

At the moment water is lifted by a diesel pump installed near the groundwater dam, a solar pump installed in the well, and a gravity-driven hydram at the spring. Water is stored in stone masonry tanks for gravity flow irrigation of fields and gardens. Rainwater is also collected from the roofs of six buildings. The total water storage capacity on the BBCDC campus is now about 110 000 litres, of which 45 000 litres is rainwater collection from roofs. Water can be delivered to fields through a combination of flood, sprinkler and drip irrigation systems. During dry weather, swales can be flooded to water forage and fruit trees. The diesel pump can either fill storage tanks or operate up to 20 sprinklers. Drip irrigation sets are used on small market gardens and fed by gravity from the storage tanks. Grey (domestic waste water) and black (sewage) water from the school is also used to support the growth of ornamental plants and trees on the campus.

Restoration ecology and the community

As the capacity of BBCDC has grown, it has been able to increase its outreach activities in the surrounding community. In June 1996, BBCDC began a two-year "landscape design" extension programme with drought mitigation funds from the European Union. In the first year, BBCDC formed a partnership programme in the village of Ha Teboho with a number of families that volunteered to take part. Individual homesteads were swaled and gardens were terraced. The programme provided for the transportation of stones for constructing terraces, surveying, fruit trees and hand tools. Money was also provided to run workshops on surveying, land degradation, composting, and horticulture. These workshops were learner-centred and participatory and included discussions, presentations, fieldwork, skill building, group work, planning exercises and site visits. The local community responded enthusiastically.

This approach was proactive, beneficial and direct. The 1997, the programme went on to build on these successes and began to promote the fencing of home gardens and orchards. More co-operators from the village of Ha Teboho joined the programme and two years later the programme was extended to another three villages. By 2002, BBCDC was working with six villages in the Phamong Valley.

The resources available for this programme are modest and average less than US$5,000 per annum. A next step is the extension of this effort to the broader landscape, fields and pastures.

Conclusions

Energy and water balances on the BBCDC campus have certainly improved over the last decade. The water collected by the swales has triggered vegetation growth, proving how effective landscaping (such as constructing swales) and bioengineering (the engineering work done by plants) can be. Although we cannot influence the timing or distribution of rainfall, we can prepare carefully for the day when it does rain and try to ensure that as much rainwater as possible stays where it falls. This water must be stored and guided carefully through the landscape. If this is not done, all the pumps and tanks in the world will be of little use.

A groundwater dam is one of the multiple water sources available to the BBCDC campus. Photo: BBCDC.

Creating water storage to halt or slow down overland water flows is essential, because good moisture infiltration takes time. In regions of chronic degradation, water is a destructive force because the natural collection system provided by living plants has been destroyed. An aggressive strategy of water collection is, therefore, an important first step in the rehabilitation of degraded land.

BBCDC's work with local communities has been successful because the local communities recognise the risks and consequences of existing practices and have actively participated in the process of rehabilitation. While development agencies, extension services and participatory learning and action (PLA) methods help, they are no substitute for communities that are eager to learn, innovative and open to change. BBCDC made progress because its interventions were based on a commitment to create a culture of learning and innovation in which local communities felt a sense of ownership in the improved systems they were working to develop and maintain.

■

We wish to thank the local community for its enthusiastic support along with Helvetas, the Swiss Association for International Cooperation, and Ireland Aid in Lesotho for supporting programs and capacity building at BBCDC.

Farmer innovations in water harvesting

Deborah Duveskog, Charles Mburu and Åsa Forsman

The farm of Alex Ole-Pere is often described as an oasis in the desert. From afar you can see a large Bluegum (Eucalyptus) tree, which would not normally survive in this dry climate. As you approach his farm, there are trees visible on the plains where typically the only vegetation is Acacia bush. Alex is one of the farmers identified as an innovator in the "Promoting Farmer Innovation in Farmer Field Schools" (PFI-FFS) programme in Kenya. His simple yet ingenious idea of a rainwater reservoir to capture run-off water from the surrounding mountains has been spread to other farmers in the area. In addition, his plot now serves as a water reserve for surrounding farmers and pastoralists in the dry season.

Spreading innovations

Africa has enormous resources of rich traditions, untapped knowledge and promising innovations relating to soil and water management. A large number of farmers experiment with soil and water conservation techniques on their own and spontaneously try out new practices, without the direct support of formal research and extension. Like the invention of Alex Ole-Pere, many of these small-scale initiatives have the potential to benefit other smallholders if they are applied on a wider scale. Farmers in drylands often suffer from extension systems that do not function well because of the large distances involved and the marginal nature of arid areas. This often leads to the failure of recommended technologies. Instead of relying on technologies that are often inappropriate and introduced from the outside, there is a real possibility in dryland Africa to build on local resources of knowledge and traditions, and the inventiveness that comes from necessity.

In East Africa in recent years, increasing attention has been paid to capturing local knowledge and initiatives and disseminating this information to other farmers. For example, UNDP and FAO have been working since 1997 to increase the recognition given to indigenous knowledge in agricultural extension by supporting farmer-to-farmer knowledge sharing and the identification and dissemination of local innovations (see Box).

Innovation initiative in East Africa

The Promoting Farmer Innovation (PFI) process is a 10-step guideline to identifying and disseminating farmer innovations. It was developed by a UNDP supported project in 1999. The project was piloted in Kenya, Tanzania and Uganda with the aim of identifying farmer innovators. The ideas of these innovators were disseminated through farmer-to-farmer extension and farmer exchange visits. In Kenya, an ongoing initiative supported by UNDP and FAO known as the "Promoting Farmer Innovation in Farmer Field Schools (PFI-FFS)" project has merged the PFI process with the Farmer Field School (FFS) approach to participatory extension. The objective of the initiative is to facilitate increased interactions between innovators and FFS groups and in this way to stimulate the process of innovation and discovery among farmers. Innovators are identified by FFS extension staff and are often included in the FFS as group members, guest speakers or resource persons. Alternatively, the FFS groups go on study visits to see the innovations.

About 250 farmer innovations have now been identified within the Kenyan PFI-FFS project. Around 40 percent of innovations are related to the efficient use of water resources, including water harvesting, small-scale irrigation and other ways to use surface water efficiently.

Dam building

Alex Ole-Pere is a Maasai who lives in a semi-arid area in southern Kenya. Although the district receives up to 600 mm of rainfall per year, this rainfall is highly erratic and unpredictable. The risk for crop failures due to drought is high. People in the area traditionally depend on livestock, but as it gets harder to sustain large cattle herds on grazing land that is gradually shrinking, more and more people have started to turn to crop production. Alex realised that every rainy season a lot of water from the nearby mountains seemed to be wasted as it raced towards the rivers. He came up with the idea of collecting this rainwater by building a dam. He built a reservoir close to his homestead and constructed a diversion from a local waterway. The diversion directed the flow of water from the stream into the reservoir. The dam, which is about 20 by 30 metres wide, was built by digging out the earth and putting it on the outside of the reservoir.

Alex Ole-Pere next to his reservoir. Photo: Åsa Forsman.

Water collected in this way is used for irrigating vegetables and tree seedlings. While most of the area around Alex's farm appears barren because trees and bushes are continually being cut for firewood, Alex plants more and more trees every season on his plot. Apart from sustaining the crops and trees on Alex's farm, the reservoir also serves the larger community. *"My neighbours normally come to fetch water from my dam in bad times. They can take both for their families and for their livestock. I have enough"*, he says proudly.

Earth banks

Agnes Mughi is a farmer in a very dry zone of Mwingi district. Her farm was suffering from water scarcity and she decided to do something about it herself. The area where Agnes lives is often affected by drought and the soil is compacted and eroded. However, her farm now appears green and productive all year round, in sharp contrast to the surrounding area. By using her own creative ideas, Agnes tamed the floods from a nearby seasonal stream by digging a series of earth banks across the direction of flow in the valley bottom above her plot. The banks, which were about 30 metre long and about 2 metres wide, slowed the floodwater down, giving it more time to infiltrate into the ground. This meant that there was an increase in soil moisture on her farm and the water level rose in the well she had dug in the centre of her plot. The well now provides clean drinking water for Agnes's family and neighbours as well as water for irrigating vegetables.

Like many other farmer innovators, Agnes Mughi is experimenting with a number of different approaches to enhance the productivity

Agnes Mughi's productive farm.

of her land. Her second innovation is a bio-pesticide made from dried chilli peppers, neem leaves and local aloe.

Agnes is a part-time social worker, and a role model for other local women. She has great strength of character and believes strongly in what she has to offer. In Mwingi district she has frequently been invited by Farmer Field Schools to explain her innovations to other farmers.

Rainwater harvesting

Peter Olochoki Letoya's first innovation came when he moved to a much drier area in East Mau. He realised that he needed to do something about the water shortage that was distressing his crops and threatening the livelihood of his family. Three years ago, he had the idea to collect rainwater runoff from his rooftop and store it in underground reservoirs. Since then, his reservoirs have been full. Today, it is clear that his idea has been a success but in the beginning he was afraid it would not work.

"When I first started to dig the holes for the reservoirs, I was hiding behind the house so that the neighbours would not see me. I did not want people to think I was crazy", he recalls.

Now that Peter Olochoki Letoya's rainwater harvesting technique has proved to be functional and efficient, his neighbours are no longer suspicious and some of them have started to adopt his method on their own farms. Working together with other farmers in the PFI-FFS project, Peter has been able to spread his ideas to other farmers and families outside of his community. He often gets visits from other farmers and farmers groups who want to learn how to harvest rainwater from rooftops. He has also benefited from visiting other innovative farmers and has been inspired by their ideas.

The tank that Peter Letoya invented is built underground by excavating soil and lining the sides of the pit with plastic sheets to avoid seepage. The top of the tank is covered with cedar posts. He chose cedar as a covering material because it does not rot easily and is not damaged by insects. Peter's tanks have attracted much attention in the area because in comparison with the common tank structures recommended by district engineers that are made out of concrete, they are very cheap to construct. *"My tank is about 10 percent of the price of the normal tanks found in this area"*, he says.

Peter Olochoke Letoya now has three underground rainwater reservoirs. These range in storage capacity from 1000 to 2500 litres. His family uses one for drinking water and the other two for watering trees and bushes on their land. At present he is thinking about collecting rainwater in an elevated tank so that he can start working with drip irrigation.

Another of his ingenious ideas is to use banana trees as nurseries for sugar canes. Peter discovered that the layers of spirally arranged, overlapping leaf bases in the stem of the banana tree form "pockets" that contain water. He placed some sugar cane cuttings in the pockets in the stem and these grew very quickly. In addition to the water from the banana tree, the improvised sugar cane "nursery" also receives moisture every morning from the dew that condenses on the banana leaves. Once they have grown roots, Peter plants the sugar cane cuttings in his fields.

Conclusions

Today, a significant proportion of poor people who depend directly upon the natural environment live in water scarce regions. All over the world, smallholders need water for their agriculture, livestock and households. Small-scale water solutions seem to be a key for enhancing food productivity for poor farmers and pastoralists in dry areas. Local innovators like Alex Ole-Pere, Agnes Mughi and Peter Olochoki Letoya can be found everywhere in Kenya and many other countries too. The challenge is to find ways of encouraging their inventiveness and originality so that their ideas can be developed and shared with other land users.

Peter Olochoki Letoya's rainwater harvesting system.
Photo: Åsa Forsman.

Findings from the PFI-FFS project show that there is a real possibility for bringing together external and indigenous sources of knowledge in agricultural extension activities. Initial results of the PFI-FFS programme suggest that farmers show a higher level of adoption when new technologies are introduced by fellow farmers rather than by extension workers and outsiders. East African farming conditions are very diverse and therefore require solutions appropriate to the local context. By capturing local innovations and promoting indigenous knowledge in extension and development activities, sustainable solutions can be found and scaled up.

Reflecting on farm pond development

Michiel Verweij

Many initiatives have contributed to developing farm pond technology in Bolivia. Over time, different stakeholders have come together to scale up this technology. Strong organisation at community level has helped rural people to influence this process.

Ponds are not new in Bolivia. In the past, they were associated with large-scale cattle ranches in the lowlands of Santa Cruz. However, traces of traditional ponds are also found all over the semi-dry inter-Andean mountainous region between 1000 and 3000 m. These ponds were simple, mostly used for watering livestock, and usually had a storage capacity of less than 500 m^3. They were constructed by individuals or local organisations and remained a local initiative.

PDAR at work

Pond building first appeared on the institutional agenda in the 1990s, when the Programme for Alternative Development (PDAR) began promoting the technology as a way of improving production and stimulating social organisation. PDAR wanted to prevent subsistence farmers migrating from Cochabamba to the coca producing areas. Regional government departments, local NGOs and private enterprises were mobilised to implement the project.

Self-help and community participation were key to PDAR's strategy. Peasant farmers took up the idea of building ponds to harvest rainwater and worked hard to convince engineers to try them out. Ideas emerged to divert floodwater from the seasonal streams to a series of ponds in the valleys and several of these pond systems were built, including the well-known example in the Oloy community (see *LEISA Magazine* Vol 17.3 p 43).

Most of the ponds constructed by PDAR were simple 'holes in the ground' and many had serious construction and management problems. A few years after construction, only 25 percent of ponds were still working at full capacity and many had collapsed or were abandoned. An evaluation in 1992 recommended that if ponds were built for individual families, maintenance and operational problems would be avoided. By making their own financial contribution to pond building, families would also gain a greater sense of ownership. Better designs and construction guidelines were also required.

Maturing initiatives

CORACA, a farmers' organisation in Aiquile, began working with farm ponds in the mid 1990s. Together with the University of Cochabamba, they studied the successful experiences of Oloy to see how ponds had benefited farmers' families and their communities. They found Oloy had developed a flourishing fruit and vegetable production that complemented traditional cattle rearing farming systems well. New (informal) organisations and groups had been created to deal with water management, production, credit and commercialisation and, by exchanging experiences with other communities, Oloy had become a resource community for pond farming in the region.

The confidence generated by the Oloy experience encouraged more NGOs, local governments and farmer organisations to start implementing farm pond projects. Rural people in the Andean region are organised in farmers unions (*sindicatos agrarios*) with tiers at local, regional and national level. In many cases, these unions provided the organisational entry point for water harvesting activities.

Although different organisations had different working methodologies and pond designs, there was some exchange of ideas between them, such as encouraging farmers to make a 10 to 30 percent contribution towards their ponds. Some organisations chose to build ponds for collective use, but as these often encountered problems of ownership and maintenance - individual ponds proved a better option. The quality of pond infrastructure remained a problem in family ponds because of the need to keep costs low.

With the introduction of the Popular Participation Act (*Ley de Participacion Popular*) in 1994 and political decentralisation at the administrative level, peasant farmers became more able to participate and influence district development policy. A proportion of the central government budget was now available at local level. This meant that local politicians and organisations came under pressure to make the districts more productive, while the rural population became increasingly active in demanding support from local government.

Lobbying got ponds onto the local and regional development agenda and very quickly political parties realised the political potential in the movement. NGOs started to link up with local government to access funds and material available locally to support the pond programme. Organisations like CORACA, for example, made strategic alliances with district governments and started to work with private contractors.

In 1998, Cochabamba experienced an earthquake. Funds made available for reconstruction also stimulated a larger institutional irrigation effort. A technical unit was formed to work with local organisations implementing projects at field level. Standards for the design and implementation of ponds were developed because experience had shown that there was a need for higher technical and administrative standards. As a result, the quality of ponds increased although, problematically, costs also increased significantly.

Acceptance

As ponds and pond farming became more widely known, they became better accepted. The subject now has a formal status and is included on the curricula of universities and training centres. It is also firmly established on both local and regional political agendas.

Communication and collaboration between communities, local government and local development organisations has improved considerably during recent years and pond farming is now seen as a useful initiative to work on together. The next joint effort should be to adapt the pond technology to make it cheaper. Bolivia's experience of pond farming has shown that no matter how relevant a technology may seem at the time of project implementation, there is always room for improvement. It is important to return to a project area to evaluate and learn from the long-term results.

Managing Water Together

Mona Dhamankar

Today, many villages in India are facing severe water scarcity. Erratic rainfall and poor soil and water management, including relentless ground water extraction has led to cycles of droughts and ongoing water scarcity. As a result, there is renewed interest in rehabilitating the small, traditional water harvesting and irrigation systems that have existed in India for centuries.

Here we describe the efforts of a community and their government to take 'rehabilitation' beyond technical interventions, to include farmer participation and coordination of the efforts of different institutions. Over the past two years, people in the community have not only demonstrated a capacity to understand and analyse their own problems, they have also invited several partners with different resources to join them in their efforts to rebuild their water resources.

The setting

The Marathwada region of Mahrashtra is a drought-prone area in Western India. Almost 80 percent of this region is under rain-fed agriculture. Aurangabad, one of the largest districts in the region, receives on average around 700 mm of rainfall per year. For the past three to four years, farmers in the district have been forced to meet their needs with only 50 percent of average rainfall. Most of the "talukas"(units of civil administration within a district) have been declared permanent drought-prone areas and even talukas with a reasonable rainfall pattern have been struck by famine in recent years.

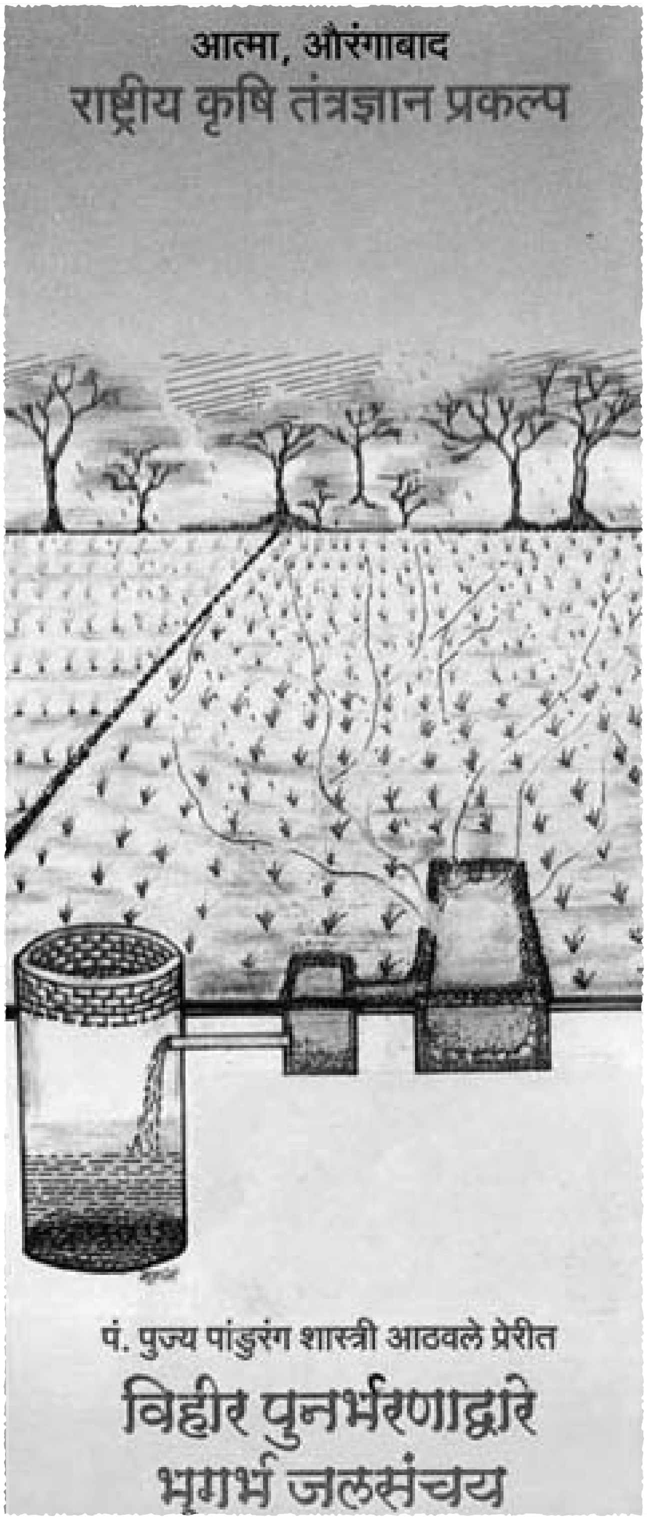
The majority of farms in the area are small and medium sized. Around 55 percent of the farmers can be categorised as smallholders, with an average land holding of up to two hectares. Medium-sized farms are between two and five hectares, of which between one and two hectares is irrigated. The rest is rain-fed agriculture. Most of the large farms have been divided between family members in order to take advantage of government schemes and subsidies for smallholder farmers. Most farmers labour on their own farms and find hiring tractors more efficient and more economical than hiring agricultural labour.

Inspired by a farmer

While documenting indigenous technical knowledge in the area, officers of the Agricultural Technology Management Agency (ATMA) met a farmer called Shri Vasant Katbane. Shri Katbane had tried out the two-pit well recharging technology in 1985, and went on using it for about ten years with only nominal maintenance expense.
Satish Shiradkar, Deputy Project Director of ATMA, Aurangabad, describes the origins of the programme:
"*It all started on 24 July, 2001 in a brainstorming meeting called by the Divisional Commissioner of Aurangabad to address the severe drought problems of the district. Several government officials and NGO representatives were present when our Project Director Mr K V Deshmukh shared information about a successful well recharging experiment carried out by a farmer in Dhangaon in Paithan Taluka eight years ago….*"

"At first everyone was apprehensive, but when our District Collector showed interest, we organised an exposure visit-cum-workshop to see Shri Katbane's well. He was the only farmer in the area who had enough water to irrigate a Rabbi (winter) crop in a dryland area. As several senior government officials and progressive farmers came along, the visit got a lot of media attention, and also generated curiosity among farmers in neighbouring villages. In all, over 2000 people came for this workshop in August, almost at the end of the monsoon season."

After the initial visit-cum-workshop, ATMA officers conducted block-level meetings with village heads to share the technology. A prominent social activist and expert on water management joined ATMA in their efforts to motivate farmers in *Garaj,* one of the most water-scarce villages in the district. The farmers here took up recharging works as a group activity and, as a



Diagrammatic representation of two-pit technology.

result, 52 out of the 102 wells in the village were recharged. The people provided their labour and an initial investment to meet the cost of pipes, and the agriculture department provided technical inputs. The village was fortunate to receive the last monsoon showers in September and early October and these filled the recharged wells to the brim. Careful use of the artificially recharged water made it possible to give protective irrigation to the existing Kharif (summer) crop, and also offered farmers the opportunity to irrigate an additional 50 hectares. They were convinced of the benefits of the technology.
ATMA officers recorded the performance of the 52 wells, and their observations formed the basis for launching a more comprehensive 'water resource and agriculture improvement management' programme - the *Amrutdhara Jal Abhiyaan*.
This programme was designed with the help of people who volunteered their time, labour and met the initial costs of the interventions. In April 2002, a start was made with 114 villages and about 50 of them became focus villages for the programme. ATMA provided an inventory of other simple, low cost technologies (see Box).

Amrutdhara Jal Abhiyaan programme components

1) **Well recharging for agricultural purposes**
2) **Rooftop rainwater harvesting**
   Individual pucca houses
   Government buildings
3) **Revitalising existing structures**
   Collective de-silting
   Sluice gate management
4) **Soil and water conservation works**
   Plantations on farm bunds
   Loose boulder structures
   Low-cost water harvesting structures e.g. farm ponds, check bunds
   Continuous Contour Trenches
   Kisan nurseries
   Soak pits
   Kitchen gardens
5) **Improved crop management**
   Vermicomposting
   Sendriya Sanjivani (improved organic fertiliser)
   Zero Energy Chambers to store vegetables and fruits
6) **Integrated pest management (Cotton)**
   Trap crops
   Pheromone traps, Light traps
   Neem sprays
7) **Livestock development**
   Improved fodder varieties cultivation
   Better management practices
   Mass de-worming and pest management
8) **Village level information centres**

Revitalising existing structures

Throughout the area, tanks and ponds have been the mainstay of rural communities for centuries. Aurangabad has around 390 structures, with an estimated irrigation potential of 20 000-22 000 hectares. These structures include a large number of nala bunds (tank-like small water harvesting structures) percolation tanks, and small and medium irrigation tanks constructed by the State Irrigation Department. In most cases the tank beds are silted up, reducing the storage capacity far below their potential by about 40 percent. Prolonged siltation had also resulted in the reduced carrying capacity of canals. The government, which is constantly short of resources, has not been able to invest in maintenance and repair. Some farmers do limited maintenance work before the irrigation season begins, in the parts of the canal closest to their fields, like cleaning out weeds, grass and other foreign matter. However, they do not undertake to de-silt the tanks or canals, strengthening the canal walls or deepening their beds.

Well recharging in Panvadod village, Tal. Kannad. Photo: Mona Dhamankar.

In spite of realising the importance of these structures, farmers are hesitant to voluntarily manage them because of the high royalty that must be paid for the silt, and the cumbersome formalities needed to get permission to use it. This problem was discussed in the initial meeting of *Amrutdhara Jal Abhiyaan* stakeholders, where the District Collector promptly agreed to waive the royalty if the farmers came forward to de-silt the tanks and carry the silt to their own farms at their own expense. Government officers from several departments set the pace by contributing a day's work (shramadan). This motivated the farmers, and up to now around 375 water bodies have been de-silted through collective action.

Water harvesting through well recharging

Through the process of revitalising the existing water-harvesting structures, the farmers realised that silt was nothing but their own fertile soil that was being carried off with the rain. Whenever it rained, the villagers saw the runoff in the streams and rivulets that flowed through the village. They decided to use that water for recharging their dry wells and asked the agriculture department to help them. ATMA provided information about the Swaydhay well-recharging system (see Box).

Well Recharging

(inspired by social reformer, Shri Pandurang Shastri Athawal, founder of the Swadhay Parviar movement)

The well-recharging system is very simple. Two percolation pits are dug next to a well. The large pit is approximately 2.4 x 1.8 x 1.8 metres and the small one is 1.2 x 1.2 x 2.4 metres and is built along the slope of the larger pit, about 3 metres away from the well. The smaller pit is filled with stones, gravel, and coal, which act as a filter. A cement pipe (23 cm diameter) fitted with a wire mesh filter is fixed at the bottom of the smaller pit. This pipe opens into the well. Rainwater that collects in the larger pit, flows into the smaller pit and is filtered clean before it flows into the well through the pipe. The silt that accumulates in the pits can be used in the fields. In this way, soil is conserved as well.

This technology became immensely popular because it was low cost. At an initial expense of Rs.1500-2000 (US$ 25-30) towards labour (approximately 3-4 person days) and pipes, the farmers reaped benefits throughout the year. Annual maintenance too was negligible at Rs.100. Data from Garaj village, Aurangabad district (2002) indicated that production increased substantially in areas where well recharging was taken up in comparison to those where it was not. Rabbi sorghum increased from 6.5 to 9.3 quintals/ha, wheat from 9.6 to 16.3 quintals/ha and cotton from 6.1 to 10.7 quintals/ha.

Shafiyabad's Water Budget

While working on soil and water conservation measures, the people realised that however much water they collected, it would not be enough if they did not pay very careful attention to how it was used. It was not enough to harvest rainwater and promote viable agriculture packages. Location-specific land-use planning modules were also required. Shafiyabad was one of the first villages to act on this understanding.

Until ten years ago, farmers in Shafiyabad cultivated sugar cane and bananas. Almost every farmer had a pump fitted to his well and drew water relentlessly. Over the years the groundwater was used up, and in recent times these crops are nowhere to be found. The people joined the Abhiyaan in the hope of rejuvenating their water resources, and promised to use their resources sensibly. In consultation with the Agriculture Department they prepared a 'water budget'. They appointed a committee that helped each farmer work out his/her own requirements. Crops that needed more water were discouraged and replaced with perennial crops and new varieties with short gestation periods.

Stakholders inspecting a farm pond. Photo: Mona Dhamankar.

Thereafter, the water requirement for the entire catchment area, including that for livestock, was worked out and displayed on the wall of the gram panchayat office in the centre of the village. Several other villages have now followed suit and prepared their own water budgets.

Looking ahead

Though only a few of the programme activities are described above, almost all components of the programme have been implemented with the same zeal and participation. The spirit and enthusiasm with which all stakeholders participated gave it a momentum comparable to a peoples' movement, with a promise to redefine the future of agriculture in the region.

A farmer taking his bumper cauliflower crop to the market. Photo: Mona Dhamankar.

Besides improved agricultural productivity, the programme has also produced a cadre of efficient *barefoot* technicians and trainers for water resource development interventions. These farmers are being invited by other neighbouring villages to help them design their own interventions. In the rest of the district, the traditional institutions for managing water harvesting structures are starting to revive spontaneously, and there is a community-wide dialogue on ways of sustaining and enhancing the water retention. About 15 villages have taken up water resource development activities on their own, and have approached the agriculture department for technical guidance.

The *Amrutdhara Jal Abhiyaan* officially ended in March 2003. As a strategy to maintain the tempo of work and sustain farmers' interest, the 50 focus villages are now part of a larger government-sponsored watershed development programme. For the first time, the state government's Employment Guarantee Scheme is taking up soil and water conservation measures that require higher investments and 1-2 years of consistent support.

Drought-proofing villages in Gansu Province

Zhu Qiang and Li Yuanhong

The semi-arid Gansu Province is one of the poorest and driest areas in China. Droughts and dry spells are extremely common in this mountainous area, where people depend primarily on rainfed subsistence agriculture. Since the late 1980s, a project for supplying water for domestic use and irrigation has been developed in the area. A simple and affordable rainwater harvesting system combined with an integrated approach to improving agricultural production has effectively improved the lives of Gansu farmers.

Background

In the mountainous Gansu Province over 90 percent of the population live in the rural areas. In this area of primarily subsistence agriculture, most farmers have traditionally relied on the unfavourably distributed rain. Two-thirds of the rain falls between July and September each year, often in the form of heavy thunderstorms. Only about 20 percent of the rain falls in the spring, when crops need water most. It is only possible to grow one crop per year.

The main crops grown in Gansu are wheat and maize. In the middle Gansu, spring wheat is the main crop, but recently maize grown with plastic mulching has been widely adopted owing to its higher yield and adaptability to the natural rainfall. This is sown in late April and harvested in late September. Plastic mulch is essential for growing maize in this area as it raises the soil temperature, which allows the crop to mature. In the eastern Gansu, winter wheat and maize are the two main crops. In the mountainous areas, cows and horses are used as draught animals for sowing, ploughing, and tillage. Harvesting is done mainly by hand.

Water resources in the area are scarce. Most of the river runoff is salty and cannot be used for drinking or irrigation. Groundwater is also very limited and of poor quality. Owing to the mountainous topography and geological condition, it is difficult and expensive to divert water from other watersheds. Drought occurs frequently. Studies in Gansu show that heavy drought, reducing yields by more than 30 percent, has occurred in 11 out of the last 40 years.

Under these adverse conditions, yields are as low as 1000 kg/ha in a normal year. In dry years, yields do not even cover the cost of seed. Without irrigation, it is impossible to grow most cash crops. As a result, the annual family income from a little less than one hectare of land is between US$500-US$750. The poor productivity of land has forced farmers to reclaim as much ground as possible even on steep slopes. This has caused more soil erosion and land degradation and this in turn has had a negative effect on agricultural productivity. The environment has deteriorated rapidly. Inadequate drinking water supply, food insecurity, low income, serious soil erosion and a deteriorated environment have become common features in the area.

Taking action

Experiences in the past decades have shown that water is a key factor in the struggle to change basic conditions in the area. Rainwater harvesting (RWH) is the most effective way for the local people to get water. People in the area have a long tradition of harvesting rainwater for domestic water use, but the water collected was far from sufficient to meet the domestic demand for water, let alone the water needs of agricultural crops.

Since 1988, the Gansu Research Institute for Water Conservancy (GRIWAC) has undertaken a project for Research, Demonstration and Extension of RWH, aiming at improving the efficiency of rainwater utilisation and working out RWH technologies suitable to local conditions. The Project was very successful in supplying water both for household and crop use. By the end of 1994, about 40 000 rural households had built their own RWH systems.

When it is raining, the ditches can lead water collected from the road and hill slope to the two rows of tanks. The tank water is used to irrigate crops and trees on the lands below. At the right below, land is sheeted with plastic films to prevent erosion and raise soil temperature. Photo: Author.

In 1995, a once-in-sixty-year drought occurred. Millions of people suffered from thirst and almost all the summer wheat died. Because of the successful experiences of the GRIWAC RWH project, the local government decided to initiate a "**1-2-1**" rainwater harvesting project, aiming to solve the drinking water problem for one million people in the area. In this project, government and donors supported each household with cement equivalent to US$50 to enable them to build **one** collection field, **two** underground tanks and to irrigate **one** piece of land with rainwater to develop the courtyard economy enabling them, for example, to plant vegetables or fruit trees in the courtyard, raise animals and poultry and process agricultural raw materials. By the end of 1996, there were 1.2 million beneficiaries of this project.

The apple orchard yields around 40 percent more on average with supplemental irrigation. In dry years, the increase is even higher. Photo: Author.

In 1996, a follow-up RWH Irrigation Project was initiated, starting with pilot projects at 12 sites with different natural and social conditions. The project was later extended to a much larger area. By the end of 2001, using the methods recommended by GRIWAC, there were 2.2 million newly built storage tanks which made possible the supplemental irrigation of 236,000 ha of land. At the same time, the beneficiaries of the domestic water project had increased to nearly two million people.

Benefits

The 15-year experiences of RWH in Gansu have proved that RWH not only can provide safe and cheap water for domestic use, but can also increase production by providing supplemental irrigation to crops. Crop yields have increased by around 40 percent in a normal year and by much more in a dry year.

With water in their tanks, farmers can diversify their cropping systems. Before the project, the only foods available at the family table were potato, onion and cabbage. Now, many crops that are sensitive to water stress can be grown, like cucumber, tomato, eggplant, pepper, tobacco, and herbs. Simple greenhouses have also been developed to grow vegetables and flowers. Water collected from the roofs of greenhouses can meet 40 percent of the water needed to have three harvests of vegetables. The remaining 60 percent of water needs to come from other catchments. The simplified green-house built with bamboo and steel rods and covered with plastic films costs about US$1000, while the annual net profit can be up to US$350-US$500. At this rate, investment can be recovered in 2 to 3 years.

When land productivity improved, farmers started to participate more in the Land Conversion Programme initiated by the State Government. This programme encourages farmers to plant less fertile land with trees and grassland species to improve the ecosystem. Irrigation with rainwater is a precondition for the establishment of new vegetation.

The RWH system

The RWH system consists of a rainwater collection field, tanks for water storage and water supply and irrigation facilities. Less permeable surfaces of existing structures are used for rainwater collection. In the RWH system for domestic water use, tiled roofs and concrete lined courtyards are used to produce cleaner water. Paved highways, country roads, threshing yards and sport grounds are used for collecting rainwater for irrigation purposes. Sometimes, hilltops or slopes are lined with concrete slabs to increase runoff.

Traditional underground tanks, known locally as *Shuijiao* and *Shuiyao,* are the most common types of water storage. The total investment for each *Shuijiao* is about US$120, of which US$50 is subsidised by the government. The remaining investment is supplied by farmers in the form of labour, local materials and some cash.

The tanks usually have a bottle shape with a diameter of about 3-4 m and a depth of 5-6 m. Irrigation tanks usually have a capacity of 30-50 m^3. A concrete, dome-shaped top with a thickness of 10-12 cm helps to sustain the soil weight and the load on the surface. A hole in the centre acts as both a water outlet and a manhole. The bottom of the tank is made of 10 cm thick concrete.

The underground tank has the advantages of preventing evaporation loss and maintaining a low temperature, which helps to maintain water quality. Each tank is used for the supplementary irrigation of one Chinese *mu* (approximately 670 m^2). One such structure generates two water applications of approximately 20mm each, enough to mitigate one dry spell during the growing season.

Water for domestic use is usually supplied by hand pump. The limited amount of rainwater available for irrigation is applied sparingly to crops, using the principle of limited irrigation. This means that water is applied in limited amounts during a few critical periods of crop growth. For this purpose, a lot of experiments have been conducted to determine the best time to provide the different crops in the area with supplemental irrigation. The most commonly used methods are very simple,

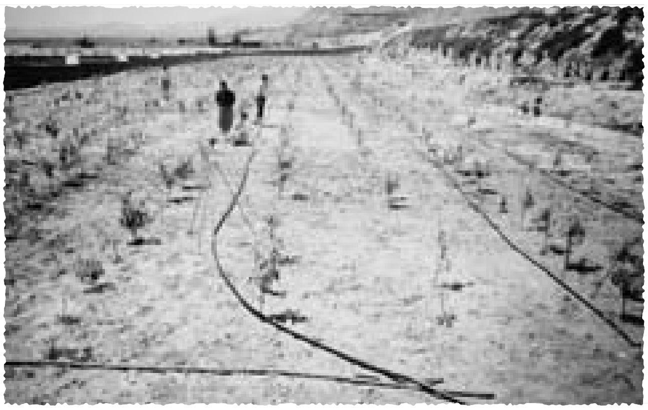
A ditch diverts water collected on a paved highway to a tank, which provides supplemental irrigation to the crops. The crop in the photo is maize. Photo: Author.

affordable and effective. For example, irrigation when the seeds are being planted or supplying water through the holes in the plastic sheeting. If farmers can get support or a loan, they also use drip irrigation and mini-sprinkling for high value crops.

Drought-proofing villages

Luoma Village is located in the northern part of Huining County, one of the 592 key impoverished counties in China. The annual rainfall is only 250 mm. There are 65 households in the village, which has a population of 323. Before the RWH project, the annual food production per capita was less than 300 kg, and annual income per capita was less than US$50. Local people had no water supply for domestic use.

This village was chosen as one of the pilot RWH projects in Gansu Province. From 1996 to 1998, the village built 330 *Shuijiao*s, 130 for the domestic use, 65 for the courtyard economy and the remaining 195 for field irrigation. During the recurring droughts between 1999 and 2000, the RWH system not only ensured water for domestic use and animal husbandry, but also provided enough water for the supplemental irrigation of 22 hectares of land.



Drip irrigation of fruit trees. Photo: Author.

Now that they have water, farmers have changed their cropping system by planting maize instead of summer wheat. Maize can produce much higher yields than wheat in this area owing to a longer growing period and a higher adaptability to natural rainfall patterns. However, it requires more water and heat in order to mature properly. Annual yields have now increased from 975 kg/ha of wheat to 3950 kg/ha of maize. Annual food production has increased by 144 percent and income per capita has increased by 187 percent. Even in years of severe drought, households have enough to meet their food needs.

Simple greenhouses have become very popular. Photo: Author.

Villager Luo Zhenjun's family was one of the poorest in the community before the project. His family of four harvested only 800-1000 kg of wheat in a normal year. During the RWH project implementation, he built six Shuijiaos with total storage capacity of 120 m^3. Using water from the RWH system, he now plants 0.4 ha of plastic-sheeted maize each year, yielding 6000 kg/ha/yr. Using supplemental irrigation, his small orchard doubled its production.

With more tank water available, he now keeps two pigs and 17 sheep, nine more sheep than before the project. His total food production has increased from 900 kg to 3675 kg per year, and his annual net income has increased from US$190 to US$700.

Experiences

The great success of the RWH project in Gansu is considered to be the result of the wide participation of the farmers and the firm support of the government. The main experiences of the project in Gansu can be summarised as follows:

- Household ownership of RWH system is the key factor to the high degree of motivation shown by farmers. Unlike the key water projects owned by the State or big enterprises, which farmers regard as "welfare", most of the RWH systems belong to the households themselves.
- Both the farmers and government can afford the inputs for the RWH system. The high profits gained from the RWH system means that investments can be recovered quite quickly.
- RWH is a tradition of the local people, but it has been updated with appropriate modern technology. This meant that farmers were more ready to accept it.
- With a little assistance from villager technicians, farmers can build their own RWH system. This decentralised approach of the RWH project suits the natural and social conditions of this mountainous and impoverished area.
- Proper preparation, organisation and management of project implementation are also important success factors. Demonstrations were very important in showing the benefit of the projects to both farmers and decision makers. From the very beginning, GRIWAC helped thousands of "scientific households" to build RWH systems that provided good examples for both the general public and the politicians. Research on the technical and economic feasibility of the RWH project was carried out over a 3-year period before the project increased in size. Technical guidance and training courses at different levels were also essential elements in the implementation of the project.

What we have learned

Roland Bunch and Gabino Lopez

This article looks back on seven years of action-research with small farmers by COSECHA, a Honduran NGO (see *LEISA Newsletter* Vol 16.1 p 22). The purpose of this research was to develop water management technologies that could be adopted by individual farmers cultivating one hectare or less.
We decided on this goal in part because a lot of research has been done on larger, multi-family systems, but there seemed to be a lack of research on technologies that an individual family can adopt spontaneously. We limited ourselves to technologies that cost less than US$50.00/technology/farmer, and have worked hard to lower costs even further. Our work has been carried out in the hillside environment where most Honduran small-scale farmers live.

The technologies described here are not necessarily in their final form. We hope that all of them can, in time, be modified so they work better and cost less. They are already very popular with farmers and we welcome any experiences or suggestions that people might have to improve them.

Priorities

During our years of research, we have learnt some valuable lessons about people's priorities for water use. At first, we thought that people used the water they managed mainly for their grain crops. How wrong we were! In fact, the first priorities are domestic: water to drink, wash and bathe. Then comes their animals and water for irrigating perennial home gardens, and more valuable crops, such as fruit orchards or commercial vegetables. Only then do they use water to irrigate their basic grain and root crops.

Looking at this list, we can understand why women are so interested in water. It also helps us understand why the first micro-tank built for any family can best be located near their home. In the Latin American context, we have found that of all the work we have done in agricultural development, it is our work with water that has attracted the attention of women the most. Women are interested in water for domestic use and to water their animals and irrigate their home garden. These activities are usually their responsibility. Of course, women are also concerned that there are enough vegetables and crops for subsistence despite irregular rainfall. However, in most Latin American countries, the production of basic grains is not their direct responsibility, and they are happy to keep it that way.

Sources of water

There are far more sources of water than most people think. We have gradually realised that many sources we previously thought useless have turned out to be very valuable. As we learned how to recycle household water, and as we have developed pumps that are less expensive, we have come to realise that twice as many people in the area have access to water sources than we originally thought.

One of the most important lessons we have learned is that almost any water source, no matter how seemingly insignificant, may become very useful. For instance, many water sources that flow only during the rainy season may be all a farmer needs, if the primary purpose of the water is to save crops from unexpected droughts during the rainy season.

Farmers can even use water sources that have so little water that they do not flow, but simply drip or ooze. If the farmer has a microtank and an appreciable amount of water collects over a period of time, this is also a useful source. In one Honduran example, there are five families that get all their domestic water from a "spring" where the water barely oozes out of the soil.

Access to different water sources can be important. In Honduras, farmers have lost interest in making microtanks where they can only fill the tanks with harvested rainwater. However, they remain very enthusiastic about microtanks where they also have access to some other source of water. This is because a microtank that is only fed by rainwater will only fill up and be used two or three times during the year. Farmers who have a more constant source of water and can keep their microtank filled throughout the year may well fill the tank and empty it again every three days, using as many as 100 tankfuls each year. Thus, farmers with an additional source of water will find it easier to repay their initial investment in the tank.

Reusing household water

With local materials and less than a day's labour, a farmer can make a small, soil-surface filter that will make grey water (carrying dirt and soap) safe for crops. A normal 5-member family produces about one oil drum per day of soapy water. Filtered, this water will usually mean a good piece of land near the house can become useful again. With this much water, a woman can often increase the size of her perennial home garden by 50 or even 100 percent, and perhaps grow enough vegetables for the family throughout the year.

To build a filter, one needs only river sand, gravel, used firewood and some old pieces of used plastic (or a bag of cement). The filter is made by digging about 50cm into the soil. It can be lined with cement, but a cheaper approach is to line it with several layers of old, used plastic bags. Equal amounts of first gravel, then river sand, and pieces of burnt firewood from the kitchen are then placed in the filter. The firewood acts as a charcoal filter and must be replaced about once every six months, depending on the size of the filter and the amount of water going through it. From the filter, the water should go to some sort of storage unit, although this might be quite small (about one cubic metre) if the filter is the only source of water for the tank.

Farmers particularly appreciate water harvesting when they also have another source that, for instance, requires a hand pump. In this case, the microtank is filled most of the time by pumping water, but farmers are very happy to have the rains fill up the microtank whenever possible.

Transporting water

In most cases, water is not directly available in the place where it is needed, but has to be transported from the source to the household or the field. This is often very resource demanding and can be a major constraint to increased water use.

Traditionally, water is either carried in containers or transported from the source to a storage tank in ditches. A simple polyurethane hose can replace the ditches. It is usually much less expensive, and is also preferable because it is easy to use and can follow the topography of the land more easily, for example, dropping a certain vertical distance and then climbing the same distance. All of the farmers in the Sabana Grande area choose to use a hose rather than a ditch. The hose also loses less water along the way, it does not deform the land it passes, and it can be moved easily from one place to another. If the hose is buried, it is more difficult for people along the way to steal water. However, the hose is also more vulnerable to vandalism than a ditch.

Pumps are often needed to get water uphill from the source. Although we worked with "washer pumps" for several years, we recently learned of a pump that could be made with a small amount of PVC pipe and a few plastic and metal fittings that are available in most hardware stores, plus two marbles. It is a simple suction pump much like those on top of spring water bottles, but much more durable. It is simple enough for nearly any farmer to make. The total cost of the materials for a pump is about US$40, and it is capable of lifting water 30 vertical metres.

This pump has become extremely popular among farmers who have water sources just below their farm plots. It takes a good deal of effort to pump the water, but most farmers are still thrilled to be able to make such a pump. For those who can afford a more efficient system, we are presently working to fit two such pumps to a treadle, so that a farmer can use his or her legs, thereby pumping twice as much water for a longer period of time. With such a system, we estimate that one person could lift enough water to irrigate a half-hectare of land some 25 vertical metres.

The pumps can be used to lift water from storage tanks, from rivers and streams, and from springs. They are not only easy to make, but very light, so they can be carried home each evening, in order to avoid theft. One of them is enough to allow one person to water a large vegetable garden (20 by 30 metres), or about fifty trees.

Storing water

Storage is the heart of any water system. Unfortunately, it often represents the most costly part of the system. It has become increasingly clear that by far the most efficient way of ensuring that our crops have sufficient water is to store rainwater in the soil itself. It is far cheaper to double or triple the infiltration of water into the soil, thereby almost doubling the water-holding capacity of the soil, than it is even to build a medium-sized microtank. How? Basically, by increasing the organic matter content of the soil.

Microtank in use during the dry season. Photo: Anita Ingevall.

The impact of even a fairly small amount of organic matter in the soil is often greatly underestimated. Research in Southern Africa, for instance, showed that contour hedgerows halved the amount of water flowing down a hillside during rainstorms even before they started having a terracing effect. The main reason for this was the large quantity of organic matter that had fallen under the hedgerows, making that strip of soil much more porous and thereby increasing the infiltration rate under the hedgerows dramatically. Thus, our first line of defence against drought must be green manure/cover crops, intercropping, agroforestry practices, and anything else that will increase the organic matter content of our soils.

Microtanks are still important for storing additional water. COSECHA has been able to get the cost of building microtanks down through the use of local materials, such as clay, river sand and rocks, plus only one bag of cement for each cubic metre of capacity. Such microtanks are totally impermeable to water and, with a little shade, suffer virtually no evaporation losses. There has been a problem with a few of them cracking, but only when the choice of location was not good - either the surrounding soil was leaking water, or the soil was a very heavy clay that cracked when dry. Small cracks can easily be repaired.

When we first began working with water management, we thought farmers would prefer to make a series of microtanks of about 0.5 to 1.0 cubic metres in capacity, thereby simplifying the distribution of the water. Rather than taking that approach, farmers have universally preferred to make just one tank, usually of about 5 to 7 cu metres in capacity. In a few cases, tanks of up to 25 cubic metres have been built.

Care must be taken to avoid the possibility of children falling into the microtanks and drowning. Most families put the tanks on their own land near the house, so that other people's infants will not have access to them. If they have children themselves, they keep the microtanks well covered, for example with tree branches, old pieces of plastic or roofing tin.

Health is another serious issue that should be considered when building microtanks. Standing water can cause health problems in the tropics, especially in Africa. The major concern in Central America is the possible spread of both malaria and dengue fever by mosquitoes. If farmers have a continuous source of water, they need to completely empty the microtank at least once a week. When the water is held longer in the microtank, problems can arise. Honduran farmers have found a number of promising solutions. For example, common cooking oil produces a film on top of the water, killing the mosquito larvae. Neem (*Azadirachta indica*) and mother of cacao (*Gliricidia sepium*) leaves can also be crushed up and thrown into the water to control mosquito larvae, and frogs and fish can be kept to eat the larvae. We need to experiment more with each of these solutions in order to make sure they are effective.

Using water

At first, farmers are often not worried about using their newly acquired water efficiently, unless they have to pump the water or the quantity of water available is very limited. They usually prefer sprinklers, because they are easy to use. As they begin to irrigate larger and larger plots, however, they become more concerned about using water efficiently.

The most efficient way to irrigate crops is drip irrigation. Farmers in Honduras have developed or tried out at least three drip systems, but the most popular by far is a simple system that involves passing wooden screws through an ordinary PVC hose at regular intervals. One side of the hose holds the screw tightly in place, while the other side is only partially penetrated by the screw, allowing the water to leak out. This allows farmers to take the screw out when the hole is plugged up by water-borne impurities, and adjust the screw to regulate the flow of water out of the hole. Because it uses an ordinary hose, this system is less than half as expensive as any other system we know about.

The suction pump is light and can be stored at home. Photo: Anita Ingevall.

Conclusions

The initial technology we share with farmers has to have a rapid, recognisable impact on yields if it is to be adopted. Even though we believe that the technologies should be as simple as possible, in the case of water management we must also work with the farmer's soils to improve fertility, water infiltration and water-holding capacity, as well as to provide the shade needed to reduce evaporation and transpiration. Applying water to hard, impenetrable, infertile soil exposed to the tropical sun will often have little impact on yields. It is, therefore, important to consider soil conservation measures, as well as measures to improve the organic matter content of the soil such as green manure or cover crops, as an essential component of water management.

Working with water is not easy, because programme extensionists and farmers often need to learn a great deal about a new subject, and because of the need to work with soil improvement at the same time. Nevertheless, the results can be tremendously heartening.

■

We are happy to send the plans and designs for any of the above technologies to anyone who requests them. We can be contacted at the address or email provided below.

Soil management in semi-arid savannas

Joseph Mwalley and Johan Rockström

In Sub-Saharan Africa, 40 percent of the farmland is located in semi-arid and dry sub-humid savannas. These areas are characterised by extreme rainfall variability and high intensity rainstorms. Rainfall ranges from 400 – 900 mm and is concentrated in short 3 – 4 month rainy seasons, when all the crops are grown. It is in these farming systems that most resource poor farmers make their living, and it is here water harvesting can make the largest contribution to livelihood improvements.

Surprisingly, despite the frequent occurrence of water scarcity, in most years there is more than enough water to potentially produce a good crop. The problem is that large volumes of water are lost through surface runoff, soil evaporation and deep percolation, because of a combination of land mismanagement and the intensity of tropical rainfall. On average, 70 – 85 percent of rainfall leaves the farmer's field without contributing to crop growth. In hot and dry tropical climates conventional ploughing, where the soil is turned, contributes strongly to the rapid loss of organic matter, compaction of soil and soil crust formation. Conservation Farming, also known as Conservation Agriculture or Conservation Tillage, may offer an opportunity to reverse this development. This article presents experiences from farmer-driven trials with conservation agriculture techniques in Tanzania.

Minimum or no-till farming systems have now been adopted on a large scale by farmers in Latin America, North America and parts of Asia. These farming systems rely strongly on organic mulch to help maintain infiltration and water holding capacities. This requires an environment that can support considerable biomass growth. In semi-arid savannas, the biomass to secure year-round mulching is simply not available. In these areas, therefore, Conservation Farming takes a different approach. The goal is still to minimise the disturbance of the soil but instead of applying minimum or zero tillage, farmers use rippers and sub-soilers to open parts of the soil for rainfall infiltration. Conservation Farming in this context is a water harvesting system that integrates soil improvement and water conservation.

Farmer-driven technology adaptation

In north-western Tanzania, on the semi-arid savannas of Arusha, Arumeru and Babati districts, decades of ploughing have resulted in severe land degradation and in places even the desertification of previously fertile land. Commercial farmers in the region have adopted Conservation Farming practices over the last decade, abandoning disc ploughing in favour of tractor drawn chisel ploughs, in order to harvest water and to save on diesel costs. However, no affordable conservation tillage options have been available to smallholder farmers. In 1998, the Soil Conservation and Agroforestry Pilot Programme Arusha (SCAPA) established a farmer-extension partnership to introduce, adapt and build capacity on simple low-cost Conservation Farming practices.

Initially, farmers were highly sceptical. Abandoning the plough, the very foundation of farming, was a completely alien idea that seemed very drastic. However, due to the agrarian crisis facing farmers in the area, they were very receptive to new ideas. Sessions were held with farmers to discuss water flow in agriculture and the causes of runoff, with a particular emphasis on the effects of soil compaction and organic matter depletion due to ploughing and removal of crop residue.

Farmers were then introduced to the principles of Conservation Farming. New implements were demonstrated, including an animal drawn ripper (see Figure 1) and a sub-soiler. Conservation Farming was explained and discussed with the farmers, addressing the impacts of Conservation Farming on timing of operations, weeding, fertility management, mulching, cover crops, pest management, harvest and post- harvest management.

The farmers wanted proof that this new farming practice really worked. As a result, the farmers designed a number of Conservation Farming production systems for testing. On-farm experimental plots were set up on 8 – 10 farms, testing three major production systems: (1) Conservation Farming based on animal drawn ripping, using a sub-soiler only the first year on seriously degraded soil; (2) Conservation Farming based on a manual system using hand hoes to dig small planting pits; and (3) conventional animal-drawn mouldboard ploughing (farmers' usual practice).

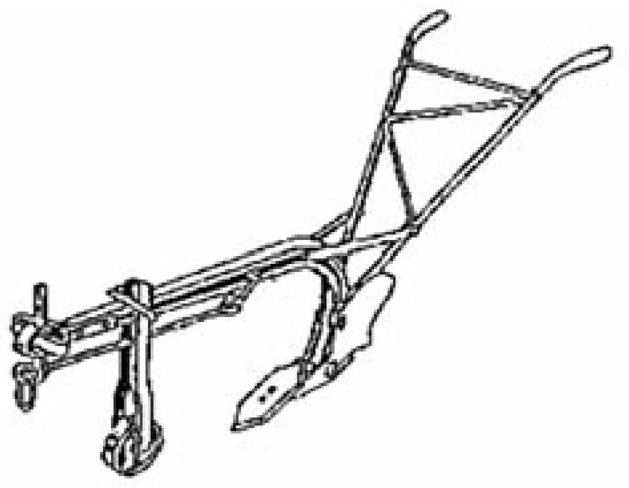

Figure 1: The animal-drawn Magoye Ripper, attached to the normal plough frame used by farmers.

Farmers were very keen on knowing the effect of improved water harvesting through the change in tillage practices, and also the effect of combining water harvesting with soil fertility management, where Conservation Farming enables better spot application of manure and fertilisers along the planting furrows created by the ripper. To do this the farmers decided to test each tillage system (conventional ploughing and Conservation Farming practices) both with and without fertiliser application.

In order to investigate the effects of a cover crop, a Conservation Farming with *Dolicos lablab* trial was added to the experiment. This is a favourite cover crop with farmers and the beans are sold on the markets in Arusha. On the Conservation Farming demonstration farms, rainfall was monitored by the women participating in the trials and labour needs were documented. Because ripping requires less draught animal power, it enables land preparation before the onset of the rains – a critical opportunity in semi-arid regions where 25 percent of a season's rain may fall during the first few rainstorms. Therefore, all the Conservation Farming systems were dry planted. Manure and locally manufactured rock phosphate was applied in the permanently ripped planting lines. Low amounts of nitrogen fertiliser (30 kg N/ha) were applied twice: once before planting and again as a top dressing 4 – 5 weeks after the crop emerged.

Weeding is a major concern in Conservation Farming systems, in particular during the first years. Without ploughing to suppress the weeds, weed control posed a dilemma for farmers. Weed control was discussed at length, and finally it was agreed that the favoured solution was to add an additional third weeding late in the season in order to avoid weed seeds falling onto the soil. Farmers did not consider using herbicides, which are seen as too expensive.

Yields and water productivity increases

Each season yield results were discussed and analysed with the farmers. Yields were expressed in the number of 90 kg bags produced per acre, which is the yield measure best understood by the farmers in the area. Experiences were shared and adaptations made to the trials. The farmer's conventional practice (ploughing only) resulted in an average yield of 1.6 t/ha, which is actually a higher yield than the 1 t/ha generally experienced in the region by smallholder farmers. Water harvesting alone – where the plough is abandoned in favour of ripping without soil nutrient management – resulted in a 60 percent yield increase to an average of 2.5 t/ha. Interestingly though, water harvesting alone did not give the strongest yield increase, and it was only when soil fertility management was combined with water harvesting that the full effect of Conservation Farming adoption was experienced, with a 240 percent yield increase to an average of 3.9 t/ha. Farmers were very excited about the synergy effect between water and nutrient management. The importance of both factors was clearly shown by the fact that addressing soil fertility alone – ploughing with fertility management – resulted in a roughly similar yield level (2.8 t/ha) to that obtained with water harvesting alone (2.5 t/ha).

Manual pitting resulted in approximately the same average yield as the animal drawn system (3.5 t/ha). To farmers, this was the preferred system. The reason is that manual pitting is cheap, does not require oxen or new implements, and above all gives the farmer full control over the use of precious inputs such as seed, manure and fertilisers, as these can be placed carefully at perfect depth in each planting pit. Farmers agreed though, that the pitting system was very labour intensive compared to the ripping. Ripping saved on average 50 percent of the labour needs compared to conventional ploughing.

More crop per drop

It is clear to the farmers that the primary benefit of Conservation Farming as it is practiced among the pilot farmers in Tanzania, comes from the increased amount of water that reaches the root zone of the crop. Farmers claim that no surface runoff is observed from properly ripped fields, while even in terraced fields (all trials were conducted on fields with good soil conservation measures in place), runoff occurs on ploughed soil. For the farmers Conservation Farming has become the answer to the common concern of "what to do between the terraces" since they experience that despite successful adoption of soil conservation measure, there has been little impact on yields.

The rainwater harvesting effect of Conservation Farming can be quantified by estimating the amount of crop produced per drop of water. Only 2.6 kg of grain is produced per mm of rainfall in the current farming system, based on ploughing and poor soil fertility management, compared to 7.4 kg/mm of rainfall for the Conservation Farming system. This indicates that the crop's capacity to take up water from the soil has increased. It is likely that soil evaporation has also been reduced as a result of a more vigorous crop cover.

Gender sensitive

Improving crop yields and the amount of crop per drop of water is important, but one of the most essential benefits of Conservation Farming is improved timing of operations and the savings in labour achieved. Ripping is only done along permanent planting lines. The 80 cm space in-between the rows is left undisturbed. This translates into a large reduction in the amount of traction needed. Ripping also enables off-season land preparation. The present practice is that farmers wait until the soil is moist before ploughing. This means that essentially all water from the initial rainfall events are lost through evaporation, and that ploughing is done on wet soil, which increases the problem of compaction. Also, this practice hits hard on poverty stricken female-headed households as these farmers do not have their own oxen but rely on neighbours for ploughing. Ploughing is carried out after the owner of the oxen has finished ploughing, which may already be late. The crops of these woman farmers, therefore, have a very late start. Ripping changes things entirely.

Now women farmers can borrow oxen during the dry season, and prepare the land well before the onset of the rains. Dry planting of seed will give the crop an important head start, which may mean the difference between total crop failure and getting a harvest. As the number of female-headed households is increasing rapidly due to the HIV pandemic, this is a significant improvement in farming practices.

Conservation Farming enables planting well ahead of rains and high rainfall infiltration. This is illustrated here by a well-established maize crop under CF practices (to the left) and a late planted conventionally ploughed maize (to the right). Photo: Johan Rockstrom.

Sustainability

The Tanzanian cases presented above show that Conservation Farming is a very important water harvesting strategy in efforts to upgrade semi-arid rain fed farming systems. Similar experiences have been recorded in Kenya and in Zambia. Tractor driven sub-soiling among smallholder farmers in the neighbouring Babati district, south of Arusha, has also shown a progressive increase in yield levels and improved rainwater harvesting over the last decade.

The long-term challenge is to build up soil quality through wise tillage combined with the proper management of cover crops and mulching. At present farmers in the semi-arid savannas of sub-Saharan Africa have great difficulties in securing a mulch cover, due to the combined effect of high competition for crop residues, free post-harvest grazing and the use of residues for

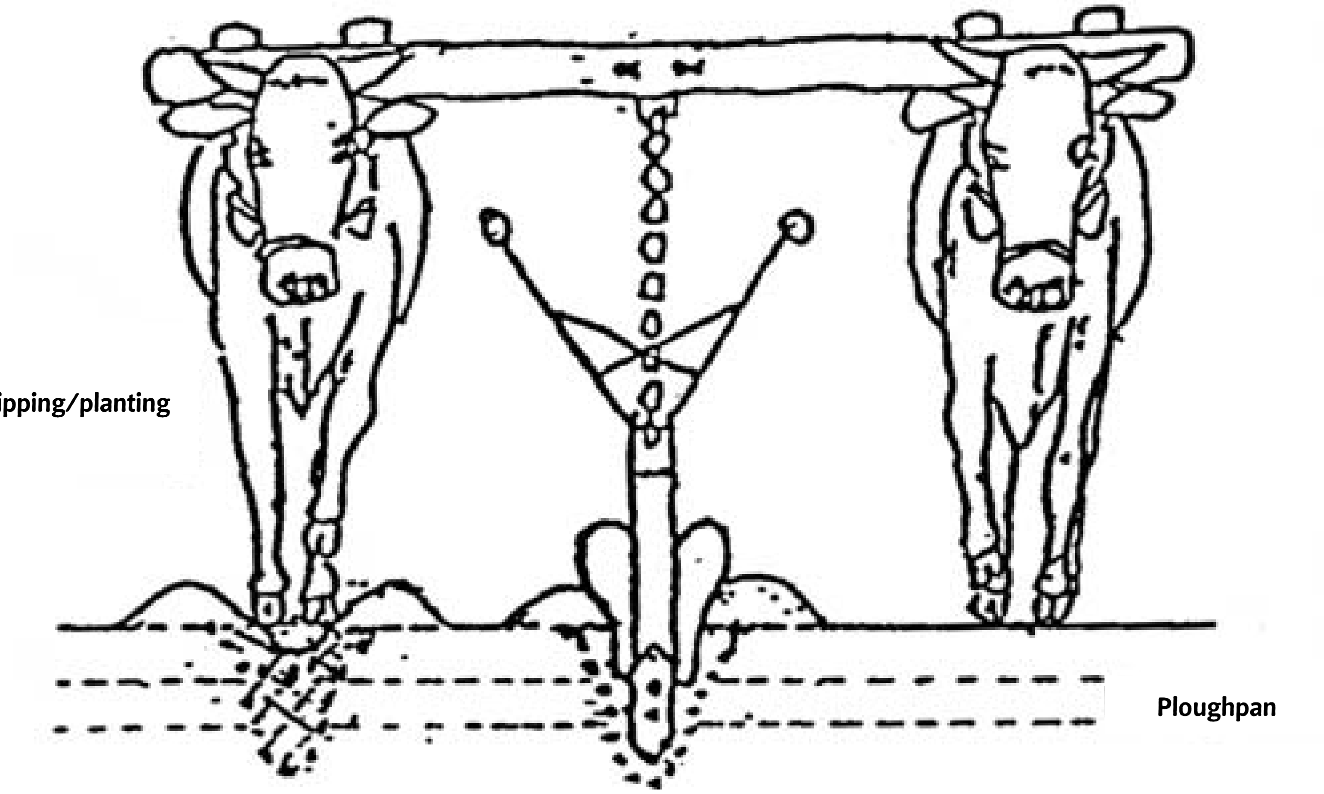

Figure 2: Oxen carrying out ripping.

fuel and construction, low inherent biomass growth, long dry seasons, up to 8 months with no rains, and high termite activity. Still, it is absolutely necessary to try to incorporate a (preferably leguminous) cover crop into the system in order to secure a progressive build-up of soil properties. The mulch is also the key to suppressing weeds and conserving moisture. Weed infestation is one of the major concerns raised by farmers. Animal drawn cultivators have been introduced for weeding and work well but are expensive to buy. So far, it seems clear that persistent weeding during the first 3 – 4 years will be necessary in order to progressively reduce weed infestation.

Conservation Farming is much more than just a change of implements. Abandoning the plough changes every component of the farming system. This is why a systems approach is required where all aspects of water, soil, and crop are addressed. Farmers and extension workers need capacity building in order to deal with the implications of a full shift from present plough-based farming to Conservation Farming. Particular emphasis should be given to training women as most of the critical management aspects of successful Conservation Farming concerns timing, weeding, soil fertility management and the post-harvest management of residue – tasks mostly performed by women. Tillage is important, but a relatively small step. However, it should be noted that a serious effort is needed to train oxen to walk in straight lines during ripping. Ripping is done with a wider yoke than ordinary ploughing in order to secure a line spacing of 75 – 80 cm, which means that oxen do not have a furrow to follow or a neighbour ox to lean on.

Rippers and sub-soilers are new implements that are not readily available on the market. Resource poor farmers need access to not only good quality implements but also affordable ones. This is a major bottleneck at present, even though there are good signs of progress.

In Kenya local *Jua-Kali* implement manufacturers have been trained to produce local Conservation Farming equipment. In Tanzania and Zambia there are several workshops producing implements for commercial purposes. In both Kenya and Uganda, the Food and Agriculture Organisation of the United Nations (FAO) has recently supported two Technical Cooperation Projects to promote manufacturing and to encourage Conservation Farming practices. These are promising developments, which may turn out to be the initial steps in an agricultural revolution for smallholder farmers in Sub-Saharan Africa, and perhaps a major water harvesting development in drought prone savannas.

Improving soil moisture with conservation agriculture

José Benites and Antonio Castellanos

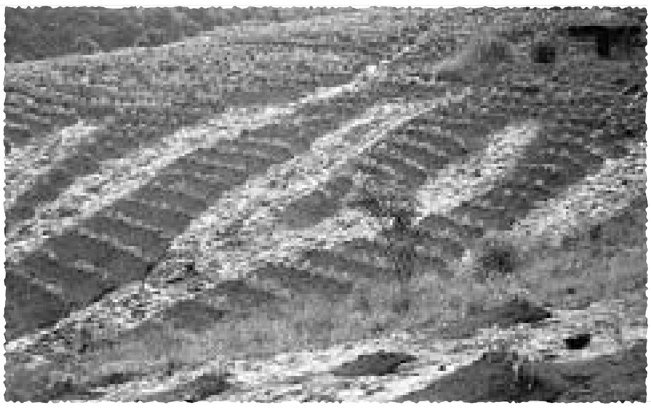
Irregular or insufficient rainfall can be a serious limitation to agricultural production, causing low yields and even crop failure. This is particularly true in drylands, where productivity levels are generally very low. In most cases, a great deal can be done to improve the efficiency of rainwater use. Conservation Agriculture is one way of improving soil moisture management.

Soil moisture management

A significant cause of low production and crop failure in rainfed agriculture is lack of water in the soil. This is caused by a combination of low and erratic rainfall, and poor utilisation of the water that is available. Soil moisture management is, therefore, a key factor when trying to enhance agricultural production.

Increasing the amount of water stored in the soil can result in:
- Improved yields (if there are also enough nutrients)
- Reduced risk of yield losses due to drought
- Recharge of groundwater, securing the water level in wells and the continuity of river and stream flows.

As little can be done to increase the amount of rainfall or the number of rainfall events, we should focus on improving the capture of rainfall, the availability of water in the soil and water use efficiency in rainfed agricultural lands. This means that the amount of water that enters the soil (infiltration) must be increased and that the moisture lost through runoff and evaporation must be reduced. Increasing soil cover and better soil management can help achieve this. Soil should be disturbed as little as possible, there should be permanent soil cover and the amount of organic matter should be increased.

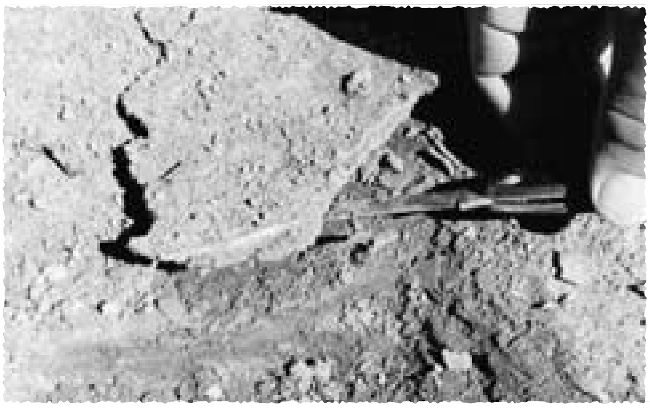


Sub-surface compaction by continuing tillage has resulted in structural degradation and runoff. Photo: T.F. Shaxson.

Treasure hunting in drylands

When rain falls on the soil surface, part of it will infiltrate into the soil to replenish soil water or flow through to recharge the groundwater. Another part will run off as overland flow, and the remainder will evaporate directly from unprotected soil surfaces and from plant leaves.

The amount of water that can be held in the soil and made available for crop use is not only determined by the amount of rain that falls, but also by the chemical and physical properties



A thin surface crust caused by raindrop impact on a bare soil with poor structure. Photo: T.F. Shaxson.

of the soil. When most people think about soil, they think about the solid part. But the pore spaces or the structure of the soil are just as important.

Soils differ in their capacity to hold water and make it available to crops. This depends on:
- Soil texture (the proportions of sand, silt and clay)
- Soil depth (shallow soils hold less water than deep soils)
- Soil structure (pore spaces)
- Organic matter content (more organic matter means more water is held)
- Biological activity (earthworm holes, for example, greatly increase the possibility for water to enter the soil).

Pore spaces

The number, size and connections between pore spaces play a crucial role in determining the amount of water that can infiltrate into the soil, and the amount of water that the soil can absorb, hold and supply back to plants.

It is important to have many interconnected pores of a wide range of sizes, particularly at the soil surface. This improves infiltration, reduces runoff and benefits crop growth.

The number, size and connections between soil pores vary according to the type of soil and the way it is managed. Little can be done about the type of soil, but good land management can have a great impact on restoring, improving and protecting soil porosity. This in turn will increase available soil water content, and the interconnected pores will minimise any potential risk of waterlogging.

Crop water stress

Crop water stress develops when the plant cannot extract water from the soil through its roots as fast as it loses moisture from the surfaces of its leaves. To ensure that the crops will be able to utilise the available rainfall, we must understand the causes of poor soil structure, at the surface as well as below the surface.

At the soil surface, the impact of raindrops on a bare soil surface can decrease porosity through the formation of surface seals and crusts. These limit the rate of infiltration, leading to increased runoff. Runoff is responsible for soil erosion and peak-river flows. However, it is a consequence of soil degradation, not a primary cause. Physical structures like contour banks do slow down runoff and protect the soil from erosion, but do not resolve the problem of soil degradation as they do not increase the porosity of soils.

Any traffic in the field, such as machinery, ploughing, or the impact of human feet or animal hooves, can put pressure on the sub-soil, especially when the soil is in a moist condition. Pressure destroys pore spaces, in particular the interconnected pore space. The soil becomes compacted and water infiltration and storage capacity is reduced. Plant roots have difficulty in penetrating compacted soil and their root systems do not develop well.

Tillage, in particular turning over the soil by ploughing, can also lead to a decline in soil fertility. It decreases organic matter content and has a negative effect on soil biological activity, for example by destroying the burrows of earthworms.

The role of Conservation Agriculture

The four basic principles of Conservation Agriculture can help achieve and maintain an absorptive and biologically rich soil. These four principles are:

Maintaining permanent soil cover

Permanent soil cover, either plant residues or growing crops, protects the soil surface from the negative effect of raindrop impacts. It reduces crust formation and susceptibility to erosion, and enhances porosity on the soil surface. It also reduces direct water loss through evaporation from the upper layers of the soil and establishes better conditions. It also maintains a continuous food supply for soil organisms – from microbes to earthworms.

Minimising mechanical soil disturbance

Reducing or stopping tillage means that the soil is not disturbed and that the moisture loss and soil compaction that follows tillage is avoided. This increases the infiltration and percolation of water through the soil, leading to better root development and crop growth. Decomposition of organic matter and subsequent loss to the atmosphere is also reduced. Sometimes a once-only de-compaction is required to bring the soil back into a better starting condition. One of the most important impacts of minimising soil disturbance is that it improves the living conditions of beneficial organisms and so enhances their activity. Crop roots and soil organisms are responsible for the creation of a network of interconnected pores. These organisms undertake biological tillage and improve soil structure. In addition, biological activity ensures that crop residues are incorporated into the soil.

Controlling in-field traffic

It is vital to ensure that in-field traffic follows permanent tracks. In this way soil compaction is restricted to defined areas, year after year. When this is combined with zero or reduced tillage, the rest of the field is free of compaction. Soil porosity and water infiltration are maximised, earthworms and other soil animals prosper and organic matter is not lost but becomes closely bound and integrated with the soil. The overall impact is a productive soil system, able to carry crops through dry conditions because of the enhanced soil water store, the deep rooting of the crops, the biological activity and the high content of organic matter.

Crop rotation

The use of crop rotation and cover crops helps to increase soil organic matter, reduce erosion and bring biological diversity back to the soil. The rotation of different crops, with their different root systems, optimises the network of root channels in the soil, leading to increased water penetration, increased water holding capacity and more water being available for crop use, to deeper soil depths. Crop rotation also enhances biological diversity and helps reduce the risk of pest or disease outbreaks.

Monitoring soil moisture

We cannot know in advance how much rain will fall during the growing season. It is possible, however, to find out how much plant-available soil water is present before sowing the crop. Knowing how much plant-available water is present in the soil can help in making a wise decision about which crop to plant.

Measurements of soil water content can be made with a variety of equipment but most farmers will have to make an estimation based on the feel and appearance of their soil. This will vary with soil texture and moisture content, but with experience soil moisture can be estimated to an accuracy of about five percent.

Alternatively, a soil moisture probe can be used to determine the amount of water that is available for plants. This is estimated from the depth of insertion of the probe. Again, it has to be interpreted with knowledge of the soil texture.

Different rates of infiltration under zero tillage (left) and conventional tillage (right). Photo: Bruce Radford.

Conclusion

The four basic principles of Conservation Agriculture work together to create a soil that has a greater capacity to absorb rainwater. Although there is no single recipe to suit all conditions, Conservation Agriculture improves the physical and biological condition of the soil. A soil that is porous, absorptive, and rich in organic matter and biological activity is able to support maximum crop production for every drop of water it receives.

Using every drop of water

Editorial

Water is an essential resource – it forms the basis for life on earth. Water is also important for production, not only in agriculture but also in many industrial processes. In addition, it is used to remove waste products from cities and industries. Growing populations, rapid urbanisation and increasing industrial and agricultural production are combining to increase pressure on this precious and finite resource. At the same time, climate change is beginning to affect the global pattern of rainfall, and will probably lead to even higher temperatures and lower rainfall in tropical areas. Many warn that we are facing a global water crisis. A number of international initiatives are being developed to promote awareness and get water issues onto the political agenda (see Networking p 35).

A girl waters her family's garden (Mozambique). Photo: FAO/M.T.Palazzolo.

As water is increasingly needed for so many different purposes, the huge proportion of water required for agricultural production is increasingly challenged. During the Green Revolution, heavily subsidised water-intensive technologies were promoted to support modernised agriculture, including large-scale groundwater development and the introduction of modern irrigation techniques and pumping technology.

Looking back on 50 years experience with these approaches to water management, it is possible to see that in many parts of the world not only have they had negative environmental impacts, but they have led to an erosion of knowledge about other more appropriate and sustainable systems of water management.

Most of the world's farmers make their living from rainfed agriculture, which is practiced on 80 percent of the arable land worldwide. Approximately 40 percent of these farmers live in water-scarce tropical landscapes, with highly unreliable rainfall and high evaporation losses. Droughts are common, but even more common are dry spells - short periods of water shortage during the growing season of a crop that can cause yield reduction or even crop failure. Despite these challenges, it is clear that rainfed agriculture will have to contribute substantially to the world's future food needs.

Small-scale water solutions can help improve the lives of smallholder farmers considerably. When they are introduced, water harvesting systems are rarely used for only one purpose. Farmers' first priority is always to secure the supply of domestic water (Bunch and Lopez p 11). Farm ponds, earth dams and sub-surface tanks, even if originally designed for supplemental irrigation of crops or full off-season irrigation of vegetables, will generally also serve as source of drinking water and water for livestock during periods of water scarcity (Duveskog *et al* p 22).

Water harvesting opens new livelihood options for resource poor farmers in vulnerable environments. Subsistence farmers, who invest in water harvesting systems with a storage component, often diversify their farming system to include the production of some cash crops, such as vegetables for the local market during off-season periods when prices are high (Qiang and Yuanhong p 14). This diversification increases the resilience of farm households, as they are better equipped to cope with periods of climatic hazards such as droughts and floods that can entirely destroy their staple food crops.

Adding water to rainfed systems in water scarce regions can help improve production where it is most needed. In this issue, the examples of smallholder water harvesting practices show a wide range of systems for water conservation including runoff farming, stone bunds, terracing, micro basins, mulching, flood water harvesting systems to reduce risks of erosive storm flows, and storage systems for supplemental and full irrigation.

Nothing new

Water harvesting is nothing new. For thousands of years, systems designed to increase the amount of water for crop production have been used in the semi-arid and arid tropics. The first water harvesting techniques are believed to have originated in Iraq over 5000 years ago. Many civilisations have developed water harvesting practices and for some, they have been the basis for their survival.

With the promotion of modern agricultural practices, conventional irrigation and pump technology, traditional technologies have gradually been abandoned. Much traditional knowledge has been lost. Recently, farmers and development agencies have started to pay more attention to traditional technologies and how they can contribute to modern water harvesting projects (Oweis and Hachum, p 26).

Catching water where it falls

In water-scarce farming systems, erratic rainfall cause droughts and dry spells. The only way to manage these successfully is to make sure that the rain that does fall is efficiently stored in the soil, or to collect runoff for productive use. In many areas, even where water is scarce, there is enough available to produce a good crop, provided the water is used efficiently (Mwalley and Rockström, p 8).

In order to be productive, water needs to get to the roots of the crop. This can be achieved by "catching" the water where it falls and making sure it infiltrates into the soil, through simple mechanisms such as earth banks, bunds, contour terracing or swales (Duveskog et al p 22, Yaholnitsky p 24, Oweis and Hachum p 26).

Market garden under drip irrigation. BBCDC, Lesotho, 2000. Photo: BBCDC.

Collecting and storing rainwater is a simple and effective way to make water available. It is wiser to collect runoff flow as close as possible to where the rainfall falls, instead of letting it flow – often in an erosive journey – downhill and then lifting it back up again. Rainwater for irrigation does not need to be as clean as water for domestic uses and can be collected from all kinds of catchments including roofs, roads, and fields. Storage systems vary and many are described in this issue (for example Qiang and Yuanhong p 14, Shone p 17, Bunch and Lopez p 11, Dhamankar p 18, Oweis and Hachum p 26).

Improving yields

Water harvesting has tended to be promoted as an isolated technique of improved water management. In water-scarce tropical agro-ecosystems, however, water is not necessarily the most limiting factor for improved crop yields: soil fertility is often just as limiting. Almost all articles in this issue clearly show that optimal yields cannot be achieved by simply supplying more water to a crop. Combining water harvesting with other methodologies for improved water and soil management can have a synergy effect with large added value to the farming systems. Therefore, successful water harvesting practices should involve an integrated approach to soil and water management.

Conservation Agriculture (also known as Conservation Farming or Conservation Tillage) practices, through minimum disturbance of the soil and the addition of organic matter from cover crops and mulch, improve soil biology and structure, allowing plants to use water more efficiently (Benites and Castellanos p 6). In participatory trials with Conservation Farming practices for smallholder farmers in Tanzania, crop yields of maize more than doubled when Conservation Farming practices to increase rain infiltration into the soil were combined with soil fertility management (Mwalley and Rockström p 8).

In hot tropical climates, huge amounts of water are lost to evaporation (50 to 80 percent of rainfall). Integrating various types of mulch management in water harvesting systems can help to reduce evaporation, as shown by Bunch and Lopez (p 11).

Issues of scale

Water harvesting can be done at field level or at the level of larger catchment areas. Small-scale, local innovations do not need to remain isolated incidents. Duveskog *et al* (p 22) describe the experiences of three farmer innovators in Kenya who have been identified as part of a programme to share the experiences of farmer innovators through Farmer Field Schools.

At the larger scale, runoff water is often seen as a nuisance to be removed, for example through cut-off drains and culverts. Instead, such runoff can be carefully managed to contribute to production. Even small-scale structures can help improve water management throughout the wider ecosystem. For example, in tropical areas with steep slopes where intensive rainfall generates storm floods, small-scale water harvesting structures can be effectively used to slow down surface runoff and let it infiltrate to recharge groundwater. This not only conserves soil, it also generates a lasting water supply for wells downstream (Lo p 29).

Water harvesting systems often operate on a scale beyond the farm. As soon as water harvesting systems include the diversion of runoff flow from gullies or the storage of water in small dams for gravity fed supplemental irrigation, skills are required to design the systems in an appropriate way (Verweij p 21). There is still very limited human capacity among service-providing institutions, such as extension services, to promote and assist farmers in adopting water harvesting systems that operate beyond farm level. There is still a considerable need still to train trainers in design and sustainable promotion of water harvesting systems.

Social issues and water management

Small micro systems can be fully contained within one household and within the farm. If the catchment area, the storage and the water utilisation all take place within the farm, the system is directly controlled and managed by the farmer. When moving to larger systems, such as rainwater harvesting on communal areas or dam building, the issue of access and rights to the water becomes important. Larger systems require a social organisation that is able to regulate the use of the water efficiently and equitably to the participating households, and that can ensure that all members carry out their responsibilities relating to maintenance and management. To further complicate matters, local organisations and communities will often come into contact with government regulations and institutions if they try to utilise public resources. There are also issues of conflicting interest between upstream and down stream water users, as well as competing interests between agriculture and water use for other purposes.

In this edition of LEISA Magazine, we have not dealt with these issues, but have focussed on techniques and basic ideas that can be of help to the individual farmer. In the following LEISA Magazine we will take a closer look at the complicated issues of access to and control over land and natural resources.

CONTENTS

In the dry sub-humid savannas of Sub-Saharan Africa, it is surprising to realise that despite the frequent occurrence of water scarcity, in most years there is more than enough water to potentially produce a good crop. The problem is that large volumes of water are lost through surface runoff, soil evaporation and deep percolation, because of a combination of land mismanagement and the intensity of tropical rainfall. In hot and dry tropical climates conventional ploughing, where the soil is turned, contributes strongly to the rapid loss of organic matter, compaction of soil and soil crust formation. Conservation agriculture may offer an opportunity to reverse this development.

Today, many villages in India are facing severe water scarcity. Erratic rainfall and poor soil and water management, including relentless ground water extraction has led to cycles of drought and water scarcity. As a result, there is renewed interest in rehabilitating the small, traditional water harvesting and irrigation systems that have existed in India for centuries. This article describes the efforts of a community and their government to take 'rehabilitation' beyond technical interventions, to include farmer participation and coordination of the efforts of different institutions.

ILEIA is the Centre for Information on Low External Input and Sustainable Agriculture (LEISA). ILEIA seeks to promote the adoption of LEISA through the LEISA magazines and other publications. It also maintains a specialised information database and an informative and interactive website on LEISA (**http://www.ileia.org**). The web site provides access to many other sources of information on the development of sustainable agriculture.

LEISA is about Low-External-Input and Sustainable Agriculture. It is about the technical and social options open to farmers who seek to improve productivity and income in an ecologically sound way. LEISA is about the optimal use of local resources and natural processes and, if necessary, the safe and efficient use of external inputs. It is about the empowerment of male and female farmers and the communities who seek to build their future on the basis of their own knowledge, skills, values, culture and institutions. LEISA is also about participatory methodologies to strengthen the capacity of farmers and other actors to improve agriculture and adapt it to changing needs and conditions. LEISA seeks to combine indigenous and scientific knowledge, and to influence policy formulation in creating an environment conducive for its further development. LEISA is a concept, an approach and a political message.

14 Drought-proofing villages in Gansu province

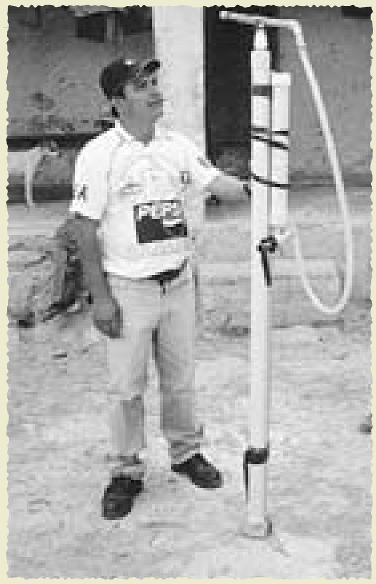
Zhu Qiang and Li Yuanhong

The semi-arid Gansu Province is one of the poorest and driest areas in China. Droughts and dry spells are extremely common in this mountainous area, where people depend on rainfed subsistence agriculture. Since the late 1980s, a project for supplying water for domestic use and irrigation has been developed in the area. A simple and affordable rainwater harvesting system, combined with an integrated approach to improving agricultural production, has improved the lives of Gansu farmers.

11 What we have learned

Rolando Bunch and Gabino Lopez

This article looks back on seven years of action-research by COSECHA, Honduras, with small farmers. The aim of the research was to develop simple, economical water management technologies that could be adopted by individual families. The technologies described are not necessarily in their final form, but they are already very popular with farmers.



DEAR READERS

Water is an essential and precious resource upon which our ecosystems and agricultural production depend. As population increases and urbanisation intensifies, the present mismanagement of water together with the effects of climate change have caused many to warn that we will soon have to come to terms with a global water crisis. For many farmers, however, the water crisis is already a feature of daily life. Farmers and those living in dry areas face water shortage daily as they try to meet their personal needs and the needs of their agricultural systems. As soils and ecosystems in many parts of the world continue to be degraded, water becomes an increasingly scarce resource.

In this issue, we try to illustrate principles that can help increase water efficiency and make more water available for agricultural production. We also take a closer look at some of the technologies available to small farmers. We have consciously left out many of the important social issues surrounding water management, as we hope that many of these will be highlighted in the September issue of LEISA, which deals with access to and control over resources.

Magazine on Low External Input and Sustainable Agriculture

Using every drop of water

Visiting a coffee plantation with the IJAT'Z farmers.

Visit to Central America

In November 2002, Teresa Gianella, Editor of LEISA Revista de Agroecologia, *and Anita Ingevall, Director of ILEIA, travelled together in Central America. The purpose of the trip was to present the* LEISA Revista *magazine to the region and to make contacts for future information exchange. Teresa and Anita had the opportunity to meet and discuss with farmers, technicians and NGO representatives in El Salvador, Honduras and Guatemala.*

Here we only have room for a brief account of one of our visits in Guatemala. We also have other stories to tell from our visits in Guatemala, El Salvador, and Honduras. We have fond memories of all our visits and promise to share more of our experiences in future LEISA magazines, and on our web sites.

Visit to the coffee farmers assisted by IJAT'Z

Coffee is the most important agricultural product for the Mayan farmers on the slopes of San Lucas de Toliman, three hours from Quetzaltenango in Guatemala. Coffee has been grown in Guatemala since the 18th century, but over the past few decades it has been promoted intensively as an export crop, with packages of inputs and technology provided to farmers to increase their yields. Unfortunately, these technologies had negative effects on the agro-ecosystem and on farmers health. Over time, yields declined and higher inputs of agro-chemicals were required to maintain production.

In San Lucas de Toliman we meet Guillermo Campa, Germán Xep Ajcalon and Inocente Jacinto, some of the Mayan farmers who are involved in IJAT'Z. IJAT'Z started as a reaction to the problems the farmers were facing. German tells us that when he became ill from the pesticides he was using, he started to think that there must be another way of farming. He also remembered older people telling him about the traditional Mayan agriculture. German decided to try and find more information. He got in touch with a few of the oldest farmers who still remembered the old ways and started to experiment on his own.

More than ten years later, IJAT'Z has become a training and promotion centre for the local farmers association, where they share their experience in ecological coffee growing with other members of the association. Our hosts were all local farmers, who are available to provide advice and training to other farmers who wish to grow ecologically, particularly organic coffee.

We were able to visit the coffee plantation of one of the participating farmers. The coffee was growing in the shade of a variety of fruit trees. Between the coffee and fruit trees grew a variety of green manure crops, as well as plants for erosion control and for increasing water retention. Minimum tillage is also practiced. The farmers said that their vision was to create "a forest of food". Guillermo pointed out that management is one of the most important aspects of farming "One must be very conscientious about pruning, incorporating green fertilisers, maintaining the plant cover and managing pests".

The number of coffee farmers adopting ecological methods is increasing, not only because of the health benefits but also because it improves their economic security. Diversified crops ensure food security for their families, and agro-chemical free coffee can be sold at better prices. The elimination of agro-chemicals in the area also means less pollution in the water courses. To make the change to ecological farming, the farmers associated through IJAT'Z drew up their own project proposal and obtained the assistance of a small grants programme (SGP-GEF-UNDP) in Guatemala.

The initiative taken by these farmers has not been an instant success – their commitment and persistence in innovating has carried them through a number of difficulties and it is finally starting to pay off. We were very impressed by their commitment and enthusiasm.

Thank you...

We are grateful for the co-operation of all the technicians and NGO staff who welcomed us and gave us the opportunity to gain valuable experience in getting to know the rural areas of Central America, the hazards and challenges they deal with and their progress. Special thanks to the farmers who made time to see us during their very busy working day.

Teresa Gianella-Estrems
Anita Ingevall

Issue 19.3, September 2003

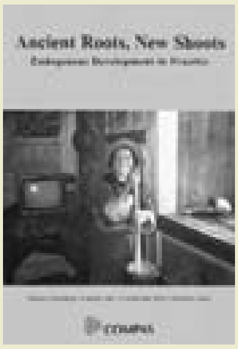
Access to and control over resources

Around the world, many different systems and arrangements determine who has access to and control over land and other natural resources, and under what conditions. Systems of access and control range from formal to informal, from traditional to very new, from collective to private. Arrangements change and evolve over time, in most cases moving towards increasing privatisation and formalisation. Resources regulated by these systems include not only land but also resources such as trees, water, grazing and manure. Water users associations, Joint Forest Management, tree pattas, private land deeds, and share cropping are just some examples of mechanisms that communities and societies develop to regulate their resource use. How do these systems work, and why? This issue of LEISA will try to bring into focus some of the practical aspects of different systems for access and control. We invite you to share your experiences.
Deadline for contributions is the 1st of June, 2003.

Issue 19.4, December 2003

Rehabilitation of degraded land

You are invited to contribute to these issues with articles (about 800, 1600 or 2400 words + 2-3 illustrations and references), suggest possible authors, and send us information about publications, training courses, meetings and websites. Editorial support is provided by ILEIA. Authors of published articles are entitled to a standard fee of USD 75,-.



Ancient roots, new shoots: endogenous development in practice by Haverkort B, Hooft K (van 't), Hiemstra, W (eds). 2002. 264 p. ISBN 1 84277 335 6. ETC/Compas, PO Box 64, 3830 AB Leusden, The Netherlands. Zed Books, 7 Cynthia Street, London N1 9JF, UK / zed@zedbooks.demon.co.uk
The present global problems of poverty, ecological destruction and loss of cultural diversity call for innovative solutions. Experiences indicate that the cultural identity and initiatives of local people can provide important keys to sustainable rural development. This book describes the processes whereby the present-day diversity of knowledge and cultures has emerged. It presents a number of field experiences of endogenous development, or development from within, in Sub-Saharan Africa, Asia, South America and Europe. By building on local needs and resources, innovative methodologies have been developed to understand and experiment with indigenous practices, and to find synergy with modern knowledge systems. The activities include identifying development niches, retaining benefits within local areas, maximising local control, and making selective use of external resources. With a good balance of theory and practice, this book can be immensely useful to development practitioners, researchers and policy makers, especially in the field of rural development, agriculture, natural resource management and health.

Silent invaders: Pesticides, livelihoods and women's health by Jacobs M, Dinham B. 2003. 342 p. ISBN 1 85649 996 0; GBP 14.95. Pesticide Action Network (PAN), Eurolink Centre, 49 Effa road, London SW2 1BZ, UK / admin@pan-uk.org ; www.pan-uk.org
This book brings together 30 case studies and scientific papers that show the effects of pesticides, particularly on farming communities and agricultural workers. It gives details of pesticide hazards and explanations of the toxicity manifested. It focuses specifically on the dangers they present to women. Silent Invaders shows the importance of studying impacts on both women and men, taking account of gender divisions of labour, of the imbalances in the economic and political realities of women and men's lives, and of the clear physiological differences between the sexes.

The final section provides details about community action to overcome pesticide hazards, ranging from community-based pesticide monitoring in Indonesia, Malaysia, Korea and other Asian countries, to the establishment of a free local health care centre for victims of the Bhopal gas disaster, and to a successful community and trade union campaign in the UK to have Linden banned. The section details practical strategies (including FFS) for sustainable agriculture that can help farmers manage pests while reducing their reliance on hazardous pesticides. Recommended (WR).

Planning for country : Cross-cultural approaches to decision-making on aboriginal lands by Walsh F, Mitchell P (eds.). 2002. 203 p. Jukurrpa Books, PO Box 2531 Alice Springs, Northern Territory 0871, Australia / press@iad.edu.au.
Pictures and stories speak a thousand words. This message emerges from this volume of experiences from central Australia. The editors have created a wonderful reading journey with dozens of evocative pictures, striking photos and stories about well-tried methods. It is clear from their selection of experiences and focused editing that both authors are themselves skilled in participatory planning.

The book opens with a context-setting description of Aboriginal people in central Australia. This helps the reader understand some of specific issues about the Aboriginal context and implications for planning. A section on participatory planning highlights key ethical questions, such as misappropriation of Aboriginal information and Aboriginal language and "high English". This is followed by a series of frequently asked questions that are both thought provoking and practical.

Methods are also discussed in the book. The authors discuss conflicts, problems, and the considerable time and negotiation that are present in all multi-stakeholder participatory planning processes. The stories offer innovative solutions to problems that many others will recognise from their practice. (IG)

Milk producer group resource book: a practical guide to assist milk producer groups by Draaijer J. 2002. 86 p. Food and Agriculture Organization of the United Nations (FAO), Animal and Health Division, Viale delle Terme di Caracalla 00100 Rome, Italy / www.fao.org
This book is part of a series of practical field guides produced by FAO for people working in small-scale dairying in developing countries. Milk producers can increase their income and utilise their skills and resources better if they work in groups. It promotes the organisation of small-scale milk collection and processing as a sustainable, income-generating activity for household food security. It also seeks to provide a means for improving the safety, quantity and quality of milk and milk products available for consumers in developing countries.
This book aims to play a role in poverty alleviation in developing countries, in a gender sensitive and sustainable way. Participation is a key pillar of the strategies promoted throughout the book without gender, age, race, social class or any other bias. The intended readers are (future) leaders of milk producer groups, extension workers, project staff and group promoters who are working to set up milk producer groups, and those developing already existing groups at village level in rural areas.

Traditional use and availability of aquatic biodiversity in rice-based ecosystems; 1. Kampong Thom Province, Kingdom of Cambodia by Balze, T, Balzer P, Pon S. 2002. CD Rom. ISBN 92 5 104820 7. Food and Agriculture Organization of the United Nations (FAO), Viale delle Terme di Caracalla 00100 Rome, Italy / www.fao.org; Matthias.Halwart@fao.org. (Traditional Use and Availability of Aquatic Biodiversity in Rice-based Ecosystems no 1).
This CD-Rom contains the report and annexes of a case study of Tonle Sap (the Great Lake) ecosystem and ricefield fisheries in Cambodia. More than 100 aquatic species (fishes, reptiles, amphibians, crustaceans, molluscs, insects and plants) collected in rice fields and used daily by rural households are presented. The species descriptions and photos are linked to information on collection tools and methods, uses and traditional knowledge. In conclusion, the authors caution against measures threatening aquatic organisms such as pesticide use, clearing of flooded forests and destructive fishing tools, and outline promising approaches for the sustainable management and use of this rich aquatic biodiversity.

Community IPM website
http://www.communityipm.org/index.htm
This site includes many very useful documents and teaching materials related to Farmer Field Schools. It was originally created as an activity of the FAO Programme for Community IPM in Asia. The site is being maintained as an archive of information relating to the groundbreaking work carried out by government agencies, NGOs and farmer groups that were associated with the FAO Programme. The Community IPM website is managed on the principle of "information for all", meaning that anybody can visit the site and download the content.

CGIAR task force on Farmer Participatory Research for Integrated Pest Management (FPR-IPM)
http://www.ciat.cgiar.org/fpr-ipm/inicio.html
A forum for people and institutions interested in fostering farmer participation in research and development of Integrated Pest Management. Visit the file library to download the FPR-IPM proposal and documents contributed by the FAO-Intercountry Rice and Vegetable IPM, CIP/CARE, UPWARD/CIP and ISNAR. These include case studies, evaluations of impact and press releases. If you have case studies or other documents relevant to farmer participatory research for IPM or other approaches to sustainable agriculture, send them to be posted in the file library.

ECOPORT
http://www.ecoport.org/
This Internet portal provides resources and databases on ecology, including information about pests. There is a lot of information available though it is not organised in a very user friendly way. Navigate this site via the columns on the left.

Soil Productivity Improvement through Farmer Field Schools
http://www.fao.org/ag/agl/agll/farmspi/default.stm
The Land and Water Development Division of FAO has just launched this web site on Soil Productivity Improvement (SPI) through Farmer Field Schools (FFS). It provides information on FAO's pilot programme on SPI-FFS. Specifically, it aims at promoting the exchange of information and experiences on the development and implementation of FFS for enhancing and sustaining soil productivity. The site is targeting those involved in developing participatory or FFS land management and conservation programmes, resource persons and senior extension officers as well as agricultural development specialists.

IPM forum
http://www.cabi-publishing.org/IPM/links.htm
This CABI site provides a wealth in links and background material on IPM, included teaching material.

The Communication Initiative
http://www.comminit.com
This website aims to improve strategic communication thinking on development issues, expand dialogue, debate and review of key communication issues and programmes. The work of The Communication Initiative is primarily in support of communication practitioners in developing countries, management staff in local, national and international social development organisations - including NGOs, government, bilateral aid organisations, foundations and academic institutions

Capacity Development Resource Book
http://magnet.undp.org/cdrb/
This resources book presents the lessons from four decades of technical cooperation -and the fundamental changes that UNDP has instituted to capitalise on the potential contributions of capacity development. These processes are designed through facilitative and participatory approaches, and they are responsive and accountable to national priorities and objectives. These characteristics renew the main goals of development co-operation: long-term sustainability and an enabling environment that facilitates human development. This document is available in English, French and Spanish (pdf) and also in English, in html format.

Global IPM facility IPPM expert database
http://www.wisard.org/wisard/clients/ippm/index.htm
This is a directory of experts in Integrated Production and Pest Management (IPPM) from all over the world, including experts on FFS. This joint initiative aims to enhance the access and use of expert knowledge in local and intermediary organisations dealing with IPPM issues.

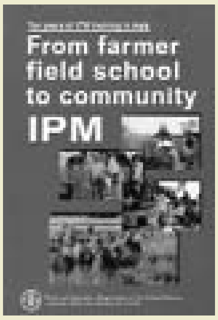
CM-Training Resource homepage
http://www.eseap.cipotato.org/Training-resources.htm
This Integrated Crop Management (ICM) Training Resource for potato and sweetpotato is a compilation of training guides and modules developed within a range CIP projects. It contains both technical background information on the various components of ICM, and methodological guidelines for facilitating farmer learning. These guides and modules can be downloaded, modified and used as needed, provided that reference is made to the original document. The site is managed by a task force of the ICM Working Group.

Links for development change in Natural Resource Management
http://nrm.massey.ac.nz/changelinks/
An on-line resource guide for those seeking to improve the use of collaborative and learning-based approaches.

Participatory Training and Extension in Farmers' Water Management
http://www.fao.org/ag/agl/aglw/farmerwatertraining/default.htm
This site provides training material for participatory training in farmers water management. It aims to provide tools to introduce effective water management technologies and practices, to put farmers in charge in water management, and to establish effective support services. All the material can be downloaded and is also available on CD-Rom. CD-Roms can be ordered by email from farmer-water-training@fao.org

Visit our website: www.ileia.org

Farmer Field Schools: From IPM to platforms for learning and empowerment. Users' perspectives with agricultural research and development. 2003. 83 p. CIP-UPWARD, Los Baños, Laguna, Philippines. ISBN 971 614 023 1.
This publication features highlights of the **International Learning Workshop on Farmer Field Schools: Emerging Issues and Challenges**, held in Indonesia on 21-25 October 2002. It synthesizes global experiences in FFS, derived from 30 case and thematic papers, as well as the outputs of the small-group and plenary discussions. The key lessons, issues and challenges cover the following: 1) Adaptation of FFS from rice IPM to other crops, systems and constraints; 2) Application of FFS for research and development, training and extension, and other learning purposes; 3) FFS institutionalisation, scaling-up and policy development; and 4) FFS monitoring and evaluation. This publication is the first in a series of workshop outputs, which also include a volume of papers and a CD-ROM documentation of the activity. To obtain a copy of the publication, contact Dr. Dindo Campilan, cip-manila@cgiar.org or visit www.eseap.cipotato.org/upward.



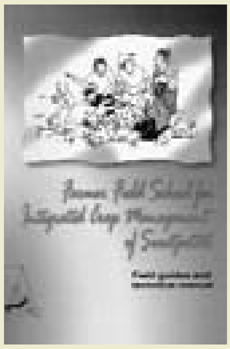
From farmer field school to community IPM: Ten years of IPM training in Asia by Pontius J, Dilts R, Bartlett A. 2002. 106 p. FAO Community IPM programme. FAO regional office for Asia and the Pacific, 39 Phra Atit road, Bangkok 10200, Thailand / www.fao.or.th/Publications; Doris.vonWerner@fao.org; Chongyao.Shen@fao.org
This is a comprehensive account of integrated pest management (IPM) as a farmer-centred and local need-responsive approach, developed on the rice farms of South-east Asia to tackle the risks arising from the excessive pesticide use promoted by the Green Revolution. The FAO programme owes it success to the pioneering Farmer Field School (FFS) approach that was first tried with Indonesian paddy farmers in early 1990, and has since become a model for farmer education in Asia, several parts of Africa and Latin America. More than 2 million rice farmers in Asia have taken part in over 75 000 farmer field schools between 1990 and 1999, boosting their yields and incomes, cutting down the use of chemical pesticides and improving the ecological health of their fields. Above all, it has given them greater control over their livelihoods and greater confidence to face up to new challenges. The publication includes step-by-step instructions on organising and running farmer field schools, along with detailed case studies of farmer field schools in South-east Asia and several personal experiences of farmers who have gained from the programme. A separate section outlines the IPM programme activities in Bangladesh, Cambodia, China, Indonesia, Nepal, Sri Lanka and Viet Nam.

Making farmers better decision-makers through the farmer field school by Rola AC, Provido ZS, Olanday MO, [et al]. 1998. 28 p. ISBN 971 560 013 1. Regional Center for Graduate Study and Research in Agriculture (SEAMEO), College, Los Baños, Laguna, Philippines. SEARCA www.searca.org/SEARCA/publications/books3.html
Farmer Field Schools (FFS) were established to introduce farmers to discovery-based learning in dealing with pest management in particular, and good crop management in general. Their ultimate goal was to improve farmer's decision-making abilities to cope with both biotic and abiotic stresses. This publication describes a village-level case study in the Philippines that measured the educational, economic, and efficiency impacts of the FFS. This four-season study compares decision-making between FFS graduates and non-FFS farmers. (WR)

New ways of developing agricultural technologies: the Zanzibar experience with participatory integrated pest management by Bruin GCA, Zeeman F. 2001. 167 p. ISBN 90 6754 624 0. Wageningen University and Research Centre. Technical Centre for Agricultural and Rural Cooperation (CTA), PO Box 380, 6700 AJ Wageningen, The Netherlands / cta@cta.nl
This work shows that FFS can function in an East African context if certain conditions are met. See the review in issue 18(1).

Facilitating sustainable agriculture: participatory learning and adaptive management in times of environmental uncertainty by Röling NG, Wagemakers MAE. 1998. 318 p. ISBN 0 521 58174 5. Department of Communication and Innovation Studies, Wageningen Agricultural University, Wageningen, The Netherlands. Cambridge University Press, The Edinburgh Building, Cambridge CB2 2RU, UK.
This still-impressive information source examines the implications of adopting more ecologically sound agricultural practices, at the level of both individual farmers and large-scale agro-ecosystems. The emphasis is on human and social aspects, learning through participatory approaches, and appropriate institutional support and policy structure. Examples from around the world are provided. (WR)

Farmer field school for integrated crop management of sweetpotato; field guides and technical manual by Fliert E (van de), Braun, AR. 1999. 101 p. ISBN 92 9060 216 3. International Potato Center, Regional Office for East and Southeast Asia and the Pacific (CIP-ESEAP), PO Box 929, Bogor 16309, Indonesia, UPWARD.
Highly fluctuating prices and a weak bargaining position provide little incentive for sweetpotato farmers to produce high yields. Nevertheless, comparison of yields and profits obtained by farmers in Indonesia showed a tendency for farmers who produced higher yields to earn higher profits. This suggests that farmers can increase profits by increasing their yields through better crop management, and by learning to estimate what the yield is likely to be before entering into negotiations with a trader. How can farmers knowledge and skills be developed so that they can improve their crop management and business capacities? This book gives an answer to this question. Integrated Crop Management (ICM) is presented as an alternative way to tackle these constraints, and FFS as a way of learning about ICM. Approximately one third of the field guides and the technical manual delve into crop protection topics, including numerous full colour photos, suggested training exercises and data recording forms, brought together by cartoon-style drawings. This publication is available in English, Indonesian, Spanish and Vietnamese, and the English version can be downloaded from the ESEAP ICM-Training Resource homepage at www.eseap.cipotato.org/Training-resources.htm



Learning integrated crop management for sweetpotato 1997. CD-Rom with video. International Potato Center, Regional Office for East and Southeast Asia and the Pacific (CIP-ESEAP), PO Box 929, Bogor 16309, Indonesia *UPWARD. http://www.eseap.cipotato.org*
This video examines common constraints faced by Indonesian farmers who grow sweetpotato. It was produced to promote ICM to sweetpotato farmers and to motivate them to attend ICM farmer field schools.

Participatory technology development for agricultural improvement: challenges for institutional integration by Lizares-Bodegon S, Gonsalves J [et al]. 2002. 110 p + CD-Rom. ISBN 1 930261 06 3. International Institute of Rural Reconstruction (IIRR), Y.C.James Yen Center, Biga, Silang, Cavite, Philippines / www.iirr.org; Bookstore@iirr.org, ETC Ecoculture.

This workshop report focuses on the insights, lessons and recommendations derived from formal presentations, analysis of cases, poster sessions, small group discussions, and individual contributions. The workshop aimed at the institutionalisation of PTD in the following settings: research institutions, civil society actors such as farmer organisations and NGOs, extension development agencies, and multi-stakeholder platforms. Each of these settings has a chapter in the report with issues, lessons and recommendations on PTD. The annexes provide abstracts of 19 case studies from all over the world, as well as the PTD framework. The workshop report is also available on CD-Rom, which is useful. It is a pity that the CD-Rom contains only the basic text of the report and one chapter of a related study. IIRR missed an opportunity to provide an extensive information source without much effort. (WR)

Farmer field school on integrated soil management: facilitator's manual. 1998. 218 p. Farmer-Centred Agricultural Resource Management Programme (FARM), FAO-RAP, Maliwan Mansion, Phra Atit Road, Banglumpoo, Bangkok 10200, Thailand / FAO-RAP@fao.org.

The Farmer Field School (FFS) approach on Integrated Soil Management (ISM) has been successfully experimented with at field sites in China, Philippines, Thailand and Vietnam. This facilitator's manual was developed on the basis of these experiences. The objective of the manual is to assist facilitators by providing a basic framework and materials on FFS-ISM. The training materials can help farmers to make their own decisions, to organise themselves and their communities, and to create a strong working network with other farmers, extension workers and researchers. The manual is meant for field-based extension officers, farmer leaders and field-level development workers and their trainers and co-ordinators. It contains a large number of FFS-ISM exercises on general FFS-related topics and a selected range of soil management topics. (CR)

Way out of the woods: learning how to manage trees and forests by Mele P van (ed). 2003. 143 p. ISBN 1 872691 67 6 : EURO 50.-. Marnix Book store, Nederkouter 109, B-9000 Gent, Belgium / info@marnixbooks.be

This book is an account of how the success of forestry and agroforestry projects in three countries (Nepal, Kenya and Bolivia) depends on understanding biological, social and cultural diversity and applying this knowledge to meet the needs of rural people. "Way out of the woods" explores the roles that scientists and rural people play in finding a way to sustainable management of trees and forests. New ideas come from existing knowledge articulated with the help of researchers or local facilitators. This knowledge illuminates the path out of darkness, the metaphorical place in the woods, where the ability to see forward and beyond the trees is restricted. The solutions to sustainable management lie in using local and scientific knowledge and the case histories show how simple approaches can provide new solutions to old problems. An important lesson is that this can only take place if actors trust each other and communication between groups is open.
Profit of the sales of Way Out of the Woods is directly invested in the Centre for Agro-Ecology and Development, the Nepalese NGO who contributed one of the chapters of the book. More information on their activities can be found at http://www.alternatives.org.np/

The group promoter's resource book: a practical guide to building rural self-help groups by Groverman V, Cook J, Thomas G (eds). 1994. 112 p. Food and Agriculture Organization of the United Nations (FAO), Viale delle Terme di Caracalla, 00100 Rome, Italy.

This resource book is now available in electronic version, in English, French, Spanish and Arabic. It shows how group promoters can help men and women in rural communities to join together and work to improve their income and living conditions. It presents a participatory approach in which group promoters play a key role. Their task is to help the poor to form sustainable self-help groups and undertake income-generating activities. http://www.fao.org/sd/2001/PE0303_en.htm

IPM farmer field schools: a work in progress by Quebral, NC. 2002. 54 p. University of the Philippines, Los Baños, 4031 College, Laguna, Philippines.

This publication is based on a Philippine study that centred on the transfer of rice IPM principles to coconut ecosystems. The 15-month study had three objectives: to identify some of the constraints to institutionalising the IPM farmer field school approach, to advise on the social and technological issues arising from the FFSs, and to test research and extension methodologies compatible with IPM concepts. The report provides an evaluation of the project with an overview of constraints and recommendations to overcome them. (WR)

ICRA

23rd ICRA training in interdisciplinary team work for participatory rural development

January 12 - July 23, 2004
(English, Wageningen, the Netherlands)
January 19 - July 30, 2004
(French, Montpellier, France)

ICRA offers an experiential learning programme for professionals working in rural development. The programme focuses on designing interdisciplinary development and research activities for sustainable development.
The programme consists of the following elements:
- 10 weeks - knowledge acquisition, workshops including a field exercise in the Netherlands
- 16 weeks - interdisciplinary team work to conduct a professional assignment for a Client Institute in the South on a specific problem and formulating plans for future action
- 2 weeks - exchange of results of the professional assignments, individual action plans and evaluation.

Requirements: PhD/MSc, 2 years relevant working experience after last degree, age under 40.
The full cost is EURO 29 500 including all travel, accommodation, tuition, field costs and allowances.
A limited number of fellowships are available for candidates from developing and transition countries.
Deadline for applications is 1 October 2003. Applications for fellowships should be received before 1 July 2003

For further details and application forms, please contact: ICRA
P.O. Box 88, 6700 AB Wageningen, The Netherlands
e-mail: secretariat.icra@wur.nl web site: http://www.icra-edu.org

FFS for tree crops

James Mangan and Margaret S. Mangan

Since 1997, Farmer Field Schools (FFS) have been developed in Indonesia for Integrated Pest Management (IPM) in five tree crops - cashew, cocoa, coffee, pepper and tea. Applying the FFS approach to IPM for perennial tree crops has required several adaptations, including changes in content and duration of the FFS, and in the methods employed in Agro-Ecosystem Analysis (AESA). This article is based on our experiences with the IPM Smallholder Estate Crop project (IPM-SEC project) and the SUCCESS Project to control Cocoa Podborer (CPB).

Adapting to perennial ecosystems

The five tree crops mentioned above are perennials. Tree age before complete renewal varies from crop to crop and even from farmer to farmer, but averages around 20 years. The rice ecosystem, where the FFS approach was developed, undergoes destruction and hence catastrophic change during harvest. But the perennial ecosystem remains fundamentally unaltered, particularly in the case of continuously harvested crops like cocoa, which produces fruit throughout the year and cashew, which has three flushes per year. Tea also grows leaves continuously throughout the year. Of these five perennial tree crops, only one - coffee - can be said to have a significant period during which no flowering and fruiting takes place. This means that any pests are presented with two conditions not present in an annual crop like rice or cotton: a continuous food supply and a dependable habitat.

As a consequence, certain mechanical practices are not possible with perennials. One example is the practice of "ploughing down" after a clear harvest, which results in the drastic

Some IPM constraints and opportunities for various tree crops

IPM method	Conservation of predators and parasitoids	Augmentation of natural populations of predators and parasitoids	"Classical" Biocontrol (introduction of exotic predators and parasitoids to control introduced pests)	Mechanical/ Cultural methods for pest control	Use of pathogens for biological control
CASHEW	Excellent control of Lawana sp., Machaerota rostrata (both Flatid Homopterans) and Cricula trifenestrata by natural enemies; good control of Helopeltis by weaver ants and spiders and other natural enemies	Augmentation of Aphanomerus sp., an egg parasitoid of Machaerota rostrata, may be possible		Pruning and cutting back canopy so trees do not touch each other prevents expansion of Helopeltis	Trichoderma can control root rot; Synnematium can control Flatid pests; Beauvaria attacks Helopeltis.
COCOA	CPB has too few natural enemies; good potential for control of Helopeltis and Apogonia with weaver ants; encouraging black ants (Dolichoderus spp.) may reduce Helopeltis and CPB	Some possibility of control of CPB by release of Trichogramma spp., and Goryphus mesoxanthus, but no functioning insectaries		Continuous flowering and fruiting means there is no seasonal die-off of CPB. Pruning, sanitation, bagging pods, frequent harvesting and fertiliser diminish CPB	Trichoderma can control Phytophthora; Beauveria bassiana 725 can be effective against CPB; Beauvaria attacks Helopeltis.
COFFEE	Coffee Berry Borer (CBB) has few natural enemies. Zeuzera coffea, a branch borer, has parasitoids and some predators. Weaver ants may provide some protection against CBB, but there are as yet no experimental results on this.		Complete seasonal harvest prevents establishment of CBB parasitoid Cephalonomia stephanoderis, first introduced in 1989. Ample populations of Coccinelid Curinus, introduced in 1986 to control jumping lice in the lamtoro bean now limits green and white scale in coffee.	Simultaneous flowering and fruiting has not resulted in a CBB die-off; little is known about alternative hosts during the fallow period.	Beauvaria bassiana 615 can be effective against CBB
PEPPER	Lots of jumping spiders and robber flies; a parasitoid Spathius piperis can control the branch boring weevil Lophobaris; as aresult disease, not pests, is the main problem.	Use of green cover crop, Arachis pintoi, to provide refuge for beneficials	Within Indonesia, the parasitoid Spathius piperis may need to be introduced to certain islands like Bangka, where it has not been observed to occur.	Pruning of affected branches can help control the branch borer, Lophobaris piperis	Trichoderma can control Phytophthora
TEA	Loopers are parasitised by Tachinid and Ichneumonoid parasitoids, but there is not a very rich range of spiders feeding on Helopeltis.			Cutting out bushes infected by Ganoderma pseudoferreum, trenching around infected area and applying sulphur	Ganoderma can be controlled by Trichoderma; Beauveria attacks Helopeltis.

Coffee (two level)

Cashew (older tree)

Cacao (pruned to reduce CPB)

reduction of a pest, for example rice yellow stemborer in China or cotton pink bollworm, through destruction of its food supply and habitat.

Pest difficulty

The "natural" condition for perennial ecosystems is one in which the pest is always present in the cropping system. Some tree crop pests are difficult, others less serious. Each crop requires its own observation techniques, its own cultural/mechanical practices, and has its own particular pests and diseases. The most difficult pests, such as Cocoa Podborer, spend all of their larval life inside the fruit to be harvested, invulnerable to natural enemies and pesticides while they are inside. Leaf eaters are a less serious problem (except on tea). There are two reasons to reassess the seriousness of tree crop pests. First, we need to know the true pest impact if we are to figure out mechanical or biological controls. Second, we need to overcome the tendency of pest protection bureaus to exaggerate the danger of minor pests, as this can distort the decisions resulting from weekly AESA.

Ecological IPM began with rice, whose pests all have a rich array of natural enemies, both aquatic and terrestrial. By the start of the FAO IPM Programme, a substantial body of research already existed on the role of natural enemies in the control of the chief rice pest, Brown Planthopper. Compared with rice, very little research on the ecosystems of perennial crops has been done in Indonesia. Tree crops also lack the aquatic element of the rice ecosystem, which provides many beneficial insects and spiders. More research is needed on the habits and biology of the most important pests and beneficials - but lack of research cannot prevent us from proceeding with IPM control methods that work.

AESA in high trees and vines

AESA includes observation of pests, natural enemies, neutrals such as detritivores, disease, and plant nutrition, which should all be taken into account when making a decision on pest management. In rice, this observation is carried out weekly in ten randomly selected spots (hills) throughout the field. It involves the entire rice plant from roots to the tip of the flag leaf. Each tree crop, however, requires its own approach to AESA and its own frequency of observation. Pepper and coffee usually undergo AESA once in two weeks, whereas cashew, cocoa, and tea require weekly observation.

Tree canopies are also much more difficult to observe than rice plants. Some cashew trees grow to more than ten meters high. Some coffee canopies are two-tiered. Ladders are required for AESA on cashew, high coffee, and pepper vines. This also entails some risk - during training, one facilitator trainee fell from a tree.

More complete canopy observation using a ladder should be carried out on one tree in every three, but this is just a rule of thumb. Budding branches in cashew, fruits in coffee and cocoa, and leaf condition must be observed, especially for disease. Roots require inspection for fungus or nematodes. In this way, AESA delivers more information about the ecosystem than any scouting method for simply counting pests.

Adjusting the FFS training season

In the SUCCESS Cocoa Podborer (CPB) project, the content of the FFS was changed radically in order to deal with a single pest. The FFS format was changed to emphasise knowledge of one major pest and the cultural methods that will best control it, instead of knowledge of the entire crop ecosystem through AESA. This adaptation involved shortening the FFS to just seven meetings, five of which were field-learning meetings. In terms of content, four cultural methods for control of CPB were emphasised: frequent harvesting; pruning to open the canopy; adequate use of fertiliser; and crop sanitation. These changes were in large part driven by donor desires to reach all Sulawesi Cocoa farmers with the new technologies.

In perennial agro-ecosystems, there are solid reasons for doing full season training for IPM: ecosystem changes can be followed throughout the crop season, including the outcomes of pest simulation experiments. However, a full season for coffee, including all cultural practices, would be a whole year long if all methods were done in season. This is far too long and costly to be practical. Other crops do not need such a long season. In the IPM-SEC project, a standard FFS length of six months was decided upon for bureaucratic and budgetary reasons, and this is adequate for all crops. Duration was set at 20 sessions for all FFS, regardless of the duration from flowering to harvest.

Assessing the trade-offs

Each crop has its own particular pests and diseases, and requires its own observation techniques and cultural/mechanical practices. Adjustments and changes in the FFS approach had to be made accordingly.

The FFS approach of involving farmers in participatory field learning activities remains a powerful one. In adapting the approach, however, a number of trade-offs are involved. In the case of the SUCCESS project, the adaptations meant exchanging open-ended field experimentation – the classic FFS approach – with teaching a few specific mechanical methods for pest control. The impact of training is still positive and effective, but other consequences of these tradeoffs need to be evaluated.

Towards self-financed farmer field schools

Farmers conducting field observations on groundnuts. Photo: James Okoth

James Robert Okoth, Godrick S. Khisa and Thomas Julianus

The effectiveness of Farmer Field Schools often depends on their financial sustainability. This article looks at several innovations for financially sustainable FFSs that were developed by the East African Sub-regional Pilot Project on Integrated Production and Pest Management Farmer Field Schools, and are now being taken up by a number of other FFS programmes. The cornerstone of these innovations has been the evolution of an initial grant system (semi-self financed FFSs) into an educational revolving fund (self-financed FFSs), supported by the proceeds of commercial plots that are managed alongside the study plots. Involving farmers right from the start has been crucial in successfully implementing these innovations.

Semi-self financed FFS

The semi-self financed FFSs were initiated in 1999 with the introduction of the grant system, in which farmer groups wrote simple proposals for grants to run their FFSs. Figure 1 provides a flow chart of steps in the development of a semi-self financed IPPM FFS. Step One is for a group to submit a proposal in response to an announcement that grants are available. Grant forms include guidelines and application forms for groups. Currently, IPPM FFS grants require that the group have three officers (Chairperson, Treasurer and Secretary) of which at least one is a woman (in mixed gender cultures). Groups must have a multi-signatory savings account and agree to record keeping and audits, and the grant must be used for at least one high value crop and a food crop. The group may also include other topics such as IPPM for poultry. An indicative budget is provided for partial guidance, but it is also stated that extension staff should be paid based on officially published rates, although these can be negotiated. The grant form provides space for background, justification for grant and activities, work plans and budget, and should include the signatures of all group members as well as the local agriculture officer.

Once the grant is approved, Step Two is to transfer the grants to the groups. Typically this is a combination of materials and cash or cash alone. Materials such as flip-chart paper, crayons and other stationary are more cheaply available (or only available) in large cities, so it is more efficient to provide some materials. Cash is provided in at least two instalments over the season, depending on the length of the FFS (for example, annual crops are usually 4-5 months, soil and perennial crops are 12-18 months). The size of the grant for IPPM FFSs is typically US$100 to US$400 per season of study. The grant reporting must include bookkeeping, maintaining receipts and accepting an audit. Grants can in some cases be transferred electronically to accounts, and in other cases they are provided in cash. In many cases the opportunity to handle and control funds has led to increased ownership with farmers providing co-financing as well.

In Step Three, payments to field school facilitators are made directly by the field school group at pre-agreed rates. If the facilitator lacks technical skills, is a poor facilitator or even has inappropriate social skills (arrogance and top-down approaches are leading problems), the group may “release” or “fire” the facilitator – and this has indeed been known to happen.

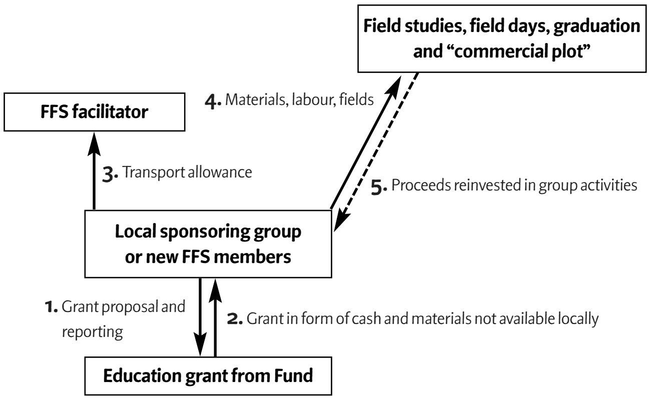

Figure 1. Semi-self financed field school with capital provided by grant and group proceeds reinvested into group activities.

Facilitators receive important feedback from this! If the facilitator does not show up or shows up in an inappropriate state (for example, drunk or late), the group can withhold payment. On the other hand, the facilitators usually receive payment on the day they travel – a far better situation, they feel, than filling out paperwork and waiting for a delayed payment, as is typical of most extension travel allowances. Groups may also request that information on special topics such as soils, nutrition, or environment be delivered by specialised staff, in which case they use the grant to pay transport for the specialist.

IPPM FFS participants also arrange their own field study plots (as shown in Step Four in Figure 1). The study plots are typically 0.2 to 1 ha. in size, and include various educational features – such as comparison trials between IPPM and conventional practices, fertility management methods, and new variety testing. Groups in Western Province, Kenya were the first to begin the “commercial plots” which are larger fields that the group manages together in order to raise more funds. These groups converted the “snack” budget line to field inputs to get started. This has now been institutionalised and it is recommended that all groups have commercial plots. The land arrangements depend on local conditions and include the use of village land, as well as donations from larger landowners and the sharing of crop produce with owners. It is the responsibility of the participants to provide the land and the labour for both the study fields and commercial plots. It is the responsibility of the facilitator to provide a profitable educational activity, including bringing in socially important issues such as HIV/AIDS, women's reproductive health, and soil fertility management.

In Step Five, proceeds from the FFS plots are re-invested in the groups own account. This has now become possible because all grant-recipient FFSs must have their own accounts and means of managing them. The funds are used by the group for further study, and the purchase of animals or other activities. Each group is also requested to assist in training one other group, and farmer-led field schools are quite successful.

As a result of this grant process, groups have shown a very high level of ownership of the FFS process. Many FFSs enjoy a high level of matching funds, material inputs provided by the community and participants, and display an increasing ability to manage funds and activities on their own. Groups become more independent of extension services, and they are also better partners for the extension services – even though many extension services still have difficulty seeing this. The process of applying for grants, making work plans and budgets, organising fields, paying facilitators and managing funds, enables groups to organise themselves to continue on their own. Although FFS grants are intended to support a group for a set time period, many field school participants go on to develop longer-term associations due to the cohesion, trust and joint fund-raising ability developed during the FFS period. The grants provide capital to groups and catalyse new ways of working together. Case studies from various beneficiary semi-self financed groups indicate that if well guided, the groups are able to recover the whole grant after a couple of seasons. As a result, self-financed FFSs are emerging, where the grant has been transformed into an educational revolving loan.

Self-financed FFS

Although semi-self financed IPPM FFSs partially solve at least one issue some of the problems of maintaining the sustainability of farmer groups, extension officers need a new set of funds each season to keep the programme expanding year after year. Thus, new ideas have been sought by IPPM facilitators and farmers, resulting in the self-financed model. The basic difference between this model and the semi-self financed FFS is that the group is the recipient of revolving funds, rather than a grant. The loan-requesting group must agree – by group contract – that they will return the operational costs of the IPPM FFS to the revolving fund. The concept is similar to revolving seed funds, in which one kilogram of seed provided at the beginning of the season is repaid with one or more kilograms of seed at the end of the season. In the case of self-financed field schools, operational costs are pre-financed and the group returns the operational fee at the end of the season through funds raised in the field plots and educational fees.

The model allows very resource-poor farmers to participate, as they are able to help generate funds for the FFS fund by contributing their labour during part of the season. It is conceivable and perhaps even more effective, that instead of cash repayment, farmers could replenish the fund with in-kind contributions.

Operational guidelines are currently being developed on the best way to implement the educational revolving fund, taking into consideration key concerns like the security of the revolving fund from local "leakage" and the problem of payback during drought or flood. The second issue is more problematic, but it is felt that either farmers will have to pay with educational fees, or the repayment could be reduced in proportion to typical yield losses seen in the field. The rationale for the guidelines is the need to come up with an operational framework that can blend into the existing structures such as FFS networks, the extension system, political structures and civil organisations with minimum overhead costs. So far, the FFS networks provide the most suitable structure for handling the revolving fund.

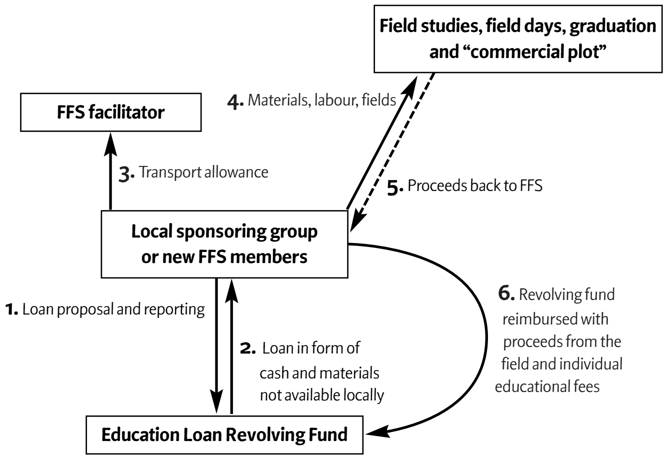

Figure 2. Self-Financed Field School with capital provided by revolving fund. The group reimburses the fund at end of season.

A major concern is the issue of reputation. The model requires that farmers trust the knowledge and teaching ability of IPPM facilitators before signing the contract. Unfortunately, the top-down programmes of the past have given many extension systems a poor reputation, so this may be a very serious problem. Retraining of extension staff into IPPM facilitators with technical and facilitation skills has helped, but the farmers long-term experiences with extension services may be difficult to overcome.

One positive development is the increasing interest of local governments and some NGOs in the approach, to the extent of committing some of their meagre funds to sponsoring the establishment of FFSs. As a result, the FFSs are recognised as a major channel for community development. Similarly, rural micro-finance institutions are also using the FFSs as an entry point for group loans. In Uganda, Village Banks have been established by private sector promotion centres in the three pilot districts, where the FFSs are able to buy shares and acquire simple loans. The same Centres provide financial management skills to the groups. In Kenya some farmers have began pulling together resources and funding FFS activities, the so-called self-sponsored Farmer Field Schools. This level of confidence in the FFSs indicates a very bright future, which will be strengthened more by the self-financing approach. ■

Gender field schools

Mansour Fakih

Since it began in 1989, the majority of participants and facilitators in the successful Indonesian IPM FFS programme have been men. Some efforts have been made from the beginning of the programme to include women, but with limited success. While there are now more women trainers and women participants involved in IPM FFS than in the beginning, evaluations of the IPM Network still indicate that the experiences of women in IPM FFS are different of those of men. Many of the women engaged in IPM felt “there is something missing”, something that has not been understood or addressed. They wanted to see a move from “women’s involvement” to gender equality.

Going one step further

As a result of the ongoing perception that FFSs in Indonesia are still not gender equal, a special programme is now being introduced into IPM activities. This programme is firmly rooted in the participatory approach and aims to make all those involved in IPM FFS aware of what gender discrimination is, and why and how it occurs.

This requires a supportive policy framework, as well as a commitment from the programme staff to integrate gender issues. The National IPM Farmers Association stated its support and established a policy framework for the programme in 2001, providing the necessary framework for the first National Gender Workshop.

The first National Gender Workshop, organised by farmers, concentrated on developing a strategy, a plan of activities and a curriculum that would support a wholly participatory approach to mainstreaming gender into IPM FFS activities. At the same time, farm-level discussions were initiated. Farmers involved in IPM FFS agreed to take part in gender training and curriculum-building activities, as well as to collect information on gender issues that could later be discussed and analysed.

A core team was recruited from amongst women facilitators who were experienced in FFS and interested in gender issues. A gender-training curriculum was set up, using the FFS approach, to introduce and explore the concept of gender inequality in rural communities. The curriculum focused on the actual incidences of gender injustice and sought to inventorise the social and political factors underlying gender inequality. Strategies for effectively collecting information on gender issues and clarifying what gender inequality means at farm level were discussed extensively, and farmers were given a key role in collecting data and in developing family case studies. Farmers enthusiasm for the initiative resulted in a strong process of farmer-initiated knowledge development and gender analysis.

Key questions

Farmers and the core team of facilitators met in field-based provincial and district workshops, where they developed tools that could be included in the first curriculum. During these workshops, insights were gained into how to raise gender consciousness in rural areas and within the IPM network.

Two key questions raised during these workshops were: “Why do we want to introduce gender into IPM?” and “What is in it for

Towards a gender sensitive approach

In 1990-91, during the first cycle of the National IPM programme, it became clear that women had more limited access to and opportunity to benefit from IPM training than men. In addition, Indonesian women often feel less competent than and inferior to men, which can hamper their active involvement in training.

This had serious implications for the IPM programme. Women make up 50% of the farm labour force in Indonesia, and in rice growing areas such as Central Java, agricultural tasks are shared equally between men and women. Not only are women involved in transplanting, weeding, routine observation of the crop, supplying food to hired labourers, harvesting, threshing and selling the harvest, they also have the important task of managing the household money.

In addition, a significant number of women head farm households in Central Java, either because their husbands are migrant labourers or because they are alone. Women with a lower socio-economic status are heavily represented in the female-headed household group. In general, they have low levels of education and tend to be overlooked in development programmes.

The fact that women farmers in Indonesia are often “screened out” of FFSs is a direct result of the inclination of local officials to automatically select male heads of households for IPM training. They also tend to select men from high and middle - income groups. This not only prevents women from participating in IPM FFSs, it also means there is little “trickle over” of knowledge because men in these socio-economic groups often do not farm themselves – they usually hire labour – and they have very little contact with women of lower socio-economic status.

Domestic and educational factors also play a role. Women have household tasks that make it difficult for them to consistently follow weekly FFSs for an entire session. In some sections of Indonesian society, women feel less competent than men and this can inhibit them in group learning situations. For example, in Central Java, it was found that when women were selected for FFSs they participated actively in all activities except those involving group presentations.

Women are not deliberately excluded from IPM training. As one official put it “I just never thought about the issue”. No specific attention had been given to identifying the social conventions and cultural practices that limited women access to agricultural development programmes until, in 1989, the National IPM programme and the local NEO IPM programme, coordinated by World Education, developed a training preparation process that specifically addressed the issue. Gender analysis and needs identification were carried out with farm communities and village officials and by 1995, results showed that in all parts of Indonesia women’s participation in IPM FFS had increased by an average of 15%.

The National IPM programme concluded that women’s involvement in IPM FFS could be enhanced by a training preparation process prior to the FFS, strengthening the role of farmer trainers and extension officers, and emphasising women’s leadership development. After 2001 and on the bases of these experiences, policy was initiated that lead to the development of Gender Field Schools.

Source: Fliert, E, van de and Proost, J. (eds.), 1999. Women and IPM: crop protection practices and strategies, KIT, Amsterdam, 1999. Email elske.vandefliert@fao.org.vn men?" The answer to the first question revealed the depth and complexity of the gender inequality. Women responded in direct and emotional terms. "We are second-class in our own culture" and "We are just followers". They showed they were well aware of the fact that discrimination was accepted as normal *because* women were regarded as second-class people. The question "What is in it for men" was answered during the course of the workshop. Participants concluded that tackling gender issues did not imply an attack on men's status, but could have a direct benefit for the family and community by strengthened women's confidence, self-esteem and status. Exploring problems in the context of gender inequality also opened the way for effective solutions.

In discussing gender inequality, workshop participants made a clear distinction between the biological definition of sexual difference and the socio-cultural concept of gender that included culture-specific roles such as the male breadwinner and the female homemaker.

FFS for gender - Gender Field Schools

The participatory approach chosen for integrating gender in the IPM movement places farmers, both men and women, at the centre. It is a long-term, process-oriented activity. Farmers use their own experiences to identify what exactly gender inequality and discrimination meant to them and they use these insights to make adjustments to their own IPM programme. The members of the core gender team also become the facilitators working with the first farmers groups on gender.

Gender Field Schools have become the basis for efforts to "mainstream" gender in the IPM network in Indonesia. Participants follow five basic steps towards a more in-depth understanding of gender issues in their community.

- The first step is gender training, to raise awareness of gender issues and enable farmers to conduct participatory gender research.
- The second step is data collection. The farmers use their training to identify gender issues in the farmers household and community and collect data on these issues. The data collected are grouped into five categories: access; participation; control; benefit; burden and level of violence.
- The third step is the Gender Analysis. The facilitator helps the farmers analyse the data collected. Farmers come to understand the way local perceptions of gender affect women's lives.
- The fourth step is to plan for action to reduce and eliminate the identified inequalities between women and men.
- The fifth step is monitoring and evaluation. The evaluation helps to identify the activities that will increase women's access to, control over, and benefits from the IPM programme, and expand women's participation in the IPM farmers organisations, programmes and processes.

The development of core groups to pioneer the process of gender mainstreaming in the IPM networks is considered crucial in the process. To start with, the farmer communities to be involved in Gender Field School experiments are carefully selected. For the time being, eight GFS groups have been started, all of them with farmers groups that have previously been involved with FFS for IPM. The GFS are farmer-run and farmer-financed.

After a GFS is conducted, a Farmers Family Crisis Centre (Tim Pembimbing Keluarga Petani-TPKP) is established. The Centre is located in the IPM farmers community. It is hoped that the Centres will help to lower divorce rates, and minimise domestic violence and other forms of discrimination against women. So far, eight such Centres have been established.

Lessons learnt

From the experiences of the farmers IPM network in trying to integrate gender into their development programme, it is clear that if such initiatives are to be successful, farmers must be fully involved and the farming communities participating in the Gender Field Schools experiments must be carefully selected. It is also important that the farmers have prior experience with FFS. Other lessons learnt include:

- Integrating gender into development programme cannot be induced from outside. It requires a process led by farmers themselves, both men and women.
- Gender mainstreaming needs political will and the commitment of the leadership of the IPM programme. A strong effort and appropriate mechanisms are needed to integrate gender into the national IPM structure, and into the activities of the National IPM Farmers Association.
- Gender mainstreaming is a process of education, research and action. Capacity building is therefore essential. Capacity building support has been provided to the farmers to conduct gender data collection and for the creation of an information system, through a participatory approach. The capacity building process should include enabling farmers to establish their own vision, mission and strategies, as well as the organisational structure for mainstreaming gender.

Conclusions

So far, the efforts to mainstream gender have increased the capacity of the IPM farmers networks to integrate gender into their policy, planning and monitoring. The IPM project staff have increased their awareness about their roles in the gender mainstreaming process. The experiences gained through this process of gender mainstreaming can contribute not only to the FAO-IPM project, but also to other groups who are pioneering the field of gender equality in rural areas. ■

The greening of Self Help Groups

Seema Tripathi and Shiraz Wajih

Self-help groups (SHGs) for women living in the Terai of Eastern Uttar Pradesh are moving beyond the usual SHG goal of helping women improve their socio-economic status. These groups are also being utilised to mobilise their members as agents of change and advocates for not only gender issues, but also sustainable agriculture. Farmer Field Schools have played an important role in the capacity building aspect of this "greening" process, which has involved bringing together many different extension and support mechanisms.

Self-Help Groups

The plains in the Terai region, at the foothills of Nepal Himalayas, have good rainfall and fertile alluvial soil. The majority of farmers can be categorised as small or marginal, with average land holdings of less than an acre (about 0.4 hectare). Agriculture is the main source of employment and livelihood in this region.

The area has a feudal background with a caste-dominated society. Rural women of the region have very limited access to credit, information and extension services, in spite of their major contribution to agricultural activities and their ever-increasing responsibilities as their men migrate to the cities. To help empower these women, Gorakhpur Environmental Action Group (GEAG) initiated the formation of women self-help groups in 30 villages in Gorakhpur district. Self Help Groups were originally started in Bangladesh as an innovative and "self help" approach to savings and credit, and have proved effective in empowering rural women.

The GEAG SHGs have grown from three groups in 1996, to a total of 310 groups by mid-2002, with approximately 4500 women members in 30 villages. Most SHGs range in size from 10-18 members and 73% of these groups belong to the category of oppressed classes (Dalits) and small-marginal farming families. The group members make a monthly deposit ranging from Rs. 10 to 20 (roughly US$0.20-0.40c). SHGs have their accounts in a nearby bank. GEAG has ensured a commitment that these banks will provide a loan to the SHGs of up to 4 times their original deposit.

SHGs in a village federate themselves to form a "Sangha". This organisation is entrusted with the responsibility of nurturing SHGs and making collective efforts for the development of village. The self-help groups and the federation, besides facilitating credit flow for consumption and productive purposes, have played a pivotal role in creating a self-sustained agriculture production support system.

Greening the groups

SHGs have been promoted not only as appropriate institutions to help women improve their socio-economic status, but also as a means to mobilise them as agents of change and advocates for gender issues and sustainable agriculture. GEAG has consciously developed the capacity of these groups through a "greening" process, to equip them with appropriate, sustainable technologies, conceptually as well as technically. These "greened" SHGs have been working to promote and disseminate LEISA techniques and practices, and to establish self-sustained, community-owned extension systems. The groups have spearheaded the ecological agriculture movement and become extension agents of green technologies.

So far, approximately Rs.1,200,000 (roughly US$24,000) have been lent by the bank and repayment is almost 100%. The savings and loans obtained are used for agricultural production activities such as purchasing seeds, developing vermicompost, buying agricultural equipment and marketing. This has helped to ensure the women have direct control over these productive resources.

SHG Members adopting LEISA practices

LESIA Practice	Number of SHG Members
Bio-pesticide (cow urine, neem products, tobacco, ash etc)	3100
Composting (pit)	2500
Tree plantation	750
Vermicomposting	432
Liquid compost	528
Nadep compost	238
Seed treatment	940
Seed production	580

The major components of the greening process are as follows:

Farmer Field Schools (FFS)

To facilitate sharing of experiences, innovations, ideas and the dissemination of technical know-how on LEISA techniques, FFSs have been operationalised. The FFS have gained popularity amongst farmers not only from the project villages but also from other neighbouring villages. They are run by experienced farmers, who have extensive practical knowledge of the topics covered. Occasionally, experts from outside are also invited. On average 40 farmers, mostly women, participate regularly in monthly FFS sessions. FFS are managed by the SHGs/*Sangha*, who also decide on the place and topics, on the basis of the felt seasonal demand. There is one such FFS for every five villages in the project area.

Agro Service Centres (ASC)

In order to ensure the availability of quality inputs such as seeds, vermicompost, bio-fertilisers, bio-pesticides, and treadle pumps (low-cost, manually driven pumps for irrigation), and to facilitate direct marketing of these inputs, Agro Service Centres have been established. These ASCs, established in the clusters of 5 villages, are controlled and managed by the women's self-help groups. Soil samples are also collected in these centres for analysis in a small laboratory established by GEAG. This laboratory makes the necessary recommendations on LEISA approaches.

Master Trainers (MT)

A number of interested farmers have become Master Trainers, after receiving intensive training in facilitation techniques and communication skills. The Master Trainers are selected by the SHGs/*Sangha*, according to their background expertise and the specific needs of the area. As the Master Trainers live in the villages, they are always available and also ensure ongoing interaction with SHGs.

There are usually two Master Trainers in each village, and they organise regular training sessions in the village according to the felt demand. These MTs are also invited by other NGOs and projects to contribute their expertise. Tijia Devi, for example, an illiterate woman farmer from Awadhpur village, was invited as a resource person for training sessions organised by CARITAS for its Project Managers in Madhya Pradesh. There are several other examples where farmer MTs have helped orient people towards, and convinced them of the viability of LEISA techniques using the examples of their personal field experiences.

Extension System through the SHGs

The three major components of the "greening" process mentioned above are inter-linked and interdependent. However, there are also a number of other support mechanisms linked to this LEISA promotion system:

- **Laghu Seemant Krishak Morcha (Small-marginal Farmers Forum):** Farmers are unionising in this forum to advocate their interests and promote LEISA, at village, district and state levels.
- **Farmer Interest Groups (FIG) and Participatory Technology Development (PTD):** Farmers with specific needs, problems and interests (such as landless farmers, vegetable growers, seed producers, livestock farmers) are being organised to facilitate more focused interventions and linkages. These Farmer's Interest Groups are formed by members from different SHGs who share a common interest. Non-SHG farmers who share the same interest are also welcome. In the Sardarnagar area they are involved in seed production and collective farming, while in Campierganj most of the interest groups are involved in vegetable growing and livestock rearing. The FIGs are also developed around common problems such as pest and fertility management, and finding solutions through participatory technology development.
- **Demonstration farms:** Farmers have taken the lead in developing their own farms. These are integrated with households and livestock and function as demonstration models of LEISA farming.
- **Experimentation site:** GEAG has provided land where farmers can experiment, take risks and innovate.
- **Awareness Group:** Selected women from different SHGs, as well as interested men, have come together and formed a cultural group to promote LEISA through local culture, for example, through street plays.
- **Soil Health Laboratory:** Through the SHGs, farmers can get their soil samples tested in the laboratory established by GEAG and get necessary advice.

The SHG extension system

Looking ahead

Extension of LEISA practices through women Self-Help Groups has been effective and meaningful. It has ensured that women have access to information, techniques, institutions and the means to experiment with new techniques. Women are able to do better within their recognised roles through the skills acquired and the confidence gained during this process. At the same time, gender-mainstreaming efforts have enhanced their position and contributed to their emancipation. They are now able to unionise and advocate for their rights in a traditionally male-dominated society. Their enhanced control over resources and increased decision-making capacity, backed by the skills they have acquired, have given a meaningful dimension to low-external-input agriculture in the area. The adoption of LEISA practices has significantly reduced the use of high-cost external inputs like chemical pesticides and fertilisers, thereby increasing the net gain to small and marginal farming communities. ■

The Egyptian experience with FFS

Jaap van de Pol

In Egypt, implementation of the Farmer Field School(FFS) approach has posed a number of challenges. This article describes the development and adaptation of FFS in the Egyptian setting, from the initial Farmer Learning Groups (FLGs) through to the more recently established FFSs in Fayoum Governorate, which follow the original FFS concept more closely.

In 1996 and 1997, two Egyptian-German projects started implementing the first Egyptian FFSs for IPM in cucumber, tomato, citrus, mango and cotton. These projects used the basic FFS concept as it was originally developed in Asia, but several modifications were necessary for the approach to function in the Egyptian context. Soon after introduction, the FFSs were renamed Farmer Learning Groups (FLGs). More than 15,000 FLGs, involving 175,000 farmers, have now been organised.

Farmer Learning Groups

When the two projects started to implement their first FLGs, the Egyptian agricultural extension culture was dominated by a high involvement of government in the agricultural production of a limited number of strategic crops, and this is to some extent still true today. For these strategic crops, the government extension units assist farmers with all kinds of support including inputs, marketing and advice. To be able to provide this support, the government established a huge extension organisation between 1978 and 1982, resulting in a very high density of agricultural extension workers. One village extension worker for 130-150 farm-households was, and still is, quite common in Egypt.

Since 1984, the Egyptian government has been working towards greater liberalisation. It therefore welcomed the initiative of the two Egyptian-German projects to increase the involvement of the farmers in agricultural extension. The extension organisation, however, was used to a technology transfer approach - the participatory approach was something quite new. Only a few NGOs in Egypt had obtained some experience in participatory extension. Most of the government field staff and farmers had never experienced working with each other in a "participatory" atmosphere.

Village extension workers were trained as facilitators in a one-week basic training course on Principles of Participatory Extension, and a two-week advanced course on Participatory Extension and Communication Skills. However, a number of challenges presented themselves in implementing the FLGs. When the Egyptian-German projects asked the village extension workers to mobilise farmers for the FLGs, it turned out to be very difficult to organise groups of 25 farmers. Most of the extension workers were used to working only with individual farmers. They started by inviting 15 farmers, but regularly ended up with less than 10 farmers per session. It also turned out to be difficult to organise sessions of 3-4 hours. Farmers were used to officials visiting them. In addition, they were used to the government making it attractive for them if they were asked to participate in an extension activity. Therefore, it was difficult for the FLG facilitators to ask the farmers to invest more than two hours of their time.

Second, the frequency of meetings needed to be modified. In the FLG on vegetables and cotton, the farmers met on a bi-weekly basis, and in the FLG on mango and citrus they met on a monthly basis. As a result, the FLG facilitators spend only a third of the time (14-16 hours) with the farmers compared with their colleagues in the "original FFS" (40-50 hours). Finally, the facilitators found it difficult to offer the farmers principles instead of practices. As members of the governmental extension organisation, they were used to giving farmers the official technical advice on crop cultivation, and farmers were used to receiving clear recommendations from them. This meant that the FLG sessions became focussed on understanding the official agricultural recommendations, instead of educating farmers to become better decision-makers in their own farming system. Farmers hardly carried out any field experiments during the FLGs and most FLG sessions turned into discussion sessions. As a result, most of the educational impact of the FFS approach was lost. An evaluation concluded that the main reason for this was that at all levels, insufficient time had been invested in training, because of pressure to reach large numbers of farmers rapidly.

From FLG to "real" field schools?

Two years after the two Egyptian-German projects started to implement their FLGs, the Egyptian-Dutch projects in Fayoum Governorate started piloting the FFS approach. Making use of the experiences of the two earlier projects, greater priority and more time was given to training the first group of facilitators and to the development of the FFS curricula. Only a few FFSs were established, following the original FFS concept as closely as possible. In 2001, after two years of piloting, the real scaling-up of the number of FFSs in Fayoum started, and the projects were joined together in the Fayoum IPM Project. It is planned to establish 1500 FFSs by the end of 2004.

The FFS facilitators, selected from amongst government extension officers, now receive intensive training. After an introductory training of two weeks, the facilitators continue to receive 2-3 days training per week for one full year. During the other days, they facilitate FFSs under the supervision of a senior facilitator. Besides learning about technical topics, the training pays considerable attention to how to facilitate these technical topics during the FFS sessions. After one year, the facilitators still receive one day training per week, mainly from their colleagues. During these training days, a lot of observations and ideas from field level are channelled back to project management. Most of the modifications and adaptations made in the FFSs were based on these observations and ideas received from the field.

Most of the adaptations made to the FFS concept are a result of the cultural and social characteristics of the local farming communities and the Egyptian extension organisation. The FFSs in Fayoum meet weekly, like the original Indonesian FFSs for field crops like cotton, tomato, and beans, but for fruit crops they meet on a monthly basis. The FFS curriculum focuses on IPM, but is placed in the context of a broad range of crop management topics. Field-crop FFSs last for one year, following a cropping cycle of two or three crops. Fruit-tree FFSs follow a two-year programme. Separate FFSs are held for female farmers. The number of farmers participating in a FFS on field crops is on the average between 22 for men and 25 for women. In the FFS on fruit crops, the average number is 15.

Men farmers discussing the results of their Agro-Ecosystem Analysis in mango during their FFS on fruit crops. Photo: Hans Feijen.

The Egyptian-Dutch project has still not managed to increase the average length of a FFS session. As in the FLGs, the FFS sessions in Fayoum do not last for more than two hours. The main reason for this is that the facilitators find it difficult to do practical things with the farmers during the sessions. The social structures and customs in the local farming communities make it difficult for the facilitators to organise practical group activities. If something practical needs to be done, for example in the study field, it will be done after the FFS session and/or by hired labour. Further, the project is still looking for suitable "group dynamic activities" and "icebreakers". Most of these activities, developed in Asia, do not work in Egypt. The Arabic-Egyptian culture differs too much from the Asian cultures.

Women farmers performing Agro-Ecosystem Analysis in a field with recently transplanted camomile, a popular medicinal/aromatic crop in Fayoum, grown by women farmers. Photo: Hans Feijen.

The process of adapting the FFS in Fayoum has also included adding new elements. Because farmers need education on IPM in relation to more than one crop, the FFSs started to deal with more crops and crop rotations simultaneously. To be able to do this, the total length of an FFS was extended to one full year. Further, a very broad interpretation of IPM was chosen. This broad interpretation of IPM gives the facilitators the possibility to include all crop, pest, soil and water management practices in the curriculum of the FFS. This broadening of the FFS curriculum has made the FFS a more complete tool in agricultural extension.

Although the FFSs in Fayoum differ in a number of characteristics from the "original FFS concept" they are certainly "real" FFSs. They follow the main FFS principle of educating farmers to become better decision-makers. That this is really happening, can be concluded from cases where farmers have continued meeting each other after graduation from the FFSs, and continued to implement some farmer experiments. Further, the farmers attendance during the FFS sessions does not drop during this long period of one year. With 50-52 sessions, in total 100 hours of training, the FFSs in Fayoum are twice as long as the "original" FFS. Farmers are willing to invest their time because they are learning what they like to learn during the field schools, and consider the FFS to be their own activity.

A lot can be learnt from the modification and adaptation process of the FFS concept in Egypt. Starting with the same "original FFS concept" in mind, the process went different ways, resulting in different products. Important lessons learned from these experiences are first, that in an environment where there is little or no experience with working in a participatory atmosphere, it is very important to pay a lot of attention to the training of facilitators and development of the FFS curriculum. Second, the adaptation process of the FFS approach to the local circumstances has to be a joint activity of farmers, facilitators and project management. ■

Picturing Impact!

John Pontius

Over the years, many participatory approaches have been used by the staff of IPM projects in Indonesia to examine the results of IPM activities. The most recent, a photo study in the Ciamis district of West Java, was carried out by Farmer Study Groups to learn about the impact of Community IPM on poverty in farming communities.

A total of three villages were selected for the study, one in each of three different sub-districts, Padaherang, Lakbok, and Cikoneng. By 1999, the final year of the national IPM farmer training project, there existed in all three sub-districts:

- Government trainers who had conducted FFS;
- Farmer IPM trainers who had conducted farmer-to-farmer FFS;
- Groups of FFS alumni conducting field studies;
- IPM trainers who had facilitated technical and planning meetings for alumni at the sub-district level.

Farmer Field Schools for Integrated Pest Management (IPM) began in the Ciamis district in the early 1990's, but there have been no nationally funded IPM activities in Ciamis since 1999. However, numerous activities have been funded or supported by the district governments, by FAO's Community IPM programme, and by the National IPM Farmers Association. Two field workers from Ciamis District Agriculture Services, who were part of the national IPM farmer training project, have been coordinating the support from these organisations and providing technical support to the activities of FFS "alumni" (graduates of the field schools) in the area.

Farmer Study Groups were formed over the last two years as action research groups for FFS alumni. The FSG have become the organisational foundation for FFS alumni in the villages, as they work to establish farmer-led community IPM programmes. The members of the FSG have been conducting various field studies in vegetable and rice production systems. One of the primary concerns of the groups is soil ecology. As a consequence, the groups have worked on issues related to composting and organic soil amendments. The three FSGs have also been assessing the effectiveness of SRI (System of Rice Intensification). The groups have been trying to increase the numbers of farmers applying IPM approaches in their villages. Although there are similarities among the three FSGs, their activities have varied due to the differing social and ecological conditions. These groups and their members are the driving force for Community IPM in their villages.

CINTA ALAM FARMER STUDY GROUP
Sidaharja Village, Lakbok Sub-district

Marsim and Samini are members of the evaluation team

This is rice straw. Before we had IPM, this straw was burned. Now the straw is being composted or turned under. Also we have learned that using a cangkul for field preparation is better for the soil than using a tractor. And once the land is prepared we spread ash. These things help the fertility of our soil. Marsim

This is the yard of my neighbour, a non-alumnus. You can see eggplant, chillies, and cassava. My neighbour used to let this land go to waste. Now, having seen what alumni are doing with organic fertiliser and their back yards, my neighbour is copying them and planting empty ground with vegetables and using organic fertiliser. Now my neighbour has a "living store" that helps with daily needs and provides some income. Marsim

This photo shows the study plots of our Farmer Study Group, Cinta Alam. We have planted vegetables and are using organic fertiliser. The plots help to provide an example for other folks and we learn about growing vegetables and using organic fertilisers. The idea is to help us increase our incomes. Our meeting place is in the background. Marsim

FSG Cinta Alam organised advocacy led to the repair of this irrigation ditch in our village. This ditch was broken and caused our homes to flood. Alumni have helped the whole village by their advocacy to local government to get support to repair this ditch that provides water to over 25 hectares of rice fields. To do the job, 6 million rupee was needed. We collected US$ 2 million from farmers. Negotiations led by Bapak Sukendar, a Farmer IPM Trainer, between alumni and the Public Works Department led to their contributing the other 4 million. The houses next to these ditches use to be continually flooded. The fields didn't get enough water. Now, with the repairs, the fields will get water and the houses stay dry. Samini

Methods

Participatory evaluation should set out to capture the perspectives, voices, preferences and decisions of the least powerful stakeholders related to a given project. In the case of Community IPM, this means farmers. Photographs can be used to help the individual, group or community reflect on itself (Freire 1989).

For the study, five members from the FSG in each of the three villages were selected to become members of the evaluation team. They were mostly the newer members of the FSGs, and their task was to conduct the evaluation study in each of their villages. In brief, the teams were asked to take photographs that showed the impact of IPM on poverty in their villages. Each team member wrote short explanations for the photographs that he or she made.

The study took place in three stages. The first stage was a four-day workshop with three objectives: establishing a perceptual focus for the study among team members; reviewing IPM activities in the villages and what members perceived as the results; and familiarising the evaluation team members with the cameras that they were to use.

During the second stage of the study, team members returned to their villages. Each participant carried a roll of film and a battery for the camera. There was one camera per village and it rotated among the five evaluation team members in each village. Each person had the camera for a day and each could take as many pictures as they wanted up to the capacity of the role of film that they carried (36 photos).

The third stage of the study was a follow-up workshop. During this workshop, team members:

- wrote an accompanying text describing the photographs and made "IPM impact albums";
- analysed their results and made team presentations on the impact of IPM activities on poverty in each village;
- discussed and presented their conclusions about what they learned during the study;
- developed action plans for their FSGs;
- evaluated the study process that they had experienced over the last several weeks.

Below are a few of the photographs and accompanying explanations made by the evaluation team. In a very real sense, each of these photographs portrays the impact of IPM activities.

Analysis and Conclusions

During the follow-up workshop, each village evaluation team was asked to present an analysis of the impact of IPM on poverty in their village based on the data that they collected during the study. Discussion followed the presentations and the teams went on to note that in general, community IPM activities had led to greater creativity, independence, lowered costs and improved incomes.

Growing pesticide-free rice and vegetables with organic fertilisers allows alumni to make ponds in their fields that can be used to produce fish. This provides additional income. Samini

This is the kitchen in Bapak Parijan's house. He uses the ashes from the cooking stove to enrich his soil. He learned in his FFS that wood ashes could be used to create better soil, increase soil fertility, and fight pest and disease in his plants. Nasiman

TURANGGA FARMER STUDY GROUP
Mangunjaya Village, Padaherang Sub-district

Mafahir, Nasiman, Iin Suryanih and Sakiman Holil are members of the evaluation team

This is Bapak Zakaria and his wife. He is an IPM Farmer Trainer and has become the head of his hamlet. He has been a part of Turangga's activities and he is now using ground that was once empty to grow chillies. He uses compost to help improve his soil. Iin Suryanih

A creative farmer makes use of his land by planting mung beans after rice. This yields beans and green fertiliser is made from the leaves of the mung bean plant. These farmers are drying mung beans. Mafahir

The following quotes are further examples of their analysis.

IPM activities have increased creativity among farmers. The teams cited examples including the following:

- "*Trichoderma*, which is an antagonist of *fusarium*, can be used effectively in chillies. Because we want to apply IPM and avoid using pesticides we are forced to be creative to find alternative approaches to pest control."
- "The FFS opened my eyes. Because my family was able to analyse its daily needs and could determine how to try to fulfil those needs by, among other things, using our yard for a vegetable garden, we have been able to improve ourselves. I learned about these things in my FFS."
- "Making use of used plastic bags and plastic ware as pots for planting vegetables"
- The use of inter-cropping and organic fertiliser.
- The use of open land and yards for vegetables and fish ponds.
- "Producing and using "bio-lahang" lowers our dependence on commercially produced decomposers."
- "Before IPM, all farmers were planting certified seeds which were unsatisfactory, now we produce our own seeds which have better rates of germination and higher yields."
- "The application of rice-fish practices."

This creativity has led to either decreased costs or increased incomes, while decreasing dependence on others for inputs and meeting daily needs. Included in the examples presented by the team as evidence of this are:

- "IPM and not using pesticide increases our confidence in using rice-fish culture. The fish will be able to survive. This increases our income."
- "Our studies of SRI in which IPM and soil ecology principles are applied show increased yield rates."
- "Using cow urine to control oteng-oteng (a chrysomelidae beetle) in cucumbers and mustard greens has lowered production costs."
- "Composting of cheap and available organic materials to produce organic fertiliser is a way to overcome the high costs of chemical fertilisers."
- "Producing and using "bio-lahang" lowers our dependence on commercially produced decomposers."

The benefits from IPM activities are not limited to only alumni, but are accessible by all in a village. Examples of this that were pointed out by the team included:

- "Our irrigation ditches were causing problems. For six years in a row, every rainy season there would be flooding. Our group organised activities to lobby local government for repair of the ditches in 1998-1999. These activities resulted in repairs being made (work organised and completed by farmers). The repairs have lowered flooding and fields that once couldn't be planted can now be planted."
- "The use of open land and yards for vegetables and fish ponds. This has lowered dependence on others for vegetables and increased incomes. Many who have not attended an FFS now use these practises. This is just one example of how everyone in a village has access to IPM knowledge."

Produce your own seeds! In the bags are seeds that I have saved. After we studied the problem of seed quality, it turned out that farmers can produce higher quality seeds than we can buy. IPM farmers are not anxious to buy from others. Sakiman Holil

Ibu Uli is collecting rice husks. She uses the rice husks to make compost and she also sells the husks for additional income. Iin Suryanih

This photo shows that composted land is easy to prepare and you can find lots of eels there. The tractor in the picture is working a field that has been heavily composted over several years. The boys are catching eels uncovered by the plough. Sakiman Holil

TIRTA BUMI FARMER STUDY GROUP
Budiasih Village, Cikoneng Sub-district

Yakub Syah, Euis Holisoh, Aleh Soleh and Jarot Indraloka are members of the evaluation team

Our decomposer is made from "lahang" (sugar palm sap), slices of banana tree trunks, and water. Tirta Bumi tested the decomposer against a product called EMBIO, which is quite expensive. Biolahang is the equal of EMBIO. Yakub Syah

During the first workshop, the team developed a "Farmer Poverty Framework" of conditions that they felt arise because one is poor. According to them, poverty leads to:

- Limited opportunities for learning both for children and adults.
- Limited access to a balanced diet.
- Limited scope for work.
- Reduced living conditions.
- Decreased self-regard.
- Increased discrimination.

The framework can be used to determine whether and in what ways Community IPM activities have affected or could affect these conditions. The data show that FSGs and community IPM support a wide variety of activities, from farmer research to advocacy. The data also show how these activities affect the conditions identified in the "Farmer Poverty Framework".

The major conclusion of the evaluation team was that IPM has helped to alleviate poverty in their villages. Besides this major conclusion, the evaluation team concluded that there were some definite benefits in doing this study both for them and potentially for their village:

- "We learned how to use a camera and this is important because we can continue to document the IPM activities in our village."
- "We have analysed and summarised our data and now have a document to show other people in our villages, as well as being able to tell them what we discovered about the impact of IPM."
- "We have been able to discover what is being done in the village because of IPM and can describe the impact of IPM on poverty in the village. This is important for at least two reasons. We can evaluate our activities and improve them. We can raise the awareness of others regarding the importance of IPM in the alleviation of poverty."
- "We understand the characteristics of poverty, its causes, and what arises because of poverty. This will help us to discuss poverty with others and find ways to alleviate poverty."
- "We will be better able to provide leadership in the village related to poverty because the study has motivated us to follow-up on activities that have had the greatest impact on poverty in the village. The study has increased our awareness, confidence and determination."

I took this photo of a goat shed at the edge of the rice field to show how farmers have made it easy to have manure on hand to compost for their fields. Euis Holisoh

The farmer in this picture is watering his plants with a mixture of cow urine and water. Cow urine can keep away hama kutuh daun. Urine replaces pesticide. Aleh Soleh

It used to be that farmers were told what to do by the extension worker. Now we have learned for ourselves how to do such things as reproducing trichoderma. It used to be that only the agriculture department lab made this. Euis Holisoh

By not using pesticides we can create a healthy agro-ecosystem. This makes it possible for farmers to diversify by raising fish in combination with rice or vegetables. Jarot Indraloka

Evaluation in FFS: a burden or a blessing?

Kim Groeneweg and Jorge Chavez Tafur

Looking at the many training and extension programmes currently taking place in the rural areas of Peru, there is not one that does not include the word "evaluation" as one of its activities. On paper, all projects and programmes evaluate many of their activities and resources. In practice, however, the picture is not so clear or straightforward: evaluations are perceived as being very difficult and complex. So much so, that often they simply do not take place.

A short field survey, carried out as part of the FFS process initiated with an FAO IPM-FFS Project in Peru, showed many of the limitations all FFS actors face around the processes of monitoring and evaluations. The following five most significant limitations and difficulties could be identified:

- ***Lack of time and resources*** of FFS facilitators
- ***Lack of ownership*** giving facilitators limited possibility to control and influence the process.
- ***Little experience and capacity*** for monitoring and evaluation, and this experience is limited to the use of quantitative indicators.
- ***Little diffusion or use of what is found*** - evaluation results are seldom published and reports are not distributed.
- ***Negative perception of evaluations*** by field workers who often see them as "control-tools" applied by those in charge.

Trying out PM&E

In this context, the FAO project tried to identify whether and how monitoring and evaluation could become beneficial to FFS trainers and their organizations. It did so by trying out different Participatory Monitoring & Evaluation (PM&E) processes, hoping to throw off the image of evaluation as a burden. PM&E was seen not as a structured set of steps and activities, but rather as a multifunctional toolbox containing guidelines, methods and tools to facilitate participatory assessments, interactions and understanding between the actors involved. In short, the process implemented showed that PM&E is useful to: strengthen institutional involvement; learn and improve performance and link different actors.

A poem presented as part of a final FFS evaluation. Photo: Kim Groeneweg.

Strengthening institutional involvement

The FAO IPM FFS project offered the FFS methodology for potato and cotton cultivation to several institutions, as an alternative to their usual agricultural extension and training activities. However, after a complete training process and implementation phase, many of the decision makers were still not convinced about the effectiveness of the FFS methodology. Many of the "bosses" had very little notion of their field workers' new activity. The achievements of facilitators in their FFS were rarely discussed in staff meetings, neither were they included in the institutions' reports or analyses. Consequently, facilitators received very little assistance from their own institutions.

In order to strengthen the involvement of the whole institution in FFS activities, the project's Board of Directors was asked to evaluate the FFS methodology and to give their opinion on the project's achievements. An evaluation plan was designed jointly with all representatives, requiring their direct involvement in the process. The members of the Board identified their own indicators based on what *they* considered a "good" project should contain. Later, in a full day visit to the field, these Directors implemented their plans, "evaluating" according to their indicators. Returning from the field, they all sat together to analyse and present their results, trying to come to collective conclusions. Their visions, opinions and conclusions were presented the next day to a group of FFS facilitators. This provided an opportunity to exchange perceptions and experiences; to jointly reflect upon the strengths and limitations of the methodology; and to develop a common understanding between decision makers and FFS facilitators.

This brief experience demonstrated that evaluation can be an effective way of provoking interest and involvement, even in those situations where knowledge and interest are initially modest. It showed that actors feel appreciated when their help and opinion is asked for, and moreover, it provided valuable information on the institutions' perceptions, interest and values. After having evaluated the FFS methodology, the members of the Board who participated in the evaluation showed much more interest in and appreciation of the methodology. At the same time, the project workers gained a much better idea of the Board's point of view.

Improving immediate performance

Two main evaluation activities are common to all FFS training processes. The most significant is Agro-Ecosystem Analysis (AESA). This is based on a series of field and crop observations carried out during the whole cropping season. Farmers are trained in various AESA tools, which enable them to make informed decisions on crop management. A second integrated evaluation approach is the "ballot box", an exercise involving tests that measure farmers understanding and abilities before and after an FFS training season. This is usually based on relevant, practical agro-ecology such as crop growth strategies, weeds, insect pests, the damage they cause and their natural enemies.

In both AESA and the "ballot box" exercise, evaluation is considered an essential element for farmer learning. It is accepted that field evaluations improve farmers capacities. So why not utilize evaluation to improve the capacities of facilitators and other actors involved in FFS? This was tried in the context of the IPM-FFS project, with the objective to ensure quality throughout the whole FFS implementation. Evaluation was considered part of a process rather than a separate activity. Facilitators were encouraged to evaluate *every* FFS session, to reflect on their own performance and carefully prepare each new session. In addition, PM&E tools were elaborated to strengthen the analyses of IPM, crop production and experimentation results. This meant focusing on evaluation not only immediately after harvesting, or at the final session of the FFS training process, but at each stage of the training process, as a continuous activity included in each FFS session.

In a short training session on participatory methods, all facilitators designed PM&E plans for their field schools. Each plan identified clear objectives for evaluation, including who should participate and what inputs were required. A set of indicators were selected to be discussed and analysed with the participants, including for example yields, costs, quality of product and the presence of pests. Issues of immediate relevance were discussed in every meeting, such as those related to the facilitator's performance, the topics discussed, the whole learning process and interest showed by participants. Practical methods and tools were also used that could be easily applied in farmer communities such as matrix scoring, role plays, songs, poems, letters and drawings.

Both farmers and trainers expressed their satisfaction at being able to exchange opinions and discuss items of importance in a relaxed and entertaining way. The methods enhanced not only the interactions between facilitators and farmers, but also reinforced the interfaces between farmers themselves. Facilitators emphasised that PM&E improved their relationship with farmers and provided them with valuable feedback. This left them feeling a lot more secure about their performance and motivated to improve their FFS. At the same time, farmers felt appreciated and enjoyed this dynamic way of evaluation.

Linking actors

PM&E tools and methods were also used to create platforms for discussion between the different actors, both to validate the FFS methodology and to stimulate interaction. Various types of workshops were organised with the participation of representatives of the different institutions, facilitators, farmers, and members of the FAO Project.

In every workshop, members of each group were invited to define the most important aspects to be evaluated. This showed clearly that each actor or group of actors had different backgrounds, interests, and expectations, which did not always coincide with the FFS principles. A thorough analysis was needed to gain an understanding of these different backgrounds and objectives, and to determine the type of benefit that the FFS methodology could provide to the specific actor. It was noted that with indicators of their own choosing, each actor found it easier to analyse both the process and the results achieved through the FFS. Farmers appreciated the opportunity to express their opinions, analyse the achievements and limitations of the methodology and identify future plans. These workshops made both the project and actors aware of the different perspectives of those involved, opening a door for increased co-operation and common work.

Participatory Monitoring & Evaluation in the FFS cycle

COMMUNITY AND PARTICIPANT SELECTION

- ▶ Baseline study (needs and problem analysis using PRA tools)
  Mapping of farmers practices provides material for final evaluation
- Introduction of the FFS methodology to the community
- Selection and inscription of participants

PREPARATIONS

- Elaboration of curriculum, official FFS agreement and time-schedule
- Training norms, group forming and identification of role of host team

GETTING STARTED

- ▶ Pre-ballot box test
  Evaluation of participants knowledge, to adapt training and monitor advances
- Analysis and design of FFS
- Analysis of soil health and fertility and selection of seed
- Field preparation
- ▶ Introduction of record keeping for all expenses
  Tool for analysis of field production results (cost-benefit analysis)

IMPLEMENTATION OF FFS TRAINING SESSIONS

- Opening
- Review and evaluation of agreements
- ▶ Agro-ecosystem analysis (AESA)
  Decisions on pest management made based on field evaluations
- Special topic
- Group dynamics and energizers
- Agreements and compromises
- ▶ Evaluation of session
  Decisions on content and process are based on evaluations with all participants and trainers at the end of every FFS session

HARVEST AND ANALYSIS OF FIELD RESULTS

- Analysis of production and ICM
- ▶ Evaluation of FFS process and activities
  Participants develop indicators for analysis of field results, the process and activities,using PRA tools & baseline study data
- ▶ Post-ballot box test
  Final test to assess participants' advances which can provide a basis for planning follow-up activities
- Planning of future activities
- Closing ceremony

Limitations

Various constraints and limitations were also identified in the use of PM&E. First of all, the methodology is relatively unknown, and it usually requires those involved to change some of their attitudes. Undoubtedly, this also means changes in the institutional policies and M&E methods and tools currently applied, something that is not likely to happen overnight. It should be mentioned, however, that within the existing systems there are many possibilities for this approach, as more and more development organisations and fieldworkers share a positive view and express a need for *participatory* methodologies.

A recurring problem is that few facilitators have the necessary skills. Therefore, intensive training is recommended in rapid and practical methods and tools for PM&E. Assistance is also required for strategic planning to develop location- and actor-specific PM&E mechanisms. Considering FFS practitioners lack of time and resources, development of easy, fast, dynamic, time and cost-effective PM&E methods is necessary.

Conclusions

The activities implemented showed that PM&E enhances involvement by inviting key actors to evaluate activities, leading to an increased sense of ownership. PM&E activities strengthen participation, raise awareness of the current situation, and enhance the willingness to continue participating. They encourage dialogue and motivate actors to look closely at the situation and develop an opinion. Interaction and understanding between the different actors is stimulated through the creation of platforms for dialogue.

As with other kinds of evaluation, time and resources are limited. There is still, therefore, a need for simple and fast methods, and specific training programmes are required. PM&E requires clear and well-defined objectives to avoid unnecessary and ineffective work, which, not surprisingly, is perceived as a heavy burden. Efforts should be made to include evaluations as an integral part of FFS implementation, rather than a separate activity.

PM&E encourages learning, as it generates feedback and self-reflection. It motivates FFS facilitators and farmers to improve their activities and skills because they themselves identify what is achieved. They become aware of their own strengths and weaknesses, and of the results of their actions. Hence, PM&E enhances peoples self-esteem, confidence and motivation to improve their activities undertaken. In contrast to conventional evaluations, PM&E has the *power to empower*.

Community forest management and FFS

Hukum Singh

Sharada Devi forest has been protected and used by local communities under community forestry arrangements since the 1980s. Here, as in many other parts of Nepal, the rights and responsibilities for forest resource management have been successfully transferred to the local Forest User Group (FUG). However, although the condition of both forest and water resources have visibly improved under these arrangements, the flow of products from the community forest is far below its capacity for sustainable production. Community forestry has succeeded in protecting the forest, but has failed to provide the expected benefits to users. The main reasons for this are a tendency to over protect community forests, and a lack of forest management support to the FUGs. Recent initiatives to set up Farmers Forest Management Schools (FFMSs) have attempted to address these issues.

What are Farmers Forest Management Schools?

Farmers Forest Management Schools (FFMS) are fora for group learning. The FFMS aim to add value to community forestry practices by developing ways of managing the forest to ensure that it yields substantial benefits to its users. FFMSs bring farmer users and forest management practitioners together to explore ways of combining the principals of formal forestry science and technical forest management with local community experience and knowledge. Together, they are able to develop methodologies for active management of community forest areas. Through training and joint action, the formal science of the facilitator and the knowledge of local farmers interface to become a new body of knowledge. With these insights, FFMS can facilitate a process of negotiation that can result in new plans and principals for forest management (see table p. 14).

Sharada Devi Forest User Group

The case of the Sharada Devi Forest User Group illustrates one set of experiences in integrating FFMS into community forest practices. The Sharada Devi FUG is located in the middle hill district of Kabhre Palanchok, about 25 km east of Kathmandu, at an elevation of 1500m. The FUG had been registered with the District Forest Office since 1993 and has been granted authority to manage the forest. Prior to this, community forestry practice was based on traditional institutional arrangements.

The Sharada Devi community forest covers about 44 hectares. It lies above the village and consists mainly of *Schima castanopsis* (Katus-Chilaune) forest. The principal tree species are *Schima wallichii* (Chilaune), *Castanopsis tribuloides* (Musure Katus) and *Myrica esculenta* (Kafal). The forest is mostly at a young stage with vigorously growing saplings. However, in terms of stocking levels and volume of timber, it is in a moderate to poor condition.

Most of the 152 households affiliated to the Sharada Devi FUG are farm households but some farmers also have off-farm employment and businesses. Most households depend directly on drinking water sources found in the forest area. Local people have observed that both the forest and the water sources have improved since they were formally handed over to the community.

The FUG in Sharada Devi is represented by an elected executive committee consisting of 13 members, including two women. Negotiations and compromise among village-level political parties has resulted in all major political parties being represented on the committee. The only group without representation are the lowest caste, the Dalits.

Piloting FFMS in Sharada Devi

The idea of using the FFMS approach originated during a national level training workshop for forest rangers and project staff organised by the Regional Community Forestry Training Centre (RECOFTC).

Good training is an important aspect of FFMS, and therefore capacity-building for facilitators and selected users from the FUGs was the first step. A training workshop was organised for 16 men and women from the FUG who were interested in taking part. Facilitation training for the FFMS was carried out through a process of questioning, brainstorming and field practice, and included the development of action plans.

Consultations then took place with the FUG committee, and an informal FFMS group was established.

With help from the Nepal-Australia Community Resource Management Project (NACRMP) and RECOFTC, the FFMS began to experiment with different silviculture options. Three trial plots were established and the way the forest regenerated under various thinning intensities was observed and analysed. The trials had three specific objectives. First, to establish an appropriate cutting regime and determine how frequently, when and with what intensity *Schima-Castanopsis* forest should be harvested in order to maximise fuel wood production. Second, to demonstrate the effects of different forestry management practices to FUG households and third, to introduce FUG members to innovative forest management practices.

As data became available, project staff helped those involved in the experiment to record their results in a register (see box). Although this way of recording data and assessing results was foreign to most households in the FUG, they were also able to observe directly the effects of different treatments on the experimental plots.

Some findings of the FFMS trials in the Sharada Devi Forest

- Farmers observed that tree growth in the coppice system (vegetative re-growth from tree stumps) was many times better than in control (protection only) systems.
- Kali Mayal had the fastest growth rate, followed by Musure Katus, Chilaune, Kafal and Phalaat.
- Musure Katus had the highest vigour in terms of capacity to produce the maximum number of shoots.
- Musure Katus grew better in a coppice under a standard system than in a coppice with clear felling. Chilaune performed well in a coppice where there was a clear felling system. Phalaat performed equally in both systems.
- The shorter the stump height, the better the health and growth of coppice shoots.
- The appropriate girth size (or circumference) of the stump was between 25 cm and 50 cm for all species.

Positive impact

The men and women taking part in the FFMS reported that the most successful part of the programme had been the collection of data on forest growth. Working closely together, they observed the rate of growth of different species of trees, analysed the data and verbally presented the results of what they had learned to the members of the FUG Committee. The group assemblies were used to inform other members of the FUG how experiments were progressing.

During the trials, many non-FFMS members passed by the experimental plots to see what was going on. Some of those who had initially criticised FFMS participants for destroying the forest in the name of their experiments later made it clear they valued the results, and suggested that other trial plots should be established to investigate other aspects of forest management. During the trials, the FFMS participants carried out most of the activities. Project staff provided support during the application of different treatments, and when measurements and data analysis were being carried out.

The results of the Sharada Devi FUG FFMS trials provided the group with information relevant to the development of appropriate community forest management practices for their region.

However, despite farmer enthusiasm for the trials, there are very real challenges when it comes to translating the results into practice. Although RECOFTC and some of its collaborators have clear objectives as far as FFMS are concerned, the continuation of the FFMS process is far from certain once project staff have withdrawn their support. Although the Sharada Devi FUG trial plots indicated ways in which the availability of fuel wood could be maximised, these insights have yet to be incorporated into the formally approved forest management operational plan for the FUG.

Challenges

The value and innovative aspects of the FFMS have been acknowledged, and to some extent absorbed by some of the participants and service providers in experiments such as those conducted in Sharada Devi. In practice, however, the full

Potential added value of the FFMS to Community Forestry (CF)

Elements	Current practice of CF	Possible added value to CF
Regime type	Protection only	Sustainable production
Management Objective	Subsistence – fulfilment of basic needs	Considers both subsistence and commercial production of forest products
Management mode	Passive management, focusing on selection felling of dead, diseased and dying trees	Active management, focusing on timber and non-timber forest products
Source of knowledge and technology	Based on farmers experience and local knowledge	Both local knowledge and formal forestry knowledge
Emphasis on communication	Among community members only	Between community members and outsiders
Model of Technology Transfer	Training, publications, extension materials	Demonstration, observation, memory, verbal
Main role of facilitator	Capacity building of local institutions	Capacity building of local institutions, and also facilitators' own capacity building working together with communities
Who is involved?	Committee & local elites	Committee, user groups, facilitators & community
Who generates the technical information?	Outsider facilitators, forest technicians and professionals	Facilitators and users together
Who implements the programme?	Facilitators train the users, and users implement programme	Both facilitators and users learn together and users implement the programme
Who monitors the programme?	Service providers	Both users and service providers

potential of the approach has yet to materialise. Following are some of the challenges that can be identified from the experiences of the Sharada Devi FUG in implementing FFMS.

First, the on-site training was conducted by outsiders and little attention was given to strengthening the FUG itself. Project staff from RECOFTC were required to train under-paid and overburdened middle-level managers in the skills they needed to facilitate the FFMS process. However, creating new knowledge and developing good facilitation skills does not necessarily mean that these managers will provide the sort of support a community needs to manage its forest resources in a sustainable way. In addition, not all facilitators will be equally effective, and some will be more committed to setting up FFMS sites than others. This means that the process of developing a methodology for forest management using the FFMS approach must take into account the need to strengthen the capacity of local institutions such as the FUGs, and the need to ensure that appropriate institutional changes take place at government level.

Second, a broader uptake of the FFMS approach has been hindered by a lack of information. Currently, information and publications on the FFMS training approach, methods and process is limited and only accessible to very few people, even at the level of service providers such as the District Forestry Office. In addition, most of the literature on FFMS is published in English. Access to this type of information is therefore limited to those in donor-funded organisations who can read and write English. Equally important, no materials have been developed so far for illiterate community members.

Third, very little attention has been given to organised training, demonstrations and exposure visits on FFMS for community members. In those FUGs where FFMS are being initiated, very few people are actually involved in planning, designing and implementing FFMS. Those who are involved are usually committee members or persons selected by the committee. The majority of FUG members do not know how selections are made, what an FFMS is or what it is designed to do.

Finally, social issues including the exclusion of the Dalits and women from FUGs and FFMSs needs to be adequately addressed. The issue of social exclusion has been raised by many different development organisations, and is discussed during facilitator training. In practice, however, Dalits and women are still excluded in many cases. This implies that they are excluded from planning how forest products should be extracted, setting prices, and deciding when to harvest and how the harvest should be distributed. In defence of the FFMS, it has been argued that the FFMS in Nepal is still a pilot programme, and that marginal groups can be included later when the programme is better established.

Opportunities

Despite the challenges mentioned above, the experiences of the Sharada Devi FFMS also show that FFMS have had a positive impact, and that there are opportunities for developing the approach further.

The need for a production-oriented regime is now widely accepted among professionals and community members, and there is a consensus that the current focus on forest protection should be changed to one of active management. Some FUGs have begun to manage their forests in order to optimise their productive capacity. Visits by FUGs and professionals to FFMS sites have resulted in FFMS being facilitated in an increasing number of areas. Lessons continue to be learned from those sites where FFMS are more established.

There is considerable donor support for community forestry projects in almost every district in the hills and also in some districts in the Terai region. This means there are human and financial resources available to carry out forest management activities so that the condition of the forest resources, and the people who depend on them, can be improved. More than 11000 FUGs have been established throughout Nepal, and many of them are functioning well and are willing to adapt to active forest management. There is also an enabling policy environment. Community forestry legislation is in place and FUGs have their own operational plan that allows them to carry out harvesting operations and to market forest products themselves.

A Forest User Group harvesting their forest. Photo: Hukum Singh

Conclusion

Experience has shown that during the process of developing the concept of FFMS, a number of basic challenges must be faced. Facilitators must have enough institutional and organisational support to enable them to work consistently and effectively. Also, fundamental issues such as appropriate follow-up training, and making forestry officials in general more aware of the potential of FFMS, must be dealt with, as well as constraints of time and finance that can inhibit facilitator effectiveness. On another level, the policy and legislative environment and current practices – including procedures for drawing up and ensuring compliance with operational plans for timber production – must all be taken into account when new approaches are being negotiated.

Today, in addition to the District Forest Offices, there are many service-providing organisations, including bilateral projects, NGOs, local organisations and the FUG federation, who are willing to support the community forestry programme. Synergies between their competencies, roles and responsibilities can be utilised to convert the current protection-oriented regime of the community forests into a sustainable production regime. FFMSs have a role to play in this process, as the Sharada Devi experience has shown. ■

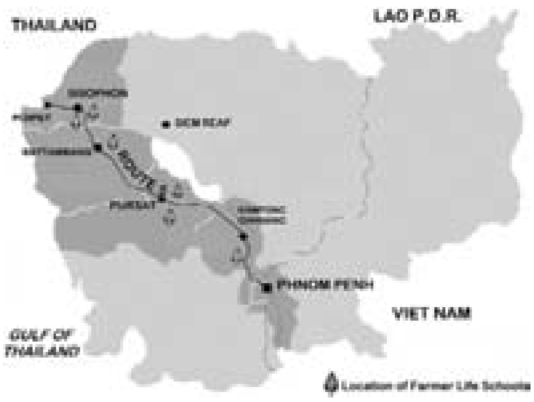
Farmer Life Schools in Cambodia

Polo Yech

National Route 5 in Cambodia is part of the Trans-Asia highway linking India, Thailand, Cambodia and Vietnam. Since the border between Thailand and Cambodia reopened in 1998, traffic and cross-border trade has increased rapidly, along with a corresponding increase in the mobility of people along its route. The highway is being upgraded to further increase the flow of goods, services and people. Unfortunately, as the movement of people along the route increases, so does the spread of HIV/AIDS.

Cambodia is one of the major centres of HIV/AIDS infections in South-east Asia. The epidemic is having a devastating effect on rural populations that already live in poor conditions. In addition, the situation has created a population highly vulnerable to diseases such as HIV/AIDS. HIV can develop rapidly.

To tackle the rapid spread of HIV/AIDS, and the increasing vulnerability of the rural population to chronic illnesses, the UNDP South-east Asian HIV Programme and the FAO Community Integrated Pest Management programme decided to develop a pilot programme based on Farmer Field School community strategies. The learning principles and processes of IPM FFS were successfully applied to HIV/AIDS work, and they are now being used to strengthen the resilience of farming communities to HIV/AIDS through “Farmer Life Schools” (FLS). Importantly, FLS are organised through a network of farmers who have completed IPM FFS, and who are motivated to work on other issues affecting their livelihood.



Location of Farmer Life Schools along Route 5.

Empowering communities

The goal of FLS is the mobilisation and empowerment of farming communities to reduce vulnerability to HIV/AIDS and other threats to people’s livelihoods. Health issues are approached in a holistic way - HIV/AIDS is seen as only one part of the issue of chronic illnesses that affect farming families in the region.

FLS aim to:

- Strengthen farmers understanding of how their socio-economic vulnerability leads to risk-taking behaviour;
- Prevent adverse social and economic effects from HIV/AIDS and other threats in farming communities in the project areas; and
- Establish a farmer network to better address local issues in the interests of sustainable farm livelihoods.

From FFS to FLS

IPM FFSs are potentially an excellent entry point for a wide range of community development activities. The discovery-based learning approaches applied in FFS can help farmers to gain a deep understanding of ecological concepts, as well as their practical applications. This approach to identifying problems and alternatives for solutions has been developed to help understand the agro-ecological principles underlying IPM. However, the same processes can be easily translated to HIV/AIDS and other livelihood issues. FLS approaches help to develop farmers critical thinking on the relationships between human behaviour and important livelihood issues, much like the study of field ecology helps to understand relationships between plants and the other organisms which affect their growth.

Farmer Field School	→	Farmer Life School
Crop Ecology	→	Human Ecology
Integrated Pest Management	→	Integrated Livelihood Management

From Farmer Field Schools to Farmer Life Schools

What is a Farmer Life School?

Farmer Life Schools are based on a non-formal, experiential learning process, similar to the FFS. Often, the FLS is a natural follow-on activity from a previous IPM FFS. A FLS consists of a group of about 20-25 farmers who meet somewhere in the village, one morning a week for 18 weeks.

The curriculum design of the FLS follows the same general processes used in the ecology-based FFS, but with a different content. While the main learning context in an FFS is the field, the FLS is based in the community, addressing the complex range of issues related to farmers livelihoods. Each weekly meeting consists of a defined set of activities: Human Ecosystem Analysis (HESA), presentation of the HESA, a special topic and group dynamics.

Human Ecosystem Analysis

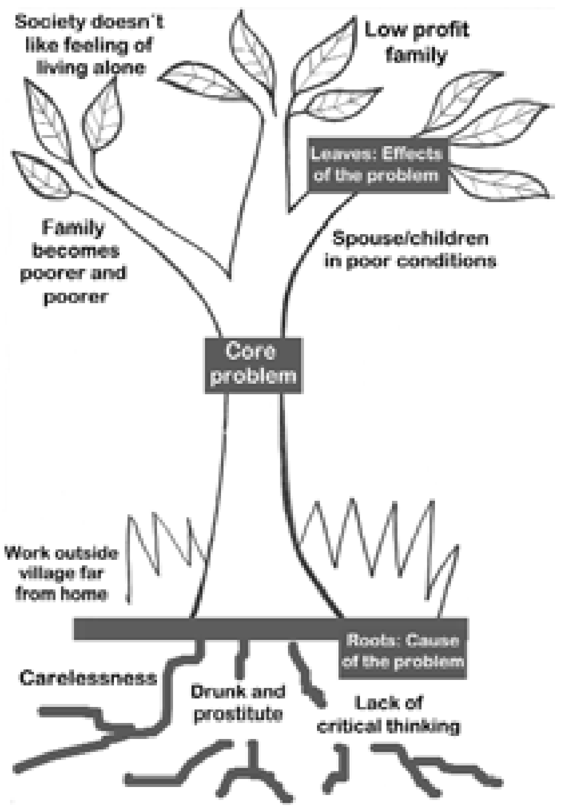
In FFS, farmers learn through the process of Agro-Ecosystem Analysis (AESA) and field experiments. It is a discovery-based learning method using field observations, discussions, and analysis, sharing among different groups and making appropriate decisions to manage their crops better.

Human Ecosystem Analysis is a similar process developed for the FLS, and it is used during each weekly meeting. In HESA, the farmers research issues related to their daily lives. They prioritise issues and select families for further investigation in smaller groups. They share their findings and select topics to study in-depth to achieve a more holistic understanding of the way people live and the factors that contribute to or detract from a healthy life. From this, they can make decisions on how best to eliminate risky behaviour (in the case of HIV/AIDS) or other threats, and adjust their lives so they are healthier and more peaceful. The HESA process is used as a basis for group discussion and decision-making as well as individual decision-making. Discussions identify factors that support or do not support positive behaviour and usually include topics in six categories: health, family economy, family education, social relationships, environment, and culture. The topics selected for discussion during the HESA process depend on the farmer's needs and interests.

An important HESA process is the observation and interviewing of selected families within the community. Usually, three families are identified for further investigation of each issue raised by the group. Participants are divided into three smaller groups to observe and discuss these issues with each of the three families. They try to help understand the root causes of the issues being examined, as well as their present and future impacts on the family. Farmers use a problem tree method to discuss and analyse issues. They then discuss what alternatives are available to resolve the problems faced by the families. Farmer Trainers play a key role in facilitating this process, and provide appropriate inputs/suggestions to the person interviewed to improve his or her life situation. No specialists or experts are involved to offer solutions or strategies.

After each group has compiled their findings and drawn their conclusions, they make presentations and share them with other groups. Then they discuss together to compare the root causes and the impacts of each issue on the different families. The interviewees are informed of the discussions and suggestions of the group.

The HESA promotes learning, critical thinking and analysis by farmers of real life situations in their own communities. They learn from the different lives and experiences of people in their community, and use this knowledge to help strengthen the livelihoods of other families. Through improved understanding of how various factors impact upon their lives, they become willing to make changes to reduce risky behaviour which might lead to chronic diseases such as HIV/AIDS, and plan to achieve healthier and more peaceful lives.



Copy of a problem tree analysis used during the HESA process of a FLS.

Special topics

After the presentation of the HESA, farmer participants discuss and select topics for further investigation and study. The topics can include health, problem cycles, ageing, human needs, daily behaviour of farmers, resources in the community, life skills, communication related to farmers living in the community, farming, marketing, and other social issues. These topics contribute to increasing farmers knowledge, awareness and realisation of what they need to do to improve their livelihoods. Group dynamics activities are also included in the curriculum to help participants relax and develop closer trust and friendship.

Follow-up activities

The end of the FLS is not the end of the learning process. Farmers need to continue to increase their knowledge and the capacity gained from the FLS. After the FLS, the graduated farmers and farmer trainers still meet regularly to discuss and review the decisions and the action plans they have developed. They discuss future plans to improve their life skills related to health and agriculture. They often initiate training or exchange visits, or start farmer groups or associations to build their networking capacity and help reduce poverty.

Impacts

Some of the impacts from FLS include:

- Farmers develop the ability to identify and analyse issues facing their communities, including the threat of HIV/AIDS.
- Farmers become aware of the possible consequences of risk-taking behaviour related to HIV/AIDS infection and other public health threats. This leads to a reduction in risk-taking behaviour.
- Farmers become trained and develop skills in leadership, networking, training, planning and organisation, to the benefit of their communities.
- Farmers initiate activities to help their communities after the FLS. Examples include the establishment of self-help groups or farmer associations (e.g. savings account, research group on rice, vegetables or animal rearing).

Important lessons learnt

FLS provides farmers with an opportunity to learn in a way that relates directly to their own lives.

They help farmers to become more positive towards change, to express their feelings and to share experiences with each other. Before the FLS they always felt shy and kept problems to themselves. They never discussed these with others, not even with their family members.

The FLS helps farmers to form an informal network with its own identity - an identity they create themselves. These activities will become increasingly important in the future fight against poverty, HIV/AIDS and other social problems affecting their communities.

They also provide farmers with the chance to take charge of their futures, rather than waiting passively for help from outsiders once a threat has arrived.

Farmer Life Schools are making a valuable contribution to the sustainable livelihoods of rural communities.

Field schools for Kenyan dairy farmers

B. Minjauw, H.G. Muriuki and D. Romney

In the Central and Rift Valley Provinces of Kenya, approximately 90% of rural households are agricultural and of these, 73% have dairy cattle. Studies in Rift Valley Province have shown that smallholder farmers consider the major constraints to increased dairy production to be endemic diseases, particularly tick-borne diseases (TBD), and inadequate supplies of feed resources.

Currently, over 1000 Farmer Field Schools (FFS) on integrated pest management (IPM) and/or integrated soil management are being successfully implemented in Kenya - and many more in Africa as a whole. Can the FFS methodology be developed for similarly complex issues like animal production and health, where responses to interventions may not be as fast?

A sub-group prepares their AESA presentation. Photo: Bruno Minjauw

In 2001, the DFID/FAO project on Farmer Field Schools for livestock began adapting and testing the FFS methodology for animal health and production, focusing on smallholder dairy farmers. Ten pilot FFS have been established in five different agro-ecological zones in Central, Rift Valley and Coastal Provinces of Kenya. In implementing these FFS, Agro-Ecosystem Analysis (AESA, see Gallagher page 5) is adapted to make animals the focal point, and participatory technology development (PTD) techniques are utilised to address livestock-related issues. The project is also developing approaches and methods to test and introduce integrated methods to control tick-borne diseases and helminth infections, and to improve animal husbandry practices and the efficiency of utilisation of available feed resources within the crop-dairy system. These activities contribute to the ongoing DFID Smallholder Dairy Project (SDP).

Initiating FFS for livestock

All facilitators were trained during a two-week training of trainers (TOT) course. This was run as a learning workshop, where participants learned the basic principles of the FFS and at the same time used them to develop specific examples of activities, tools and techniques suitable for smallholder dairy production systems.

Facilitators trained in FFS approaches worked with established groups to prioritise the main constraints to improving the efficiency of milk production, using participatory techniques (pair-wise and matrix ranking). Issues highlighted for all groups were similar and included, in order of priority: 1) feeding strategies; 2) fodder establishment and conservation; 3) calf rearing and mortality; 4) diseases (tick-borne and mastitis); and 5) water management and breeding. Equal priority was given to the last two issues. Based on the results of this exercise, individual grant proposals were prepared by each group, including a detailed work plan with a corresponding budget.

A grant of US$600 was deposited in an account controlled by elected members of the FFS group to cover the cost of field activities and the cost of facilitation (the transport and lunch allowances for the extension worker). Management of this budget empowered the farmers to control activities covered by the FFS and ensured that the extension services offered responded to farmers actual priority problems and needs. The FFS groups usually meet on a weekly basis, but some vary their frequency to once every two weeks. The main participatory techniques used, including Agro-Ecosystem Analysis and Participatory Technology Development, were adapted to suit the specific needs of learning about livestock issues. For livestock FFS, understanding the impact of animal health on productivity and how to control disease occurrence, is of major importance.

Activities

Since the main objective of the FFS is to develop farmers learning skills, rather than to increase knowledge on a particular technical issue, record keeping and accurate observation are important components. Agro-ecosystem analysis is designed to improve observation skills and to develop decision-making skills, and this technique is utilised to record and observe the results of the PTD experiments. This observation process forms the basis for understanding the interactions between livestock and other elements of the ecosystem, as they relate to the problem or technology being studied. For example, where the subject is expected to have a direct outcome on the animal, such as a feeding or health management practice, the AESA is focused on the animal.

Measuring girth for the evaluation of body life weight. Photo: Bruno Minjauw

In practice, farmers are divided into small groups and they observe an animal from one of their farms. Observations are guided by a checklist that includes general information such as the life history of the animal, parameters defining the level of production, and observations describing the health status of the animal. Each group presents their results in a standardised format

to the rest of the school. These findings are then discussed, allowing farmer-to-farmer information dissemination as well as an evaluation of progress.

The establishment of the PTD process is one of the biggest challenges in livestock FFS. Indeed, while it is relatively easy to design a comparative study for integrated pest management in crops, the high economic value of cattle does not permit experiments that might involve any risk or even short-term losses in animal productivity. Therefore, one of the objectives of the on-going livestock FFS project is to establish the kind of technology development that can be performed without any risk or detrimental effect, while still allowing farmers to experiment with new technologies. Three types of "PTDs" have emerged from on-going activities:

1) Classical experiments: Although livestock are the focus of livestock FFS, many of the activities of the livestock keeper are crop-related. This is particularly the case for fodder production and grazing improvement. "PTDs" include:
- Establishing alternative sources of fodder. A range of fodders are planted using different planting methods, treatments and/or different fertiliser regimes.
- Preservation of fodder using different techniques such as silage making and a box baler for hay.

2) Comparison of existing farmer practices: Observation and evaluation of the different practices of farmers, within and outside the FFS group, provides the opportunity for farmers to address issues that do not lend themselves to experimentation because of the high risk in terms of animal well-being or high costs for implementing the experiment. Examples include:
- Tick control: comparison of efficacy of different acaricides and/or of different application regimes.
- Vaccination efficacy: comparison of disease incidence in immunised and non-immunised animals
- Comparison of milk quality and losses due to milk spoilage in relation to the quality of the milk parlour infrastructure.

3) Ex-post analysis: In ex-post analysis, farmers compare actual experimental results with practices that were used before. Results may be quantitative, if records are available from the past or from similar situations, or qualitative, where farmer perceptions are evaluated. This also includes the "Stop and Go" method, where the treatment is stopped and re-introduced several times to show its effect, using an animal as its own control. Examples include:
- Water availability: the amount of water available to the dairy animal is changed according to the calculated needs. Milk production using the new regime is compared with previous records of production using the old regime.
- Genetic material: artificial insemination is used to compare calf birth weight with other calves or with expected weight.
- Prophylactic programme: a programme of preventive treatment is applied to a group of cattle and their performance is compared with previous productivity and with neighbouring herds. This could include de-worming, a trypanocide and/or vaccination against prevalent diseases.

Presentation during a field day of fodder conservation techniques. Photo: Bruno Minjauw

Not every problem can be easily dealt with using a "learning by doing" approach. Some problems, such as those relating to contagious diseases, for example, are not suitable or too dangerous for experimentation. Others may be too abstract to be demonstrated physically, such as the importance of epidemiological status or immunological reactions, and these can be addressed in special topic sessions where issues are discussed. Since the facilitator cannot be an expert in every subject, he or she will help the farmer group to invite the right person to talk about the subject chosen by the farmers. This empowers the FFS group to contact other organisations such as NGOs or national or international research institutes. Special topics can also include livestock and non-livestock related issues, giving farmers the chance to access the information that addresses their priorities at a particular moment. For example, talking to the community about trypanosomiasis when the village is threatened with a cholera outbreak is unlikely to be addressing a priority issue. Advice about cholera control will certainly be more relevant.

Conclusions

If scientific research is to achieve a real impact on farm productivity and livelihoods, new methodologies for dissemination of information have to be developed. Participatory approaches, which facilitate farmer demand for knowledge, give them the opportunity to choose, test and adapt technologies according to their needs. Through participation in FFS, farmers develop skills that allow them to analyse their own situation and adapt to changing circumstances. The ILRI livestock FFS project, funded by the DFID Animal Health Programme, is testing and adapting a participatory method to create a sustainable relation between farmers, extension officers and research institutes. These relationships are thought to be a fundamental tool, allowing scientists to collect appropriate data and to transform developed technologies into products adapted to farmers needs.

Using the FFS approach, the project is developing an innovative process through which farmers adapt existing technologies and try out new ideas. These ideas are developed through interactions between farmers, scientists and extension workers. This unique relationship is an excellent platform for epidemiological studies using participatory methods, to disseminate information on disease prevalence, to design relevant participatory technology development, and to introduce more successful disease surveillance and control strategies.

PTD practitioners: back to school?

Rik Thijssen

Farmer Field Schools (FFS) and Participatory Technology Development (PTD) are both participatory approaches for promoting sustainable agricultural development. They both work towards improving farmer decision-making capacity and stimulating local innovation. But what are the differences? Are these approaches overlapping or complementary? And what can they learn from one another?

FFS were developed in the late 1980s to train Indonesian rice farmers on integrated pest management (IPM). They were developed in response to the Green Revolution. The aim was to re-educate farmers in agro-ecology and develop their critical thinking, based on the knowledge already available about rice ecosystems. Farmer field schools focused on bringing this knowledge and understanding to farmers through group learning, based on adult education principles.

PTD was also developed in the late 1980s. The concept arose out of the ideas and "best practices" of small NGOs and the farming systems research and extension movement. PTD refers to a process of joint experimentation by development workers and farmers. The aim is to combine the best of local and external knowledge, and work together to generate and disseminate agricultural innovations.

Connecting and expanding knowledge

During an ethno-botanical study in Taropo Village on Sumbawa Island in Indonesia, a local farmer explained about a plant species known as "pupuk" (fertiliser). As he pulled out the small, clearly leguminous shrub, the many root nodules were very evident. The study team asked the farmer why this plant was named "pupuk". He said that "pupuk" had the ability to improve soil fertility and this species was, therefore, valued during fallow periods. We also checked with this farmer if he knew what the function of the root-nodules was. Without any hesitation, he claimed that they were for water storage. Small farmers possess a good deal of wisdom and experience, with which they manage to survive and produce for their families. But they do not know all of the components and processes that play key roles in agro-ecosystems.

What would be the added value if the farmer from Taropo Village knew about the nitrogen-fixing capacity of root nodules of "pupuk"? First, it validates the local observation that this plant species can play a role in soil fertility improvement. It could also provide the farmer with information that explains other indigenous knowledge held by the community, or contradicts certain local beliefs. Farmers could, for instance, draw a link to other species with root nodules, and thus widen the range of locally available species with potential for soil fertility improvement. The monitoring aspect of FFS, using indicators, could provoke some comparative studies, where farmers evaluate the real potential of different species. Finally, based on an increased awareness and understanding of a phenomena that is not obvious or easily observable, a farmer like the one from Taropo Village could become a valuable contributor to a team working on agricultural technology development.

Contrasting elements

PTD activities include:

- Critical analysis of community-managed changes in the agro-ecosystem;
- Identification and use of indigenous technical knowledge;
- Reconstruction of successful local innovation;
- Self-organisation and
- Self-implementation of systematic experiments.

These can sometimes be difficult to accommodate in the FFS setting. This is mainly because of the creative limitations of a "school" set-up, and the time limits on FFS imposed by a project approach. Not least, limitations are imposed by the attitude of many FFS-facilitators: they can be teachers, but they are not necessarily capable facilitators of a participatory approach, as intended in the PTD philosophy.

The crucial contrasting elements between the two approaches - FFS and PTD - could be summarised as follows:

- *Perception of "participation"*: while PTD promotes a bottom-up learning environment based on indigenous knowledge, FFS provide a more traditional teacher-student setting for learning about knowledge held by outsiders.
- *Attitudinal changes*: where PTD seeks major changes in attitudes of researchers and extensionists, FFS could be seen as the most effective way to accommodate the existing attitudes of these professionals.
- *The learning process*: although both approaches are largely based on self-discovery activities, FFS set "fixed" learning targets, while PTD is an open-ended process.

Conclusion

Clearly, the basic concepts of the two approaches are complementary, and the FFS approach provides fertile grounds for PTD. It is, however, important to distinguish between enhancing the basic knowledge of farmers so that they can experiment according to their specific circumstances (FFS), and agricultural technology development by or with farmers (PTD).

FFSs fill gaps in local knowledge, conduct holistic research on agro-ecosystems, and increase awareness and understanding of phenomena that are not obvious or easily observable. Their strength lies in increasing farmers skills as agro-ecosystem managers. The strength of the PTD-platforms lies in their systematic evaluation of locally acceptable, technological alternatives, as well as their ability to influence the research agendas of formal research and extension systems.

Growing interest in both FFS and PTD by a wide range of financing and implementing organisations reflects an underlying perception that they form viable new alternatives. Both approaches will evolve further, and their development should be carefully managed so as to draw on their underlying synergy. In order to fill the basic knowledge gaps that still exist, PTD groups can borrow from the FFS principle of educating farmers on agro-ecological components, patterns and processes. In turn, FFSs should pay more attention to revising the attitudes of agricultural development professionals to enable them to become more involved in PTD work.

Fundamental Elements of a Farmer Field School

Kevin Gallagher

In general, Farmer Field Schools (FFS) consist of groups of people with a common interest, who get together on a regular basis to study the "*how and why*" of a particular topic. The topics covered can vary considerably - from IPM, organic agriculture, animal husbandry, and soil husbandry, to income-generating activities such as handicrafts. FFS are comparable to programmes such as Study Circles, religious studies at a church, mosque or temple, or specialised study programmes for any skill. The FFS, however, are particularly adapted to field study, where specific hands-on management skills and conceptual understanding is required.

So what are the essential elements of a FFS? Below is a list of elements that commonly appear in successful FFS programmes:

The group

A group of people with a common interest form the core of the FFS. The group may be mixed with men and women together, or separated, depending on culture and topic. The group could be an established one, such as a self-help, women's, or youth group. Participatory technology groups, for example, sometimes undertake a season of study in FFSs before starting their research. The FFS tends to strengthen existing groups or may lead to the formation of new groups. Some FFS groups do not continue after the study period. The FFS is not developed with the intention of creating a long-term organisation - although it often becomes one.

The field

FFSs are about practical, hands-on topics. Study Circles and other study methods do not take place in the field, as they are about more theoretical topics. In the FFS, the field is the teacher, and it provides most of the training materials like plants, pests and real problems. Any new "language" learned in the course of study can be applied directly to real objects, and local names can be used and agreed on. Farmers are usually much more comfortable in field situations than in classrooms. In most cases, communities can provide a study site with a shaded area for follow-up discussions.

The facilitator

Each FFS needs a technically competent facilitator to lead members through the hands-on exercises. There is no lecturing involved, so the facilitator can be an extension officer or a Farmer Field School graduate. Extension officers with different organisational backgrounds, for example government, NGOs and private companies, have all been involved in FFS. In most programmes, a key objective is to move towards farmer facilitators, because they are often better facilitators than outside extension staff - they know the community and its members, speak a similar language, are recognised by members as colleagues, and know the area well. From a financial perspective, farmer facilitators require less transport and other financial support than formal extensionists. They can also operate more independently (and therefore cheaply), outside formal hierarchical structures.

All facilitators need training. Extension facilitators need season-long training to (re)learn facilitation skills, learn to grow crops with their own hands, and develop management skills such as fund-raising and development of local programmes. Computer literacy is often included in the training of facilitators, especially for preparing local training materials, budgets and project proposals. Email is also becoming more widely available. Once the facilitators have completed their training and are leading the FFS process, it is easy to identify capable farmers who are interested in becoming facilitators. Farmer Field School graduates are usually given special farmer facilitator training (10-14 days) to improve technical, facilitation and organisational skills.

A typical FFS session in the original Indonesian setting

8:00	Opening (often with prayer) Attendance call Day's briefing of activities Stretching exercises
8:30	Go to the field in small teams Make observations that are noted by the facilitator and one other person in the group records. Facilitator points out interesting new developments
9:30	Return to shade. Begin making agro-ecosystem analysis (see box) drawing and discuss management decisions.
10:15	Each team presents results and the group arrives at a consensus on management needs for the coming week.
11:00	Short tea/coffee/water break
11:15	Energiser or group building exercise
11:30	Special study topic or second crop/livestock study. This could include nutrition, or chicken or parasites, or something else of special interest to group.
12:30	Closing (often with prayer).

The curriculum

The FFS curriculum follows the natural cycle of its subject, be it crop, animal, soil, or handicrafts. For example, the cycle may be "seed to seed" or "egg to egg". This approach allows all aspects of the subject to be covered, in parallel with what is happening in the FFS member's field. For example, rice transplanting in the FFS takes place at the same time as farmers are transplanting their own crops - the lessons learned can be applied directly.
One key factor in the success of the FFSs has been that there are

no lectures – all activities are based on experiential (learning-by-doing), participatory, hands-on work. This builds on adult learning theory and practice. Each activity has a procedure for action, observation, analysis and decision making. The emphasis is not only on "how" but also on "why". Experience has shown that structured, hands-on activities provide a sound basis for continued innovation and local adaptation, after the FFS itself has been completed. It is also one of the main reasons that farmer facilitators can easily run FFSs - once they know how to facilitate an activity, the outcomes become obvious from the exercise itself.

Activities are sometimes season-long experiments - especially those related to soils or plant physiology (for example soil or variety trials, plant compensation trials). Other activities in the curriculum include 30-120 minutes for specific topics. Icebreakers, energisers, and team/organisation building exercises are also included in each session. The curriculum of many FFSs is combined with other topics. In Kenya, for example, the FFSs follow a one-year cycle including cash crops, food crops, chickens or goats and special topics on nutrition, HIV/AIDS, water sanitation and marketing. FFSs for literacy are also promoted where there is a need.

The programme leader

Most FFS programmes exist within a larger programme, run by government or a civil society organisation. It is essential to have a good programme leader who can support the training of facilitators, get materials organised for the field, solve problems in participatory ways and nurture field staff facilitators. This person needs to keep a close watch on the FFSs for potential technical or human relations problems. They are also the person likely to be responsible for monitoring and evaluation. The programme leader must be a good leader and an empowering person. He or she is the key to successful programme development and needs support and training to develop the necessary skills.

Financing

FFSs can be expensive or low-cost, depending on who implements them and how they are conducted. When carried out within a World Bank-type programme, they are usually expensive, due to high allowances, transportation costs and several layers of supervision (about US$30-50 per farmer). Obviously, the greater the distance that facilitators need to travel to get to the field, the higher the cost of transport. Transport is one of the biggest costs in any extension programme. When the FFS is carried out by local organisations and farmer facilitators, initial start-up costs may be moderate, but the running costs will be much lower (about US$1-20 per farmer). A trend in East Africa is to manage small commercial plots alongside the FFS study plots, so that the FFS can actually raise more funds than it uses for inputs and stationary (Okoth p. 27).

Final word

Farmer Field Schools are not difficult or mysterious. However, they are meant to empower through education on skills and concepts (how's and why's) and therefore, require an empowering environment. The basis for a successful FFS starts with the programme's culture of operation - from a nurturing and empowering programme leader and good facilitators, to transparent budgets and open management. FFSs are not difficult to set up if there is a commitment to, and faith in farmers' and facilitators' ability to learn locally and apply learning to local problems themselves. ■

AESA in a typical FFS for rice

The basic format of an IPM Farmer Field School consists of three activities: agro-ecosystem observation, analysis, and presentation of results; a "special topic"; and a "group dynamics" activity. The Agro-Ecosystem Analysis (AESA) is the FFS's core activity, and other activities are designed to support it.

The agro-ecosystem analysis process sharpens farmers skills in the areas of observation and decision-making, and helps develop their powers of critical thinking. The process begins with small group observation of the IPM and non-IPM plots. During the observation process participants collect field data such as the number of tillers per hill, the varieties of insects and their populations and samples of insects and plants. These data are collected from ten rice hills. The facilitator is present throughout the observation to help participants in their observations.

Following the field observation, the farmers return to the meeting place and, using crayons, draw what they have just observed in the fields on a large piece of newsprint or poster paper. The drawings include:
a) pests and natural enemies observed in the fields (pests on one side, natural enemies on the other);
b) the plant (or animal) indicating the size and stage of growth, along with other important growth features such as the number of stems/tillers, the colour of the plant and any visible damage;
c) important features of the environment (the water level in the field, sunlight, shade trees, weeds, and inputs).

All members of the small groups are involved in the creation of the drawing and data analysis. While drawing, farmers discuss and analyse the data they have collected. Based on their analysis they determine a set of management decisions to be carried out in the field. A summary of these management decisions as agreed by the group is also included in the drawing.

One member of each small group then presents these findings and decisions to the larger group. After this brief presentation of results there is time for open questions and discussion. Good large group discussions often involve posing alternative scenarios, for example, questions such as "What would you do if...." This cycle of presentation, question, answer and discussion is repeated until all the small groups have presented their results. Agro-ecosystem drawings from previous weeks are kept on hand as a reference and as material for discussion later in the season.

The role of the facilitator is central to the EASA process. In the field, they will guide participants to see what they may not have seen before, such as tiny predators or changes in soil. To ensure a balanced and participatory discussion, a good facilitator understands that the more participants talk, the more they learn, and encourages discussion rather than lecturing. During presentations, the facilitator ensures that all participants have an opportunity to present during the season, and that the group covers all the important issues. The facilitator needs farming and technical skills and needs to know how to ask good questions, guide participants through exercises and ensure that sound management decisions are taken by the group by introducing new information when appropriate.

FFS: beyond the rice field

Editorial

IPM Farmer Field Schools (FFSs) for rice farmers in Asia have been immensely successful. Since the Indonesian National IPM Programme initiated the first FFS in 1989, the approach has reached over two million rice farmers. These farmers have increased their yields and incomes, reduced pesticide use, and use inputs such as water and fertiliser more efficiently. They have gained the knowledge and practical experience necessary to manage their agro-ecosystems sustainably. They use their knowledge and understanding to innovate and solve their own problems, and share their knowledge with their neighbours. FFS graduates have become leaders in establishing sustainable agricultural systems in their villages.

The success of the IPM FFS in Asia has attracted the attention of development workers - and donors - around the world. As with every successful approach, there is a strong movement to copy and adapt it to other situations. The FFS concept has been developed far beyond IPM in rice. FFS now exist in over 30 countries around the world, encouraging farmer learning in areas as diverse as dairy farming (Minjauw *et al* p. 8), conservation agriculture (for example see LEISA 18.3, pp.18-19), and even community health (Yech, p. 10). These approaches do not all fit the original FFS model exactly. Adaptations are necessary to meet the needs of different topics (such as IPM in tree crops, Mangan p. 30) or to adapt to different cultural situations (for example in Egypt, Van de Pol p. 22).

This issue of LEISA looks at the development of the FFS concept beyond rice IPM and into a seemingly limitless realm of possibilities for assisting and educating farmers. But how far can the concepts and principles of the Farmer Field School be developed and modified, and what are the core elements that need to be maintained to reproduce their original success?

A new blueprint for agricultural development?

The IPM Farmer Field School has become a model approach for farmer education in Asia and many parts of Africa, Latin America and the Middle East (LEISA 17-3, pp. 18-21). The FFS have many standard features, each of which contributes to their success. The schools usually comprise season-long regular meetings with a set pattern of activities, including Agro-Ecosystem Analysis (AESA), presentations and special additional topics, as well as group building activities. Gallagher (p. 5) describes the elements that appear commonly across successful FFS programmes.

But Farmer Field Schools are no blueprint. A FFS is a learning activity, not an institution - although FFS often give rise to new organisations, groups and networks through a process of building capacity and developing connections between people with common interests. FFS are often combined with other approaches, and can be integrated into existing groups and extension services. For example, Tripathi and Wajih (p. 14) describe the role they play in the "greening" process of bringing the topic of sustainable agriculture to women's self-help groups in India.

The challenges of expansion

Every new adaptation and expansion, and every move away from the original setting involves a trade-off. The original IPM FFS's in Indonesia were developed in a specific context. For example, considerable knowledge on rice pests and the rice ecosystem was already available. The FFS were developed to encourage farmers to learn about ecology and gain knowledge that would enable them to control pests and manage their rice ecosystem productively, but not necessarily to develop new knowledge. In some areas, however, there is a need to develop new, locally specific knowledge and technologies. One such example is the CIP sweet potato programme (see Sources, p. 32). In such cases, approaches such as PTD can add a new dynamic dimension to a FFS programme (Thijssen p. 17).

The process of developing critical thinking, introduced in IPM FFS, can be utilised to address other topics, for example through Farmer Life Schools (Yech, p. 10). Although the topic is quite different from IPM, the way of thinking is easily translated from "agro-ecosystems" to "human ecosystems", because the participants have previous experience with FFS for IPM. A greater challenge is to initiate an IPM FFS successfully in a different cultural setting, for example in Egypt (Van de Pol, p. 22).

FFSs are suitable for rapidly scaling-up new programmes. The basic curriculum is well developed, and farmer graduates can become farmer trainers, as the hands-on nature of the training means that farmers can easily facilitate the learning activities. However, the manner in which the scaling-up process is developed, particularly the initial training, can be critical to the success of the project. The FFS approach needs to expand from a well-trained nucleus of facilitators who have a good understanding of the concepts involved, as well as the skills to facilitate FFSs effectively (Van de Pol, p. 22).

As with other agricultural extension activities, the cost of FFS becomes a major issue as the approach becomes more widespread. Innovative solutions to this issue have been developed by a FAO/IFAD project, based on pioneering work by women's groups in their project area. Okoth *et al* (p. 28) describe the self-financing methods developed by this project.

Many different groups now call their activities "FFS", and fears are beginning to emerge that they may be making major trade-offs that lower the quality of the approach. Initiators of the Farmer Field School movement fear that the term "FFS" may become jargon to add to project documents, without those involved fully understanding the basis for a successful FFS programme. One of the most interesting aspects of this issue is the range of different perspectives presented on the basic question, "What makes a Farmer Field School a Farmer Field School?" These views are based on different experiences in different environments, with different limiting factors. It could also be asked, if a programme has a beneficial impact, does it really matter whether it fulfils all the criteria for a "real" FFS?

These questions may have more than one answer, and need to be addressed and guided by those involved, or wanting to be involved, in farmer education. Farmer Field Schools, like any other approach, are a tool, and their effectiveness depends on both the context and the way in which they are used. They are, however, a very special tool. They cultivate a critical, holistic and creative way of thinking. The process of learning about ecology leads farmers to a greater understanding of the inter-connectedness of their environment and the broader impacts of the decisions they make. Such understanding leads to empowerment.

National Route 5 in Cambodia is part of the Trans-Asia highway linking India, Thailand, Cambodia and Vietnam. Along its route, the movement of people is steadily increasing – and so is the spread of HIV/AIDS. Farmer Life Schools, based on Farmer Field School community strategies, are now being developed along Route 5 to mobilise and empower farming communities, and reduce vulnerability to HIV/AIDS. These schools are often a natural follow-on activity from a previous IPM FFS. They carry out Human Ecosystem Analysis, including observation and interviewing of selected families within the community, and discuss the alternatives available to resolve health issues faced by these families. Through improved understanding of how various factors impact upon their lives, the farming communities are able to make changes to reduce risky behaviour which might lead to chronic diseases, and plan to achieve healthier and more peaceful lives.

A common point of concern for those considering FFS as an extension mechanism is the cost. This article describes several innovations to improve the financial sustainability of FFSs that have been developed and introduced by the East African Sub-regional Pilot Programme on Integrated Production and Pest Management (IPPM). The cornerstone of these innovations has been the evolution of the original grant system (semi-self financed FFSs) into an educational revolving fund (self-financed FFSs), supported by the proceeds of commercial plots that are managed alongside the study plots. Local governments, NGOs and rural micro-finance institutions are now becoming more and more interested in the approach, and in Kenya some farmers have even begun gathering resources together to fund their own FFS activities, the so-called self-sponsored Farmer Field Schools.

ILEIA is the Centre for Information on Low External Input and Sustainable Agriculture (LEISA) in the tropics. ILEIA seeks to promote the adoption of LEISA through the LEISA Magazine and other publications. It also maintains a specialised information database and an informative and interactive website on LEISA (**http://www.ileia.org**). The web site provides access to many other sources of information on the development of sustainable agriculture.

LEISA is about Low-External-Input and Sustainable Agriculture. It is about the technical and social options open to farmers who seek to improve productivity and income in an ecologically sound way. LEISA is about the optimal use of local resources and natural processes and, if necessary, the safe and efficient use of external inputs. It is about the empowerment of male and female farmers and the communities who seek to build their future on the basis of their own knowledge, skills, values, culture and institutions. LEISA is also about participatory methodologies to strengthen the capacity of farmers and other actors to improve agriculture and adapt it to changing needs and conditions. LEISA seeks to combine indigenous and scientific knowledge, and to influence policy formulation in creating an environment conducive for its further development. LEISA is a concept, an approach and a political message.

22 The Egyptian experience with FFS

Jaap van de Pol

Implementing the Farmer Field School approach in the Egyptian context has posed a number of challenges. The traditional approach for Egyptian extensionists has been one of technology transfer, and the hands-on, participatory focus of the FFS has required a change of mindset. Many aspects of the traditional IPM FFS have needed to be rethought to make the approach work in the Egyptian setting, and a lot can be learnt from these experiences. Lessons include the importance of training, and the need for the adaptation process to be a joint activity of farmers, facilitators and project management.

24 The greening of Self Help Groups

Seema Tripathi and Shiraz Wajih

Self-help groups for women living in the Terai of Eastern Uttar Pradesh have been used not only as appropriate institutions to help women improve their socio-economic status, but also to mobilise them as agents of change. The process of "greening" these groups towards sustainable agriculture has brought together many different extension and support mechanisms, including agro-service centres, master trainers and Farmer Field Schools.

DEAR READERS

Farmer Field Schools have proven to be a very effective tool for cultivating farmer learning and empowerment. In particular, they encourage farmers to develop their critical thinking, and this leads to greater self-sufficiency. FFS can also be integrated with other approaches, and they facilitate the scaling-up of successful experiences. As the FFS approach becomes increasingly popular, however, new issues and challenges emerge, such as maintaining quality in their implementation, and ensuring that the core principles of the approach continue to be reflected.

These were the issues addressed by an international learning workshop held in Indonesia in October 2002, "Farmer Field Schools - Emerging Issues and Challenges". Organisers included the Rockefeller Foundation, the International Potato Center (CIP) through the Users' Perspectives With Agricultural Research and Development (UPWARD) Network, and Farmers for Innovation in Ecological Livelihood and Democracy (FIELD) Indonesia. This issue of LEISA highlights the important contribution of the workshop to the ongoing international debate on extension approaches. In many cases, the articles presented here are shorter, modified versions of the original workshop papers. More information on the workshop, including full versions of all papers presented, can be found on the UPWARD website at www.eseap.cipotato.org/upward.

Learning with Farmer Field Schools

Linking Natural Resources, Agriculture and Human Health: Case Studies from East Africa

Hugo Li-Pun, Johann Baumgaertner, Juergen Greiling, Hiremagalur Gopalan, Mohammad Jabbar, Victor Mares, John McDermott, Martin Odiit and Mohamed Saleem

Past attempts to alleviate the problems of poor farmers engaged in mixed crop-livestock production have generally focussed on the design and diffusion of new technologies targeted on specific components of the agroecosystem. Unfortunately, such piecemeal efforts have had little impact in the developing world, including the East African highlands, the main focus of this report.

In the case of human health, the traditional R&D approach has tended to be narrowly sectoral. The health of people has been separated from that of crops, animals and the environment, with different disciplines and institutions concentrating on different constraints. Despite the progress reported, improvements to human health have fallen far short of expectations. A key limitation of the sectoral approach is that it does not consider interactions among priority human health conditions and their socio-economic and ecological determinants, such as poverty, malnutrition and degraded natural resources. Nor does it account for the close associations between people and livestock, as in the case of human sleeping sickness and bovine trypanosomiasis, both vectored by tsetse flies.

If future development efforts are to have significant, long-lasting impact on the people they are intended to help, they must be based on a firm understanding of the complex links among the environment, natural resources, agriculture, food security and human welfare. Furthermore, the ensuing interventions must not be limited to technological solutions. Rather, they must include better policy formulation, health and education, and the building of local community assets.

In recent years, participatory and multidisciplinary research methods have begun to make inroads in many parts of the world. For example, several international programmes are attempting to address agricultural productivity and resource sustainability issues through so-called ecoregional research. These efforts involve various mixes of partners: international agricultural research centres, advanced research institutions in industrialised countries, national agricultural research systems in developing countries, non-governmental organisations and funding agencies.

Below we describe recent experiences of two research centres with a global reach: the International Livestock Research Institute (ILRI) and the International Centre of Insect Physiology and Ecology (ICIPE). Both are currently conducting research in the East African highlands, based on holistic, participatory methods. Each centre's strategy integrates activities intended to improve food security and nutrition, human and environmental health, asset building and farm income, through natural resource management (NRM) and higher crop and livestock productivity. Computer modelling is one of the research tools used to assess the potential impact of using better methods to manage soil nutrients, graze and feed animals, enhance livestock health and control tsetse flies and other vectors.

A smoky home environment. For lack of alternatives, Ethiopians often burn dung for household cooking. This reduces indoor air quality and contributes to high incidences of upper respiratory disease. Agroforestry and woodlots could provide better domestic fuel, leaving precious manure as fertiliser for crops and pastures. ICIPE photo: Shifa Ballo.

Human health in the highlands

Widespread poverty, malnutrition and disease, along with low farm productivity and degraded natural resources, are major problems in the East African highlands. For example, in Ethiopia, which makes up 60% of the 3.5 million square kilometres of highlands, per capita annual income is a little over US$100. Some two-fifths of the rural population live in absolute poverty and one-third are malnourished. Nearly two-thirds of children suffer from protein-energy malnutrition, sometimes with irreversible damage to cognitive development. Deficiencies in micronutrients, particularly vitamin A, iron and iodine, are also commonplace.

Poverty and malnutrition are aggravated by large-scale resource degradation such as soil erosion, nutrient depletion, deforestation and the decline of pastureland, all of which undermine agricultural productivity and food security. It is estimated that half of the Ethiopian highlands' arable lands are moderately to severely eroded. If the erosion rates of the 1980s persist, over 7 million ha of crop land could be lost by 2010.

The burden of ill health in sub-Saharan Africa is twice the global average and life expectancy lags some 25 years behind that of people in the wealthiest nations. In the East African highlands, a region with a population of 150 million, women and children are especially at risk of ill health. This is due not only to malnutrition but also to the fact that these family members are more closely connected with unhealthy household environments. Indoor air pollution from burning wood and dung, for example, causes acute and chronic respiratory diseases. Women and children are also at high risk from insect-borne diseases such as sleeping sickness, malaria and dengue fever. A major reason is that the sites where they collect water and wash clothes tend to be insect-breeding areas as well.

Among the vector-borne diseases, malaria (transmitted by female anopheles mosquitoes) is the most important health risk. As for human trypanosomiasis, or sleeping sickness, the epidemic levels of the 1930s have returned, with the case load now estimated at 300,000 per year. Unsafe water supplies and limited access to clinics and health posts, combined with domestic and environmental health hazards and poorly developed communications, contribute to high incidences of disease. Zoonotic infections spreading from animals to people are also of increasing concern in the region.

Livestock as leverage

Mixed crop-livestock systems are common in the highlands. While grain yields have shown modest increases in the past two decades, they are still under 2 tons per hectare. This is due to the low usage of agricultural inputs such as fertilisers, as well as to damage by pests and plant diseases.

Farm animals play multiple roles in these systems, providing food and income, as well as farm inputs such as draught power and manure for crop production. Manure is also used as fuel. Livestock are a family's most important and flexible marketable asset. They can be sold in times of need, particularly when crops fail.

The beneficial role of livestock in intensifying production, alleviating poverty and malnutrition, and conserving natural resources has not been adequately exploited. Livestock productivity remains well below potential due to insufficient and poor-quality feeds, along with animal diseases. Available forage in sub-Saharan Africa is currently insufficient to meet needed livestock output, with protein being in even shorter supply than total energy. The amount of available pasture land is declining, as crops encroach on traditional dry-season pastures. Mineral fertiliser is needed to boost the supply of quality feed from both pastures and cropland.

Infectious diseases, particularly those transmitted by tsetse flies (*Glossinidae*) and ticks (*Ixodidae*), pose a constant threat to livestock. Cattle deaths related to trypanosomiasis are estimated at 3 million head annually, mainly young animals. Up to one-quarter of pre-weaning calves succumb. Sick animals have lower milk and meat yields and fewer offspring. Crop production is indirectly affected as there is less draught power for ploughing and less manure for fertiliser. This results in fewer crop residues and by-products for animal feed.

In the Ethiopian highlands, livestock are a farm family's most important and flexible marketable asset. Milk and meat are also important sources of protein and micronutrients. ICIPE photo: Shifa Ballo.

The consumption of even small amounts of meat and milk products improves human nutrition and makes people, especially pregnant women and young children, less susceptible to diet-related diseases.

The consumption of even small amounts of meat and milk products improves human nutrition and makes people, especially pregnant women and young children, less susceptible to diet-related diseases. Animal products are rich in micronutrients, such as vitamins A and B12, iron and zinc. These are essential to good child health and the development of cognitive and motor skills. What's more, agriculture and food-based approaches to combatting macro- and micronutrient deficiencies may be more sustainable than chemical supplementation such as consumption of vitamin A tablets.

Nutritional benefits of greater agricultural production, particularly dairy, depend partly on mothers' knowledge of nutrition. Since that knowledge is currently low among poor farmers, effective nutrition education is required. However, better education and family health in turn depend on community participation and empowerment. Stakeholder participation in the diagnosis of constraints and in the design and implementation of solutions is essential to the success and sustainability of development efforts.

ILRI's experience

Over the years, ILRI's research in the Ethiopian highlands on several component technologies has shown the potential for improving human welfare through increased crop and livestock productivity, better NRM and related interventions. Here are some examples:

- Vertisols are an under-exploited soil resource because of waterlogging. Animal-powered drainage equipment (called a broad bed maker, or BBM), combined with improved wheat technology (better varieties for early planting, fertiliser and agronomic practices), can increase wheat yield from less than 1 ton per ha to over 2. Besides helping alleviate the country's perennial food deficit, the drainage technology also significantly reduces soil erosion compared with traditional vertisol management.
- Modification of the BBM for row planting via a seeder attachment resulted in a large saving in seeds. The technology required 90 to 110 kilograms per hectare, compared with 150 to 250 kilograms for traditional broadcasting. Tillage and planting tests during the onset of the main rains showed that the time required to establish a crop via minimum tillage was about one-third that needed with traditional methods.
- On-farm studies have shown that improved dairy technologies (better breeds, feeds and management) can significantly increase production and income, and improve household nutrition and food security, particularly of women and children.
- Results from a study of grazing pressure suggest that a no-grazing strategy does not help conserve biodiversity or improve

soil quality. Recycling nutrients through manure ensures sufficient biomass production for regulated grazing and provides soil with a protective cover. Using dung for fuel aggravates the negative nutrient balance in the soil and depresses biomass production.

- An adoption study regarding multipurpose trees showed that farmer-to-farmer diffusion through seed sharing – a good indicator of potential for further adoption – has been occurring. The species selected by farmers varied with biophysical factors such as altitude and rainfall. Most farmers were using the trees for fencing, fuel and construction.

Given the limitations of development strategies based on component technologies or organized by sector, ILRI and its partners carried out a three-year project using a participatory “agroecosystem health” approach to assessing the sustainability of crop-livestock production systems. The overall aim of this work, based in Ginchi, a community of the Awash watershed, is to improve human health and nutrition through better management of livestock and natural resources.

After a 1998 workshop to refine the methodology, researchers gathered detailed biophysical and socioeconomic information on the Ginchi micro-watershed. They used a variety of methods, such as on-farm trials, site surveys and participatory rural appraisal. Then, together with members of the target community, they defined indicators of agroecosystem health, related to factors such as household food security, disease incidence, gender-related equity, soil erosion and biodiversity.

A bioeconomic model, based on Ginchi field data, was designed for *ex ante* assessment of the impact of improved crop and livestock technologies and NRM strategies on economic, ecological and food-production sustainability. It has allowed researchers to evaluate both short- and long-term impacts (up to 12 years) of technology and policy interventions. In a nutshell, this “dynamic” model quantifies the tradeoffs involved when farmers attempt to increase or maximise one of three factors: their income, their food self-sufficiency, or the sustainability of their farming system (by reducing soil erosion).

Results of modelling

The modelling reveals strong tradeoffs between the attainment of food self-sufficiency, high income and reduction in soil erosion. For example, with the application of fertiliser to teff and wheat in an otherwise traditional production system, farmers’ cash incomes would rise by 50% from a currently low base. However, annual soil losses would be 31 tons per hectare, which is still higher than the permissible level for the highlands.

Under a scenario involving the introduction of a set of new technologies – such as higher-yielding crop varieties, agroforestry methods, and techniques to reduce soil waterlogging – the modelling results are quite different. It would be possible, over 12 years, to increase cash income tenfold and decrease aggregate soil erosion by 20%. Moreover, farm outputs would be sufficient to provide a minimum daily intake of 2,000 calories per adult.

However, farmers would be increasingly dependent on livestock for manure, draught power, milk and cash flow. And the use of agroforestry methods and zero grazing would demand a longer planning horizon – which would be feasible only if farmers had more secure land tenure than at present.

The results of the modelling have been shared with farmers in the watershed and district extension agencies as an aid to resource-use decision making. They will also be extrapolated to other regions.

Trypanosomiasis in Uganda

ILRI and partner agencies have also begun investigating ecosystem-centred ways to fight rhodesiense-type trypanosomiasis in neighbouring Uganda. Major outbreaks occurred in 1976-82 and 1984-89. Since then, there have been roughly 1,000 cases per year. The population of the affected area of 7,000 square kilometres is a little over 2 million and more than half these people live on less than US$1 a day. Small-scale crop-livestock farms predominate. Indigenous zebu cattle, which provide rural people with milk, meat, traction and savings, number about 500,000.

The goal of this three-year project, targeted initially on six high-risk communities, is to improve human health through a mix of trypanosomiasis-control interventions, in the areas of NRM, policy, social dynamics and public health. A major ILRI partner is the Livestock Health Research Institute (LIRI), part of Uganda’s National Agricultural Research Organisation.

The research is participatory and transdisciplinary, drawing on expertise in epidemiology, geographic information systems, ecology and systems analysis. It combines the practical problem-solving approach of rural Africans with the best of systems analysis tools developed by researchers.

With community help, the research team has discovered that the incidence of sleeping sickness is higher where human populations are less dense and where people live close to bushland, woodland and swamp vegetation. Through village-level planning workshops, people now have a better understanding of common problems and priorities. Although the risk of sleeping sickness is a shared concern, they recognise that, more generally, poverty and ill health are crucial constraints to farming and other daily activities. However, they also lack resources including knowledge of best practices and access to farm implements to improve their situation.

People, particularly those who live far from roads and services, feel cut off from sources of help. This same isolation makes them appear to have lower incidences of sleeping sickness simply because their cases are less frequently reported to health care workers. The initial participatory collaboration suggests that by engaging in this research, villages affected by sleeping sickness are beginning to develop community action plans to lift themselves out of poverty and into a state of better health.

ICIPE’s experience

The BioVillage Initiative is an integrated NRM project designed to improve human health and alleviate poverty in rural Ethiopia. Recently launched by ICIPE, it responds to a community request following a successful tsetse control operation in the country’s southwest.

The tsetse control system, established with community participation, was based on mass trapping of flies. As in ILRI’s tsetse and trypanosomiasis control work in nearby communities, the programme resulted in a significant reduction in the incidence of farm animal disease. While farmers saw the value of the technique for improving livestock health, they also noted its limitations as a means of addressing human health problems and poverty. In fact, the farmers stressed that in order to plough fields and grow crops for human food, animal feed and income, both oxen and men need to be healthy. They also recognised that a healthy farming community can engage in other income-generating activities such as bee keeping.

Hence, it was agreed that a comprehensive programme for farm animal and human health management was needed as a way to

Tsetse flies transmit trypanosomiasis to both people and livestock. Photo: ICIPE.

Farmers stressed that in order to plough fields and grow crops for human food, animal feed and income, both oxen and men need to be healthy.

Catching tsetse flies in Ethiopia. Photo: Andreas Schriber.

solve the most urgent problems of rural development.
The resulting management scheme is built on three elements: fly and disease control, sustainable management of natural resources, and community participation.

Fly and disease control
The BioVillage Initiative builds in part on the experience of African rural communities whose housing for people and livestock has apparently been designed to divert malaria-transmitting mosquitoes from human hosts to animal hosts. The traditional straw-thatch design is kept in the new system, but improved to reduce insect access to houses.

The disease control and resource management measures are also designed to minimise breeding sites for mosquitoes and filth flies, thus improving health and sanitation. In addition, the BioVillage Initiative incorporates zero grazing methods as complementary means of protecting cattle from tsetse flies.

Natural resource management
The programme aims to reduce the need for external inputs, particularly energy and fertiliser. Biogas digesters are used to extract energy from organic waste and manure, and the slurry is transformed into organic fertilisers through composting. The loss of nutrients such as nitrogen is minimised by separating urine from other organic waste and processing it separately. An expert from the Swiss Federal Institute of Technology provides the BioVillage Initiative with advice on organic waste processing, including composting.

Besides providing the fertiliser needed to make cropping systems more productive, such waste management techniques also reduce the breeding sites of disease vectors. In addition, the resulting supply of biogas reduces the need to collect firewood for cooking purposes and conserves local trees which may also supply fruits and pest-control materials. The use of biogas also promotes a healthier household environment by reducing disease-causing indoor pollution caused by wood burning.

The BioVillage community intends to make use of the biogas energy to pump water from the ground to the village. Easy access to clean drinking water is an important contribution to human health and helps free up time for income-generating activities.

Community participation
Local participation is essential to the project. Community members assist with the design and construction of demonstration sites for the health and NRM components and participate in training courses. They also transfer technologies to neighbouring villages. The farming communities interact with project management via an ICIPE staff member who serves as BioVillage manager.

Concluding note: The special role of women
Livestock play a central role in environmental protection, food security, and human health and welfare in the African highlands and, indeed, in most developing countries. They are critical for asset building, soil-nutrient cycling and climatic risk buffering, and they constitute a sustained and irreplaceable source of macro- and micronutrients, especially for women and children. In designing interventions for mixed farming systems, researchers and their partners need to understand the complex interactions between people, livestock, crops and the environment. An ecosystem approach to human health provides a valuable perspective in this regard.

Both individually and collectively, women are key repositories of knowledge about the nutritional value of livestock products. This role should be recognised and enhanced by encouraging women to actively participate in the design, implementation, monitoring and evaluation of educational and other programmes aimed at income generation and better family nutrition and health. At the same time, sustained investments in R&D are needed. These too should take into account women's vital contribution to agricultural production, thus making the ongoing search for solutions especially relevant and widely applicable to the realities of developing countries.

International Forum on Ecosystem Approaches to Human Health, Montréal, Canada, May 18-23, 2003

The goal of the Forum is to stimulate discussion on ecosystem approaches to human health, the evidence from the field, and the relevance of these approaches to improving well-being. The Forum offers the opportunity for researchers, policy makers, practitioners and civil society representatives from around the world to share knowledge, and for institutions to consider strategies for further progress. For more information, contact IDRC. E-mail: ecohealth@idrc.ca.

Forum themes:

- Definition and conceptualisation;
- Successes and challenges through case studies;
- Links between research results and policy development;
- Institutionalisation of ecosystem approaches to human health research and practices.

Further exploration

Many information sources address the links between human health and ecosystem management. The web sites listed below, some operated by organizations that participated in the consultation reported in this special supplement to LEISA, generally provide easy access to public domain materials.

IDRC's web site, **www.idrc.ca**, provides a wealth of on-line information about research for development. The Centre's ecohealth link is **www.idrc.ca/research/xecohealth_e.html**. Readers with access to e-mail but not to the World Wide Web can send an e-mail to **www4mail@web.bellanet.org** leaving the subject line blank, but including the URL of the web page of interest in the body of the e-mail message. For more information on this service, see **www.bellanet.org/email.htm**. UNEP also maintains an extensive web site at **www.unep.org**.

Summary of workshop discussions

An emerging consensus on ecosystems and human health

Participants from diverse professional and cultural backgrounds met in working groups to discuss human health in relation to the degradation and management of agricultural, coastal and urban ecosystems. Consensus emerged on two broad questions:

Can an ecosystem approach help improve human health where you work and live?

The consensus was "yes". While an ecosystem approach cannot cure acute illnesses, it can make the environment more conducive to good human health and well-being. To arrive at this conclusion, participants covered several topics. These included definitions and concepts of ecosystems and human health, the role of people within ecosystems, and the methodological approaches to analysis, understanding and management of ecosystems.

Defining an ecosystem

An ecosystem is a geographically coherent area that includes all living and non-living things along with the myriad of interactions among them. In the human development context, living things include people and their cultures. Human activity often leads to changes in infrastructure such as roads, dams, buildings and fences that make up many of the non-living things. Ecosystems are not isolated or static entities; rather, they interact with adjacent areas. Through phenomena such as climate, migration and global trade, they also affect and are influenced by more distant regions of the world. An ecosystem's boundary is an arbitrary characteristic assigned by people for specific purposes. An ecosystem can be a very small area, such as a field, pond or household, or a much larger one, such as a watershed or ecoregion. The biosphere itself is an ecosystem. Large ecosystems consist of many smaller ones nested within them. Their inhabitants and other stakeholders have differing perceptions of boundary locations, and these depend on their unique and ever-changing world views.

Desirable characteristics of healthy ecosystems include stability, resilience, rich biodiversity, minimal human health risks, and a flow of goods and services conducive to human well-being.

The consultation emphasised agroecosystems, but participants noted that ecosystem concepts also apply to cities and towns, where people and elements of human origin dominate. Urban livelihoods are less dependent on the internal natural environment, and poverty and violence are common. Distinguishing constraints to human development are lack of water, sanitation, shelter, air quality, green space and other basic services. Governance and cultural diversity are often more complex in urban ecosystems than in rural agroecosystems, and economic and political forces are more influential. Drawing a boundary around an urban ecosystem is difficult. Inclusion of peri-urban areas may be useful. Because many urban centres are located on the edge of rivers, lakes and oceans, urban and coastal ecosystems can overlap.

Coastal areas represent zones in which land and fresh or saline water bodies meet and influence each other. Most participants focussed on areas lying by the sea. The amount of ocean or land area to be included is arbitrary and participants agreed that how the boundaries of such ecosystems are defined depends on the nature of the human health issues to be addressed. The distinction between urban, agricultural and coastal systems is often murky. While large numbers of people do not normally inhabit the aquatic or marine portions of the coastal ecosystems on which they depend, human activity nevertheless greatly affects the health of marine and aquatic resources. The state of these resources, in turn, can either promote or constrain human well-being.

Workshop participants debated whether ecosystems reflect the inherent structure of nature or are primarily constructs of the human mind. The latter view was the consensus. Scientists are unable to identify and describe the life cycles, demographics, ecological roles, physiology and genetic variation of every life form in even relatively small ecosystems. The classification of plants, animals and microbes is a culturally specific phenomenon, limited by our observational capacity. Science itself is an outgrowth of a subset of the world's cultural practices. Although people are components of ecosystems, there was much debate over their importance. From a human health perspective, people are clearly most important. Their attributes dominate our understanding of the community and its environment. However, one can argue that plants, water and air are more important because without them people cannot survive. Balancing the two is an ethical issue that society must address.

Defining human health

The participants acknowledged that human health is a broad concept, covering much more than the absence of disease. It includes adequate nutrition, as well as social, mental and spiritual well-being. Within an ecosystem context, both individual and population health are important. Communities have culturally specific norms that spell out what is meant by "quality of life". The concept of health evolves as societies change.

Defining ecosystem health

This is the state of an ecosystem with respect to its long-term capacity to satisfy demand for the range of goods and services required by its current and future human inhabitants and also by more distant consumers. Healthy ecosystems have the capacity to mitigate or absorb the harmful effects and by-products of human activity so that the well-being of both its residents and people living elsewhere is not jeopardised. Particularly in urban ecosystems, people depend heavily on externally produced goods, and they face a growing challenge in managing accumulating pollutants and industrial and human wastes generated by their activities. Given the broad definition of human health, some participants felt that ecosystem health is an anthropocentric concept with human health as the driving goal. Desirable characteristics of healthy ecosystems include stability, resilience, rich biodiversity, minimal human health risks, and a flow of goods and services conducive to human well-being. The participants recognised the need to find suitable indicators for these. The maintenance of ecosystem health standards imposes constraints on any human development that relies on resource exploitation and consumption. Indeed, it may force a shift in development thinking from consumption to service and social capital building.

Applying an ecosystem approach to human health

This demands an integrated effort by professionals in many disciplines, along with representatives of the communities who stand to gain or lose from future ecosystem management. Inclusion of policy makers, government and development workers influences the institutional, policy and financial environment in which human development takes place. Together, these individuals are able to increase their understanding of the complex web of causal factors affecting the priority health issues that residents of ecosystems face.

Researchers now realise, however, that these biophysical, socio-economic and cultural systems are so complex that our ability to accurately predict their behaviour is at best very limited. Nevertheless, joint recognition of this complexity provides a tool for conflict resolution and community-based natural resource management. It enables people to prioritise technologies, policies and changes in their livelihood behaviours that can “nudge” the ecosystem toward positive change. An iterative process of stewardship is needed to ensure a continuing cycle of assessment of ecosystem health and human well-being, reflection, priority setting, action and re-assessment, leading to a better quality of human life over the long term.

Based on your own experience and on this UNEP-IDRC consultation, what do you see as the most important challenges in applying an ecosystem approach to improve human health?

Having agreed that an ecosystem approach to health is useful, the working groups highlighted challenges that must be met to make it work:

Understanding and managing complexity

No single human being can grasp the full reality of the complex sets of interacting factors that mould human and ecosystem health. Bringing teams of diverse people together is essential. The disciplines in which expertise is required include ecology, natural resource management, climate change, public health, economics, sociology, anthropology, governance, law, policy and ethics. And community participation should reflect the various social strata within the target population. The transdisciplinary process of building a new understanding of the interactions among the ecosystem’s non-human elements, as well as between those elements collectively and human well-being, is a daunting task. Success will come from integrated and shared work and learning in which participants are equal partners, rather than from attempts to achieve some kind of absolute understanding. The challenge is to recruit a new generation of research and development workers and communities who are prepared to go beyond their traditional horizons and practices to find flexible solutions to complex problems.

Transforming the institutional environment

Our systems of governance and learning are founded on reductionist principles which assume that we can achieve sustainable development by solving many small development problems in isolation. Financial support systems reinforce this sectoral approach to R&D. They constrain institutions’ capacity to work outside legislated mandates. Different levels of government may end up working against each other because the geographic scales and development objectives they are addressing are different. Government actions often respond to the status quo in power relations among people. As a result, the poor have no influence, receive few benefits, and therefore remain poor. The challenge is to transform the institutional environment to create greater opportunities for research and human development using an ecosystem approach. Greater funding for ecosystems research is needed. New approaches to policy can allow people to benefit equitably from the results. Balancing some people’s demands for short-term goods and services from an ecosystem with longer-term needs to conserve vulnerable habitats and biodiversity will test policy-making, regulatory and enforcement processes.

Building the awareness and capacity of stakeholders

Participants emphasised the challenge of raising awareness and understanding of the ecosystem approach among all stakeholders. People need to see the potential health benefits of applying preventative measures that take into account the web of ecological, social and economic forces at work in their communities. This awareness is especially important where poverty and marginalisation exclude certain groups from the formal health care system. Increased acceptance of the ecosystem approach by individuals with political and financial power is a prerequisite to progress. Even one individual (such as a government minister or a village clergy member who is not on board) can undermine successful development based on ecosystem approaches. Training and stakeholder consultations, reinforced by public awareness and institutional support, are needed to continually raise collective capacity to improve the quality of life within the community. Patience with the process is needed. ■

FUTURE℠ HARVEST

Many of the collaborative projects discussed in this consultation report are conducted by one or more of the 16 Future Harvest centres supported by the Consultative Group on International Agricultural Research (CGIAR).

Future Harvest is an international non-profit organisation. It is dedicated to raising public awareness of the close links between agriculture and other global issues such as military conflict, water and land shortages, loss of biodiversity, the spread of human disease, climate change and poverty. The organisation believes that agriculture itself, based on good science, holds solutions to many of the compelling problems facing the world today.

Future Harvest promotes a hopeful vision of the future – a “green and prosperous earth that provides abundance, health, and peace to its peoples.” It cautions, however, that this can only be achieved if we devote attention and resources to scientific research for food, the environment and the world’s poor.

Ecuador: Pesticides, Health and Changes in Potato Technology

Health/agroecosystem links

How do pesticides affect the health of farm families who grow and eat potatoes? What are the effects of pesticide-related behaviour in the household? Can health be improved and agricultural productivity maintained by training farmers to handle pesticides more safely and use integrated pest and disease management techniques?

Research organisations

Instituto Nacional Autónomo de Investigaciones Agropecuarias (INIAP), Ecuador; International Potato Center (CIP); McMaster Institute of Environment and Health (MIEH), Canada; Programme for Appropriate Technology in Health (PATH-Canada); University of Montana, USA.

Background

In the Andean valleys of Ecuador's Carchi Province, about 8,000 growers account for 40% of national potato production. They are among the country's heaviest pesticide consumers. Using backpack sprayers, they apply methamidophos and carbofuran to control foliage-damaging insects and the tuber-damaging larvae of Andean weevils. Two fungicides, maneb and mancozeb, are also widely used to combat late blight.

Earlier Canadian research linked to this project revealed that pesticides were applied an average of seven times during crop growth. It also showed that farm people had significantly more nervous-system disorders, such as impaired motor skills, than non-farmers. Skin disorders were also common. The pesticide poisoning rate of 171 per 100,000 population was similar to the highest rates recorded elsewhere in the developing world. Direct skin contact with pesticides during mixing, leaky sprayers and lack of protective clothing during application explain some of the health problems. However, different factors may account for ill health in other members of the farming community. These include contamination from pesticide residues on potatoes prepared and eaten in the home, as well as household storage of pesticides and washing of work clothes.

Project description

This research covers the health component of a major ecoregional project by CIP, INIAP and the University of Montana. That project has developed and tested a multidisciplinary model, based on Andean potato farming, for integrated assessment of the sustainability of agricultural production systems. Field-based surveys of crop production, household practices, poverty levels, dietary habits and the nutritional status of farm family members generated the necessary information for the model. The model quantifies how farmers' methods and decisions (such as those related to pesticide use) affect crop productivity, farm incomes, the environment and human health. Then, using statistical techniques, it aggregates those effects at the regional level for policy analysis – for example, to decide on pesticide subsidies or disincentives, or to formulate extension strategies. The project's conceptual framework makes it possible to link results from individual disciplines, thereby producing "second level" results from the combined analysis.

Florescent dye on a person's hands reveals traces of pesticide. Exposure has serious adverse effects, both neurological and skin-related, on potato farmers in Ecuador. Photo: CIP.

The health component of the research focusses on 40 farm families in two micowatersheds of Carchi, taking into account gender differences. It attempts to answer several questions. First, do differences in food preparation methods, diets and other household practices affect neurobehavioural function? Second, can participatory programmes for men and women change potato production and household management methods in a way that decreases pesticide exposure, thereby improving health? Third, what are the tradeoffs between human health, food production and environmental protection in the broader region? Finally, how would safer use of pesticides and integrated pest/disease management affect those tradeoffs?

Results and conclusions

Exposure to pesticides has serious adverse effects – neurological and skin-related – on local human health. In turn, health disorders undermine farmers' ability to make efficient farming decisions. Farmers with higher neurobehavioural scores had lower production costs per hectare and thus higher productivity, consistent with better managerial capacity. Farmers would be both healthier and more productive if use of the pesticide carbofuran were reduced. Productivity gains from improved health outweigh losses from reduced pesticide use.

Males are exposed to pesticides mainly through preparing and applying pesticides in the field. For women, exposure occurs mainly in and around the home where pesticides are often stored and where work clothes impregnated with pesticides are washed. Exposure of children is mostly accidental – for example, when they are helping their parents. Children age 5 and younger are the age group with the highest number of hospital-treated cases of pesticide intoxication. Pesticides are also used frequently by other household members in suicide attempts. As pathways of pesticide exposure differ according to gender and age, the project has tailored protection strategies to each group at risk.

Tradeoff analysis suggests that safer pesticide handling and use of IPM to cut carbofuran use could reduce the pesticide's adverse health effects by 50% or more without reducing potato production. A key policy implication is that education and extension programmes are less costly than taxes on pesticides as a way to reduce the health burden of pesticide use and make the ecosystem more sustainable.

Brazil: Mercury Poisoning in the Amazon

Health/agroecosystem links

What role do gold mining, crop-related deforestation and soil erosion play in methylmercury contamination of fish in the Brazilian Amazon and poisoning of local people who eat fish? What ecosystem management practices might reduce overall levels of mercury in the environment?

Research organisations and partners

Background

The presence of mercury in the food chain and its absorption by people are universally recognized as health hazards. Once mercury is released into rivers, lakes and other aquatic environments, bacteria can transform the mercury into its organic form, highly toxic methylmercury. In this form it can be absorbed by aquatic fauna, increasing in concentration (biomagnifying) as it moves up the food chain to fish and then to humans.

One of the best known cases of methylmercury poisoning was discovered in 1956 in communities near Minamata Bay, Japan, where mercury discharged from a chemical plant accumulated in fish. Thousands of people who lived in the area and ate fish and shellfish from the bay developed what came to be known as Minamata Disease.

A number of studies have reported on mercury contamination of fish in some rivers of the Amazon. People who live along those rivers and depend on fish for a major part of their diet have relatively high levels of mercury in their hair, an indicator of mercury exposure. For years, the use of mercury to extract gold from river sediment and soil, a method still in use, was thought to be the source.

Project description and results

Concerned about the effects of mercury on human health in the Amazon, scientists from the Federal University of Pará and UQAM teamed up in 1994 to explore the problem further. Their focus was Brazil's Tapajós River, where thousands of miners have panned for gold over the last 30 years. In the following six years, understanding of the behaviour and toxicity of mercury in Amazonian ecosystems increased. Now researchers are turning their attention to ecosystem approaches to reducing exposure to this heavy metal.

To determine mercury levels, the team collected and analysed water, river sediment and soil at intervals along the river, starting at gold mining sites and ending hundreds of kilometres away. They also analysed hair, blood and urine samples from fish-consuming villagers who live near the river and conducted simple co-ordination and visions tests to determine the health impact.

The researchers expected mercury levels to drop as distance increased from mining sites. Instead, concentrations were relatively constant along the Tapajós River, even hundreds of kilometres downstream from the sites. Thus, the scientists suspected another major source of mercury.

Analysis of riverbed sediments, sampled in half-centimeter increments, showed the most recent layers contained 1.5 to 3 times more mercury than layers deposited 40 years ago. This was true even of sediments 400 kilometres downstream of the gold mining sites. Sampling and analysis of nearby soils revealed high mercury concentrations throughout the soil profiles, down to a depth of 1 metre. The researchers concluded that deforestation had allowed rain to erode the surface layers of the watershed's soil, followed later by erosion of deeper strata. Indeed, in some areas along the Tapajós River, up to 15 centimetres of soil have been lost. Further study revealed that subsurface leaching of mercury from the land to the river also contributes to mercury accumulation in the aquatic environment. Deforestation and the whole process of erosion have led to the transfer of high mercury loads from the land to the aquatic ecosystems. Finally, the researchers now suspect that mats of floating macrophytes (large aquatic plants) are key sites of transformation of inorganic mercury into the toxic methylated form.

The explanation of mercury contamination based on deforestation and soil erosion is consistent with the recent history of the Tapajós River basin. Some 40 years ago, immigrants from northern Brazil began colonizing the area beside the river. They slashed and burned the trees in preparation for cropping and other activities.

Hair samples from adults in the village of Brasilia Legal contained an average of 15.9 parts per million (ppm), well below the threshold considered safe by the World Health Organization.

The WHO threshold of 50 ppm is based on the lowest level at which previous studies have reported the first clinical signs of mercury poisoning in adults. Further tests on the villagers showed, however, that their co-ordination, manual dexterity and certain visual functions had declined. The researchers concluded that mercury can damage human health even at levels well below accepted international safety standards. Testing also revealed that the mercury levels in people were highest during the rainy season when lots of large carnivorous fish were available.

Researchers are working with local people, including a women's group in Brasilia Legal, to design and implement intervention strategies. One set of activities, including study of the links between fish diet and mercury content of hair, aims to reduce the consumption of fish with high mercury content (see text below). For example, there are a number of species of edible herbivorous fish that could be promoted for human consumption. Other work focuses on identifying possible sites and mechanisms of mercury methylation in the Tapajós River. Limiting the proliferation of patches of floating macrophytes, through shoreline forest conservation and restoration, is one strategy under investigation.

Future directions

Over the longer term, the project team hopes to scale up both research and interventions to the regional level. Proposed activities aim to shift family agricultural practices toward better land management to protect and restore these important Amazonian ecosystems and improve the quality of life of the region's poor farmers.

Report contributors: **D. Mergler** and **M. Lucotte** (UQUAM), **R. Davidson** (Biodôme de Montréal). Further information: http://www.unites.uqam.ca/cinbiose/; www.idrc.ca/reports/read_article_english.cfm?article_num=168; www.idrc.ca/media/mercurypoisoning_e.html.

"Eat fish that don't eat other fish"

Since 1994, villagers from the town of Brasilia Legal have actively participated in the IDRC-funded study of mercury on the Tapajós River. In 1995, about 100 people provided hair samples for mercury analysis and underwent testing for nervous system functions. Although hair mercury levels were below those considered "safe", results showed dose-effect relations, with fine motor movements and vision decreasing with increasing mercury levels.

After a workshop and discussion, the villagers agreed on a short-term solution. People would alter their diets to reduce mercury absorption but still maintain fish consumption. "Eat fish that don't eat other fish" became the slogan since mercury levels are lowest at the bottom of the food chain.

In 2000, hair samples provided by 45 people from the original 1995 group were analyzed for mercury. The results were highly encouraging: hair mercury levels had decreased by more than one-third. While people were eating exactly the same amount of fish, they had reduced the proportion of carnivorous species in their diet.

Eastern and Southern Africa: AIDS and Food Security

Health/agroecosystem links

How does HIV/AIDS affect food production and security, agricultural labour patterns, and agroecosystem management in African countries hit hardest by the epidemic? How and where is food insecurity leading to further spread of HIV infection? What importance should national agricultural R&D institutions accord to the links – in both directions – between HIV/AIDS and agriculture? In which types of agroecosystems are people's livelihoods most at risk? What can R&D institutions do to support local responses to the emerging threats?

Research organisations

International Service for National Agricultural Research (ISNAR); Institute of Tropical Medicine, Belgium; agricultural R&D and public health organisations in Malawi, Tanzania and Uganda; other selected research institutions within and outside the region.

Background

There is growing evidence that, without decisive action, HIV/AIDS will reverse human development gains achieved in recent decades in parts of sub-Saharan Africa. Infection rates are increasing faster than expected just a few years ago. In at least seven countries – Botswana, Lesotho, Namibia, South Africa, Swaziland, Zambia and Zimbabwe – 20 percent or more of adults are now infected with HIV. Once concentrated in towns and cities, infection is now widespread in rural areas and more prevalent among African women than men. AIDS and its associated diseases, especially tuberculosis, are now the leading causes of both adult and child deaths in Africa.

AIDS affects many aspects of rural life. In severely affected agricultural areas, there is evidence of declining labour availability as people fall ill and die and as family members, particularly women, devote more time to caring for the sick. Family finances are under severe pressure since assets often have to be liquidated to pay for medical and funeral expenses. And as sick family members return to villages from the cities to be cared for by their families, there is an added burden on rural households. In some cases, children are removed from school to make up for farm labour shortages.

AIDS degrades agricultural systems, impoverishes those whose livelihoods depend on them, erodes the agricultural knowledge base, and shifts survivors' farming behaviour to shorter-term objectives. The epidemic's spread is exacerbated by food insecurity and by the inability of rural people to make a living where they live. One common response is to leave the home community in search of work. Particularly when they move alone, migrants are often at increased risk of HIV infection. Once infected, they may in turn increase the risk for others in the areas into which they move. Chronic rural unemployment and insecurity may also contribute to attitudes that favour risky sexual behaviour. Diversification of livelihood opportunities in and around agriculture may help reduce vulnerability to HIV infection. Conversely, agricultural production and development that induce people to migrate may inadvertently increase this vulnerability.

AIDS is now widely viewed as a developmental crisis, yet the capacity to act lags behind. A few organisations have supported the coping strategies of AIDS-affected households – for example, by

Blood samples are prepared for HIV testing at a medical microbiology laboratory in Kenya. Previously concentrated in towns and cities, AIDS and HIV infection are now taking a heavy toll on rural communities in Eastern and Southern Africa. A new study led by ISNAR aims to help national agricultural research organisations cope with the problem. IDRC photo: Gerry Toomey.

providing lighter farm implements that can be handled by women and children. However, most agricultural R&D organisations in the region have been slow to respond. The toll that AIDS is taking on these organisations' own staff further limits their responses.

Project objectives and methodology

The overall aim of this recently launched project is to prevent and mitigate the impact of AIDS on agricultural systems and on the livelihoods of those who depend on them. The research will help fill critical gaps in current knowledge of the reciprocal links between HIV/AIDS and agricultural development and how agricultural R&D institutions are responding to the problem. It will enable such institutions to set and act on realistic priorities for response, in collaboration with communities and other partners.

The research strategy is based on a layered framework of analysis that supports research priority setting at various levels. The project results should help agricultural research organisations address a number of interrelated questions: Is the actual or potential impact of AIDS within the institution's mandated area sufficiently great to warrant taking AIDS into account? If so, what level of resources should be allocated to the problem? In light of local disease prevalence and other factors, which specific agricultural systems should be targeted and with what type of assistance?

The project will focus initially on three severely affected countries: Malawi, Tanzania and Uganda. Country teams, drawn from key agricultural R&D and public health institutions, will conduct research (literature reviews and field studies) to characterise and analyse the impact and response aspects of AIDS. They will then work with concerned agricultural R&D institutions in the participating countries to transform the findings into priorities for action. The teams will share information and lessons. A group of experts from within and outside the region, working in agricultural and public health research and in R&D planning and management, will support the teams.

Kenya: Agroecosystem Management for Community-Based Malaria Control

Health/agroecosystem links

How does rice irrigation affect human health? What are its links with domestic water supply and sanitation? Can new options for water and livestock management cut malaria transmission? Which types of intervention are socioeconomically feasible?

Research organisations and partners

CGIAR Systemwide Initiative on Malaria & Agriculture; International Centre of Insect Physiology and Ecology (ICIPE); International Water Management Institute (IWMI); World Health Organization Panel of Experts on Environmental Management for Vector Control (PEEM); College of Agriculture and Veterinary Sciences, University of Nairobi, Kenya; Kenya Agricultural Research Institute (KARI); Division of Vector-Borne Disease (DVBD), Ministry of Health, Kenya; National Irrigation Board (NIB), Kenya; Kenya Medical Research Institute (KEMRI).

Background

Every year, malaria kills around two million people, 90% of them in Africa. About three-quarters of Africans live in areas of highly endemic but stable transmission. Another 18% inhabit areas where malaria transmission is seasonal and unstable. The latter areas are particularly vulnerable to deadly epidemics.

Malaria control has centred on two strategies: treating sick people with drugs that target the plasmodium parasite, and using insecticides to eliminate the vector mosquitoes. These methods are not only very expensive for most African countries, but also increasingly ineffective as mosquitoes and malaria parasites continue to build resistance to insecticides and drugs respectively. The risk of environmental damage from insecticides is also a growing concern.

As demand for rice grows in Africa, so does the proportion of cultivated land brought under irrigation. These schemes provide a favourable breeding habitat for malaria-bearing anopheline mosquitoes. In a recent survey to assess the knowledge and perceptions of farmers in a rice irrigation scheme, all 104 families interviewed ranked malaria as their main health problem.

The deteriorating malaria situation in many African communities urgently demands new lines of attack to complement existing control measures. Farm-level strategies for managing water and livestock have the potential to lessen human exposure to mosquitoes while making the ecosystem more sustainable.

Project description

This $1\frac{1}{2}$-year project aims to improve the health and economic well-being of communities in irrigation schemes. It will do this through the design of improved agroecosystem management practices that also reduce malaria and other health risks. The research will contribute to the development of an agroecosystem intervention model that can also be used elsewhere in Africa. The research results will feed into the design of farm-based malaria control measures which will be assessed for their social and economic feasibility before being promoted. The measures focus on two strategies: water management (for example, intermittent irrigation) and the use of livestock (particularly cattle) to divert blood-seeking mosquitoes away from people. Cattle are dead-end hosts for malaria parasites. However, since opinions differ about the exact role of livestock in malaria transmission, the researchers will first attempt to clarify this link.

Researchers are conducting their core studies within the Mwea Rice Irrigation Scheme, about 100 kilometres northeast of Nairobi, Kenya. Nearly half the settlement's 13,640 hectares is used for paddy farming, while the rest is devoted to subsistence farming, grazing and communal activities. The tenant population, dispersed in 36 villages, comprises 3,100 families. Malaria transmission in this area is low but stable, with a parasite prevalence of less than 20%.

Researchers have begun the work with a health risk assessment aimed initially at determining whether rice irrigation increases or decreases health risks. This study takes into account a variety of socioeconomic, environmental and institutional factors. The main ones are age, sex, education, occupation, income, religious and cultural affiliation, family size, nutritional status, water management practices, location, and the role and effectiveness of public health agencies. In parallel, the researchers are documenting and assessing the mixed crop and livestock production systems of the Mwea Scheme. Their aim is to identify opportunities for enhancing nutrition and income generation. Malnutrition generally lowers people's immunity to disease, including malaria. In the Mwea region, the staple diet of cereals is rich in calories but deficient in essential micronutrients available in livestock products, grain legumes, vegetables and fruits.

More efficient use of local resources could enhance the productivity and sustainability of the crop/livestock production system. Farmers would thus have a good mix of consumables, cash and further inputs for the farm enterprise such as draught power and manure. Having cattle near households may not only help divert mosquitoes away from people and provide animal protein but also contribute significantly to an increase in home-garden production.

Mwea villagers will contribute to all phases of the research, from data gathering and analysis, to design and implementation of action plans. Participatory rural appraisal methods will be used throughout the project. Since women are often more vulnerable to environmental hazards than men, yet have less decision-making power over the domestic environment, much of the research project's data gathering and analysis will be gender-specific. ■

Thailand: Shifting Cultivation and Health of Karen Hill Tribe Families

Health/agroecosystem links

How do shortened fallow periods in shifting cultivation affect soil fertility, rice productivity, food supply and consumption? What is the link between management of this agroecosystem and farm families' nutritional status?

Research organisations

International Centre for Research in Agroforestry (linked to the CGIAR Alternatives to Slash and Burn Initiative); Chiang Mai University Department of Pediatrics, Thailand; University of British Columbia Department of Forest Sciences, Canada.

Background

The Karen and Lua hill tribe farmers of northern Thailand have practised shifting cultivation for centuries. They clear forest plots by slashing and burning, plant crops such as upland rice for a year or two, then abandon the land. Traditionally, the fallow period was a decade or more, allowing land to regain fertility. In recent decades, though, population growth, natural resource policies and changes in land tenure have resulted in much shorter fallow periods – in some instances less than six years. There are fears that the new production cycle threatens soil fertility, upland rice productivity and food supplies. In 1992, local Thai authorities reported, for example, that only about 50% of minority hill tribe families in Mae Chem District had a sufficient rice supply. Switching from slash-and-burn to permanent rice paddy farming also presents problems. These include environmental and health hazards from agrochemicals, increased production costs, and potential loss of plant biodiversity in fallow fields.

Project description

The project is investigating links between ecosystem management under shorter-follow production and the health of the Karen farmers in the village of Mae Hae Tai, Mae Chaem District. The 4,000 square kilometre watershed of Mae Chaem is a benchmark site for the System-Wide Alternatives to Slash and Burn Initiative of the Consultative Group on International Agricultural Research (CGIAR). The researchers are examining rice productivity, food supply and consumption, taking into account the special role of women as gardeners, food collectors and preparers. Links between rice productivity and soil fertility are also being analysed. Health workers are assessing the nutritional status of local families, who in turn participate in data review and help design interventions to solve health and ecological problems. Resulting indicators of health and ecological status will allow researchers to assess and compare conditions in other communities, including those involved in long-fallow and permanent (as opposed to shifting) agriculture. Their findings will support Thai policy making in the areas of land use transformation and health promotion in the country's northern watersheds.

Results* to date, preliminary conclusions, future directions

Under the health component of this three-year project, researchers assessed about 100 Karen people, half of them adults, half of them children. Results showed all of the children were at risk of vitamin A deficiency. The prevalence of anaemia among children was 15% but this was not due to vitamin B12 and folic acid deficiencies, nutritional factors often associated with anaemia. (Vitamin B12 deficiency is common in vegetarians; the children in the study group, however, were all non-vegetarians.) Low iron reserve was observed in 63% of the children. Based on weight-for-age, nearly all the Karen children examined were classified as malnourished, though not severely. In addition, more than half had parasitic infections. Among the 49 Karen adults assessed, only a few were obese, whereas about one-fifth, mostly women, were underweight.

Ecological field studies of crop productivity and the role of nutrients in forest-fallow shifting cultivation revealed an average upland rice yield of about 1 ton per hectare for the1999 cropping season. Rice productivity, however, is subject to year-to-year fluctuations due to the spatial variability of soil fertility in shifting cultivation fields and to local climate. During the six-year rotation (one year of cropping, followed by five years of fallow), soil changes included an increase in soil organic matter and total nitrogen due to the addition of litterfall, but a decline in pH, available phosphorus, extractable potassium, calcium and magnesium due to the diminishing effects of ash. Standing tree, shrub and herb biomass increased gradually over the fallow period. The second-year rice experiment with fertiliser trials revealed that nitrogen and phosphorus were the two most deficient nutrients in the system.

The current fallow period of five years appears long enough to maintain annual rice yields. However, any further reduction could threaten soil fertility and thus the relative sustainability of the system. The reduced duration of fallow (compared with a fallow period twice as long in some neighbouring systems of shifting cultivation) has resulted in a substantial drop in the biomass of fallow fields. It also threatens the survival of some tree species found in the late stages of longer fallows.

The results show shifting cultivation has provided stable rice production over the years. However, rice is low in protein and the observed malnutrition among Karen children may be due to insufficient consumption from other food groups. It is a common hypothesis among development workers that longer fallows supply non-rice products that may be nutritionally important.

A next step is to determine rice deficiency/sufficiency by assessing consumption at the household level. Researchers will also examine whether malnutrition is worse under short- versus long-cycle systems and whether major shifts in food sources have resulted from this change in production.
Other local food sources, such as wild and domestic animals and plants, will be studied to determine their nutritional contribution to local diets.

Peru: Health, Biodiversity and Natural Resource Use on the Amazon Frontier

Beyond abstraction. A Peruvian child gets a close-up view of water-borne parasites. Photo: Tamsyn Murray.

Health/agroecosystem links

How do the hydrological cycle, market access, ethnicity and the use of natural resources in slash-and-burn farming, fishing, cattle ranching, oil palm production, hunting and gathering influence food availability, disease levels and the nutritional status of local people?

Research organisations and partners

International Center for Tropical Agriculture (CIAT); Ucayali Ministry of Health, Peru; Universidad Nacional de Ucayali (UNU); Instituto de Investigaciones de la Amazonia Peruana (IIAP); Asociación de Mujeres Campesinas de Ucayali (AMUCAU); Federación de las Comunidades Nativas de Ucayali (FECONAU); Organización de Mujeres Indigenas de la Amazonia Peruana (OMIAP), Peruvian Ministry of Fisheries (DIREPE); Universidad Peruana Cayetano Heredia (UPCH); Instituto de Investigación Nutricional (IIN); British Institute of Tropical Medicine, University of Liverpool; Programme for Appropriate Technology in Health (PATH Canada); University of Guelph, Canada; University of Waterloo, Canada.

Background

The Ucayali Region of the Peruvian Amazon is home to 370,000 people and covers 100,000 square kilometres. In the 1940s a road was built between Lima and the city of Pucallpa on the Ucayali River, a major tributary of the Amazon. This hastened settlement of the region. Now, about 80% of the population lives either in Pucallpa or along the road to the capital.

Despite Ucayali's rich biological diversity, remote communities struggle to meet basic needs. They also face a barrage of nutritional and health problems. With an estimated two-thirds of rural households living in absolute poverty, human deprivation is the norm here, not the exception. Chronic malnutrition affects over half of rural children under 5. Anaemia and vitamin A deficiency are widespread and cases of malaria, dengue fever and persistent diarrhoea are on the rise. People in the region make a living from a mix of enterprises: cropping, fishing, logging, ranching, plantation operations, hunting and gathering. While it is widely accepted that slash-and-burn farming and unregulated logging accelerate deforestation, it still isn't clear how these diverse livelihood strategies affect household health and income, or whether health and earnings are related. Yet, answers to these questions underpin the design of viable development options for the people of this vast region of forest margins.

Project description

Ucayali is a benchmark site for the Alternatives to Slash and Burn Initiative of the Consultative Group on International Agricultural Research (CGIAR). It provides a valuable opportunity to understand a complex natural and human environment from an agroecosystem perspective. Research findings here may also have applications in other forest margin areas. The research is participatory and interdisciplinary, drawing on local knowledge as well as scientific expertise in nutrition, health, anthropology, agronomy, natural resource management, fisheries, forestry, ecology, rural planning and economics. The underlying conceptual framework, developed during earlier studies in Ucayali, is referred to as the adaptive methodology for ecosystem sustainability and health, or AMESH for short.

The project team spatially mapped the mix of ecological resources available to the rural population and conducted household surveys to define food production, consumption and family income patterns. In addition, basic mortality and morbidity rates were measured. This work included field tests for anaemia, parasitic infections and water quality. The research has involved 345 families in eight communities, representing a cross-section of production strategies, ethnicity, ecosystem types and market accessibility. Work was timed to record seasonal variations in production and food availability due to the annual hydrological cycle and the 8 to15 metre rise in river levels. Using three time periods and data sets, researchers analysed cycles of food production and availability, disease outbreaks and nutrient intake. This allowed for more targeted and effective interventions.

In addition, the research team used participatory methods to explore the role of local beliefs and knowledge in the selection of food and treatment of illnesses and to identify community health priorities. This information was used to formulate local definitions and indicators of health that aided development of community action plans and evaluation of Ministry of Health rural programmes.

Results, conclusions and interventions

Based on 18 months of fieldwork and initial data analysis, the researchers reached several conclusions. First, health is multidimensional. Ecological factors, resource diversity and soil fertility influence natural resource use patterns; these in turn affect nutrition and food security. Changes in vector habitats and water quality affect disease transmission. Economic factors such as labour supply, distance from markets, and access to credit influence income and access to health and educational services. Cultural differences among colonists affect social cohesion in young settlements, and lack of appropriate local knowledge undermines their ability to exploit the diverse resources available to them. Further analysis will determine which factors, or combination of factors, are most important to human health.

Second, the ever-changing ecology of the flood plain and upland terraces, as rivers flood and recede, dictates patterns of human migration, disease, nutrition, food security and resource use (as in fishing, hunting and agriculture). Interventions to promote sustainable resource use for better health and nutrition should take advantage of annual flooding rather than being drowned economically by it.

Third, the issues facing different groups vary considerably. For example, families living in the flood plain benefit from an abundant supply of fish and game, yet their health is undermined by parasitic infections due to poor water quality and sanitation caused by flooding. Food security and nutrition are therefore less of an issue than poor health status. In the upland terraces, high fish prices, scarcer game and longer cropping periods lead to seasonal food insecurity each year. Development initiatives need to accommodate such differences.

Fishing on the Ucayali River. In the Peruvian Amazon, the cycle of river flooding and receding waters strongly influences human health, migration and the availability of food such as fish, game, wild plants and cultivated crops. Photo: Tamsyn Murray.

Finally, extensive and diversified patterns of resource use, although recommended, will eventually fail if there is no landscape-level mechanism to regulate and monitor communal resources. On the Amazon frontier, the absence of government and non-existent or precarious land ownership result in an institutional and political vacuum. In addition, physical demarcation of land on the flood plain is often impossible due to changing river configurations. To maintain human health and the ecosystems that support people, an institutional, political and legal framework is needed – one that avoids narrow sectoral approaches and top-down management. Community-based management is one option for allowing different user groups to jointly negotiate long-term plans for sharing resources.

The project team is working with communities and health officials to design local action plans. These centre on interventions such as health and nutrition education programmes, testing inhabitants for parasites and anaemia, water purification, small-scale food production projects, and the introduction of improved hygiene and sanitation.

Besides generating useful data, the project's participatory methods stimulated community involvement in health improvements. For example, the impact of having mothers, fathers and children view their own parasites through a microscope far surpassed the information value of stool sample analysis. Parasites were no longer an abstract concept discussed only by Ministry of Health professionals; they became real aspects of villagers' daily experience with poor water quality and diarrhoea. In each community, villagers were immediately mobilised to find solutions to water contamination and parasite transmission.

At the regional level, project results are helping the Ministry of Health to adjust its health and nutrition programmes. An interdisciplinary course on ecosystem approaches to human health is also being designed for the National University of Ucayali.

Sri Lanka: Agroecosystem Management for Human Health in the Uda Walawe Irrigation Scheme

Health / agroecosystem links

How do changes in agricultural water management and cropping patterns affect the breeding of disease-bearing mosquitoes, the availability of water for domestic uses, and the need for agrochemicals? What management options can make the use of water for agriculture more efficient while protecting human health and the environment?

Research organisations and partners

International Water Management Institute (IWMI); Mahaweli Economic Agency, Sri Lanka; Regional Agricultural Research Center, Department of Agriculture, Sri Lanka; Anti-malaria Campaign (AMC), Sri Lanka; University of Peradeniya, Sri Lanka; Brace Centre for Water Resources Management, McGill University, Canada.

Background

Ironically, the use of irrigation to produce enough food for basic human health and nutrition has often intensified other threats to health. These include increased transmission of malaria, Japanese encephalitis and schistosomiasis. In many irrigated areas, pesticide poisoning is also a big problem due to high pesticide use without the necessary safety precautions. Drinking water can be affected when irrigation systems are rehabilitated. For example, when canals are lined, there if often less recharge of shallow wells, leading to an increase in cases of gastrointestinal disease. Irrigation schemes can also affect regional water balances and sometimes have unintended ecological repercussions downstream, such as destruction of wetland biodiversity.

At the same time, irrigation development can help improve health. In many parts of the world, including Sri Lanka, irrigation canals and other structures are important sites for bathing and doing laundry, thus enhancing hygiene. As emphasis in the irrigation sector shifts from building large new schemes to rehabilitating existing ones, there are opportunities to design changes in irrigation management that promote both human health and sustainable food production.

Women are the main providers and managers of domestic water in most rural areas of the developing world and play a major role in agriculture. However, irrigation still tends to be a male-dominated activity. Irrigation policies and practices that neglect the key role of rural women in water use and management may pose unnecessary risks to overall family health and place a disproportionately large burden of illness on women and children.

In 1963, the Sri Lankan government launched the Uda Walawe Irrigation Scheme in the country's south. About 15,000 hectares in the Walawe River basin have been developed. A key aim of the Mahaweli Authority of Sri Lanka (MASL), which controls the scheme, is to use water more efficiently so that a further 6,000 hectares can be brought under irrigation. The strategy centres on rehabilitating canals, managing water better and introducing non-rice field crops that need less water.

Recognising the need for a broad perspective on ecosystem management, MASL asked IWMI in 1997 to help assess options for better water management at three levels: farm, irrigation system and basin. With support from the Japanese Bank for International Cooperation and the Council of Agriculture and Irrigation Associations of Taiwan, IWMI began research on drip irrigation for bananas, alternate wet and dry irrigation (AWDI) technology for rice, and the water balance at the basin level.

While crop diversification and intensified production through irrigation can alleviate poverty, environmental and human health problems also need to be addressed. For example, the resurgence of malaria and numerous cases of pesticide poisoning have alarmed both community members and public health officials in recent years. Such problems have raised questions about the sustainability of the whole irrigation enterprise. With IDRC support, the research project is therefore also examining health and environmental issues to identify options for improving human health in the Uda Walawe Irrigation Scheme.

Project description

The hypothesis of the health research component of the overall project is that irrigation management can be altered to improve human health, with minimal impact on agricultural performance. AWDI technology, for instance, can help control mosquito breeding in rice fields while conserving water. Similarly, IPM could lessen farmers' dependence on pesticides. This might not only improve agricultural productivity and alleviate groundwater pollution, but also cut the number of suicides related to easy access to toxic substances.

The methodology centres on four activities: investigating mosquito ecology and disease transmission; establishing the link between irrigation water management and groundwater quality and availability in shallow wells; estimating the need for agrochemical inputs for alternative crops and water management methods; and evaluating the potential for using IPM methods. The research draws on expertise from several disciplines and is broadly participatory in that scientists work closely with local communities, women's groups, NGOs, universities and government agencies.

The data needed to assess ecosystem management options for improved health come from several sources. For example, a geographic information system is being used to map malaria incidence. The information is broken down by environmental factors such as the extent of irrigation, other land uses, soil moisture and vegetative cover. And for their analysis of agrochemical usage, the researchers are drawing on existing sales data and conducting farm surveys.

The analytical results will be integrated to generate a basin-level estimate of changes in vector breeding, agrochemical use and groundwater fluctuations under different scenarios of irrigation management. Throughout the process, the researchers are paying special attention to the role of women in water management and to the effects of policies and practices on them. ■

West Africa: Irrigation, Water Management and Vector-Borne Diseases in Rice Farming

Health/agroecosystem links

Does expansion of irrigation and other water management strategies for rice production increase malaria transmission and the associated burden of disease in rural communities?

Research organisations

West Africa Rice Development Association (WARDA); Institut d'Économie Rurale (IER), Mali; École Nationale de Médecine et de Pharmacie, Mali; Institut National de Recherches en Santé Publique, Mali; Institut Pierre Richet – Organisation de Coordination pour la Lutte contre les Grandes Énemies (OCCGE), Côte d'Ivoire; Centre Universitaire de Formation en Entomologie Médicale et Vétérinaire, Côte d'Ivoire.

Background

Rice production and consumption have gone up rapidly in West Africa in recent decades and growth in demand is likely to remain above 5% a year. Evidence suggests that rice availability and prices strongly influence the welfare of the region's poor. Rice in West Africa is no longer a luxury but a staple, especially for the urban poor. Within the region, expansion in the cultivated area of irrigated rice is the main source of production increases. The "upland/inland swamp continuum" environment of the forest and savanna zones accounts for about 80% of the cultivated rice area of West Africa and 75% of production. This environment includes both rainfed and irrigated rice systems, while the more northerly Sahelian systems are irrigated.

Overall production trends raise serious questions as to whether environmental degradation (particularly in fragile upland ecosystems of the savanna) and malaria transmission will accelerate. On the environmental side, WARDA concluded some time ago that to meet regional food requirements and protect vulnerable uplands, lowland rice cultivation should be promoted. If agroecosystem management strategies are also to contribute to prevention and control of diseases like malaria and schistosomiasis, more information is needed on the socio-economic, ecological and environmental aspects of the differing rice systems and on the epidemiology of these diseases.

Project description

The project focuses on the Sahelian and savanna/forest regions where rice is grown, with Côte d'Ivoire and Mali serving as the venues of research. Institutions in these two countries are major scientific partners. Key objectives are as follows: to characterise the irrigated rice agroecosystems of the Sahel, as well as the rainfed and irrigated lowland-valley rice systems of the upland/inland swamp continuum (savanna/forest), in relation to health risks; to identify social, biological and other factors affecting the potential of agroecosystem management for vector control; and to assess health risks posed by malaria and schistosomiasis along a north-south transect through Mali and Côte d'Ivoire. The research is expected to increase various groups' awareness of the links between rice farming and health. These groups include rural communities, donors, policy makers and health and agriculture specialists.

Results to date and preliminary conclusions

Rice irrigation in the West African Sahel substantially boosts anopheline mosquito populations. However, the larger number of vectors does not appear to result in higher transmission of malaria in that region. Although malaria transmission and incidence during the dry season (rice-growing cycle) are higher in the irrigated zone than the unirrigated, rainy season (and consequently annual) transmission and incidence are much higher in the unirrigated zone. Relatively few of the abundant anopheline mosquitoes are infective in the irrigated zone. This is most likely because few mosquitoes live long enough to allow the malaria parasite to mature. In addition, the high biting rate on alternative hosts such as cattle probably reduces the chances of malaria parasites being transmitted to people. Very high bed net use (virtually 100% year-round) in the irrigated zone, stimulated by the high number of nuisance bites, may also play a crucial role. Attempts to control mosquito populations could reduce nuisance levels and, consequently, bed net use, which could have the unintended effect of increasing malaria transmission. Promotion of insecticide-impregnated bed nets could substantially reduce malaria, especially in the unirrigated zone.

In the savanna zone, irrigation leads to a higher anopheline population and to a second period of malaria transmission associated with rice production. Despite this, malaria transmission to children is similar in villages either having no irrigated rice or having two crops per year. Strangely, malaria transmission is lower in communities having only one rice crop. These observations suggest that irrigation may not, by itself, increase malaria transmission. Other factors likely explain reduced malaria in areas with only one annual crop. The researchers observed that introducing cultivation of irrigated rice had strong impacts on social organisation, economic status of households and intra-household relations (distribution of tasks between men and women). These factors in turn affect the capacity of farmers to recognise and react to early symptoms of malaria, or to adopt protective measures.

Surprisingly, less food is available to people in villages with two rice crops than in those with only one. People complain it is more difficult to feed their families with food they have produced themselves. This may be linked to greater difficulty in transporting food products from the uplands to the lowlands, to a transfer of the responsibility to feed the family from men to women (forcing women to sell rice to pay expenses previously assumed by men), and to better crop care in single-crop environments. ■

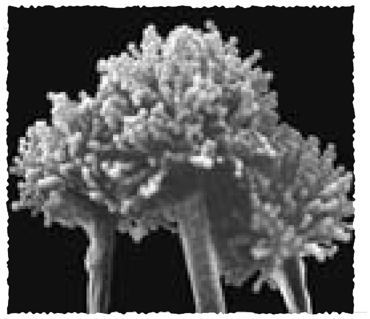
Ecology of Mycotoxins in Maize and Groundnuts

David Miller and Wally Marasas

Exposure to mycotoxins present in food and feed crops has long been recognised as a serious threat to human and animal health. And, according to a 1996 United Nations report, "Freedom from mycotoxins in food ... is an indicator of sustainable development." Nevertheless, the sheer pervasiveness of the problem in developing countries, along with the cost of potential solutions in a sea of competing priorities, has led to a certain degree of pessimism on the part of agricultural and health authorities. Radical solutions that take into account the needs and conditions of developing countries are urgently needed.



A magnified view of *A. flavus* conidiophores and conidia. Photo: ICRISAT.

The combination of aflatoxin with hepatitis B and C is synergistic, raising more than tenfold the risk of liver cancer compared with each agent attacking alone.

Mycotoxins are chemical substances naturally produced by a modest number of species of fungi that grow on crops either in the field or in storage. In sub-Saharan Africa, two important crops are commonly contaminated: maize and groundnuts – major food crops and cash earners for millions of small-scale farmers. The best known of these chemical substances is aflatoxin, produced by *Aspergillus flavus*, found in both maize and groundnuts. More recently, fumonisin, produced by *Fusarium verticilliodes*, was discovered in maize in southern Africa. Exposure to these mycotoxins may occur simultaneously. In animal studies, the effect of aflatoxin is promoted by the concurrent presence of fumonisin. In humans, interaction between the two toxins is not understood.

Multiple health risks

For centuries, farmers in Central America reduced their exposure to aflatoxin, knowingly or unknowingly, by treating their maize with lye. Unfortunately, this procedure did not accompany maize on its eventual journey to Asia and Africa and is in any case not feasible where water is in short supply.

The exposure of people and animals to aflatoxin and fumonisin presents multiple health risks, both proven and probable (Cardwell, 1999). Aflatoxin, which damages DNA, is the most potent chemical liver carcinogen known. Many people in developing countries are infected by hepatitis B and C which are probably even more potent liver carcinogens. The combination of the two agents, aflatoxin with hepatitis B and C, is synergistic, raising more than tenfold the risk of liver cancer compared with each attacking alone. Acute aflatoxicosis occurs in poultry, swine, cattle and people. At lower but chronic exposures, aflatoxin may damage the liver, lower appetite, promote diarrhoea, inhibit growth and suppress the immune system. Recent studies conducted in West Africa are shedding light on the potential for aflatoxin-induced immune suppression in humans.

Fumonisin interferes with critical lipid pathways affecting cell function including the transport of critical vitamins such as folate. In laboratory animals, this toxin is a weak, non-DNA-damaging "complete carcinogen", but it is a powerful cancer promoter. While the effect of fumonisin on human health is poorly understood, the presence of this mycotoxin was discovered during studies of the exceptional rate of oesophageal cancer in part of the Transkei. So, despite the lack of direct evidence for a causal link, epidemiology studies associate fumonisin with this type of cancer. And recent laboratory studies suggest that fumonisin causes birth defects by damaging folate receptors.

Mycotoxins can also harm human health in other ways. First, domestic animals such as poultry and swine are very sensitive to aflatoxin and deoxynovalenol, respectively. The presence of these toxins in the poorest-quality leftover grain, which farmers feed to their livestock, reduces animal productivity and therefore the family food supply. The resulting protein-energy malnutrition increases disease prevalence, further undermining people's ability to cope with mycotoxin exposure. Second, the loss of income from lower animal production leads to greater poverty, thus reinforcing the conditions conducive to poor human health.

Contributing factors and research priorities

Improper storage is understood to enhance mycotoxin concentrations in maize and groundnuts. Evidence suggests that in sub-Saharan agroecosystems, mycotoxin-producing fungi in the soil invade plant roots, particularly when the host plant is stressed by short-term drought. Soil degradation, inappropriate farming practices and choices of crop varieties may affect the quality of the subsequent crop.

The presence of mycotoxins in the poorest-quality leftover grain, which farmers feed to their livestock, reduces animal productivity and therefore the family food supply.

There are indications that poor rural people who consume stored, homegrown maize and groundnuts are among the most affected. Crops handled by government agencies may be better inspected and thus safer for consumption. In some cases, farmers sell their high-quality produce, keeping mycotoxin-contaminated food for their own consumption. Furthermore, because the poor rarely have the luxury of diversifying their diets, their exposure to mycotoxin-laden crops is often greater than that of the reasonably well-off.

In 1997 and 2001, the Joint Expert Committee on Food Additives published evaluations of aflatoxin and fumonisin, respectively. This is a committee of the World Health Organization and the Food and Agriculture Organization of the UN, and decisions of JECFA are referenced by the World Trade Organization. According to JECFA, nearly all Africans would for some or all of their lives be exposed to aflatoxin levels known to affect population health. Again in Africa, the average exposure to fumonisin is estimated to exceed the tolerable daily intake and for about 10% of the population it is exceeded by three times. No estimate was made of the effect of concurrent exposures.

Urgent action by researchers is needed on several fronts:

- Observation of human diets in high-risk communities, to assess levels, seasons and sources of exposure to mycotoxins;
- Evaluation of health impacts of mycotoxins, particularly in food-insecure communities that depend on degraded soils for sustenance;
- Definition of social and economic structures that differentially expose one or more sub-groups to mycotoxins;
- Studies of soil ecology with a view to preventing mycotoxin-producing fungi from invading crop roots.

Because the poor rarely have the luxury of diversifying their diets, their exposure to mycotoxin-laden crops is often greater than that of the reasonably well-off.

While we think we know what tolerable levels are, in Africa there is no meaningful possibility of achieving them in the near term. So a further priority is to determine what interventions are necessary to make an intolerable situation better.

In the decade from 1985 to 1996, IDRC made important contributions to a number of technical and policy-development initiatives on mycotoxins in developing countries. These included collaborative R&D in China and significant multilateral policy work on mycotoxins in Southeast Asia (with Australia), in South America (with the International Maize and Wheat Improvement Center), and in Africa (with Denmark). These initiatives have created national capacity and helped to foster the development of key research efforts among researchers in many countries.

Other projects have also been funded and are under way. They include a critical study of the impact of aflatoxin on infectious disease, supervised by Chris Wild at Leeds University and Kitty Cardwell, formerly of the International Institute of Tropical Agriculture; studies of analytical methods for mycotoxins developed by Maya Pinereo (FAO); and a project to understand the factors that affect the formation of fumonisin in maize, involving researchers all over the world, including David Miller's group at Carleton University. We are looking for resources to do critical studies on birth defects and oesophageal cancer in South Africa and develop effective interventions. ■

Integrating from Below: Community Capacity Building

Peter Gubbels and Jagdish Ghimire

Evidence is mounting that integrated approaches to sustainable rural development are more effective than conventional ones that tend to view ecosystem components in isolation. Community health cannot be separated from issues surrounding the natural resource base on which most rural livelihoods depend. However, there are few guidelines on how social, economic, health and environmental factors can be pulled together into a coherent analytical framework for planning, executing and assessing rural development interventions.

Here we present a few results and lessons from World Neighbors' (WN) experience in formulating and applying an integrated approach to rural development. WN's gradual adoption of this approach resulted from "people-centred" problem solving rather than from any response to preconceived agendas about demographics, resource conservation or health. Our analysis indicates that for marginalised rural communities, the issues of livelihood, food security, natural resource use, family and community health, reproduction and family size are inextricably linked. Moreover, with suitable guidance and support, rural people are capable of analysing the multiple ways in which ecosystem components interact with community health. Based on collective learning and holistic analysis, rural people can choose concrete actions that lead to significant and sustainable improvements in their health.

"Integration" and "integrated development" have too often been viewed as a challenge of vertical delivery of services whereby gaps between disciplines, sectors and institutions must be bridged from above. In contrast, World Neighbors is concerned with "integration from below". We focus on processes of participatory diagnosis and learning which lead to mutually supporting community activities that reflect local priorities and capacities. The example below is from Ecuador.

A comparative study in Ecuador

In 1992, a small health and family planning clinic in the town of Guaranda, in Ecuador's Bolivar Province, was on the verge of closing down. Set up to serve rural Quechuan Indians, it had too few users to justify keeping its doors open. Then, between 1993 and 1997, a unique research project helped turn the situation around. Today, the clinic provides more than 18,000 consultations a year and has more than 2,500 users of family planning services.

The research tested a simple hypothesis: integrated community development, responding to local priorities such as food production and security, natural resource management (NRM) and public health, will lead to greater well-being and more widespread use of family planning than an approach based on family planning alone. To conduct the study, World Neighbors partnered with the Center for Medical Guidance and Family Planning (CEMOPLAF), a non-profit maternal and family planning organisation providing health services in 21 provinces, over half the country.

Twelve rural communities participated in the study. Six were involved in an integrated community development programme. This included a range of services and activities in the areas of sustainable agriculture, NRM, public and reproductive health and family planning. The other six received only reproductive health and family planning components. In both sets of communities, two instructors trained local volunteers as health promoters. The volunteers then replicated the training in their communities via mini-workshops.

A baseline survey of a random sample of 400 families was conducted. Male heads of household responded to agricultural questions while women of reproductive age answered health questions. Three years later, the same communities were surveyed again, this time based on a random sample of 480 families. This allowed the researchers to compare the attitudes, practices and outcomes among farm families in the two sets of communities.

Health and agricultural setting

Despite CEMOPLAF's success with other groups, its record with indigenous rural people was poor. Yet indigenous areas typically have the highest levels of fertility and unmet need for reproductive health and family planning services. Quechuan resistance to such services stemmed in part from suspicion about the motives of outsiders, rooted in the genocide of the Spanish conquest. In some areas, religious authorities also discourage family planning.

The proportion of women who received professional assistance during child birth was only 20 to 40%, and only about half the women brought their children to the health centre after delivery.

The baseline survey revealed significant health problems in both sets of communities. Roughly half the children were afflicted with diarrhoea and 60 to 70% had respiratory problems. The proportion of women who received professional assistance during child birth was only 20 to 40%, and only about half the women brought their children to the health centre after delivery.

Communities participating in the integrated programme were historically more under-served and more rural than those in the health-only programme. At the study's outset, knowledge of birth control methods was much lower in these communities (35%) than in the health-only communities (65%). Family planning use was modest in the health-only communities (25%) and low (12%) in the integrated-programme communities.

Erosion, loss of soil fertility and reduction of farm size due to population growth adversely affected family food security. This stimulated seasonal migration of males, shorter fallow periods and cultivation of steeper slopes. Drought followed by heavy and excessive rainfall also contributed to soil erosion and other degradation of natural resources.

The interventions

The health-only programme initially focussed on promoting oral contraception and condom use through community-based distributors. Then, in response to community requests, it expanded in the second and third years to include other services in areas such as nutrition, breast-feeding, diarrhoea, and respiratory and reproductive-tract infections.

The integrated programme consisted of a somewhat broader initial health offering, plus an agricultural/NRM component. The latter included soil and water conservation based on protective barriers composed of native and exotic trees; the use of cover crops and green manures; farmer experimentation with varieties of wheat, barley and potato; production of vegetables; and livestock improvement.

Research results

Family planning acceptance in the communities involved in the integrated programme grew more than threefold, from 11.6% in 1993 to 41.1% in 1996, while in the health-only communities, it remained more or less constant at roughly 25%. Interventions related to NRM and crop production stressed the use of local resources rather than external inputs, as well as the prevention of environmental degradation. In the integrated programme, changes were seen in farmers' knowledge, attitudes and methods in these areas. Awareness of the importance of conserving resources, especially soil and water, increased. The proportion of farmers using erosion-prevention techniques more than doubled from 23% to 50% and the proportion planting green manure to improve soil fertility increased from 0 to almost 40%. There was also a marked increase in fallow period, with 40.6% of participants leaving their land fallow for 5 to 6 months, compared with 6% at the outset.

Observations and lessons

Based on the study results, CEMOPLAF plans to extend the integrated approach to its other clinics serving rural indigenous people in Ecuador. It will also undertake more rigorous research and evaluation to examine processes by which communities adopt new practices. In the meantime, though, it is possible to draw some conclusions and lessons from the initial study.

Putting community priorities and livelihoods first

Integrated programmes to improve human health in the context of agroecosystem management succeed best when they respond to community priorities such as child health and survival, food security, food production and natural resource management. This approach builds local trust and inspires confidence. An intervention that does not speak to immediate needs is unlikely to evolve to address secondary needs.

Rural families in the study area faced tremendous economic pressures due to soil degradation, population growth, the shift from subsistence to cash crops, and other factors. They were looking for more sustainable forms of stewardship for the natural resources on which their livelihoods depend. A key strategy was to develop interventions linking short-term economic benefits to longer-term human reproductive and ecosystem health.

Building community capacity and leadership

Strengthening community organisation, leadership and capacity to identify and diagnose problems, plan and implement development activities, and monitor and evaluate results was a critical aspect of the Bolivar programmes. In many Quechuan communities, local organisation and leadership were already quite strong. However, for the first time, communities began developing their own annual plans, including health, agricultural and NRM objectives. These were used to evaluate progress at the end of the year.

Taking gender into account

Sixty-four percent of the Bolivar study participants were women, due to the growing level of male seasonal migration and consequent increase in women's livelihood responsibilities. Devising ways to increase women's participation in agroecosystem management, community structures, leadership and decision making was an important aspect of the intervention. Through this approach, women gained self-confidence and organisational capacity. A gender-sensitive approach also demanded that men be included in community and reproductive health education. Increasing the exposure of men to health issues was facilitated by combining health and agricultural activities in an integrated programme.

Identifying links between natural resources and reproduction

Alternative methods of soil and water conservation, organic composting, cover crops, green manures, agroforestry and experimentation with techniques based on local natural resources all strongly appealed to the Quechuan communities. These methods directly addressed the survival of their agroecosystem and way of life. The Bolivar programme included education about how reproduction and population growth are linked to the state of natural resources – concepts well-understood and discussed by the participants.

Concluding note: The broader picture

World Neighbors' experience in several countries suggests that successful programme outcomes depend on innovative inter-agency partnerships, sometimes at multiple levels of the agroecosystem. In the case of Ecuador, a large national health service organisation agreed to step outside its traditional domain to promote innovations for agriculture, income generation and resource management at the farm and community levels. World Neighbors played a crucial role by providing methodological, technical, capacity-building and funding support. In other countries such as Indonesia, where interventions focussed on community participation in forest management, it was necessary to set up even broader stakeholder networks involving universities, NGOs, government agencies at different administrative levels, and local communities.

In general, interventions at multiple administrative and geographic levels make the job of brokering a multi-stakeholder process of research and decision making more complex and time-consuming. Strong leadership, vision, flexible funding and considerable institutional change are required. Nevertheless, a broader ecosystem management approach, whatever its potential benefits, is simply not practical if it becomes mired in costly and protracted research and negotiation among stakeholders. In all instances, it is essential to help communities quickly pinpoint and alleviate immediate pressures on local livelihoods rather than waiting to understand the full complexity of the agroecosystem. This is the entry point for "integrating from below", for building the self-confidence and long-term capacity of rural community groups and other stakeholders to diagnose and solve problems of human health.

Since good health includes people's capacity to achieve their goals, an ecosystem approach to health must be participatory. Here, a women's focus group meets to gain a better understanding of local diets and nutrition in the Peruvian Amazon. CIAT photo: Yolanda Malqui.

An Ecosystem Approach to Health

David Waltner-Toews and James Kay

What is health?

In the public mind and even in the professional literature, medicine is often confused with the broader notion of human health and the various ways to achieve it. Medical approaches usually depend on hierarchical lines of authority, normal science, clinical diagnosis, and authoritative treatment. In contrast, health promotion requires, among other things, holistic, post-normal science driven by participation and activism. This wider perspective acknowledges the existence of health conflicts that cut across ecological and social perspectives. It also calls for constant renegotiation of these tensions through democratic and power-balanced processes. In some instances, biomedically oriented research may actually undermine health by disempowering the communities it studies.

The definition of health offered in the 1946 preamble to the constitution of the World Health Organization (WHO) has shown itself to be surprisingly resilient. Good health, according to WHO, is "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." This definition has been modified, criticised and widely discussed, and alternatives have been proposed. Discussion has focussed on the notion that "well-being" includes the capacity of people to achieve desirable and feasible goals and to adapt to environmental change and stress.

In the context of ecosystems, human health is a positive characteristic of human communities. It implies both the availability of resources and access to them. Specific positive outcomes include food security, good nutrition, low levels of disease, reproductive capacity (including women's control over the spacing and number of children), a sense of well-being, and access to knowledge, information and power. These outcomes must be seen in light of water, land and energy use, social and economic organisation, and other factors. Thus, health is a social construct negotiated in the context of our best understanding of the constraints and opportunities provided by the ecosystems of which people are an integral part.

Why do we need a new approach to health?

Despite WHO's view that health is more than the absence of disease, conventional health research has tended to choose specific disease outcomes and view them as the result of a linear chain of events. For example, water pollution from untreated sewage leads to diarrhoea in the children who drink the water. But this analytical approach is unrealistic.

A more complex and realistic view might identify certain kinds of economic activity, which, although possible causes of pollution, also generate money to improve nutrition and the public health infrastructure. Completing a commonly found feedback loop, the diarrhoea afflicting the people who consume the water undermines their efforts at improvement by decreasing their energy to work and siphoning money away from education and productive activity. This feedback may be complicated by the fact that men are engaged in the activities that generate income, and women and children are the ones who suffer the major consequences. Under this view, resolution of health-related issues – disease, education, nutrition, livelihoods – requires us to go beyond traditional health sector concerns and pay attention to the ecological and socio-economic context.

Good health, according to the World Health Organization, is 'a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.'

Thus, health for some may create ill health for others, either in this generation or the next. Disease treatment programmes, based on increased use of drugs for example, may generate new diseases that are drug resistant or that fill the ecological niche vacated by the organism being attacked. Conversely, programmes entirely unrelated to the conventional health sector, such as agriculture and dam building for electrical power, have major, usually contradictory, effects on human health. Conventional programmes aimed at creating environments that promote health are thus simplistic and, if they achieve their goals, they do so by accident rather than design. The ecosystem approach was developed to make interactions explicit.

What is the ecosystem approach?

Among the various strategies for dealing with complexity and decision making, the ecosystem approach has demonstrated the most promise, in terms of both its theoretical base and practical uses. It was developed and elaborated primarily in the context of environmental management in the Great Lakes Basin of North America and the design of related sustainability indicators. The ecosystem approach represents a view of ecological interactions which is complex in the full technical sense and leads to what some have called post-normal, democratic and/or participatory science.

Sustainability does not result from adopting a package of technologies and practices, but from establishing a process of learning and investment in local governance.

According to the Ecological Committee of the International Joint Commission, in "the ecosystem approach there is not one material ecosystem to which our definitions must conform. Rather, the human actor must accept responsibility for erecting definitions and be prepared to change them when the purpose of the description changes." Some authors generalise this view to an understanding that any complex system is subject to interpretation from different legitimate perspectives and, hence, that problem resolution cannot depend only on objective technical or scientific expertise. Rather, drawing on various bodies of accepted knowledge, stakeholders must negotiate a continuing series of resolutions within basic ecological constraints. Thus, sustainability does not result from adopting a package of technologies and practices, but from establishing a process of learning and investment in local governance.

Indeed, according to Kay and Schneider (1994): "If we are truly to use an ecosystem approach, and we must if we are to have sustainability, it means changing in a fundamental way how we govern ourselves, how we design and operate our decision-making processes and institutions, and how we approach the business of environmental science and management." And, we would add, how we approach human health issues.
In practice, the ecosystem approach brings together two major strands of activity, one focussed on systemic research-based descriptions, the other on social involvement (Kay et al., 1999).

Challenges facing an ecosystem approach

There is a need to understand the interactions between the socioeconomic and ecological aspects of ecosystems. Human and biophysical variables interact through feedback loops, many of which are non-linear and hard to track, making the prediction of long-term outcomes very difficult if not impossible. These feedback loops demonstrate that ecosystems are dynamic and self-organising and that their states can change in sudden and unexpected ways. Some types of feedback result in cross-scale conflicts (e.g., between individuals and communities) for which there may be no technical solution. For instance, a human population living within ecological constraints requires not only new births to bring in fresh ideas and ensure genetic renewal, but also a certain mortality rate to make room for the newcomers. There may thus be irreconcilable differences between what is good for an individual and what is good for a community.

Multiple models of reality (specified by gender, ethnic group or economic class, for example), together with the dynamic nature of the reality we are observing, are difficult to express in quantitative models or mathematical equations.

Reality can be described from different perspectives and at different temporal and spatial scales. There is no single scientifically acceptable description of the complexity of socio-ecological systems. Governance structures and other power-related factors strongly influence which ecosystem issues – water flows, food production, human health, and so on – will be judged worthy of attention. They also determine the scale (individual, household, community or global) at which the issues are likely to be dealt with. One's perspective, whether as a scientist, villager, bureaucrat, woman, man or member of a particular class or ethnic group, determines which aspects of reality are seen as background and which as foreground.

Visions of the future

For any complex system, the formulation of problems and the design of solutions depend on the perspectives chosen. Since good health by definition includes people's capacity or power to achieve their goals, an ecosystem approach to health must be participatory. And because we are concerned with ecological sustainability, that approach must also be explicitly anchored in a systemic understanding of the elements and relationships that determine how the complex world we live in self-organises and changes over time. These two dimensions of the ecosystem approach – participation and systemic understanding – must converge in visions of desirable, feasible futures and lead to governance, management and monitoring activities for achieving them.

Part of that work is to evaluate the synergies and tradeoffs raised by each scenario. For example, while dam construction provides electric power and flood control, which may lead to better overall nutrition in the community, it also creates a habitat for diseases such as schistosomiasis and malaria. An ecosystem approach to human health emphasises synthesis, stakeholder negotiation, and the resolution of such tensions across ecological and social perspectives.

Ecological Millennium: Setting the Bottom Line

David Suzuki

This is an abridged version of Dr. Suzuki's plenary address to the Canadian Conference on International Health. For the full text, see www.idrc.ca/ecohealth/suzukispeech.pdf.

At a time when science and technology dominate our lives, it is ironic that we need the great wisdom of traditional people around the world to remind us that the earth is our mother. Not only is it horrifying to contemplate our current assault on her, it is also obvious that the damage we are inflicting on her will have enormous repercussions on us, her children.

In graduate school at the University of Chicago, I was taught, and I later taught my students, that science is the most powerful way to know the world around us. It allows us to push back the curtains of ignorance, to reveal the deepest secrets of the cosmos. Through science, we can gain control of nature and the rest of our surroundings. Through science, I believed, life would get better and better for human beings around the world. In the years that followed Sputnik, science indeed exploded. We were overwhelmed with the success of that growing scientific community.

When I returned to Canada in 1962, I was shocked at the abysmally low level of support for science in this country. The only thing that saved me was a large American grant I received to study in Canada. Then, I was asked to do a television show. I was at the University of Alberta in the genetics department, and I jumped at the opportunity. I thought it was a great chance for me to communicate with people about why science is important and that, if I did this well enough, maybe in the long run I would get a bigger grant. It was out of self-interest that I wanted to demystify science.

David Suzuki, geneticist, broadcaster and environmentalist. Technology, population growth and a "mono-culture" approach to economics, he says, have turned human beings into a powerful and dangerous super-species. Photo: Al Harvey.

But I was distracted by someone I had never met, a woman named Rachel Carson, who wrote *Silent Spring*. Her book came out in 1962, the very year I did my first TV programme. I think anyone who read the book was never able to look at the world again in the same way. Carson put out a very powerful warning about technology. The case she focussed on was pesticides, but it could be taken as a symbol of all technology.

The cost of technology

Technology is powerful. We love technology because we invent it to do things for us. But our knowledge about how the world around us works is so limited that we can't anticipate what the costs may be down the road. Carson pointed out that we had better pay attention to the fact that for any technology we will always have to pay a price. As you all know, the environmental movement grew explosively as a result of her book, and only 10 years later the United Nations held its first world conference on the subject, in 1972. Many of the issues that we still face today were raised at that meeting in Stockholm: population growth, pollution, species extinction. And major scientists were there: Margaret Mead, Paul Ehrlich and Barry Commoner, for example. They were there warning us about the crisis we faced.

After Stockholm, we had constant reminders of the fragility of the environment – the dioxin spill in Seveso, Italy; the Union Carbide accident in Bhopal, India; the Exxon Valdez oil spill in Prince William Sound; and the Chernobyl nuclear reactor fire. We kept learning about new phenomena that we did not know existed in 1962 or 1972. We have since learned about ozone depletion, global warming and endocrine disrupters.

The year 1988 was the high point of environmentalism around the world. You may remember U.S. presidential candidate George Bush saying, "If you vote for me, I promise I will be an environmental president." Now we know how shallow election promises are. The same year, the U.K.'s Margaret Thatcher was filmed walking around a park in London, picking up litter and saying, "I'm a greeny too, I care about the environment." And in Canada, we had a new Prime Minister, Brian Mulroney. To show his born-again environmentalism, he raised the Ministry of the Environment into the inner cabinet.

So, we had reached an apex of concern about the environment and we coasted into 1992 for the largest-ever gathering of Heads of State in human history at the Earth Summit in Rio. The summit was meant to signal that, from that point on, humanity was taking a fundamentally different path, that the environment could never be ignored in any decision we make, whether economic, social or political. *Sustainable development* became the rallying cry.

Stark warning

As if to emphasise the importance of the Earth Summit, in November of 1992 a remarkable document titled *World Scientists' Warning to Humanity* was released. It was signed by more than 1,600 senior scientists from around the world, including more than half of all living Nobel Prize winners. It begins like this: "Human beings and the natural world are on a collision course. Human activities inflict harsh and often irreversible damage on the environment and on critical resources.

If not checked, many of our current practices put at serious risk the future that we wish for human society and the plant and animal kingdoms, and may so alter the living world that it will be unable to sustain life in the manner that we know. Fundamental changes are urgent....”

As a group, scientists tend to be cautious in making public pronouncements. Yet here we have a group of leading scientists saying we are on collision course with the life support systems of the planet. “No more than one or a few decades remain,” the warning continues bleakly, “before the chance to avert the threats we now confront will be lost and the prospects for humanity immeasurably diminished. We the undersigned, senior members of the world’s scientific community, hereby warn all humanity of what lies ahead. A great change in our stewardship of the Earth and life on it is required, if vast human misery is to be avoided and our global home on this planet is not to be irretrievably mutilated.” They said we may have as little as 10 years to avoid absolute catastrophe.

While the document was stark and terrifying, what was even more terrifying to me was the lack of response by the world press. Canada’s so-called national newspaper, *The Globe and Mail*, did not cover it. Nor did our national radio and TV network, the Canadian Broadcasting Corporation (CBC). Major American TV networks, *The New York Times* and *The Washington Post* didn’t bother to report it either. So, when half of all Nobel Prize winners tell us we may have as little as 10 years to avoid catastrophe, the media decide this isn’t newsworthy. What do they consider newsworthy? The historically trivial O. J. Simpson trial, the death of Princess Diana, and Bill Clinton’s relationship with Monica Lewinsky.

As a group, scientists tend to be cautious in making public pronouncements. Yet here we have a group of leading scientists saying we are on collision course with the life support systems of the planet.

Prioritising economics and the environment

Only a year after the Earth Summit, we had another election in Canada. *The Globe and Mail* editorialised that there were only three issues of concern to the Canadian electorate: the economy, the economy and the economy. While the economy has emerged in the 1990s as the dominant feature affecting our lives, the environment appears to have disappeared as a high priority. Was the whole thing a hoax? Was Rachel Carson really what Monsanto and the other chemical companies said at the time – just a frustrated old woman without scientific credentials? Was all of the concern in Stockholm in 1972 and then in 1988 a fabrication of environmentalists? Or, heaven forbid, were politicians and business people so responsible they took care of it and it’s no longer an issue? Of course, the answer to all those questions is no. Why is it, then, that in 1999 we are failing to heed serious warnings that we are on a collision course with our planet – warnings not from eco-terrorists, neo-Luddites or “do-gooders”, but from leading scientists?

An obvious reason we haven’t been able to assimilate the problem and act on it is that we are a fundamentally local species. We observe the world around us through our five senses. If we can smell, see, taste, feel or hear it, we know it’s real. But when issues are global, they are really beyond our capacity as individual people to sense them. We haven’t evolved sense organs that can tell us directly that the ozone layer is being depleted or even that it’s up there. We can’t detect that greenhouse gases are increasing in the atmosphere. We can’t sense dioxins and PCBs in our food or water. As biological creatures who evolved in a world radically different from today’s, we are no longer able to sense the real dangers confronting us. And the changes in our world have happened absolutely explosively.

Population growth and the global economy

As a distinct species, *Homo sapiens* may have existed for about half a million years. If you plot that time span on a graph, where the X axis represents time and the Y axis total human population, for 99% of human existence there were less than a billion people on earth. It took a long time, almost the entire half million years, to reach one billion people, around the year 1830. It’s only in the last pencil-width of time that you finally begin to see the curve inflect up.

In my lifetime, the planet’s population has tripled to 6 billion. Where it took nearly half a million years to reach a billion people, we are now adding a billion people every 12 to 13 years. The curve is now leaping straight off the page. As you well know, in a finite world, nothing can continue that way and it will come down. The only question is, will it come down by hitting a ceiling and then plunging? Or will it go up, and then curve gently back as we deliberately bring it down?

It’s not just our numbers and our technology that have made us so powerful. We have very recently cloaked ourselves in a concept called the global economy.

At the very time human populations are skyrocketing within a single generation, technology has grown even faster. Virtually the entire history of modern technology is encompassed in the last 100 years – from cars, to planes, to space, to nuclear energy, to computers, to birth control pills. While we are already the most numerous mammals on earth, each of these technologies gives us much more muscle power than any other species. Each human being so equipped can now attack the planet. We have become what I call a super-species. No other species has ever had the capacity to alter the biophysical features of the planet – a capacity we have developed in an incredibly short period of time. But it’s not just our numbers and our technology that have made us so powerful. We have very recently cloaked ourselves in a concept called the “global economy”.

The mono-culture of the global economy

Economics is a construct. Human beings have had economies for thousands of years and these have varied from place to place. But today we are being “mono-cultured” with a single notion of economics – the global economy – which is equated with progress. While no one is against progress, economic globalisation is based on the idea of growth going on indefinitely. For me, there are many reasons why this represents the greatest threat we now confront. But first, some background.

The great discovery of the 1960s in my area of genetics occurred when scientists began looking at individual genes within populations of a single species. They discovered, to their amazement, that rather than being highly homogeneous, single genes were tremendously diverse. It was called genetic polymorphism. The reason for that diversity, we understand now, is that throughout the evolution of life our planet has never been static. The poles have reversed and then reversed back again. The sun has increased in intensity by 25% since life began on earth 3.8 billion years ago. We have had continents colliding with each other. We have had warming periods and ice ages. Tremendous changes have happened. Life gets its resiliency from the constant presence of genetic differences. As the environment changes, some gene combinations have better survival ability under the new conditions. Life has evolved by maintaining tremendous diversity. But it’s more than just genetic diversity. Species diversity, ecosystem diversity and, in the case of humans, cultural diversity have also been the key to our long-term survival.

Monoculture is the spreading of a single genetic strain or a single species over a wide area. We have found in agriculture, fisheries and forestry that monoculture runs counter to the principle of diversity-based adaptability. It makes life vulnerable to change. And so it is with human cultures. Human cultures have flourished on this planet because of their diversity and because they are intimately tied to local areas. Our diversity has let us live in the Kalahari Desert, the Amazon rain forest and the Arctic.

But we are now mono-culturing the planet with a single economic idea of progress and development. I submit that this is unbelievably dangerous, because it makes us vulnerable to the questions: What if it’s wrong? What if conditions change and can no longer support that single notion? As a biologist, I see this as the fundamental threat posed by globalisation – the mono-culturing of our planet. If you look into economics itself, you find it is a fundamentally and unbelievably flawed system.

Economics and indefinite growth

Hazel Henderson, a leading futurist in the United States, says conventional economics is a form of brain damage. She is absolutely right. In an introductory economics course, one of the first things a professor will do is throw up a slide of the economy. Economists love this because it looks scientific – lots of arrows back and forth, raw resources, extraction, processing, manufacturing, wholesale, retail. While economists claim economics is a science, it isn’t. It is a set of values that tries to present itself as science. In principle, if you know what all the arrows represent, you can tweak them with an incentive here or a disincentive there, thus “managing” the economy.

But then a student asks: “Excuse me, Professor. Where in that economic diagram is the ozone layer? Where do you put the deep underground aquifers of fossilised water? Where do you put topsoil?” You know what the answer is? “Oh, those are externalities.” But if we externalise the real world on which we depend, then the economic construct has nothing to do with reality. You might as well be on Mars. You ensure the development of a system that will trash our planet.

To compound the insanity of conventional economics, economists actually believe that human beings are the greatest thing to hit this planet. They believe our creativity will solve all problems. They believe that if we run out of resources, we’ll find substitutes, or that we can simply go to the moon or Mars to get whatever we need. They believe there is no limit to human inventiveness. So economics is based on the idea that we can have steady growth forever. But in a finite world, nothing can grow indefinitely.

If you don’t have steady growth, conventional economics considers it an absolute disaster. Imagine a company going to a bank and saying, “We’ve got 10% of the clothing market in Canada and we’re very happy. We’re making a profit. We don’t want the firm to grow any bigger. We’ve got a plant and we turn out product, but we need a loan to upgrade our equipment.” You know what the banker will say: “No way you’re going to get a loan. You’re dead.”

Banging into natural limits

In our crazy economic system, if you’re not growing, you’re considered dying. But as Stanford ecologist Paul Ehrlich says, “There are only two systems on the planet that believe in steady growth forever. That’s economics and cancer cells.” In our belief in the necessity of steady, endless growth, we have turned the economy into our highest priority. But what kind of a society judges its politicians and its government on the basis of how well they’ve done with the economy? What about the living conditions of the frailest, most vulnerable people? That’s the criterion of success I want for my government.

But no, the economy and the Ministry of Finance, with its big budget, are considered everything, while the biosphere and the Ministry of the Environment are seen as representing just a tiny sliver of the economy. That’s our mentality. I have had politicians and business people tell me over and over again, “Listen, Suzuki, if we don’t have a strong, growing economy, we can’t afford a clean environment.” Of course, the reality is exactly the opposite. The biosphere is everything. The only legitimate issue is how big the economy can grow before it begins interacting with natural limits and breaking down parts of the biosphere. Many biologists believe we are long past having to worry about that. The economy is already banging into limits and surpassing them. We see the degradation around the world. Unless we recognise that the biosphere encompasses everything and that it can't grow, then economics and economic growth will continue to be the destructive agents that they are today.

The biosphere is everything. The only legitimate issue is how big the economy can grow before it begins interacting with natural limits and breaking down parts of the biosphere.

The point here is that we human beings have changed very suddenly. We have changed in terms of our numbers and technology. We have changed with regard to our notions of economic progress and globalisation. And we have changed as consumers on the earth. Taken together, these shifts mean we are now affecting our planet in a profound way.

The problem with science

Let me return to the history of the environmental movement for a moment. For me, Rachel Carson's book was a warning. As I began my television career in 1962, my focus switched from wanting to expound on science to a desire to explore the ecological consequences of human activity. Through the 1960s and 1970s, at the very time environmentalism was on the rise, science and technology were exploding. A statistic you've probably heard is that 95% of scientists in all of human history are alive today and publishing papers. We have had enormous benefits: new materials, oral contraception, computers, space research, genetic analysis and so on. But the crisis for me was that, despite the scientific explosion, it was clear that life was not getting better for most of humanity, and the earth itself was showing signs of tremendous stress. So, while I believed science would improve everyone's lives, I could see this was not actually happening. When I asked myself what was wrong with what I believed, I realised that the great strength of science – what makes it unique as a way of knowing – was also its fatal weakness.

Science focusses on a part of nature. Whether it's a root, an atom or a subatomic particle, we try to bring a part of nature into the lab. We try to control everything impinging on it and measure everything coming out of it, thereby gaining a profound understanding of that fragment of nature. That's called reductionism. Ever since Isaac Newton's time, we have assumed that the cosmos is like a giant clockwork or machine. By reducing nature to its elementary parts, we thought we would eventually be able to fit them back together again, like a giant three-dimensional puzzle, and recreate the universe. Reductionism, then, has been the driving force of the scientific endeavour. But 20th century physics showed that Newton was dead wrong, that the universe is not simply a clockwork mechanism. Unfortunately, most people in the areas of human development, biology and medicine simply haven't got it yet. They are still in that reductionist mode of Newtonian times.

What physicists found was that when you remove a part from nature, you lose sight of the context within which it was interesting. You lose any sense of the rhythms and the patterns within which it operated and made sense. You destroy the very fabric of meaning that you wanted to study in the first place. You may be able to describe isolated pieces, but when you put them together, they do not add up to the sum of their individual properties. They interact, with synergistic effects. As Nobel laureate Roger Sperry from Caltech said many years ago, "There are emergent properties that come from the combination that you can't predict or anticipate on the basis of their isolated parts." So you're really snookered. There's no way you can look at the most elementary particles and have any understanding of what the behaviour will be as you climb up to higher levels of complexity. Science, then, in its most reductionist state, is virtually useless when it comes to providing us with the kind of information we need for understanding and control.

Managing the planet without a blueprint

I am sure you are going to hear about health management, water management and air management. All kinds of people claim to be able to manage different aspects of the natural world. I tell you we haven't a clue.

If you want to properly manage something simple like a shoe factory, you need an inventory of everything in your factory and a blueprint that tells you how everything in that inventory interacts. With that knowledge, you should in principle be able to manage the factory indefinitely. But how well can we manage the planet? How many species are there? We have named a lot of animals and plants and of the animals so far identified, the most abundant, successful and ubiquitous are insects. It's estimated that, for every human being, there are at least 200 million insects. So, long after we're gone, there will be plenty of life flourishing – insect life.

Naming is not knowing

A few years ago, Terry Erwin of the Smithsonian Institution went down to the Amazon rain forest. He put a sheet of plastic on the forest floor and blew a fog of insecticide into the canopy. Almost every one of the insects that rained down on his sheet had never been seen by a human being before. On that basis, he estimated there are about 30 million species on earth. Since that time, the estimate has come down and the consensus figure now seems to be 10 to 15 million. How many species of plants and animals have we identified? About 1.4 to 1.6 million. (The reason for the disparity is that different scientists may classify the same organism independently and give it a name.) So, if there are 10 million species, we know less than 20% of the diversity on the planet. That's just the plants and animals. When it comes to micro-organisms, we have not got a clue.

When a scientist names an organism, that just means someone sitting in a lab has given a dead specimen a name. It does not mean we know how many individuals are out there, what they eat, what their life cycle is, how widespread they are, or how they interact with other species. As for basic biology, "We probably know less than a fraction of a fraction of 1% of all species on earth in any kind of detail," says Ed Wilson at Harvard. If we know so little about the living world, how can anyone have the temerity to say we can manage it?

You can't manage communities of organisms when you know so little about their makeup. When foresters tell me we can manage forests, I just laugh. That's because when they talk about "forests", they really mean plantations. Everyone knows that a plantation is a fundamentally different entity from a forest. No human being or company has ever grown a forest. Only nature and time do that.

Log tagging in Malaysia. Communities of organisms, such as forests, cannot be "managed" since we know so little of their makeup. "No human being or company has ever grown a forest," says Suzuki. "Only nature and time do that." IDRC photo: N. Kumar.

In reflecting on the difficulty with science, I could see that science did not have even the elementary information that would allow us to begin managing the world around us at these different levels of complexity. How, then, could we deal with our problems? Ever since Rachel Carson, I had always thought about this in a simple-minded way. The problem was that human beings take too much stuff out of the planet and put too much waste back into it. Solution: regulate how much and what we take from our surroundings, and how much and what we put back into it, and then enforce those regulations. That was my simple-minded way of looking at it. The problem with this solution is that we don't know enough to be able to regulate how much and what to take out, or how much and what to put back.

Bombs, DDT and CFCs

I want to remind you of nuclear power. When we found a way to release energy by splitting or fusing atoms, we had no idea there was such a thing as radioactive fallout. Fallout was discovered after the Second World War when scientists exploded a bomb in Bikini and then discovered radio isotopes. We did not know there were gamma rays that could knock out electrical circuits over wide areas. We did not know that nuclear winter could result from atomic explosions.

Then there was DDT which was later found to kill insects. Great invention. Great discovery. But nobody knew at the time that DDT sprayed over a broad area would be bio-magnified through the food chain and concentrated hundreds of thousands of times in the breasts of women and in the shell glands of birds. Biologists only discovered the phenomenon of biomagnification when eagles began to disappear.

When CFCs were created, they were hailed as a great discovery – inert compounds, great carriers for aerosol sprays. Only when millions of tons of CFCs were liberated into the air did we discover their scavenging effect on ozone in the upper atmosphere. For me, then, the crisis was this: How can we manage new technologies, new ideas and new chemicals, when we have so little knowledge of how the world works?

How can we manage new technologies, new ideas and new chemicals, when we have so little knowledge of how the world works?

Our ecosystem, our self

An important insight for me came in the late 1970s when we did a film on the fight against logging in the Queen Charlotte Islands. This western-most archipelago off Canada is the home of the Haida people who call the land Haida Gwaii. Macmillan Bloedel had been working there for years and there was a strong movement to stop the logging. I went there and interviewed a young artist named Guujaaw, now president of the Haida Nation. I said to him, "A lot of the loggers are Haida. So it's good for your community. You have high unemployment. What's wrong if they are logging? And with MacMillan Bloedel in the islands, millions of dollars come through your communities. And you yourself, Guujaaw, you're not a logger. Why are you fighting against the logging?"

He answered, "Well, of course, if they cut the trees down, we'll still be here. But then we won't be Haida anymore. We'll just be like everybody else." With that simple statement, I suddenly realised that here was a radically different way of looking at the world. Haida don't see themselves as ending at their skin or their fingertips. To be Haida is to be intimately connected with the land, the air, the water, the fish, the trees, the birds. Their history, their culture, their very reason for existing are tied up in the land. Ever since that interview, I have been a student. I have travelled around the world meeting indigenous people wherever I can. Everywhere it's the same. However impoverished, dysfunctional or oppressed indigenous peoples are, you find a fundamentally different sense of connection with the land. As I reflected on that, I realised they are absolutely right.

The earth is our mother. They say we are all created from the four elements: earth, air, water and fire. They are right – literally.

Before you think I have totally freaked out and gone to some New Age place, let me say that I mean this in the most serious scientific way. We are the earth itself. We have been framing the whole environmental issue the wrong way. It's not that the environment is "out there" while we are "over here" and we have to manage our interaction with the environment. We literally *are* the earth. We *are* the environment. Let me show you what I mean.

We are air
The first thing a baby needs when it leaves its mothers body is a breath of air. From that point on, we human beings need air 20 to 40 times a minute until our last gasp. I love speaking to children about air. I say, "You don't think about the air you are breathing. Try this. Take a deep breath, hold it and don't take another breath for five minutes." Within seconds, of course, your body will begin to tell you that you need air. You can't even make yourself go unconscious by holding your breath. Your body won't let you. But because air is invisible, we don't think about it. When air rushes into our lungs, it sticks to the surface lining the 300 million alveoli. And when you breathe out, about half the air remains so your lungs don't collapse.

My point is that you can't draw a line between where air ends and you begin. We literally are the air because we're stuck on it. It's the physical substance in which all of us are imbedded. It connects all of us here together, along with trees and worms, snakes and spiders, and everything else that shares the air. Air is a magic binding material I call a sacred substance.

We are the earth in a most direct way, and yet we use the soil as a garbage can.

We pride ourselves in being an intelligent species. Yet what intelligent creature would proceed to use this vital element, this sacred air, as a toxic dump? We seem to have this crazed idea that if we put all our toxins into the air, they will be diluted away. When you get to be my age, you have taken at least 300 million breaths deep into your body and filtered it! Whatever we put into the air comes right into us because we are the air!

We are water
We all know that human beings are over 60% water by weight. We're basically big blobs of water with enough organic thickener added so that we don't dribble away on the floor. The trouble with the human body is that it leaks water all the time. It comes out of our skin, our eyes, our mouth and, of course, down below. We're losing water all the time. So we have to keep topping up.

Where do you think the water to replenish ourselves comes from? It doesn't just come out of a local well. It cartwheels around the planet through the hydrological cycle. The water in our bodies has come from all of the planet's oceans, from the canopy of the Amazon rain forest, from the Canadian prairies, from the steppes of Russia. Water, like air, is another glue that holds us together. Again, we use water as a toxic dump but assume we will not be affected.

Canada sits right next to one of the greatest bodies of fresh water in the world, the Great Lakes. I am astonished by the fact that most people in Toronto now buy bottled water. They pay more for it than for a comparable amount of gasoline. We in Canada have more fresh water per capita than any other country in the world. And yet I don't hear a peep or a squawk over the fact we have so fouled this resource that we don't trust the drinking water from our own taps. What a horrible situation!

We are soil
Every bit of the food we eat was once living. We're basically a compost heap for the carcasses of the plants and animals we have consumed. We take them into our mouths and we make them into our bodies. Those organisms come from the earth, from the soil. We are the earth in a most direct way, and yet we use the soil as a garbage can. It seems to me that is what you're going to be deliberating about here. Ecosystem health? We are the ecosystems of the planet. And the state of those ecosystems will be our state for heaven's sake. This isn't brain surgery; it's the fundamentals.

We are fire
Every bit of the energy that allows us to grow, move and reproduce has come from the sun, via the chemical energy captured by plants. All the energy that we consume, whether it's from hydro-electric sources, coal, gas or wood, has come from the sun. It is captured sunlight that we liberate again.

We are the earth. And it seems to me that when you define the issue that way, there is no separation. Whatever we do to the earth, to our mother, we do to ourselves – in the most direct way. It seems to me that the idea that we need an area called ecosystem health is absurd. Why do we need that? Health is the health of our ecosystem, as well as ourselves. That should be what all health is. There is no way of separating us.

A sacred balance
These ideas are laid out in a book I wrote for my foundation called *The Sacred Balance: Rediscovering Our Place in Nature*. While I defined the basic elements of earth, air, fire and water, I also said that we are social animals and that the problems we face as such are every bit as important as those of the environment.

As social animals, our most fundamental need is love. We see this in the lives of children growing up in Rwanda after the massacres, in Romania under Ceausescu, and in Cambodia and Bosnia. Children who may be fed, clothed and sheltered, but who are denied love, are fundamentally crippled, physically and psychically. To maximise the opportunity for love, we must ensure strong families and strong local communities. This means promoting full and meaningful employment, working toward justice, security and equity, and alleviating poverty and hunger. For me, those issues are as fundamental as stopping clear-cut logging and working against mega-dams.

We are also spiritual creatures. Never have we needed spirit more desperately than we do now as we enter the new millennium. We have to know that there are forces out there beyond our understanding. All other forms of life are genetically related to us through evolution. They are not commodities or resources; they are our kin. We have to know that there are sacred places on the planet that we would never think of touching or changing. Even though we all have to die, I believe that nature, which gave us birth, will persist after our passing. We are biological creatures, social creatures, and spiritual creatures. It seems to me that if we do not respect and fulfill those needs, then we are not fully human.

Managing Agroecosystems for Better Human Health

Don Peden

Health promotion versus risk reduction

We human beings are intimately bound, even biologically, to our food-producing environment, to the natural resources that surround us. So we should not pretend, as we have often done in the past, to be dispassionate observers of agroecosystems, as if they were so many goldfish bowls. Like soil and water, plants and animals, bacteria and fungi, we, along with the infrastructure we have built around ourselves, are integral and dynamic components of these complex systems.

This paper sets out the rationale for a more holistic approach to two normally separate domains of research – human health and agriculture. The latter is meant to include the natural resource management (NRM) practices of farmers, fishers, foresters and other land users in rural areas. We also present evidence for a simple but far-reaching hypothesis: Good agroecosystem management has the potential not only to reduce health risks but also to intentionally, actively and cost-effectively promote human well-being.

The paper draws on the experience and results of several research projects supported by Canada's International Development Research Centre (IDRC). These projects, some of which feed into larger initiatives funded by other donors, are carried out by various centres of the Consultative Group on International Agricultural Research (CGIAR) as well as some non-CGIAR groups.

Past agricultural research has, of course, sometimes included human health components. Studies of the nutritional content of food, pathogens in farm products, and the harmful effects of pesticide overuse are a few examples. Similarly, health research, especially in toxicology, occupational health and epidemiology, has sometimes been agriculture-specific. However, these investigations have scratched only the surface of health-agroecosystem interactions and have not yet fully bridged the continuum represented by them.

Many other connections – biophysical, but also social, economic and policy-related – need to be examined and better understood. Without such knowledge, scientists and development promoters, mandated to alleviate poverty through information and technology, risk doing harm as well as good. What is the value of, say, helping boost crop production for improved food security if the end result is to undermine other aspects of the health of the very people who were supposed to benefit?

Agroecosystems and their interactions with human health are intricate and rarely amenable to simple linear analysis. In fact, they are sometimes said to be unpredictable, which suggests that the idea of "agroecosystem management" may be an oxymoron. Nevertheless, the interests of our partners in developing countries demand that new research attempt to create synergy between agricultural practice and health practice, rather than merely studying the two in isolation or preventing them from getting in each other's way.

Agroecosystems defined

Among the world's varied ecosystems, agricultural ecosystems occupy a dominant position. They cover 30% of the world's land mass, and farmers, the primary stewards of agroecosystems, manage more area than any other group of people.

An agroecosystem can be defined as a geographically and functionally coherent domain of agricultural activity, including all living and non-living components and the interactions among them. Determining its precise physical boundaries is rather arbitrary and depends on the purpose of the analysis. The system may be a single farm, a rural community or microwatershed composed of many farms, or a major watershed. Or it may be an entire region broadly defined by climate, vegetation and other ecological traits – as in the case of tropical forest margins or savannas.

Because agroecosystems are strongly affected by external forces, they are not closed systems. People migrate into and out of agroecosystems. Purchased inputs like seed and fertiliser are brought in from other areas. Trade means that food enters and leaves the system. Soil erodes off hillsides, washing downstream into neighbouring ecosystems, sometimes disrupting water supplies and navigation. Human and plant pathogens, in some cases vectored by insects, may invade from outside regions causing sporadic epidemics of disease and then fade. Or they may be seasonal, in step with temperature and water cycles.

Parallel paths to holism

The ecosystem approach to human health is deeply rooted in the events and debates of the last century that eventually led to the notion of sustainable development. The compartmentalisation of agricultural sciences into specialties focussing on narrowly defined production problems made the Green Revolution possible. Exploitation of the world's biological and energy resources, in the form of germplasm, soil organic matter and chemical fertilisers, triggered a global production boom and averted widespread famine. The overall benefits, however, were unevenly shared by the world's regions. And then, of course, the unforeseen but negative consequences – such as soil degradation, loss of biodiversity, pesticide abuse and pest resistance – began to take their toll.

These trends led scientists and non-scientists alike to rethink approaches to agricultural development. Farmers, researchers, governments and development workers now face the double task of continually boosting food production to meet growing demand, while mitigating or reversing the damage done to the natural resource base. Recognition of the immense challenge ahead has led, over the past two decades, to more holistic thinking about the interconnections between production and natural resource use and conservation. The rise of integrated pest management (IPM) is a good example.

The evolution of human health research and practice followed a similar pattern. Advances in sanitation, health education, nutrition, immunisation and drug therapy drastically reduced the incidence of infectious diseases during the 20th century in industrialised countries, and to a lesser extent in developing countries. The eradication of smallpox is among the most widely recognised of these achievements. Much progress depended on specialised applications of medical science, often centred on diagnosis and prescription in a clinical setting. That approach, based on a rather restricted set of specialist disciplines, tended to isolate people from the physical environment of their daily lives. Despite the notable progress, the benefits have not been shared equally among countries and social groupings. And, globally speaking, infectious and communicable diseases are still the most common cause of death. In sub-Saharan Africa they account for 70% of the burden of illness.

As with the problem of pesticide abuse and pest resistance in farming, the health sector faces the challenge of the growing resistance of disease vectors and pathogenic organisms to pesticides and antibiotic drugs. Climate change and inadequate child nutrition are other factors now seen as undermining positive advances made in global health care over the years.

Increasingly, the limitations of clinical medicine have been balanced with preventative public health care concepts. There has been a shift to a broader view of human health – one that goes beyond the biology and chemistry of people and medication, to take account of the human living conditions and ecosystems that influence health. This trend parallels the development of IPM in agriculture. It is being pushed by the fact that most developing countries cannot afford expensive health technologies, especially drugs, and are therefore looking for cost-effective alternatives to promote public health. Here, ecosystem management has much to offer.

Developing countries cannot afford expensive health technologies, especially drugs, and are therefore looking for cost-effective alternatives to promote public health. Here, ecosystem management has much to offer.

Holistic thinking has emerged in both the agricultural and health sciences. Each area now recognises that the sustainability of research benefits depends on understanding the complex interactions between the behaviour of people and the ecosystems in which they live. Each also recognises that human health is conditioned by poverty, which in turn is accentuated by stresses on those ecosystems.

These messages were brought home in Agenda 21, the action plan of the 1992 Rio "Earth Summit". Agenda 21 subsequently became a focal point for IDRC thinking and support to research in developing countries. In fact, the Centre's Ecosystem Approaches to Human Health (Ecohealth) Program Initiative, under which the projects reported here are funded, took important cues from that action plan.

Here it is important to distinguish between the more traditional environmental health approach to research and the ecosystem (or "ecohealth") approach. At its most basic level, the former has to do with identifying interactions between a specific human health indicator, such as the incidence of cancer, and a contaminant in the environment, such as dioxin. An ecohealth perspective, in contrast, is transdisciplinary and takes account of system complexity and multiple determinants of health.

Health in international agricultural research

Agricultural professionals, whether scientists or farmers, today devote much attention to promoting the health of livestock, crops and agroecosystems. Arguably, these people are in a health care profession, but one in which non-human species are the direct beneficiaries. This more recent model of "the agriculturalist as doctor" contrasts with the often prevailing view that agriculture's mission is simply to produce more and better food and to make sure it is readily available in times of need.

With the growing interest in IPM following the Green Revolution, agricultural "medicine" has shifted even further, from an emphasis on curative use of chemicals to the adoption of multiple preventative interventions – a situation not unlike what is happening in public health. Yet within the context of mainstream agricultural research, human health continues to simmer away on a back burner. For the most part, efforts are directed toward mitigating the negative impact of intensified agriculture on people while advancing plant and animal husbandry to maintain production. Little effort has gone into the design of methods for explicitly harnessing the power of agroecosystem management to actually promote human health. As primary stewards of the agroecosystems that sustain most human life, agricultural professionals nevertheless have the opportunity and responsibility to do so.

Human health, however, has emerged as a development objective in several international agricultural research centres and partner institutions. The short case studies near the end of this consultation report describe projects in which IDRC has had some involvement. The research spans a range of countries, regions, agroecosystems, health problems, time and space scales, disciplines and methodologies. The R&D partnerships formed under these projects bring together various mixes of international and national research institutions, NGOs, universities, government health agencies, women's and community organisations, and most important, local farmers and other rural people.

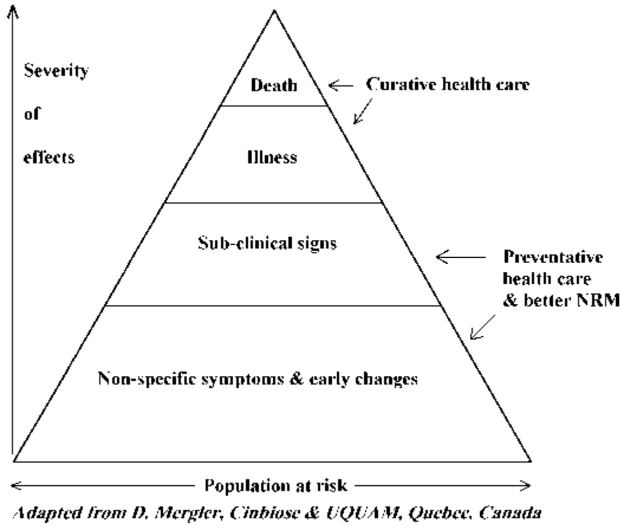
While each of the research activities can stand alone as a unique and important contribution to R&D for the developing nations, when viewed together they yield a bigger and more intricate mosaic of the interactions between health and ecosystem management. The following sections outline factors common to some or all of the projects, as well as some differences.

Health as a local priority

Evidence from many projects shows that the rural poor demand quick payoffs from research. The value they place on meeting immediate needs, especially good health, often outweighs the value assigned to the promise of future benefits from better NRM and agricultural development. But short-term goals are not necessarily at odds with those pursued over a longer time frame. Indeed, they may reinforce each other, intentionally or not.

The U.K.'s Department for International Development (DFID) says that a human livelihood is sustainable "when it can cope with and recover from stresses and shocks and maintain or enhance its capabilities and assets both now and in the future, while not undermining the natural resource base." Such resilience and attention to the future health of the natural environment are only possible if the people engaged in those livelihoods are already in good health. And once better NRM practices begin to enhance livelihoods, it is much easier for those people to maintain their good health and their livelihoods.

The case study of mercury exposure in the eastern Amazon, as well as the project on health, biodiversity and NRM use in the western Amazon's forest margins, demonstrate the catalytic effect of tying longer-term agricultural objectives to health improvement. In both cases, increased understanding of the health implications of local NRM helped sustain local interest in the research.



The concept of the "pyramid of health" demonstrates the importance of preventative public health care and natural resource management (NRM). For many health problems, only a small proportion of the population suffers clinical symptoms, including life-threatening conditions, that require curative care.

Transdisciplinarity

To varying degrees, the researchers have gone beyond the traditional boundaries of their disciplines to embrace a new, more holistic paradigm centred on the complex ecosystem within which human health thrives or atrophies. They have attempted to balance integrative thinking with the continued need for reductionist inquiry.

For example, efforts in Thailand to find sustainable soil management systems and to understand the health status of rural children in shifting-cultivation communities relied on traditional soil science and medical methodologies. The soil study results suggested that fallowing for as little as five years, a current practice among some hill tribe farmers, is sufficient for sustainable rice-based cropping. However, from a human health perspective, this production system may not be fully sustainable. As the researchers note, diets with little food-type variety may not provide the nutrients required for children to grow, develop and realise their full potential in life. To obtain adequate nutrition, people may need secure access to an area of land larger than that suggested by a narrow analysis of upland rice production systems alone. Bringing soil sciences and land tenure issues together with child health research requires a new integrative understanding of the agroecosystem. This is something that no single discipline can achieve on its own.

In Ethiopia, national and international researchers integrated information on market economics, nutrition and NRM. This allowed them to create a transdisciplinary model that quantifies the tradeoffs among soil conservation, food security and income-generating land management strategies. In the lower Amazon, Brazilian researchers integrated knowledge on fisheries, aquatic ecology, toxicology, slash-and-burn agriculture, and human health and nutrition to develop a more holistic understanding of the complex interplay of ecosystem management and human health. This learning process is going on in many settings around the world. As researchers gain insights into the dynamics of human health within an agroecosystem context, they are revealing new ways by which better NRM can be explicitly used to deliver improved health to the rural poor.

Participatory methods

An agroecosystem approach to NRM and human health quickly recognises that local people are simultaneously both the subject of study and key decision makers and actors who must eventually buy into any recommended interventions. All of the on-going projects considered in this review sought greater participation of local people in various stages of the work: setting research priorities, executing field research, choosing appropriate local interventions, and negotiating shared responsibility for NRM with various levels of government.

Gender and social groupings
All the research activities recognised that women, men and children, as well as socially distinct sub-classes, occupy different life spaces or ecological niches within their respective agroecosystems. In many cultures, women are responsible for family health care, but men have decision-making power when it comes to the use of land and other natural resources. Research in Sri Lanka demonstrates that men, who manage irrigation, often overlook women's needs for reliable and safe supplies of domestic water. Yet when women function as heads of households, their actions are more likely to reflect the need to maintain family health.

The project in Ecuador demonstrated that while men are often more exposed to toxic chemicals during spraying of potatoes, women are at high risk from washing farm labourers' contaminated clothing. And in South Africa, where women make up the majority of the rural poor, research suggests they are more at risk from diets highly contaminated by mycotoxins.

All the research activities recognised that women, men and children, as well as socially distinct sub-classes, occupy different life spaces or ecological niches within their respective agroecosystems.

Power struggles over land and other resources often aggravate disparities among social or ethnic groups. In Southeast Asia, marginalised hill tribes have lost access to traditional land and, with shorter fallow periods, consume less substantive and less diverse diets. Heavy reliance on rice may end up undermining the sustainability of community livelihoods.

Sub-clinical and non-specific symptoms of poor health
Exposure to mercury in the Amazon, to the insecticide carbofuran in the Andean highlands, and to mycotoxins in Africa reveals the potential impact of health risks that cause previously unrecognised and often non-specific symptoms of declining health (see Pyramid of Health illustration). In all three cases, there is growing evidence that the rural poor in particular suffer from nervous system degeneration and from other conditions such as cancer, birth defects and immunosuppression. Apart from these studies, the scientific literature shows that schistosomiasis and malnutrition also contribute to immune system suppression. Immunosuppression caused by agroecosystem-based factors may well be a significant factor in the high morbidity and mortality rates associated with infectious diseases in sub-Saharan Africa, South Asia and tropical America.

Ecosystem uniqueness
The research projects demonstrated the uniqueness of each study area or ecosystem. Conclusions about one system may not be applicable elsewhere, even where two ecosystems have a superficial resemblance.

A clear example arises from the three studies that consider irrigated rice production and malaria. In the West African Sahel, evidence suggests that under certain conditions, the introduction of irrigation may reduce malaria transmission. But in Kenya and Sri Lanka, researchers believe the reverse is true. In the Peruvian Amazon, the high Andes of Ecuador, the irrigated rice systems of West Africa, and the tsetse-prone areas of eastern Uganda, researchers emphasise the importance of understanding spatial and seasonal variations as ecosystem-based determinants of human health.

Tradeoff analysis
When the aims of ecosystem management are incompatible or not fully complementary, tough choices must be made. If the local development agenda includes better human health, higher agricultural production and cash income, and sustaining the ecosystem's capacity to deliver ecological services, then decision makers, including farmers, must be able to evaluate the tradeoffs.

Fortunately, there are modeling tools for this. In the highlands of Ethiopia, research indicates that, with currently available knowledge, inputs and technology, the land cannot provide sufficient calories to maintain people while simultaneously safeguarding and replenishing soil fertility. A viable strategy may be to produce high-valued agricultural products for the market and use the earned cash to buy inputs such as fertiliser, as well as nutritionally adequate food. The investigators question the tradition of depending on manure for fuel. While alternatives are not readily available, this practice prevents nutrient recycling, leading to further soil degradation, food insecurity, malnutrition and declining human health.

In Ecuador, researchers question the value of using pesticides on potato crops grown by poor farmers. Their work substantiates studies on irrigated rice systems which suggest that, under some conditions, the value of the production lost by not using pesticides is outweighed by the health costs that are avoided.

Often, the costs and benefits of increased production or changes in health and the environment are not equally shared by different segments of the community. One ethnic or economic group, for example, may have advantages over another. Similarly, consumers outside the agroecosystem, such as city dwellers, are spared the production-related health costs that rural producers must bear in the course of their work. The need thus arises for policy interventions to balance the tradeoff between health and food production and to ensure that the well-being of poor farmers and farm labourers is not jeopardised.

Impact of health on farm productivity
Most of the research described here focuses on how agroecosystem management affects health. A new study on HIV/AIDS in Africa, however, highlights the devastating effects of ill health on rural people's livelihoods, particularly labour-intensive farming and natural resource use. Sick people cannot work nearly as well as healthy people. And even healthy people must spend time caring for the sick, dying and orphans, and organising and attending funerals. The financial toll exacted by health care and burials puts enormous stress on families. The loss of educated or otherwise knowledgeable people also undermines the transfer of know-how, further reducing productivity.

Apart from HIV/AIDS, other aspects of poor health undermine agricultural productivity. Malnutrition, the subject of several of the IDRC-supported studies, reduces vigour and the human capacity to learn, thereby thwarting a community's ability to transform natural resources into food and other products. Studies of potato cultivation in Ecuador indicate that long-term exposure to pesticides actually decreases farmers' individual productivity.

Ecosystem management for human health

To remain healthy, people need a varied diet. For many of the rural poor in developing countries, the sole source of such variety is the natural resources that surround them. While reductionist science may produce specific high-quality products such as crops with enhanced micronutrient content, research rarely considers the total range of food products seasonally available within an agroecosystem and needed for good nutrition. And rarely is the menu of food sources matched with gender- and age-specific requirements. Similarly, relatively reductionist environmental health research has tended to focus on one-to-one links between a particular health hazard and a limited set of health indicators. To varying degrees, all the projects discussed here have attempted to move beyond these traditional approaches to health research.

Targeting human health improvement through NRM interventions is a clear trend emerging in the CGIAR centres and like-minded research organisations. Agroforestry, for example, is now seen as one means to improve dietary diversity, cutting over-reliance on staple carbohydrates like upland rice. In the Brazilian Amazon, it may also help reverse mercury contamination of aquatic food chains over the long term by controlling soil erosion.

Researchers on a project in Uganda believe better NRM targeted on livestock may help reduce the scourge of sleeping sickness. And in two highland settings, in Ethiopia and Thailand, livestock are seen as key contributors to enhanced nutrient recycling to maintain higher levels of food production. Animal products, in addition, provide essential nutrients such as vitamins A and B12, often lacking in people forced into a carbohydrate-heavy vegetarian diet.

Three CGIAR centres are experimenting with modified management of livestock, vegetation and irrigation schemes to help control malaria and other vector-borne diseases. Another, hoping to reduce HIV transmission, is looking at the promotion of agroecosystem-based opportunities in people's home areas to discourage labour migration. In South Africa, a team is attempting to improve soil and crop management as a way to reduce human exposure to aflatoxins and fumonisins. For example, restoring soil fertility may make host plants less susceptible to invasion by mycotoxin-producing fungi.

Conclusion: Integrating research on NRM, poverty and human health

The similarities and differences among the research projects and results described above exemplify the profound interdependence of human health, poverty and agroecosystem management. What is needed is a common framework to clarify the complementary roles that NRM and health researchers can play.

Consider the pyramid of human health (see illustration). In any human population, and for many health problems, a small number of individuals exhibit acute clinical symptoms. These are the problems that most medical professionals attempt to heal. When they fail, many patients continue to suffer and some die. However, a much larger number of people suffer from early sub-clinical changes and exhibit non-specific symptoms. These are rarely reported and are often untreatable by the health care system. They require preventative approaches that go beyond the current domain of most public health agencies.

Conventional curative medical services are expensive to deliver and focus on the needs of the minority, namely those who have clinical signs of illness and access to medical care. In places, evidence suggests that further investment in curative health care may actually lower health standards by diverting resources away from the preventative non-medical measures that are better able to deal with widespread non-clinical threats to human health.

In future, we can expect that health delivery will no longer be the monopoly of classic "western style" health professionals. Many preventative interventions are needed to promote better health among the majority of the population represented by the lower half of the pyramid. Recognition of this creates an important role for agricultural professionals. Agroecosystems contain most of the fundamental determinants of human health, particularly those that affect the rural poor. While agricultural R&D often make significant contributions to improving human health, ignorance of the human health consequences of NRM can undermine those gains. However, better understanding of the complex nature of human health within agroecosystems can pave the way for active delivery of preventative NRM and agricultural interventions that help achieve consciously formulated human health objectives.

More than lack of cash, to be poor means to suffer several or many deprivations at once – lack of access to health care, natural resources, credit, farm inputs, safe housing, knowledge, information, education, quality food and labour. Poverty leads many people to migrate in search of employment. This can expose them to additional health risks and contributes to the breakdown of social capital. To maximise cash income for immediate needs, poor and often marginalised farmers tend to forgo investments for long-term maintenance of soil productivity. They put added pressure on common property resources such as grazing areas and woodlands. And they frequently sell the highest-quality produce, leaving their families to depend on nutritionally inadequate food that may also be contaminated.

The low farm productivity and unsustainable land management practices that emerge from poverty and poor health reinforce the factors that compromised human well-being in the first place. The momentum of the poverty cycle is thus maintained. To break that cycle in poor rural communities of developing countries requires a multi-pronged attack on ecosystem degradation and related threats to human health.

This paper has scratched only the surface of existing knowledge about the interconnectedness of NRM, human health and poverty. Individually, the projects described here could easily be overlooked by policy makers and others charged with rural development. Together, however, they convey a more persuasive message: Expanded inquiry into additional causal links between human health and agroecosystem management could significantly contribute to the alleviation of rural poverty around the world.

Bare-faced risk. A farm worker without a protective mask and clothing sprays a crop. Around the world, pesticides pose a serious health hazard, not only to those who prepare and apply them, but also to women and children in and around rural households. A report on page 25 looks at the health effects on potato growers in Ecuador. CIDA photo: R. Lemoyne.

Fishing on the Tapajós River in the Brazilian Amazon. Deforestation and soil erosion along the shoreline have led to a buildup of poisonous methylmercury in fish. Local communities and researchers, however, have solutions to the problem. See page 26. Photo: Jean Lebel.

What is UNEP?

The mission of the United Nations Environment Programme (UNEP) is "to provide leadership and encourage partnerships in caring for the environment by inspiring, informing and enabling nations and people to improve their quality of life without compromising that of future generations."

UNEP was established in 1972, after the Stockholm Conference on the Human Environment, as the environmental conscience of the United Nations system.

D E A R R E A D E R S

In 1950, the world population was 2.5 billion. By 2001, it had swelled to 6.15 billion and, of course, is still growing. Our sheer numbers, along with technology applications, have given humankind more than ever before the capacity to disrupt the often delicate balance among the various elements that make up our planet's ecosystems. But we are also gradually improving our understanding of that balance and how it can be harnessed to promote human health and other aspects of sustainable livelihoods.

Canada's International Development Research Centre (IDRC) and the United Nations Environment Programme (UNEP) have been working together for some years to improve human health through better stewardship of the earth's ecosystems and natural resources. In late 1999, the two agencies co-hosted a consultation on the subject in Hull, Canada, under the umbrella of the Canadian Conference on International Health. The consultation brought together more than 75 participants from academic institutions, non-governmental organisations, international centres and national governments. They examined health in three types of ecosystems: agricultural, urban and coastal.

The following summary report focusses specifically on agroecosystems, the type of environment that received the most attention during the consultation and which is of special interest to LEISA readers. Since the meeting, the "ecohealth" projects supported by IDRC and UNEP have progressed and new insights have been gained. The overview paper, by Don Peden, has been updated to include some of these developments. It is based on an October 2000 presentation to a meeting of the Consultative Group on International Agricultural Research (CGIAR), in Washington.

17 Linking Natural Resources, Agriculture and Human Health: Case Studies from East Africa

Gulley-forming erosion in Africa. Soil degradation, a threat to food production and rural nutrition, is a growing problem in many parts of the world. Half the arable land of the Ethiopian Highlands, for example, is thought to be moderately to severely eroded. A research project there analyses tradeoffs between higher farmer income, food self-sufficiency and soil conservation. See page 17. IDRC photo: Neill McKee.

The keynote address was delivered by David Suzuki, well-known Canadian geneticist, environmentalist, writer and broadcaster. His words are a blunt, but meticulously illustrated warning that human beings are on a collision course with the life-support systems of our planet. A major part of the problem, he argues, is the conventional economic thinking that continues to promote indefinite growth and the "mono-culture of the global economy". He also stresses that paying attention to spiritual and social needs, especially love and a strong sense of community, will be as important to humanity in the new millennium as fulfilling biological needs and solving environmental problems.

This report also summarises other consultation papers on key topics: the origin of, and rationale for, an ecosystem approach to health; the benefits of livestock production to human health and ecosystem management; participatory methods and community capacity building; and the threat of mycotoxins in food. All but the first of these draw on specific case study materials. Complementing those examples are brief descriptions, beginning on page 25, of eight research projects from around the world.

IDRC and UNEP hope this special supplement will stimulate new thinking and research on how ecosystem approaches can benefit human health in both the South and the North in the coming decades. Both organisations thank ILEIA for its collaboration, as well as the many scientists and other professionals who contributed to this publication and to the innovative research it describes.

What is IDRC?

The International Development Research Centre (IDRC) works with researchers to help find practical long-term solutions to social, economic and environmental problems in developing countries. In particular, support is directed toward developing the indigenous research capacity necessary to sustain policies and technologies that can build healthier, more equitable and more prosperous societies.

IDRC was established in 1970 by an Act of the Parliament of Canada.

Reaching women

personal reflections

Eric F. Wirsiy

I have had the opportunity to work as extension officer in my country, Cameroon, for the Ministry of Agriculture and also for an NGO, the Mount Cameroon Project (MCP). During my years of service I witnessed a lot of things that kept agricultural knowledge out of the reach of women, despite their role in agriculture.

Sometimes, the needs of women can be quite different from project objectives. A group of women in a village in the Mount Cameroon region, after undergoing schooling on biodiversity conservation for a couple of years, suddenly found project staff talking farming. This was a welcome relief. But the approach used did not actually seem to be addressing the real needs of the women, as evidenced by the reaction of the women to a training workshop organised to introduce vegetable farming as a way of diversifying production and farm income. Whilst a service provider employed by the project was providing the training, a parallel project initiated by the women was going on. The women wanted improved planting material (cassava) and a technician to assist them in establishing a cassava plantation.

They complained the project had sidelined them for too long and they now needed to take their destiny into their own hands. In the past they would accept to go and sit in any workshop, despite many other pressures on their time - but this time they said: 'No sir, if you want to help us this is what we need. These are the skills and materials we need.'

I am, by this, not questioning the raison d'etre of conservation projects, but wondering aloud why farmers spend endless hours attending meetings rather than acquiring skills on how to improve their agriculture, which is their main occupation and livelihood source. As a result of inadequate diagnosis of the real needs of the farmers, or as a result of top-down approaches where project goals mask the real needs of the people, projects derail women from agriculture and involve them in project activities to the detriment of their farming activities.

Effective communication is essential, but in my experience there are many obstacles to overcome in communication with women. Illiteracy is one of the major barriers. Agriculture in Cameroon is mostly carried out by older women, who are in most cases uneducated. This poses a big challenge to frontline extension staff. For effective communication with local people, mastery of the native dialect is a prerequisite for extension workers. This condition is most often not met.

When women attend public meetings or events they play a passive role, as women in most cultures do not talk in the midst of men. They can only talk in women's gatherings. These gatherings are rare and hardly ever have anything to do with agriculture. They come together to discuss small savings and other issues, but not farming. It becomes difficult to diagnose the real needs/priorities of women, and development workers most often have to discern them.

To solve the problem of labour shortages, some women are now organised into 'work groups'. Farm work is done on a rotary basis from one member to the other on specific weekdays. These groups could potentially be exploited so that women can benefit from the training most often received by the men. Such attempts usually meet with opposition, however, as the women on whose farms work had been scheduled find part of their allocated time being diverted to something else, and they are the losers.

To overcome this problem, some agricultural extension workers have introduced group farms, so the women can devote a day to work on the group farm where no one will be cheated. On these group farms women are now taught useful farming skills and sensitised on HIV/AIDS. The group farms have their limitations but have been very useful in reaching out to women without the male dominating effect. Discussions in a group plantain farm have often resulted in an exchange visit to a members' maize farm, where a problem is assessed and discussed at length. Supporting the women to group themselves without the men is therefore a way to reach out to this vulnerable set of farmers.

In general, it is more appropriate to approach already existing women's groups than try to form others, particularly if the men will infiltrate their ranks in a new group. Experience with mixed groups has shown that women tend to get lost inside these groups.

Instead of separating agricultural production and conservation, there is the need for the introduction of the type of agriculture that is sustainable from the economic, social and environmental perspective and which takes into account the time shortage already being experienced by women.

To conclude, there is a need to get a critical mass of the women empowered. To achieve this, extension and development project staff must carry out a proper diagnosis before scheduling activities with women. More focus has to be placed on creation of purely women groups at all levels. A holistic approach to development is best. Conservation cannot work if the livelihoods of the people are not assured, and agriculture is for now the only viable livelihood source in our villages.

Capacity for development : new solutions to old problems

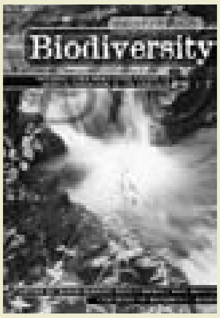
by Fukuda-Par S, Lopes C, Malik K (eds). 2002. 283 p. ISBN 1 85383 919 1 GBP 17.95. United Nations development Programme (UNDP). Earthscan Publishers, 120 Pentonville Road, London N1 9BR, UK / www.earthscan.co.uk ; earthinfo@earthscan.co.uk.

The technology revolution of the 21st century should be used to empower poor countries, not leave them further behind. This book reminds us that this process has to begin with developing local knowledge and local capacity. “Capacity for development” brings together innovative and well-supported studies of technical co-operation and its potential to build sustainable capacities in developing countries by enhancing the knowledge, skills and productive aptitudes of their populations. The authors analyse the issues from three perspectives: capacity and development; ownership; and knowledge; and present a range of views from practitioners, academics and policy-makers about what has gone right with technical co-operation in recent years, what has gone wrong , and how to do it better and perhaps very differently. (WR)

Perspectives on pastoral development : a casebook from Kenya

by Birch I, Shuria HAO. 2001. 160 p. ISBN 0 85589 467 8 USD 12.95. Oxfam / www.oxfam.org.uk. (Oxfam development casebook). OXFAM Publications, 274 Banbury Road, OX2 7DZ Oxford, UK.

With this casebook, OXFAM provides a study of the Wajir Pastoral Development Project, in a remote area near the border of Kenya and Somalia. This project, with an integrated approach to poverty reduction and with a strong emphasis on community participation, concerned the efforts of marginalised groups to develop pastoral associations to represent their own interests. The authors assess the projects’ success in supporting sustainable livelihoods, together with livestock keepers and with people who have lost their animals. They describe how the project has devised ways of responding to emergencies (such as drought and conflict) as part of a longer-term development agenda, and how it has built the capacity of local institutions to influence national policy on the future of pastoral development.(WR)



Protecting biodiversity : national laws regulating access to genetic resources in the Americas

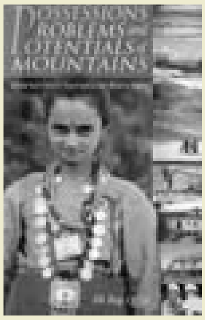
by Bass SP, Muller MR (eds.). 2000. 105 p. ISBN 0 88936 900 3. International Development Research Centre (IDRC), Canada. . ITDG Publishing, 103-105 Southampton Row, London WC1B 4HL, UK / itpubs@itpubs.org.uk.

Some of the most diverse collections of flora and fauna in the world are found in the Americas. Colombia alone carries over 50 thousand different plant species. This precious resource, however, is quickly dwindling. Pharmaceutical and biotechnology companies are tapping genetic resources in the Americas at an ever-increasing rate, and habitat destruction has pushed many species to extinction or to the brink of extinction. This book addresses one of the most fundamental aspects of this important issue: the lack of adequate national laws regulating access to, and compensation for, the use of local genetic resources. It compares existing laws and policies across a range of countries in both the industrialised and developing worlds. It also presents legal viewpoints, conclusions, and solid recommendations for future action. “Protecting Biodiversity” is a useful reference book for all experts and organisations in the field of conservation of genetic resources. (WR)

South-South workshop on smallholder dairy production and marketing : opportunities and constraints : held at NDDB, Anand India 13-16 March 2001 2002.

CD Rom. ISBN 92 9146 115 6. International Livestock Research Institute (ILRI), Addis Ababa, Ethiopia / www.ssdairy.org ; ilri-information@cgiar.org.

With these proceedings on CD-Rom, ILRI provides all the workshop papers and other interesting information about the workshop. To be able to use this beautiful information source you need a rather sophisticated computer. Fortunately the information is also available on internet at www.ssdairy.org. The workshop objectives were to facilitate information exchange and discussion amongst smallholder dairy research scientists and development specialists from Asia and sub-Saharan Africa, and to share the successful and unsuccessful experiences gained. Papers were contributed from 16 countries and covered themes like: trade regulations, dairy policies, market institutions, livestock services, and research and extension. (WR)



Possessions, problems and potentials of mountains : special reference to Nepal and its far-western region

by Ojha ER. 2002. 69 p. ISBN 99933 1 959 7 Rs 275.00. EKTA Books, Thapathali, Kathmandu, Nepal / ektabook@mos.com.np.

With this booklet, Ek Raj Ojha reviews the most crucial possessions, problems and potentials of mountains of the world, particularly in developing countries, with special reference to Nepal. Ojha highlights especially the value of the human resource and the special nature their relationship with the mountain ecosystems on which they depend. The ideas presented in lieu of recommendations can provide a useful supplement to the visions of many individuals and institutions working towards sustainable mountain development. (WR)

Strengthening livelihoods : exploring the role of beekeeping in development

by Bradbear N, Fisher E, Jackson H (eds.). 2002. 122 p. ISBN 1 898807 01 9 GBP 22.- Bees for Development, Troy, Monmouth NP25 4AB, UK / info@beesfordevelopment.org www.beesfordevelopment.org.

Beekeeping projects have often focused on strengthening physical resources (for example providing hives or processing equipment), rather than strengthening human and social resources (for example training in how to handle bees, making secondary products, in accessing markets). It is relatively easy to provide equipment. Supporting, facilitating and training beekeepers requires that experts understand people’s own perspectives on development. This book contributes to our understanding of important human aspects in rural development. The case studies from Africa, Asia, the Caribbean and Latin America, gathered in the Symposium held in 2000, provide important information on how small-scale beekeeping can contribute to livelihood security. Several case studies also pay attention to the role of women in beekeeping. (WR)

Naïve art by Adrie Martin

Dimitra Project: Rural Women and Development (FAO)

http://www.fao.org/dimitra/

Dimitra is an information and communication project which aims to highlight rural women's contribution to their community and their country. It is implemented by the Food and Agriculture Organization of the United Nations (FAO). The project joins a large network of local partners in Africa and the Near East and works to encourage and support the exchange of good practices, ideas and experiences. The Dimitra database is accessible on this website in English and French. It contains profiles on organisations based in Europe, Africa and the Near East which have projects or programmes involving or concerning rural women and development.

Honeybee database of innovations

http://www.honeybee.org/jsp/search/catdisplay.jsp

Honey Bee Network is a network for knowledge-sharing at grassroots level. The database of innovations and contemporary/ traditional innovative practices from around the world can be searched freely or by picture-category (including a wide range of categories from implements, crop protection and water management to artisan and education innovations). The lefthand column of the HoneyBee sitemap at **http://www.honeybee.org/lang/en/sitemap.html** will lead you to other interesting aspects of this network, like the ideas bank and innovator forum).

GROOTS network: grassroots organizations operating together in sisterhood

http://www.groots.org/index.htm

GROOTS operates as a flexible network, linking leaders and groups in poor rural and urban areas in the South and the North who work towards improving opportunities for women. It's activities include support for exchange visits among member groups, support for grassroots women's groups to document local strategies, and working towards helping women have more say in local decision making and policy development.

FAO website on gender and food security

http://www.fao.org/gender/

This website contains a wide range of documents and other resources. The start page is divided into a number of thematic areas which provides an overview of the topic and describes lessons learned. At the bottom of each section under "subcategories" is a list of relevant studies and training materials, some of which are available electronically. All of these documents can be ordered.

International Agricultural Centre (IAC): building capacity for sustainable development

http://www.iac.wageningen-ur.nl/

The IAC, part of Wageningen University and Research Centre, works to build capacity for sustainable development in the agriculture, food, rural development and natural resources management sectors. The IAC provides advisory services, training, seminars, action learning projects, network development and knowledge management to optimise organisational and individual learning. Information about capacity building services can be found on this website, or contact IAC at P.O. Box 88, NL 6700 AB Wageningen, the Netherlands. Email: iac@iac.agro.nl

Connecting women globally for social change

http://www.iwtc.org/

The International Women's Tribune Centre (IWTC) website has many gender and development-related resources, links and publications. In particular, the first page has links (click on pictures) to different sources of gender-related resources such as the UN *Women Watch* (including a good practices database and gender training material), *Mapping the World of Women's Information Services* (a database with over 350 women's information centres and libraries from more than 125 countries); the INSTRAW *Gender Awareness Information and Networking System (GAINS)*, and links to NGOs working on gender issues, by region.

Gender and Rural Development

http://lnweb18.worldbank.org/ESSD/essdext.nsf/22ParentDoc/Gender?Opendocument

This site of the World Bank represents an on-going effort to promote systematic integration of gender concerns into rural development activities. The site aims to reach practitioners working in gender and rural development at global, national, and grassroots levels. It contains tool kits, case studies, publications and links related to gender and rural development.

Women Farmers: Enhancing Rights and Productivity

http://www.zef.de/zef_englisch/f_veranstalt.html

This website has a list of papers available online that were presented at a workshop hosted by the German Center for Development Research (ZEF) in 1999. Topics covered include gender issues related to access to land and other resources, extension, information dissemination and technologies and innovation as well as relevant policies.

Gender Arena

http://www.genderarena.com/genderarena/homepage.htm

This is a resource website and gateway into gender/feminist academia and research on the web. The website includes links to new and existing book titles and online catalogues; links to online and offline journals, and links to professional organisations as well as news and information.

Who milks the cow? Gender and development in livestock farming by Richter M. 1997. 202 p. ISBN 3 88085 517 X. German Agency for Technical Cooperation (GTZ), PO Box 5180, 65726 Eschborn, Germany. (Schriftenreihe der GTZ ; 261).
Women play a very important role in animal husbandry - they are owners of livestock and they process and sell animal products. However, women are seldom part of the target group of livestock farming projects. This manual presents information on the roles of men and women, and provides suggestions for a gender-oriented approach in animal husbandry projects, especially from the perspective of raising the efficiency and sustainability of livestock projects. It offers assistance in concrete case design. Besides animal husbandry, the methods and procedures can be transferred to other areas of rural development. (WR)

Women and IPM : crop protection practices and strategies by Fliert E (van de), Proost J (eds). 1999. 108 p. ISBN 90 6832 710 0 : DFL 29.00. Royal Tropical Institute (KIT), PO Box 95001, 1090 HA Amsterdam, The Netherlands, e-mail: kitpress@kit.nl; Intermediate Technology Publications (ITP), 103/105 Southampton Row, London WC1B 4HH, UK, e-mail: itpubs@itpubs.org.uk.
This book builds on contributions made to the symposium on Gender Issues and Crop Protection, which was part of the 13th International Plant Protection Congress held in the Netherlands in 1995. It became clear at the Symposium that most contributions related to integrated pest management (IPM) and that this was probably not by chance. Day to day crop management is often women's work, so that the close monitoring required for IPM may follow naturally in this category. IPM cases are presented from Bhutan, Vietnam, Indonesia, Costa Rica, Honduras, Zanzibar and Ghana; other chapters deal with pesticide hazards and the role of women in the new agricultural economy in Russia. The cases provide a clear analysis of specific situations relevant top women's role in crop protection, and recommend strategies for change - such as making IPM extension and training programmes more accessible to women. The concluding chapter provides a broader view on the presented cases, including a plea for a new kind of external structuring of decision making, using mechanisms such as Farmer Field Schools. (WR)

Secondary farmers of secondary crops? Women and rootcrop livelihood in the Philippines. UPWARD. 2002. 250 p. ISBN 971 614 020 7. FAO-RAP Project, CIP-UPWARD, c/o IRRI DAPO Box 7777, Metro Manila, Philippines. Email cip-manila@cgiar.org
This publication is the output of an FAO-supported project which aimed to assess roles, opportunities and constraints faced by women farmers in sustainable rootcrop livelihood, and identify implications for household food security and genetic resources conservation in the Philippines. The volume includes eight case papers of rootcrop livelihood in the Philippines, and five synthesis papers that summarize the lessons, issues and future challenges emerging from the empirical cases. The main research objective of the project was to assess women's roles and contributions, however the case papers view gender dimensions of rootcrop livelihood as part of/within the broader social dynamics of households and communities. In particular, the case papers report on the relationships between and among male and female members, both adult and children, of individual households. This unique project provides a basis for rethinking the conventional view of rootcrops as secondary crops, and women as secondary farmers. (EK)

Transfer of tropical tuber crops technologies : means, modes and methods by Anantharaman M, [et al]. 2001. 71 p. Central Tuber Crops Research Institute (CTCRI), Sreekariyam, Thiruvananthapuram 695 017, Kerala, India / director@ctcri.ren.nic.in ; www.ctcri.org. (Technical Bulletin Series 35)..
Tuber crops, mainly grown in diverse, risk prone areas play a significant role in the livelihood of people living close to the subsistence level in India. As low cost energy producers, these crops have great potential in meeting the food security of the small and marginal farmers. CTCRI has taken up the transfer of tuber crop technologies. it has not only implemented the existing frontline extension projects but also evolved and executed its own transfer of technology projects to educate the tuber crops farmers. The methods, results and experiences of CTCRI are reflected in this booklet, a useful practical guide for extension workers. (WR)

Empowering women and fighting poverty : cocoa and land rights in West Africa 2002. 8 p. downloadable. International Food Policy Research Institute (IFPRI), 2033 K Street, N.W., Washington, D.C. 20006, USA / http://www.ifpri.org/pubs/pubs.htm.
These IFPRI papers on women and cocoa in Ghana provide case studies of how land rights, poverty and food security are related and how changes in the position of women can contribute to improving the livelihoods of the whole community. Cocoa production is particularly good for female farmers - cocoa can be grown on marginal land, and it prevents soil erosion, making it a good crop for poor farmers who do not have access to fertile land. Poor female farmers are often in this position, and cocoa helps them make most of the land available to them. This study from IFPRI showed that families and communities benefit greatly when women are involved in cocoa production in Ghana and other parts of West Africa, and that with government support, women's progress towards greater empowerment can have a dramatic and positive effect on reducing hunger and poverty. (WR)

Himawanti : women of the Hindu Kush-Himalayas by Bhatia A (ed.), Limbu P, Meyangbo P. 2001. 78 p. ISBN 92 9115 412 1. International Centre for Integrated Mountain Development (ICIMOD), G.P.O. 3226, Kathmandu, Nepal / icimod@icimod.org.np ; www.icimod.org.
With this grassroots publication, ICIMOD provides useful information on rural women in the Hindu Kush Mountains. HIMAWANTI, the Himalayan Grassroots Women's Natural Resources Management Network, has organised workshops and collected the information on women's needs, concerns and problems with natural resource management in the different countries in the region. This book is an important resource for every expert in development and every politician with interest in rural development, because it shows the point of view of the rural women themselves. The text is in three languages, English, Hindi and Nepali, the illustrations are from Param Meyangbo. (WR)

Women and farming : property and power by Shortall S, Campling J. 1999. 175 p. ISBN 0 333 66466 3. MacMillan Press Ltd, Houndmills, Basingstoke, Hampshire RG21 6XS, UK.
Sally Shortall from Queen's University Belfast, is a researcher in the fields of rural development policy, women on farms, and change in farming. This book looks at women on family farms in Ireland. It argues that farming culture affords more power to men than to women, because men and women on family farms have different relationships to property. Traditions and

customary practices sanction the transfer of land from father to son, thus restricting women's access to property. Economic power follows from property ownership, and this in turns leads to political, ideological and organisational power. Access to property is regulated by farming culture, and discriminates against women.

Power plays a central role in this study, because "to talk of power is to imply the possibility for change". The different chapters consider the transfer of land between men, the changed role of women in the dairy industry in the nineteenth century, women in farming organisations, women in agricultural education programmes, and the role of the state in shaping the lives of farm women. This book provides a good example of how gender is interwoven in European agriculture and what changes are required to come to a more equal distribution of power between the sexes. (WR)

Are we not peasants too ? : land rights and women's claims in India by Agarwal_B. 2002. 30 p. Gender, Family, and Development Population Council, One Dag Hammarskjold Plaza, New York, NY 10017, USA / seeds@popcouncil.org ; www.popcouncil.org/publications. (SEEDS no. 21, 2002).
"Seeds" is a pamphlet series about innovative and practical program ideas, developed to address the economic roles and needs of low-income women. This issue of Seeds, about Land rights and women's claims in India, provides information on why land is important for women, on obstacles that prevent women's access to land, and on possibilities to improve women's access to natural resources. Independent access to land is becoming increasingly important for women as marital and kin support erodes, and female-headed households multiply. This clearly written and informative issue is available free. (WR)

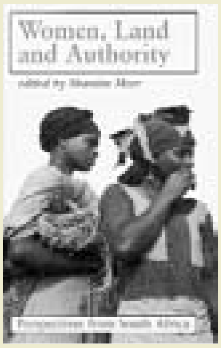
Tools for agriculture: a guide to appropriate equipment for smallholder farmers introduction by Ian Carruthers and Marc Rodriguez. 1992. 238p. ISBN 1 85339 100 X. Intermediate Technology Publications Ltd, 103-105 Southampton Row, London, WC1B 4HH, UK. Russel Press, Nottingham, UK.
This book provides a practical guide to small-scale farming equipment. Information has been selected from more than 1200 manufacturers in over 90 countries, and appropriate equipment is presented in ten fully-illustrated chapters, each progressing from the smallest manual implements to engine-powered tools, to make reference easy and logical. The ten subject areas (field power; soil preparation; sowing, planting and fertiliser distribution; pest control and operator safety; harvesting and threshing; crop processing and storage; water lifting; transport and materials handling; livestock husbandry and health; and beekeeping) are each introduced by a specialist, who sets the range of available tools against a background of good farming practice, and discusses the factors which should be weighed up when making a choice. Sources of further information and indexes of manufacturers and equipment are also provided. (EK)

Agricultural implements used by women farmers in Africa 1998. 129 p. ISBN 92 9072 008 5. International Fund for Agricultural Development (IFAD), via del Serafico, 107, 00142 Rome, Italy / ifad@ifad.org.
This research study was conducted in Burkina Faso, Senegal, Uganda, Zambia and Zimbabwe. A qualitative research technique was used with discussions and interviews with 1500 women and men farmers and 52 key informants in government and non-government institutions. The study gives a good overview of the problems and constraints small farmers, especially women, experience in areas of relatively poor agriculture in sub Saharan Africa.

Among the groups consulted it was generally felt that women needed different tools to men and that manufacturers should differentiate between the two sexes, as they do with bicycles. Many of the groups stated that the hand-hoe imposed strict limitations on production and that they would never make any progress without access to animal traction. However, the spread of this technology is slow and in some countries it can be limited by cultural factors such as taboos against women working with cattle. The study concludes that there is no simple solution to improving the production tools and implements used by women but it concludes with some recommendations on actions required from governments, NGO's and development agencies. (WR)

Gender and organisational change : training manual by Groverman V, Gurung JD. 2001. 154 p.. ISBN 92 9115 295 1. International Centre for Integrated Mountain Development(ICIMOD), GPO Box 3226, Kathmandu, Nepal / www.icimod.org ; distri@icimod.org.np.
This ICIMOD training manual has been developed to increase gender awareness in the Hindu Kush-Himalayan region. Most institutions involved in agriculture and natural resource management have not formally incorporated gender concerns into their research, extension and training programmes, which leads to the widespread exclusion of rural women from participation in research and extension activities.

The manual consists of three parts. The first part is an introduction to gender concepts in order to understand gender-related organisational change. The second part addresses the process of organisational change and the third part covers the skills required by facilitators of processes of organisational change and gender. With these three steps the book is a useful guide for larger organisations that want to increase gender awareness internally. This manual lacks a fourth and crucial step - how to reach grassroots organisations. It does not provide insights or tools to reach rural women with research and extension activities.(WR)



Women, land, and authority : perspectives from South Africa by Meer S (ed.). 1997. 160 p. ISBN 0 85589 375 2 USD 15.95. Oxfam National Land Committee, South Africa. OXFAM Publications, 274 Banbury Road, OX2 7DZ Oxford, UK.
This book reveals the circumstances of tenure and rights of access to land in a changing South Africa, from the perspective of women. Through several pioneering surveys and case studies, it explores women's attitudes to land and related resources, and examines conditions of housing, labour and subsistence for women. What emerges is a sharp sense of transition and crisis and a pressing need for women's organisation, to ensure that development and legislation are informed by the priorities of women. This book, an initiative of the Gender Task Group of the National Land Committee, aims to get these issues on the national agenda and contribute to the fledgling policy debate around land reform. (WR)

Issue 19.2, June 2003

Water harvesting, water conservation and small scale irrigation

Water is a precious resource that is essential to the life and health of farmers, animals and crops - and it is becoming steadily scarcer. Many see a global water crisis looming on the horizon, and as competition increases for water from households, industries etc., the huge proportion of water used for agriculture, although essential for food production, is increasingly challenged.

This issue of LEISA focuses on small-scale solutions for harvesting, conserving, storing and using water at the local level. What can be done to manage the local ecosystem to conserve water, for example land preparation and ground cover for moisture retention and increased infiltration? How can rainwater be harvested on a small scale? What is the best way to catch and store water? And how can it be efficiently applied to crops? We invite you to share your experiences and solutions with LEISA readers.

Deadline for contributions is the 1st of March, 2003.

Issue 19.3, September 2003

Access to and control over resources

Around the world, many different systems and arrangements determine who has access to and control over land and other natural resources, and under what conditions. The way these systems work, in law and in practice, is one of the main determining factors in the livelihood security of small farmers.

Systems of access and control range from formal to informal, from traditional to very new, from collective to private. Arrangements change and evolve over time, in most cases moving towards increasing privatisation and formalisation. Resources regulated by these systems include not only land but also resources such as trees, water, grazing and manure. Water users associations, Joint Forest Management, tree pattas, pastoralists using agricultural land for grazing, private land deeds, communal use of land, share cropping etc., are just some examples of mechanisms that communities and societies develop to regulate their resource use. How do these systems work, and why? This issue of LEISA will try to bring into focus some of the practical aspects of different systems for access and control. We invite you to share your experiences.

Deadline for contributions is the 1st of June, 2003.

Issue 19.4, December 2003

Rehabilition of degraded land

You are invited to contribute to these issues with articles (about 800, 1600 or 2400 words + 2-3 illustrations and references), suggest possible authors, and send us information about publications, training courses, meetings and websites. Editorial support is provided by ILEIA. Authors of published articles are entitled to a standard fee of USD 75,-.

A Nepalese woman carrying her spade.

Land in the hands of women?

Renate Schüssler

Land issues are issues of power. This is apparent not only in the unequal distribution of land, and the concentration of huge production areas in the hands of a few big landowners and multinational trusts. It also becomes very clear in light of the inequities between men and women in terms of access to land. This inequality is a violation of one of the central principles of Human Rights: the principle of non-discrimination.

Work but no rights - traditional limitations on women's land rights

Women in rural areas have traditionally fewer rights and fewer income opportunities than men, often because of patriarchal and conservative thinking, according to which the man is perceived as the main productive working force. Independently of how much women are active in agrarian production, their work is normally perceived as part of family and household management. For example, rural women in Latin America work 14 hours a day. In spite of this, their contribution to food security is hardly acknowledged as work. Due to the pressure for export-orientated production, land available for food production is increasingly difficult to access or provides low yields. It is becoming more and more difficult to cultivate food in sufficient quantities for the family, and production for the world market does not generate sufficient income for the purchase of household food. Because of this, women often eat less than their share in order to feed the rest of the family.

Women produce a considerable part of the world's food: 80 to 90% in African sub-Saharan states, 50 to 90% in Asia and 30% in Central and Eastern Europe, according to FAO. Despite this high contribution to agrarian production, in most cases women do not control their own land. Kenya constitutes an interesting example, as 98% of its women work full-time in the agrarian sector, but only 5% of these have land ownership titles.

Women and agrarian reforms

Demands for redistribution of land, supported by large agrarian reform movements, have during the last century led to the implementation of agrarian reform measures in various countries. Considering the difficult situation of small peasant and landless families, agrarian reforms should be a means to carry their call for social equality. For many governments, however, reforms are merely a means of social pacification. Despite sometimes-progressive agrarian reform legislation and considerable successes in some countries, in many places the measures did not reach far because of weakness in implementation - a lack of political will. In a number of countries only about 10% of the rural population benefited from changes in land ownership.

The demands for agrarian reforms were generally based on prevailing social injustice. This injustice, however, was analysed mainly on the basis of "social class", seldom according to other criteria such as gender or ethnicity. Therefore, agrarian reforms have been gender blind for a long time. More recently, gender and access to land was considered in several countries, but with varying impact. As a result of mobilisation of women from different organisations and movements, some success could be registered in the 1990s regarding an improved *formal* recognition of women.

Example Latin America
Women deprived in agrarian reform

Comparatively, women have benefited to a minor extent from the Latin American agrarian reforms. The reasons for this are juridical, structural, ideological, cultural and institutional. Agrarian legislation has sometimes been amended with an explicit reference to the formal equalisation of women, but details hide a different reality. For instance, the legislative language was used in a discriminatory way; no priority was given to women who were in charge of a household on their own; widespread non-marital living communities were left out; and very deprived target groups lacked recognition. When land redistribution was based on a point system, it proved to be either directly or indirectly discriminating.
For instance, it was directly discriminating in Brazil and Costa Rica, where male beneficiaries were attributed higher point numbers. It was indirectly discriminating in Chile and Columbia, where a higher education level gave a person more points, which deprived women because of the discrimination in the education system.

In order to ensure that also women benefit from land redistribution measures, it is necessary to develop workable strategies based on these experiences.

Participation of women in land redistribution

In order to enable women to directly benefit from land redistribution measures, different approaches have been tried. An important point is that women, accordingly to their life situation – as single women, single mothers or as spouses - obtain rights' security and a certain amount of negotiation power. It is necessary to issue ownership titles in the name of women or women's collectives. Models with different aims have been introduced into some national legislation, including (compulsory) joint land distribution to couples independent of their family situation, i.e. the registration of land property in both names.

Example Latin America – joint land distribution

In most of the Latin American countries, it was for a long time only possible to register land to one person. The compulsory joint land distribution for married and unmarried couples addresses on one hand the demand for rights' security, and on the other acknowledges the fact that in many Latin American countries, non-marital living communities (uniones de hecho) are widely spread. Between 1988 and 1995, agrarian legislation in only five countries provided for joint land distribution. Joint land distribution was compulsory in Nicaragua, Columbia and Costa Rica, and optional in Brazil and Honduras. After the Beijing Women's World Summit of 1995, other countries (Peru, Dominican Republic, and Guatemala) joined this legislation due to the growing influence of women's movements. Empirical observations suggest that because of these measures, the proportion of women among the beneficiaries has increased considerably.

Acknowledgement of the high proportion of single mothers, and the number of children in a household should be considered during the land distribution processes. Because of the unequal starting situation, it is not sufficient to give women the *same* rights as men.

Example Philippines – the same rights

The Comprehensive Agrarian Reform Law (CARL) guarantees rural women the same rights: "All qualified members of the agricultural workforce must be guaranteed and assured equal rights to ownership of the land, an equal share of the farm's produce and representation in advisory or appropriate decision-making bodies". The amended civil legislation code of 1988 guarantees the same ownership rights to men and women. Moreover, women should enjoy the same access to all government and private programs allocating credits and non-material resources, and be treated in the same way for agrarian reform and land settlement programs. Concretely however, 86% of agrarian reform measure beneficiaries are men.

In order to counter unjust, historically conditioned structures, some women's organisations demand the introduction of compensatory measures. This kind of so-called *affirmative action* appears only exceptionally in agrarian legislation.

Example South Africa – affirmative action

In South Africa, women were one of the target groups favoured in land reform processes. "Redistribution will give priority to the following: - to the marginalised and to women in need". Equality of rights, along with social justice and economical feasibility, is one of three principles of the South African land reform. In order to enable women to benefit from the land reforms, the government offers 20,000 rand that they can obtain individually. If the women are married, they can apply jointly with their husbands. Both names are registered together and appear on the beneficiaries' list. The low implementation rate of the South African land reforms, however, shows that the elaboration of progressive legislation is a fundamental requirement, but does not constitute a guarantee for real change in ownership structures that are favourable for women.

To what extent compensatory measures really improve the conditions of women, has to be assessed based on concrete results. A permanent monitoring system should be developed in

Bolivian marketplace. Women produce large part of the world's food, but in most cases do not control their own land. Photo: FIAN

order to make sure that the successes obtained are sustainable. In fact, vulnerable groups are often affected by counter-reforms or by the increasing orientation towards market mechanisms and economical liberalisation that is implemented today in many countries.

Peruvian peasant woman sowing seed. Photo: J. Van Acker (FAO)

Women and land markets

Experiences from countries in which large agrarian reform measures were implemented show that women have *benefited directly* only to a small extent. Would the women be better off within the frame of the new market-led reform processes, based on a neo-liberal logic? Market-oriented land reforms, such as those promoted by the World Bank and others, contribute partly directly, partly indirectly to the standstill of agrarian reform processes. The idea is that land redistribution shall be regulated by market mechanisms: peasants who fulfil certain criteria can apply in land banks for credits, in order to purchase land. The traditionally marginalised groups are excluded from the start, as they do not satisfy the required criteria. Many peasants who bought land this way have incurred high debts: many of them have been forced to re-sell their land. To make matters worse, the state is retiring from its role in supporting production by providing access to markets, seeds, training and technical advice.

In the 1990s, mainly thanks to the pressure of women's and Human Rights organisations, women in Latin America have benefited more from the entitlement programs than in previous agrarian reform programs; and the participation of women is proportionally higher, even though it is still drastically behind their male counterparts. Because of the general changes in agrarian policies, land redistribution processes came to a standstill, which means that in absolute figures, fewer women have received new land than previously.

Moreover, women are discriminated against on other grounds, in land markets or in a market-led land reform process . Women have very few income and ownership opportunities and little access to credit. The reasons for this are, among others, discriminating inheritance conditions, cultural responsibility for the very time-intensive but not income-generating reproductive work, and the gender specific segmentation of the work market, where women generally earn less than men and so-called typical female activities are much lower paid.

Example from the Philippines

In traditionally organised big farms, the whole family is generally employed but only the man receives a salary, paid jointly for the whole family.
In capital-intensive plantations, the men run the machines, whereas women are given ordinary and so-called "easy" work, which is generally lower paid.

Women have weaker negotiation power in land markets, and they generally have to pay more money for less productive land plots. Therefore it appears that even land markets are not gender neutral: the most important way for men to gain access to land is the purchase of land, while for women it is inheritance.

However, access to land is not the only determining factor. Other conditions, such as production conditions, are also decisive for the successful use of the land and the ability to keep the land over time This refers to the questions of the access to means of production, to education and technical assistance and to the market conditions under which the products can be sold. Particularly because of the 1990s' neo-liberal counter-reforms, small peasants are often forced to resell the land they had purchased before.

Finally, a liberalisation in land policies and the further retirement of the state has meant that compensatory measures and favouring of especially vulnerable and marginalised groups, especially women, has been abandoned. Many women's organisations therefore still demand land redistribution policies based on social criteria that not only take into account the category of gender, but also have a compensatory effect on other forms of social, regional and racial discrimination. Land markets do not constitute an alternative to agrarian reforms, as through them, land redistribution loses its function of social equalisation. Under conditions of structural injustice, justice cannot be introduced by mere equal treatment – compensatory measures are necessary.

Aims and demands of the International Agrarian Reform Campaign

The aim of FIAN's and La Vía Campesina's Global Campaign for Agrarian Reform is to support the struggle of landless and small peasants to gain access to land, water and agrarian productive resources, on the basis of the Human Right to Adequate Food. The Campaign constitutes an important forum for overcoming unequal ownership and production conditions that are not gender neutral.

To achieve greater gender democracy, it is important to pay special attention to gender perspectives in all forms of land redistribution, entitlement programs and accompanying measures. A central point is that the same starting conditions (formal equalisation) are created, and the same results (real equalisation) are achieved. This implies compensatory measures.

With this background, the International Agrarian Campaign of FIAN and La Vía Campesina campaign for the implementation of an agrarian reform based on Human Rights and creating an agricultural environment which:

- gives poor small peasants control over land, seeds and water, so that they can live in dignity;
- allows the production of food that is safe and free from genetic modifications for all;
- guarantees sustainable means of production in order to preserve the food basis of coming generations;
- strengthens the rights of rural women and other deprived groups;
- guarantees food sovereignty;
- strengthens rural communities.

Organic farming and gender roles in Northern Thailand

Rebecca Eisses and Jutamart Chaikam

High external input agriculture was first introduced to Thailand on a large scale under the First National Economic and Social Development Plan, which was developed under the auspices of the World Bank in 1961. Modern agricultural equipment, inputs and concepts were spread throughout the country by the newly established Department of Agricultural Extension and Bank of Agriculture and Agricultural Co-operatives. The Plan emphasised high yielding varieties of exportable cash crops to improve the national economy.

Small farmers, the green revolution and the global economy

The introduction of high external-input agriculture into Thailand has, for some crops, increased yields and reduced labour requirements and has allowed the production of certain non-indigenous crops that might otherwise be too difficult to grow. High external-input agriculture has not, however, generally improved quality of life for small farmers in Thailand. The purchase of external inputs can trap farmers into a debt cycle that is almost impossible for them to escape. The use of pesticides further leads to noticeable deterioration in farmers' health as well as that of the agro-ecosystem. In some cases, farmers who have been improperly trained in the use of pesticides, combined with an ineffective regulatory system, also put the health of consumers at risk.

More than these physical effects, the entry of Thailand's small farmers into the global economy has completely revolutionised the countryside. Farmers who were once largely self-sufficient and owners of their own time and resources now adhere to the adage "time is money". If the time and labour they once spent weeding their crop has now been reduced by herbicide use, for example, they must now use that time in an economically efficient manner. This is necessary mainly to earn cash to service their (usually) unsustainable debt. This change in the village economy has had particular implications for women's agricultural roles in many communities.

Under the new economy, there are two main ways in which women's roles have been marginalised. In areas far from an urban centre or with little seasonal labour demand, the introduction of labour-saving technology such as pesticides and chemical fertilisers (especially herbicides) has meant that women's role in crop production is now reduced to planting and harvesting. This often means that women have more time to devote to reproductive work and women themselves consider their situation improved. However, since in most Northern Thai households women are responsible for a significant proportion of productive work, in some cases women will find productive work elsewhere, such as factory work or day labour on other peoples' farms, or else the men will find a permanent job off-farm, leaving their wives solely responsible for agricultural production (although perhaps not in control of it). In areas close to an urban centre with a demand for seasonal labour, men leave the village, usually after planting the dry season crop, and return in time to help with the harvest. This is often done in order to earn cash to finance the inputs needed for the dry-season crop production.

Organic production – an alternative?

The Chomrom Phupholid Kaset Insee Jangwad Chiang Mai or the Chiang Mai Organic Producers Association (COPA) consists of farmers who are committed to using organic production methods to ensure environmental sustainability and to protect their own health and the health of consumers. In addition, they make their own inputs such as compost, bio-extract and botanical pesticides from locally available materials found in the forest, on their farms, or in their communities in order to reduce costs and increase self-reliance. The COPA works with consumer groups and has set up alternative markets in the city of Chiang Mai to sell members' produce at a fair price.

In order to become a member of the COPA, a village group must pass through a series of four trainings: sustainable agriculture concepts, sustainable agriculture techniques, a study tour, and finally a session on gender roles. In the COPA's experience, adoption of organic farming significantly increases labour requirements compared to conventional farming. Women often shoulder the increased labour to a greater degree than men. The gender session serves to sensitise men to the importance of reproductive tasks and the time women need to spend doing them. In most sessions, the men are quite surprised to see how much time it actually takes to prepare meals, wash clothes, care for elders and children and the other "invisible" tasks that women perform every day. Some families choose not to join their village organic farming group because the men are unwilling to help with the reproductive work, but many remain convinced of the value of organic farming and choose to divide productive and reproductive work within the household more equitably.

Women's importance in the COPA is expressed in their participation in both traditional and non-traditional roles. For example, the traditional role of women as marketers of farm produce is largely restored through the COPA's revolving markets, a role that was superseded by men with the introduction of cash crops sold to middlemen. All members of the revolving market, of whom 57 out of 60 are women, meet every month to set prices for their produce, thus avoiding competition between members on the basis of price. Women also add value to organic produce through processing, making and selling both traditional Northern Thai products such as *khao khaeb* made from rice flour and non-traditional products such as strawberry jam. Female members of the COPA serve as trainers and spokespeople, as well as in administrative posts. (So far, there has never been a female president of the COPA but the present vice-president is female and some of the member village groups have female presidents.)

The socio-economic benefits of organic agriculture

A study on dry-season soybean production by the Don Jieng Organic Farmers Group, a member of the COPA, provides a concrete example of some interesting socio-economic benefits derived from organic farming. Most men in Don Jieng do seasonal construction work in the city of Chiang Mai after planting the dry season soybean crop in late December of each year. They return in mid-April for the Thai New Year festival and soybean harvest. In the meantime, women are responsible for pesticide and chemical fertiliser application to the soybean crop, usually consisting of one or two herbicide sprays, one or two insecticide sprays, and one broadcast application of chemical fertiliser. In addition, the women become solely responsible for the care of elders, children, and livestock, as well as their regular household activities. The men who work in the city earn the cash they need to pay for the inputs for their soybean crop, to service debt and to pay for other things requiring cash such as school fees. However, since they need to rent accommodation and pay for food, they often do not return with a significant amount of money. (Indeed, due to the informal nature of the work contracts, sometimes they are not paid at all). Labour migration has also been a mode of spreading HIV/AIDS from the city to rural areas. Out of a total village population of approximately 500 people, more than 20 people in Don Jieng have died of AIDS (this figure is, of course, hardly comparable to the situation in many African countries and is in fact lower than the regional average rate of infection, but is still a significant amount for a rural village).

Members of the Don Jieng Organic Farmers Group who were growing their dry season soybeans organically did not have time to work in the city due to the increased labour requirements of their organic crop. At the same time, because their input costs were so low, it was not necessary for them to work in the city. Members of the group, especially women, felt that the social benefits of having the men stay in the village outweighed the lost opportunity to earn cash in the city. However, since the organic soybean crop was more profitable than the conventional soybean crop, due to a higher selling price, they were not at an economic disadvantage compared to the conventional farmers in the village. After a single year, membership of the Don Jieng Organic Farmers Group doubled, in part due to the socio-economic benefits of their organic soybean crop.

Linking with others

The COPA is still only a small organisation comprised of a very small proportion of the farmers in Chiang Mai province. However, it is a member of the Alternative Agriculture Network (AAN), which links like-minded NGOs and peoples' organisations around Thailand to lobby for changes in government policy. The AAN was successful in having sustainable agriculture included in the 8^{th} National Economic and Social Development Plan, an inclusion that has had implications for Ministry of Agriculture and Cooperatives research and extension. This also resulted in the Ministry committing funding to a Pilot Project to Develop Sustainable Agriculture for Small-Scale Farmers. Funds under this project are administered regionally by farmers' organisations, including the COPA.

Through its community radio program and co-operation with NGOs and GOs in farmer-to-farmer extension and advocacy for sustainable agriculture, the COPA and its members are known around the country and even internationally for their work. Women continue to play a role of ever-increasing importance in the COPA, both through the revival and celebration of traditional roles like food processing and marketing, and also through non-traditional roles such as training, administration and community politics.

Economic change and gender relations

planning in the Pearl Lagoon Basin

Orinoco children: A younger generation with changing attitudes
Photo: Jesse Hill

Denise Lapoutre

Why and how do gender relations change? Rapid appraisal methods, which mainly focus on tangible information, may not be sufficient to understand these questions. Based on experiences with development processes near the Pearl Lagoon Basin of Nicaragua, this article highlights the need for participatory, gender-based research as a basis for development planning, particularly in situations of turbulent change.

In the Pearl Lagoon Basin in the Southern Autonomous Region of Nicaragua, thirteen small farmer-fishing communities are in a state of economic flux and social despair. A major reason has been the shift from an economic model based on a combination of subsistence production and wage-labour, to a market economy. The shift began in the seventies, when foreign companies in the area started to withdraw from their unsustainable exploitation of the area's natural resources, taking with them the opportunity for wage labour. A second reason that further exacerbated the situation was the abandonment of subsistence production.

The present situation is one of rapid change, driven by an influx of cheap commodities from foreign countries. The communities' lack of experience with entrepreneurship, as well as traditional economic laws and quality standards that do not meet the demands of an international economy, mean that transition to a new sustainable production model will not be easy. Moreover, this change takes place in a setting where local structures are dominated by men and patriarchal ideologies.

The Garifuna fisherwomen's cooperative

In 1995, the University of the Autonomous Regions of the Caribbean Coast of Nicaragua (URACCAN) started an Integral Development Project for the Pearl Lagoon Basin. The project contains different components that address integrated community development as a process of dynamic interaction between cultural, social, economic and productive dimensions.

One of the target groups, the fisherwomen's cooperative of Orinoco village, is with 70 members one of the bigger organisational units in the area. When I came to work at URACCAN-Bluefields in February 1997, the only activity of the cooperative was the letting of its motorboat. A rapid assessment revealed that almost none of the members were actually involved in fishery-related activities or had any ambition to be involved. Instead, they were almost exclusively interested in raising chickens. This surprised me, as Garifuna women were known to be fishers as well as farmers. In 1991, 60% of Orinoco's fishers were still women. And why produce chickens, when outside the community people buy *Pollo Tiptop*, the frozen ones?

Research

With the community, we started a Participatory Rapid Rural Appraisal (PRRA) focusing on production. The main conclusions were the following:

1) The community has abandoned the production of at least sixteen basic food and cash crops. The major reasons for abandoning agriculture were:
   - The civil war, when people avoided the fields out of fear.
   - The lack of technical and financial support required to rehabilitate farming.
   - Fishing, especially after the introduction of the gill nets, has become more lucrative then agriculture.
2) While men and women used to fish and farm together, now few women participate. Women still engage in fish-processing and in the shrimp harvest;
3) The food security crisis could be solved. Access to credit would make it possible to produce what is now imported, and to export to outside markets.

Not taking into consideration culture, customs, needs, wishes, attitudes, etc., the inhabitants automatically took a Marxist position: With improved economic opportunities, cultural habits would change and improve. All change was expected to come from outside: Credit and a market would be the keys to prosperity. A random sample of people's reactions: "Everyone does whatever he likes, because nobody gives any help to Orinoco"; "The community doesn't develop because there is no work"; and, "With access to credit and access to a market we all would be working the fields".

After considering the results so far, I felt we were not ready to start participatory planning. The reasons behind the changing production model were not fully explored and the changes in division of labour and access to production resources by gender were taken for granted. A second research phase became necessary. URACCAN students visited one out of every ten households, interviewing men and women of different age groups. Subjects were firstly the changing livelihood systems, including personal behaviour at household, communal and (inter)national family systems. Secondly we questioned the sustainability of

Orinoco's production model and women's, men's and young people's ideas and habits by asking the interviewees to comment on three statements:

1) Orinoco is changing into a 'bedroom community': People are abandoning the fields, over-exploitation of fishery resources is leading to reduction of food and income and dependency from migrant remittances is growing;
2) Women used to be more dedicated to productive activities than they are now;
3) The new generation likes quick earnings. Investing money, time and energy in agriculture and cattle is old-fashioned.

These questions and their answers were eye-openers for the community members themselves. Until now they had been worried about the reduction in agricultural and fisheries' production per unit effort, but they had never wondered why the behaviour of women or youth had changed and what the consequences of these changes would be for the future economic and social well-being of the individual, the household and the community. The results also led to clues for discussions on gender.

Community discussions on gender dynamics

One outcome of the investigation was the revelation that more than half of the households are receiving migrant remittances from family abroad. For a quarter of the families, these are the main source of income. Discussing this point eventually led to greater awareness of the vulnerable position of women. When we asked what happens when an eighteen-year-old boy leaves his girlfriend behind for a couple of years, everybody started to laugh. It is commonly agreed that Orinoco's young men are not monogamous. Although other kinship relations than marriage play a role in a woman's subsistence strategies, the situation of poverty makes the husband's contribution crucial to subsistence. We discussed the fact that in a sample of 24 women all but two learned to farm or to fish or both, but only one of them is currently farming and four sometimes go fishing. What does this mean for Orinoco's daughters, who are growing up without learning any productive skills?

We also discussed why women might be retiring from productive activity. Since the introduction of gill nets, fishing is considered to be men's work and too hard for women. A suggestion that the increased profitability might be a determining factor for changing gender roles was rejected. Regarding women's (non) involvement in agriculture, several additional observations were made: that women today are lazier, that beliefs have changed - men should support the family and women should stay at home, and that women nowadays have fewer rights than they once did.

By comparing two generations, we were able to see how withdrawal from fisheries and agricultural labour is advancing. Almost none of the young people dedicate themselves to productive activities. The elders describe them as 'dreamers', 'preferring sports and drinking over work', 'confused about the progress of modernity', 'vicious', and 'without patience'.

Another discussion dealt with the breakdown of social networks. A conclusion was that in the Pearl Lagoon area, where traditions of barter and mutual help are breaking down, helping others with work, food, money or means of production has a gender-related price. Women appear to have limited ways to obtain cash and to exchange services and products. It was concluded that although women have less access to cash than earlier, they now have to pay for services and for using means of production or transport owned by men, things that used to be free of charge. Women feel their need for money is urgent. They do manage part of their husband's earnings, but they are generally unaware of his total income. Some women make a little money from baking bread and cake or from commercial activity. Most have a few chickens for subsistence or exchange.

Design and implementation of plans

After the community members gave feedback on the conclusions, they were able to design a long-term development plan with gender perspective for the community and a women-focused, short-term strategy.

The community stressed the importance of traditional culture for a prospering Orinoco. Revival and ownership of the traditional culture, particularly by youth, would lead to constructive attitudes towards community building. The cultural revival should extend beyond cultural activities to traditional productive and commercial activities, and this could be a focus for the socio-economic or women's component in its first phase.

The women's cooperative, supported by participants of other components of the project, made a plan for starting the production activities. In 1999 we started a credit fund managed by the community, for the cooperative to run a shop and to sell fish and shrimps bought from the fishermen. Credit was also given to individual women organised in small groups for commercial activities such as a shop or a guesthouse, cattle breeding, agriculture and horticulture. Professionals and URACCAN students provided technical assistance where needed. The high level of repayment, in a region where a culture of not refunding credit dominates, reflects the commitment of the beneficiaries - undoubtedly enhanced by the extensive identification and planning process. In the next phase, a start was made with product diversification (new crops, reforestation, pig breeding, eco- and cultural tourism etc) and the introduction of non-traditional economic activities for women.

Conclusion

Rapid Rural Appraisal methods are very useful for analysing transforming productive models, including the roles of women and men. However, they are not enough and had to be complemented with more extensive research. *After combining information on people's participation in productive work and their share in the benefits of production, their income and expenses (by age and by gender) with knowledge of their norms and perceptions (by age and by gender),* we had a rich input for discussions on community development, household development and women's development. This in turn paved the way for a participatory design of gender-sensitive development plans. The Garifuna women still face many difficulties, but they are regaining territory while developing traditional production. No longer was the solution for the precarious situation of decreasing agricultural activity, impoverishment and perceived overexploitation of natural resources only to be found in the generation of credit and new market perspectives. Instead, members of the community related the negative spiral and changing economic circumstances to changing cultural habits and preferences with gender dimensions and treated them as such. No longer do Orinoco women see breeding chickens as the only alternative to domestic work. ■

Small change crops
the marginalisation of women farmers' priorities

Carine Pionetti

In India, as in many other countries, agricultural planning and policy are largely based on 'gender-blind' data. There is no systematic effort to identify and comprehend differences in strategies, responsibilities and concerns between men and women farmers in agricultural domains like soil fertility, weed management, seed production, agrarian rituals, access to technical advice, inputs and credit, marketing of produce. Considering that women undertake 70% of all agricultural work in many parts of India, the lack of a gender-desegregated analysis is concerning. Moreover, it constitutes a major barrier to evaluating the impact of new technologies and policies on women farmers.

This article aims to provide insights into the different meanings and values attributed to crop diversity by women and men farmers in the semi-arid Deccan Plateau. Based on a wide range of participatory discussions and exercises conducted with small farmers between 1999 and 2002 in several parts of Andhra Pradesh, these observations demonstrate that gender plays a critical role in Indian agriculture.

Keeping in view the multiplicity of situations which, together, make up Indian agriculture today, we look at three farming contexts, located on different points of an imaginary continuum going from primarily subsistence farming to largely commercial farming: Shamshuddinpur (Medak District), Satmoori and Pipri (Adilabad District), Bhoraj (Adilabad District).

Shamshuddinpur
